

A novel chromosomal anomaly involving rearrangement of the *MLL* gene in a case of acute myelogenous leukemia. *K. Chun*¹, *D. Bouman*¹, *P. Chiang*¹, *M. Minden*², *M. Shago*³. 1) Dept. of Pathology, University Health Network, Toronto, Canada; 2) Dept. of Medical Oncology, University Health Network, Toronto, Canada; 3) Dept. of Pathology, Mount Sinai Hospital, Toronto, Canada.

Objectives: Initial G banding analysis of the peripheral blood from a 50-year old AML patient with monocytic features yielded a karyotype of 47,XY,+8,del(11)(q21q23). Since the presence of an 11q23 breakpoint involving the *MLL* gene can have prognostic implications, molecular cytogenetic studies were undertaken in order to characterize the abnormality in detail.

Methods: FISH analysis was performed on previously G banded metaphases using *MLL*, WCPs 9 and 11 and M-FISH probes. RT-PCR analysis of mRNA was undertaken to look for the presence of the *MLL-AF9* fusion transcript.

Results: Metaphase FISH analysis using a dual colour break apart *MLL* probe revealed that the 5' portion of the *MLL* gene had been inserted into 9p22, while the 3' region remained on chromosome 11. WCP and M-FISH experiments confirmed that part of chromosome 11 had been inserted into 9p and demonstrated that the rest of the deleted segment of 11q had not been transferred elsewhere in the genome. With this information, the karyotype was assigned as 47,XY,+8,der(9)ins(9;11)(p22;q23q23),del(11)(q21q23). RT-PCR on mRNA was positive for the *MLL-AF9* fusion transcript.

Conclusions: FISH analysis revealed a cryptic rearrangement involving the *MLL* gene at 11q23. RT-PCR confirmed that the cryptic rearrangement in this patient leads to the fusion of *MLL* and *AF9* on the der(9) chromosome. The classic t(9;11)(p22;q23) is a recurrent aberration associated with AML M5, which results in the fusion of the *MLL* gene and the *AF9* gene on the der(11) chromosome. *MLL* rearrangements are generally predictive of poor clinical outcome. However, the prognosis for children and adults with AML and the t(9;11), especially with the presence of trisomy 8, is associated with a more favorable outcome. The presence of the *MLL-AF9* transcript is consistent with the clinical phenotype of this patient.

Complete Characterization of Medulloblastoma Cell Lines: New Chromosomal Regions Potentially Involved in the Pathogenesis of This Tumor. *S. Dube*^{1, 2}, *M. Muleris*³, *F. Fortin*¹, *Y. Théorêt*², *N. Lemieux*^{1, 2}. 1) Dept. of Pathology and Cell Biology, University of Montreal, Montreal, Canada; 2) Research Center, Ste-Justine Hospital, Montreal, Canada; 3) Institut Curie, Paris.

Medulloblastoma (MB), a primitive neuroectodermal tumor of the cerebellum, represents approximately 25% of all intracranial tumors in children. Several studies showed numerous non-random chromosomal abnormalities that may play a role in the occurrence, the development and the spreading of this cancer. However, the specific oncogenic events involved in the development and progression of this tumor remain unknown. In this study, conventional karyotyping (CT), fluorescence in situ hybridization (FISH) and comparative genomic hybridization (CGH) were performed to allow a more comprehensive cytogenetic evaluation of three new MB cell lines: HSJ-MB1, HSJ-MB2 and UM-MB1. CT and FISH analyses of the three cell lines revealed DNA polyploidy and multiple complex chromosomal rearrangements resulting in gains of 7q, 8q and 11q and losses of 3p, 4q, 9p, 10q, 11p and 14. Using CGH, we validated CT and FISH results and detected 3q, 7q, 8q, 11q, 20p and 20q as over-represented regions and 4, 10 and 11p as under-represented regions. The combined analysis of all results shows many clonal imbalances which have previously been reported such as gains of 7q and 8q and losses of 3p, 9p, 10q and 11p. Those changes are described in the majority of PNET/MB tumors. Furthermore, some novel changes involving chromosomal segments 3q, 4p, 4q, 14q, 20p and 20q were revealed by our analyses. These recurrent chromosomal imbalances found in our cell lines might involve genes implicated in the tumorigenic process of MBs. Thus, some other candidate genes could be involved in addition to those already described. The results presented here demonstrate that the three new MB cell lines analyzed are cytogenetically representative of the PNET/MB tumors and should be helpful to further our understanding of the biology of these tumors. However, additional studies are needed to furnish more insight on the roles played by the chromosomal changes observed. This shows how essential it is to characterize completely medulloblastoma cell lines.

Unusual variants of the t(15;17) rearrangement and their implications in the diagnosis/prognosis of acute promyelocytic leukemia. C. Astbury, L. Christ, M. Lemos, M. Kochera, S. Schwartz. Department of Genetics and Center for Human Genetics, Case Western Reserve University and University Hospitals of Cleveland, Cleveland, OH.

Acute promyelocytic leukemia (APL), a cancer with potentially lethal coagulopathy necessitating accurate and rapid diagnosis, is characterized by the t(15;17)(q22;q21), and generally responds well to retinoid treatment. The common translocation leads to the production of a PML-RARa fusion protein, which prevents the normal function of the RARa receptor, leading to leukemogenesis. While the t(15;17) can be seen cytogenetically in the majority of patients, it is estimated that approximately 2% of APL is due to cryptic rearrangements between the PML and RARa genes. We report two unusual variants of the translocation that have important implications in the diagnosis of APL and demonstrate the impact of FISH on diagnoses and treatment. In the first patient, who presented with AML M3, the t(15;17) was not seen cytogenetically. However, FISH analysis with the Vysis dual color probe revealed an atypical fusion pattern. This rearrangement was characterized as ins(17;15)(q21.1;q22q22), with the typical yellow fusion signal on one chromosome 17 (instead of on chromosome 15). Reports cite a potential resistance to all-*trans* retinoic acid (ATRA) treatment with this cryptic rearrangement. In the second patient, who presented with AML, the common t(15;17) was seen cytogenetically. However, confirmation studies using FISH revealed an extra red signal (from the PML gene) on the der(17), as well as the yellow fusion signal on the der(15). In this patient, the PML gene had been broken in either the bcr 2 or 3, instead of the more common bcr 1. Patients with breakpoints in either of bcr 2 or 3 also may have reduced sensitivity to ATRA treatment. The studies of these two patients have important implications in the diagnosis and evaluation of APL. (1) It emphasizes the importance of FISH analysis in the diagnosis of APL, with potential implications for treatment and prognosis; and (2) it demonstrates that standard cytogenetics may not always be sufficient, leading to an underdiagnosis of cryptic rearrangements.

Chromosome 11 rearrangements and specific MLL amplification disclosed by spectral karyotyping in a RAEB patient. *G. Calabrese*^{1,2}, *D. Fantasia*^{1,2}, *E. Morizio*^{1,2}, *P.M. Toro*^{1,2}, *V. Gatta*², *P. Guanciali Franchi*^{1,2}, *M. De Cinque*^{1,2}, *A. Spadano*³, *L. Stuppia*^{1,4}, *G. Palka*^{1,2}. 1) Dip. S. Biomed/Genetica Medica, Univ G D'Annunzio, Chieti, Italy; 2) S. Genetica U., Pescara Hospital, Pescara, Italy; 3) Dip Ematologia, Pescara Hospital, Pescara, Italy; 4) Ist. Citomorfologia N&P, CNR Chieti, Italy.

A patient with refractory anaemia with excess of blasts (RAEB) had a complex karyotype 48,XY,del(3)(q13),t(5;13)(q13;q12?),-11,+3mar as defined by GTG banding technique. The karyotype was refined by spectral karyotype (SKY) analysis which classified the three markers as der(11). FISH analysis using specific probes for the MLL gene showed a complete decoration of the three der(11) while no YAC clone flanking MLL region was found on the markers. Fibre-FISH analysis using single-colour cosmid MLL probe (Appligene-Resnova, Italy) and green-red dual colour large MLL probes (Vysis-Olympus, Italy) disclosed the presence of repeated MLL-specific signals with a direct duplication pattern and confirmed isolated MLL-specific amplification. RT-PCR on RNA from bone marrow cells was also performed using specific primers scattered along MLL transcript. This analysis revealed normal size MLL products which appeared very abundant when compared to those from unaffected individuals, showing that amplification involved the whole MLL gene. To our knowledge this is the first example of isolated MLL gene amplification in a RAEB patient. He survived six months after diagnosis supporting clinical adverse effect of MLL amplification. Moreover present results further demonstrate the usefulness of SKY analysis in detecting cryptic chromosome rearrangements and disclosing the mechanism of disease progression.

HER-2/neu FISH in breast cancer: Is it the gold standard? *S. Gokhale, Z. Gatalica, A. Mohammad, A. Rampy, G.R.V.N. Velagaleti.* Department of Pathology, University of Texas Medical Br, Galveston, TX.

Overexpression of HER-2/neu oncogene in breast cancer patients is correlated with disease free survival (DFS) and overall survival (OS). The most commonly used methods for the detection of HER-2/neu status are immunohistochemistry (IHC) and FISH. However, there is a lot of controversy with regard to the best method of detecting the status of HER-2/neu. Several studies have been published with mostly contradicting results with some advocating FISH as gold standard while others IHC. Also, most of the studies chose arbitrary cut-off levels for positive results (10%) and have no validation. In order to address all these issues, we designed a retrospective pilot study of 40 samples with known IHC status. The samples were selected in such a way as to represent all 4 categories of IHC scores equally (10 samples each in 0, 1+, 2+ and 3+). FISH was performed using Vysis Pathvysion™ probe. For validation, 5 cases of reduction mammoplasty were analyzed using same protocols. Two independent scorers in a blinded fashion did scoring. Our results showed significant discordance between FISH and IHC in 3 of the 4 categories. FISH showed HER-2/neu amplification in 2/8 cases with IHC score of 0, 7/10 cases with IHC score of 1+, 3/10 cases with IHC score of 2+ and one false positive case with IHC score of 3+. The rate of discordance was much higher in the 0 and 1+ categories compared to published literature. This could be due to the lower cut-off rates for positive amplification established by validation in our study (6.5% vs 10%). Another reason could be the amplification of HER-2/neu in DCIS, which was not taken into consideration by IHC. DCIS with amplification of HER-2/neu has a higher probability of becoming invasive and hence could be a prognostic marker. Our analysis showed that FISH positive and IHC negative patients have a poor prognosis in terms of DFS and OS compared to FISH negative and IHC negative patients. Further, our results also showed that IHC in comparison to FISH has a comparable specificity (98%), but has a very low sensitivity (46%). Based on these results, we consider FISH to be the gold standard for detecting HER-2/neu status in breast cancer.

CGH analysis of 34 cases of colorectal carcinoma. *S. Cheng*¹, *R. Tang*². 1) Department of Anatomy, College of Medicine, Chang Gung University, Kweishan, Taoyuan, Taiwan; 2) Colorectal Section, Chang Gung Memorial Hospital, Linkou, Taiwan.

The carcinogenesis procedure of colorectal carcinoma has been well studied. We are particularly interested in the chromosomal changes on the genomic level in the various Dukes' stages. To broaden the spectrum of the examined region to the whole genome we used the method of comparative genomic hybridization (CGH). Of 34 collected cases of colorectal adenocarcinoma, there are a case of stage A, 15 cases of stage B, 15 cases of stage C, and 3 case of stage D, with 33 cases demonstrating copy number alternation. The DNA are extracted from both normal and tumor tissues from patients, and labeled by nick translation with digoxigenin-11-dUTP and biotin-16-dUTP, respectively. The equivalent amount of both DNA hybridized on the chromosomes of a normal male. The karyotypes and copy number were analyzed with Quips software (Applied Imaging). Among them 1q (32%), 6q (29%), 7p (41%), 7q (41%), 8q (41%), 10p (29%), 13p (29%), 13q (59%), 16q (29%), 20p (50%), 20q (56%) have higher incidence. The chromosomes with higher incidence of the copy number loses are 17p (32%), 18p (29%), and 18q (50%). Comparing the non-metastasis (A and B) with metastasis stages (C and D) the former has more incidence (average 6.6 per chromosome) of losses than the later (average 4.6); however, the later has more incidence of gain (11.9) than the former (8.4). The results may imply that during the tumorigenesis the deletion does occur in some chromosomal region. Nonetheless, the nondisjunction occurs in some chromosomes, and the copy number increases. The 20q is a frequent gained chromosomal region with 19 among 34 cases (56%) reveal a gain. Among them 10 are from 16 non-metastatic stages (63%), 9 are from 18 metastatic stages (50%). The other frequent gained chromosome is 13q (59%), with 8 of 16 (50%) non-metastatic cases, and 12 of 18 (67%) metastatic cases. Each of chromosomes 7p, 7q, and 8q has a gain in 41% (14 in 34) of cases. Most often lost chromosomes are 18q (50%), with 10 in 16 non-metastatic cases, and 7 in 18 metastatic cases. Chromosomes 17p and 18p are deleted in ~30% of cases. (This study is supported by grants NSC89-2320-B-182-092 and CMRP1236 to SDC.).

Detection of Chromosome Aberrations in CLL and Multiple Myeloma Using FISH Probe Panels. *S. Ahsan, A. Wiktor, D. Van Dyke.* Medical Genetics, Henry Ford Hospital, Detroit, MI.

Recent studies have suggested that specific chromosome aberrations have prognostic significance in Chronic Lymphocytic Leukemia (CLL) and Multiple Myeloma (MM). Cytogenetic analysis of metaphase cells is routinely used to identify many of these abnormalities but fluorescent in situ hybridization (FISH) provides a technique to detect lower level mosaicism and small deletions in both metaphase and interphase cells. We investigated the utility of FISH (Vysis, Inc.) panels in 24 CLL and 40 MM patients. Karyotype and FISH were performed on samples from 24 patients with known or suspected CLL. The CLL panel includes probes for D13S319(13q14.3), MLL1(11q23), D12Z3(12 centromere), p53(17p13.1), IGH(14q32). Karyotype and FISH were abnormal in 5/24 (21%) cases, 3(13%) had abnormalities identified by karyotype alone, and 7 (29%) by FISH alone. Karyotype and FISH were normal in 9 patients. Two patients had karyotype abnormalities not included in the panel (one each 20q deletion and loss of Y). One low-level 11q deletion karyotype was not identified by FISH. Seven cases (29%) had a normal karyotype and abnormal FISH. Five cases with abnormal karyotypes were either confirmed or clarified by the FISH studies. For known or suspected MM, 40 cases were analyzed by karyotype and FISH panel. The probes included in the MM panel are Rb1(13q14), p53(17p13.1), MLL1(11q23), IGH/CCND1(t(11;14)). Both karyotype and FISH abnormalities were identified in 4/40 (10%) MM cases, 6 (15%) had abnormalities identified by karyotype alone, and 4 (10%) by FISH alone. Karyotype and FISH were normal in 26 patients. Three patients had 45,X,-Y/46XY karyotype and normal FISH. Two patients had complex abnormalities that were not included in the panel. In one mosaic complex karyotype including 13q deletion, FISH did not identify Rb1 loss. Four patients (10%) had a normal karyotype with abnormal FISH results. Three patients had complex karyotypes and abnormal FISH results confirming the cytogenetic abnormalities. These results indicate that FISH panels improve the detection rate of common chromosomal aberrations in CLL and MM, and are therefore a useful adjunct to routine cytogenetic analysis.

Familial renal carcinoma with novel 3/8 translocation. *H.J. Decker¹, D. Reutzel^{1,2}, E. Lausch², H. Brauch³, M. Holl², B. Zabel².* 1) Medical Genetics, Bioscientia Inst Ltd, Ingelheim, Germany; 2) Moleculargenet. Laboratory Children's Hospital, Johannes-Gutenberg-University of Mainz, Germany; 3) Dr. Margarete Fischer-Bosch-Institute for Clinical Pharmacology, Stuttgart, Germany.

Up to 3% of all renal cell carcinoma (RCC) are inherited. Association of familial renal carcinoma cases with mutations in the VHL (von Hippel-Lindau) tumorsuppressor gene in clear cell RCC and the MET oncogene in papillary RCC have been demonstrated. We analysed a family with 4 members suffering from clear cell renal carcinoma (ccRCC). Molecular studies were done in two patients. Both were found negative for alterations in the VHL gene by DNA sequencing. Cytogenetic evaluation using conventional GTG-banding techniques revealed a reciprocal translocation of chromosome 3q and chromosome 8p whereas the unaffected brother showed a normal 46,XY karyotype. To refine our findings we applied FISH with combined whole chromosome painting (WCP) probes for chromosome 3 and 8. WCP-FISH revealed an additional pericentric inversion of der(3) not seen in conventional cytogenetic studies. A two step event, a reciprocal translocation (3q;8p) and a pericentric inversion of der(3) results in a specific fluorescence pattern seen in both affected patients. The breakpoint described on chromosome 3 is different from the well characterized t(3;8) translocation [t(3;8)(p14.2;q24.1)] segregating with familial clear cell renal carcinoma. Our results suggest that, apart from the known genes on chromosome 3p predisposing for renal carcinoma, there might be additional genes involved in renal tumorigenesis on chromosome 3q.

Estimates of Consensus in Cell Selection and Scoring of FISH Data. *P.E. Barker¹, P. Pinsky², W. Wang², S. Srivastava², D. Hocker¹, X. Wu³, M.R. Spitz³.* 1) DNA Technology Group/Biotechnology Division, NIST, Gaithersburg, MD; 2) Cancer Biomarkers Group, Division of Cancer Prevention, NCI/NIH; 3) Department of Epidemiology, M. D. Anderson Cancer Center, Houston, Texas.

As a collaborating laboratory of the NCI Early Detection Research Network (EDRN), the National Institute of Standards and Technology (NIST) supports validation of assays developed by discovery laboratories of the EDRN. One such assay examines cancer risk by quantifying chromosome breaks in cultured human lymphocytes. In order to standardize criteria for cell selection and classification of chromosome aberrations, a web-based validation study was conducted. Two hundred fluorescence in situ hybridization (FISH) images were collected in CD-R format and assigned random identification numbers. Detailed criteria were established for this NIST FISH Image Set 02-01 based on jointly developed NIST- M. D. Anderson Cancer Center criteria for cell selection, and for classification of metaphases as excluded, normal or abnormal. Eight observers were selected from a randomized pool (N=54) of experienced (> 5 years) volunteers who responded to an email announcement distributed in the cytogenetics community through the AMP and ACF listserves. All eight observers were certified, experienced cytogeneticists. Half were doctoral level and half were BS/MS level laboratory staff. The questions addressed were: 1) Given standard criteria, how similarly did cytogeneticists choose cells and score chromosome damage? and 2) Did concordance vary with educational level, years experience or professional certification? This is the first step toward developing a uniform, fully-validated test system for induced chromosomal damage. Results suggest greater consensus on population chromosome breakage rates than which individual cells of the population were judged adequate for analysis. These results will be used to estimate the components of assay variance that can be ascribed to definitions, technical variables or biological variables. (Supported by Interagency Agreement #Y1CN-0103-01 and CA86390 to MRS).

Unusual chromosomal abnormalities in two cases of malignant lymphoma. *M. Bertoni*¹, *A. Babu*², *V. Mizhiritskaya*², *M.J. Macera*². 1) Department of Pathology; 2) Division of Molecular Medicine and Genetics, Department of Medicine, Wyckoff Heights Medical Center.

An 80-year-old male presented with a right submandibular lymphadenopathy. Physical examination was unremarkable except for slight normochromic normocytic anemia. The tumor had existed for some time and was thought to be inflammatory. A diagnosis of low-grade small cleaved cell malignant lymphoma was established. Cytogenetic analysis of the tumor revealed both numerical and structural rearrangements. All of the abnormalities were non-clonal except for a 45,X,-Y clone. All other complements were seen as single cell abnormalities and include: 47,XY,+Y/ 47,XY,+5/ 47,XY,-1,+2mar/ 47,XY,+X,add(12)(q22),t(14;18)(q32;q21). The t(14;18) translocation appears to be the characteristic rearrangement that places the IGH transcriptional enhancer next to the BCL2 gene. This is believed to be responsible for the over expression of the anti apoptotic BCL2 protein. The remaining cells were normal. The second case, a 49 year old male who presented with fever, night sweats and weight loss, was found to have generalized lymphadenopathy. Biopsy of the lymph node revealed diffuse large B-cell malignant lymphoma. Cytogenetic evaluation revealed an abnormal clone with a near tetraploid complement. The chromosome count is in the range of 81 to 85 and includes structural as well as numerical abnormalities. Missing chromosomes in relation to tetraploidy, are the Y, 1, 6, 9(2), 10, 12, 13, 14, 15, 16 and 17(2). Both X chromosomes are structurally abnormal. The complement also includes 3 to 5 additional unidentified marker chromosomes resulting from structural rearrangements. In these two cases, the complexity and number of chromosome abnormalities is reflective of the severity of the lymphoma. It is recommended that all lymphomas be cytogenetically analyzed for clarification that can provide both an indication of disease progression and a better understanding of these malignant tumors.

Deletions of 11q22-23 and 13q14.3 detected by fluorescence in situ hybridization (FISH) are associated with aggressive clinical course in chronic lymphocytic leukemia (CLL). A.W. Block¹, J.M. Panasiewicz¹, M.L. Hackbarth², J. Ramanarayanan³, A. Chanan-Khan³. 1) Clinical Cytogenetics Lab, Roswell Park Cancer Inst, Buffalo, NY; 2) Vysis, Inc, Downer's Grove, IL; 3) Department of Medicine, Roswell Park Cancer Inst, Buffalo, NY.

Chronic lymphocytic leukemia (CLL) is a malignant disorder characterized by progressive accumulation of functionally incompetent B-lymphocytes. The outcome of the disease is variable and depends upon the clinical stage with median survival ranging from 7-10 years in limited and 2-3 years in advanced stage disease. Genomic aberrations are not yet considered part of the staging system, though various abnormalities have been noted to have clinical significance. Conventional cytogenetic analysis is often unsuccessful due to the low mitotic index of these malignant cells thus yielding limited information. We established a fluorescence in situ hybridization (FISH) - based panel to detect numerical and submicroscopic chromosome abnormalities in non-dividing interphase cells. Mononuclear cells from peripheral blood and bone marrow of 23 patients (14 males, 9 females; median age 60, range 38 - 87 years) were analyzed by FISH for chromosome 12 trisomy, deletions of chromosome bands 11q22-23 (ATM), 13q14-14.3 (Rb1/D13S25/LAMP1), and 17p13 (p53); and translocations involving 14q32 (IgH). Chromosome abnormalities were identified in 14/23 patients (pts). The most frequent changes were mono- and bi-allelic deletions of 13q (11/14 pts) and deletions or rearrangements of 11q (5/14 pts). 4/14 pts had 2 aberrations with 3/4 pts with deletions of both 11q and 13q and 1/4 pts with rearrangement of 11q and 17p deletion. One patient had a 14q32 rearrangement with an unidentified translocation partner. No trisomy 12 was observed. While 13q abnormalities have been associated with long treatment-free intervals, patients with concurrent deletion of 11q and 13q in this study population had chemotherapy-refractory advanced stage disease and poor clinical outcome.

Monoplastic Synovial Sarcoma with Clonal Complex Translocations involving Chromosome number X,2,3,8,15 and 18. *J.H. Lin, I. Akhtar, E. Seguerra, N. Motiwala, L. Freedman, H.O. Shah.* Pathology & Labs, Nassau University Medical Ctr, East Meadow, NY. / SUNY at Stony Brook, Stony Brook, NY.

This 21-year-old woman presented with two rather well circumscribed firm nodules on the postero-lateral aspect of the right elbow measuring up to 5.0 x 4.0 x 4.0 cm. She developed similar nodules at different times since she was 16 years of age for which she underwent surgery four times in Turkey and the lesions were diagnosed as inflammatory fibromatosis. Fine needle aspirate biopsy and immunohistochemistry studies showed small blue cell tumor of low-grade sarcoma, likely of synovial sarcoma. The differential diagnosis included primitive neuroectodermal tumor, Ewings sarcoma, alveolar rhabdomyosarcoma, lymphoma, and malignant melanoma. The follow-up surgical specimen revealed monophasic synovial sarcoma.

Cytogenetic study of the tumor revealed a wide array of clonal complex translocation 46,X,t(2;18;X;8)(p16;q11.2;p11.2;q24.1),t(2;3)(p13;p21)add(15)(p10). Translocation, t(X;18)(p11;q11) involving a transcriptional activation domain on the SYT gene on chromosome 18q11., to a certain degree, helps elucidating proper diagnosis in difficult cases. Abnormalities such as found in this case define, in part, the critical events in soft tumor oncogenesis and may contribute to more accurate diagnosis, prognosis and treatment strategies. To date, this kind of translocation has been seen in each case of fibrosarcoma and malignant fibrous histiocytoma.

Cryptic and complex chromosomal rearrangements and deletion of P53 gene identified by fluorescence in situ hybridization in a patient with Mantle Cell Lymphoma. *S. Li¹, L. Zhang¹, W.F. Kern², M. Gupta³, R.E. Eichner³, F.R. Bates¹, J.J. Mulvihill¹.* 1) Dept Pediatrics, BSEB224, Univ Oklahoma Hlth Sci Ctr, Oklahoma City, OK; 2) Dept Pathology, Univ Oklahoma Hlth Sci Ctr, Oklahoma; 3) Dept Medicine, Univ Oklahoma Hlth Sci Ctr, Oklahoma.

A 50-year old man was referred for an evaluation of chromosomal anomalies associated with a mantle cell lymphoma (MCL). In addition to a translocation between chromosomes 11 and 14 [t(11;14)(q13;q32)] detected by G-banded chromosome analysis, the patient also had a deletion of chromosome 10 [del(10)(q24)], and other unidentifiable, but consistent marker chromosomes in some of his peripheral blood cells. FISH analysis utilizing multiple DNA probes was performed. The patient had complex translocations among five chromosomes; 8, 11, 14, 17, and 21 and a deletion of p53 gene other than t(11;14) and the deletion of chromosome 10. Interestingly both homologues of 14, 17 and 21 were involved, and three chromosomal breaks were occurred on homologues of chromosome 14. Those translocations are cryptic and impossible to detect by conventional cytogenetic studies. Those subtle changes could be unrecognized before but commonly present in the majority of patients with mantle cell lymphoma.

Genetic status of chronic myeloid leukemia patients and the clinical course of disease. *S. Moore, J. Beerworth, A. Hillier, T. Kuczek, M. Nicola, J. Suttle, T. Hughes.* Cancer Cytogenetics Unit, Division of Hematology, Institute of Medical & Veterinary Science, Adelaide, Australia, 5000.

The effect of karyotype, BCR-ABL transcript, ABL-BCR transcript and BCR-ABL D-FISH deletion on presentation characteristics, duration of chronic phase and overall survival of CML patients was examined. The median follow up was 115 months (range 86 - 228 months). Conventional cytogenetic analysis, RT-PCR and D-FISH were performed on 55 presentation CML patient BM samples. Case notes were reviewed for the patients clinical data at presentation, response to therapy, duration of chronic phase and overall survival. An additional 17 cases were analysed by D-FISH because they had either a complex Philadelphia (Ph) rearrangement (bringing the total number in this group to 14) or additional abnormalities at presentation (bringing the total number in this group to 12).

The 55 patients in the original study group all expressed BCR-ABL; 22 had b2a2, 29 had b3a2 and 4 had both transcripts. 30 of the 55 also expressed ABL-BCR. With regard to the parameters studied there was no significant difference between these groups. All patients with ABL-BCR expression lacked D-FISH deletions. Of the 25 ABL-BCR negative patients, 7 had deletions detected by D-FISH. 6/14 patients with a complex Ph contained D-FISH deletions, although none of the 12 patients with additional cytogenetic abnormalities were seen to have a deletion of the der(9). 13 of the patients tested by D-FISH were treated with Imatinib, and of these, 4 developed resistance because of a mutation in the ABL Imatinib binding site. One of the patients with ABL mutation showed a D-FISH deletion.

Neither the type of BCR-ABL fusion transcript nor the presence of ABL-BCR fusion transcript affects clinical parameters at presentation of CML, nor do they mark patients with altered response to therapy or survival times. D-FISH deletions are not seen with greater frequency in patients who show additional abnormalities at presentation, and are more common in patients who have a complex Philadelphia rearrangement.

Complex chromosomal abnormalities in myelodysplastic syndromes (MDS) and acute myeloid leukemia (AML) studied by M-FISH. *P.W. Hsu¹, J. Sarkey¹, N. Moy¹, K. Szego¹, H.D. Preisler², A. Raza².* 1) Pediatrics, Rush Medical College, Chicago, IL; 2) Rush Cancer Institute, Rush Medical College, Chicago, IL.

Accurate identification of complex chromosomal abnormalities (CCA) in MDS and AML patients has been hampered by limitations of G-banding analysis (GA). Newly developed M-FISH and SKY technologies have improved the characterization of these complex aberrations. We performed M-FISH analysis on 16 MDS and 6 AML patients who presented with 3 or more chromosomal abnormalities. M-FISH analysis confirmed 71 (40%) and reclassified 94 (53%) abnormalities detected by GA. The reclassified abnormalities included mainly 41 (44 %) add and 36 (38%) mar. The origin of hsr and dmin was identified. M-FISH also revealed 9 new abnormalities. However, 3 abnormalities detected by GA were missed. In characterizing aberrations of chromosomes 5, 7 and 20, 21 of 22 cases (95%) had chromosome 5 rearrangements. Four cases (18%) had del(5q). The remaining 17 cases (81%) had chromosome 5 unbalanced translocations. Six of 17 (35%) cases had 5;17 unbalanced translocations. The other unbalanced chromosome 5 translocations involved chromosomes 13 and 15 in 3 (18%) and 2 (12%) cases, respectively. Moreover, 10 of 17 cases (59%) had different sizes of chromosome 5 segments involved in at least 2 independent unbalanced rearrangements. None of these 21 cases, however, had -5 as the sole chromosomal abnormality. Chromosome 7 abnormalities were detected in 12 of 22 cases (55%). -7 and der(7) were seen in 5 (42%) and 6 cases (50%), respectively. 7q- was only detected in one case (8%). Chromosome 20 abnormalities were observed in 11 of 22 cases (50%). All but one case (91%) had unbalanced translocations, frequently presenting as marker chromosomes. Only one case (9%) had del 20q. Our studies demonstrate that M-FISH significantly enhances the accuracy of the identification and interpretation of CCA. Clearly, complex unbalanced chromosome translocations, particularly involving chromosomes 5, 7 and 20, are the most frequent abnormalities in MDS and AML patients with CCA. The complexity of these changes suggests the presence of chromosomal instability in these patients.

Program Nr: 301 from 2002 ASHG Annual Meeting

Relationship between clinical diagnosis and cytogenetic findings in malignant hematological disorders. *M.H. Karimi-Nejad, M. Zanganeh, R. Karimi-Nejad.* PO Box 14665/154, Pathology & Genetics Ctr, Tehran, Iran.

More than 1000 bone marrow samples have been analyzed in our center. 583 cases were referred for malignant disorders, 159 for non malignant, and 258 without diagnosis at the time of sampling. Of the 159 non malignant cases, 50 and 53 for pre and post transplantation of anemia respectively, the 56 remainder for post transplantation of a malignant disorder. The probable clinical diagnosis of malignant cases were: 181 for ALL, 174 AML, 143 CML, 34 MDS, 28 for lymphomas and 26 for other malignancies such as MM, MPD, and CLL. 145/181 of ALL, 163/174 of AML, 130/143 of CML, 33/34 of MDS, 26/28 of lymphoma, 47/50 of anemia and all of pre- or post- bone marrow transplantation cases were conclusive. When we divided these figures into two categories of first 500 and final 500 cases, inconclusive cases have decreased significantly. The decrease in failure rates are most significant in ALL cases, from 28% to 5% and in CML, from 11% to zero. The main reason is better clinical information at time of sample reception, consequent to closer communication with clinicians enabling better culture and handling techniques. Our data indicate that close communication and necessary clinical information is a prerequisite to appropriate culture set up and handling, influencing greatly the rate of culture failure; and also essential for effective cytogenetic analysis of bone marrow spreads.

Cytogenetic study of malignant triton tumor: a case report. *A.L. Hawkins, M.H. Haddadin, D. Depew, P.P. Long, C.A. Griffin.* Departments of Pathology and Oncology, The Johns Hopkins University School of Medicine, Baltimore, Maryland.

Malignant triton tumor (MTT) is a highly malignant neoplasm, classified as a variant of malignant peripheral nerve sheath tumor (MPNST) with rhabdomyoblastic differentiation. Few cytogenetic studies of MTT have been reported using conventional G-band analysis. Here we report a comprehensive cytogenetic study of a case of sporadic MTT using G-banding, Spectral Karyotyping (SKY), and fluorescent in situ hybridization (FISH) for specific regions. A complex hyperdiploid karyotype with multiple unbalanced translocations was observed: 48~55, XY, der(7)add(7)(p?)dup(7)[2], der(7)t(7;20)(p22;?)ins(20;19)[5], der(7)ins(8;7)(?;p22q36)t(3;8)t(8;20)[15], -8[19], r(8)dup(8), +der(8)r(8;22)[4], -9[9], der(11)t(3;11)(?;p15)t(3;19)t(19;20), der(12)t(8;12)(q21;p11), der(13)t(3;13)(p11;q24), -17, -19, der(19)t(17;19)(q11.2;q13.1), -20, -22, +4~7r [cp25] / 46,XY [11] following ISCN 1995 nomenclature where possible. However, note that breakpoints were frequently omitted where only SKY information was known for a small part of an involved chromosome. Most cells also contained multiple acentric fragments and at least one large ring chromosome, which by SKY was shown to be derived from several apparently monosomic chromosomes, including multiple inclusions of chromosome 8. Our analysis revealed some breakpoints in common with previously reported MTT, MPNST and rhabdomyosarcomas (RMS), namely 7p22 and 11p15. FISH study showed high increase of copy number for CMYC and loss of a single copy of TP53, in contrast to the normal copy numbers of both genes most commonly reported in MPNSTs.

Analysis of Chromosomal Imbalances in Korean Ovarian Cancer using Degenerate Oligonucleotide Primed PCR-Comparative Genomic Hybridization. *G.J. Kim¹, J.O. Kim², J.Y. Lee¹, E.K. Hong³, Y.H. Chun¹, S.H. Park¹.* 1) Dept. of Anatomy, Korea University College of Medicine, Seoul, Korea; 2) Dept. of Obstetrics & Gynecology, Eulji University School of Medicine, Seoul, Korea; 3) Dept. of Pathology, Korean National Cancer Center.

Ovarian cancer is the fourth leading cause of cancer death among women in the world and yet its pathogenesis is poorly understood. Little is known about genetic abnormalities in ovarian cancers because of the difficulty to growing them in culture for chromosome studies. Recently, studies using technique of degenerate oligonucleotide primed PCR (DOP-PCR) - comparative genomic hybridization (CGH) permits genetic imbalances screening of the entire genome using only small amounts of tumor DNA. Twenty-three of ovarian cancers were investigated for chromosomal aberrations by DOP-PCR-CGH on microdissected tissues. Twenty-two of ovarian cancers were investigated for chromosomal aberrations by DOP-PCR-CGH on microdissected tissues. The most frequently detected chromosomal gains involved 1q32-qter (32%), 2q31-qter (32%), 3q25-qter (63%), 6p21 (63%), 7q (45%), 8q22-qter (73%), 14q31 (45%), 15q24-qte (45%), 16p (45%), 17q23-qter (90%), 20q (73%), and Xp (54%). The most frequently detected loss of chromosomal materials involved 4q21-q31 (50%), 5q13-q21 (63%), and 13q21 (50%). The recurrent gain and loss of chromosomal regions identified in this study provide candidate regions that may contain oncogenes or tumor suppressor genes respectively involved in the tumorigenesis of ovarian cancer.

Identification of chromosomal imbalances in Korea metastatic gastric cancer by degenerate oligonucleotide primed-PCR-comparative genomic hybridization. *J.Y. Lee¹, H.Y. Hwang¹, S.J. Cho², N.H. Won², Y.H. Chon¹, S.H. Park¹.* 1) Dept.of Anatomy, Korea Univ College Med, Seoul, Korea; 2) Dept.of Pathology, Korea Univ College Med, Seoul, Korea.

Gastric cancer is the major cause of cancer deaths in Asian countries, including Korea. Genetic changes during the progression and metastasis of gastric cancer remain unclear. The aim of this study was to analyze chromosomal imbalances in early and advanced metastatic gastric cancers. Comparative Genomic Hybridization (CGH) analysis was used to identify chromosomal imbalances in 12 early and 23 advanced metastatic gastric cancers. In early metastatic gastric cancer, common gains were detected at 6p22-q24 (58%), 4 (58%), 5p15.2-q33 (50%), and 8p21-qter (50%), and common losses were detected at X (42%) and 1p33-pter (25%). In advanced metastatic gastric cancer, common gains were detected at 20q (65%), 8p21-qter (65%), 5 (57%), and 7pter-q31 (52%), and common losses were detected at X (35%), 1p33-pter (30%), 16p (26%), and 17p12-p13 (22%). Chromosomal imbalances identified in this study provide candidate regions that may play some important role in the progression and metastasis of gastric cancers.

Multicolor deconvolution microscopy of thick biological specimens. *C. Maierhofer*¹, *M. Neumann*², *M. Speicher*¹. 1) TU Munich, Institute of Human Genetics, Munich, Germany; 2) Carl Zeiss Vision GmbH, Hallbergmoos, Germany.

One limitation to understanding disease at the cellular level has been the inability to analyze DNA efficiently on a cell by cell basis within the natural tissue context. However, DNA analyses at single cell resolution should be instrumental for the understanding of cancer cell biology, cancer evolution, for genetic mosaic analysis and rare cell events. Here we present a multicolor deconvolution technique for three-dimensional (3D) microscopy, which generates 3D data by optically sectioning the specimen. Images are captured using an epifluorescence microscope equipped with a motorized table to collect a stack of images at defined levels in z-direction. Deconvolution refers to a computational method used to reduce out-of-focus fluorescence in 3D microscopy images. After deconvolution, 3D-reconstruction algorithms are applied. In contrast to other, previous studies we employed up to seven different color channels for probe detection, which allowed the simultaneous analysis of multiple probes within biological specimen with a thickness of up to 30 μ m. In addition, a DNA counterstain is used for volume labeling of the nuclei which offers the opportunity for a simultaneous segmentation of nuclei. Different probe sets, consisting of various chromosome-centromere specific probes or of YAC/BAC-probes consisting of probes that are according to CGH-data of diagnostic or prognostic value for patients with breast or ovarian cancer were applied to normal and ovarian tumor specimen. The technology allows the analysis of tissues at a single-cell resolution and yields new insights into how cells in a tissue become increasingly heterogeneous and disorganized in their structural properties during carcinogenesis. Efforts are under way to use the interphase-FISH data to identify areas which may represent aggressive portions within a tumor. This information may then be used for a guided dissection of specific tissue regions for a "navigated" RNA-sampling are needed in order to improve the predictive power of expression analysis.

An Unusual translocation t(7;21) in a case of thrombocytopenia. *M.J. Macera¹, M. Mistry², P. Chandra¹, A. Babu¹.*
1) Div Mol Med & Genetics, Dept of Med, Wyckoff Heights Med Ctr, Brooklyn, NY; 2) Brookdale Hospital Med Ctr, Brooklyn, NY.

A 64 year old patient presented initially with a hypercellular marrow with granulocytic and megakaryocytic hyperplasia, and fibrosis consistent with myeloproliferative disorder. The platelets were reduced in number with some larger forms. There were nucleated red blood cells with an increase in neutrophils and a shift to the left (occasional metamyelocytes and myelocytes). The final diagnosis was leukocytosis with anemia and thrombocytopenia with leukoerythroblastic changes. Initial cytogenetic analysis of unstimulated peripheral blood, suggested a 46,XX,t(7;21)(p22;q22.1) translocation. A single normal cell was also detected. Due to the subtle nature of the translocation, dual color fluorescence in situ hybridization (FISH) with whole chromosome paints (wcp) for 7 and 21 was done for conformation. Signal for wcp 21 was seen over the entire normal 21 homologue and just a small proximal band on the derivative 21. Signal was also seen at the distal short (p) arms of both chromosome 7s. Signal for wcp 7 was seen over both of the chromosome 7s from qter up to p22, and a small proximal band on the derivative 21. A three probe combination (D21S259:D21S341:D21S342) with overlapping sequences, specific for the region 21q22.13-21q22.2 of chromosome 21 was applied to confirm the breakpoint. Signals were seen on the normal 21, and on both der(7) chromosomes. No signal was detected on the der(21). The karyotype was revised to 46,XX,t(7;21)(p22;q22.1).ish t(7;21)(p22;q22.1)(wcp7+,wcp21+, D21S259:D21S341:D21S342+;wcp7+,wcp21+,D21S259:D21S341:D21S342-),-7,+der(7)t(7;21)(p22;q22.1)(wcp7+,wcp21+,D21S259:D21S341:D21S342+). The most likely origin for this unusual aberration is an initial reciprocal translocation between chromosomes 7 and 21, followed by loss of the normal chromosome 7 and a duplication of the derivative 7, during the progression of the leukemic clone. Although this specific t(7;21)(p22;q22.1) translocation is not common, the acute myeloid leukemia 1 (AML1) gene located at chromosome 21q22, has been implicated in a number of hematopoietic disorders including familial thrombocytopenia.

Frequencies and characterization of cytogenetically unrelated clones in various hematologic malignancies: A seven year experience in a single institution. *J. Han*^{1, 2}, *K.S. Theil*², *G.A. Hoeltge*². 1) Clinical Pathology, Col Med, Dong-A-Univ, Pusan, Korea; 2) Clinical Pathology, The Cleveland Clinic Foundation, Cleveland, OH.

Cytogenetically unrelated clones are uncommon findings in hematologic disorders. In a retrospective review of 1,110 hematologic malignancies with clonal chromosome abnormalities analyzed during the last seven years, we found that 27 (2.4%) patients had karyotypically unrelated clones occurring in the same sample. Unrelated clones were found in 3.5% (7/202) of acute myeloid leukemias (AML), 5.3% (11/206) of myelodysplastic syndromes (MDS), none of 40 acute lymphoblastic leukemias (ALL), 0.4% (1/233) of myeloproliferative disorders (MPD), and 2.6% (8/306) of lymphoproliferative disorders (LPD). Twenty-five patients showed two unrelated clones and two had three unrelated clones. The most consistent clonal chromosome abnormalities were del(5q) (7 cases), +8 (6 cases), del(20q) (5 cases), and del(7q), +12, +21, and 22 (three cases each). Of interest, in nine patients the unrelated clones differed by having numerical or structural aberrations that involved the same chromosomes: three patients presented structural abnormalities of one chromosome in one clone and numerical abnormalities of the same chromosome in the unrelated clone; three showed two different structural aberrations with different breakpoints involving the same chromosomes in two unrelated clones; and the remaining three patients had two different structural chromosome abnormalities involving the same chromosomes and same breakpoints. These findings, together with the high frequency of intermediate clones and unbalanced, secondary-type cytogenetic aberrations, are evidence of karyotype instability. Unrelated clones may originate from a common precursor not recognizable as abnormal at the cytogenetic level through submicroscopic molecular genetic changes and evolutionary processes. Further study of gene expression patterns in cases with unrelated clones may help identify molecular similarities in the clones that appear to be seemingly unrelated at the karyotype level.

Mechanisms of tumorigenesis in mammary tumors from BALB/c-Trp53-heterozygous mice: A model for Li-Fraumeni syndrome. *R. Naeem*¹, *A.C Blackburn*², *M.S Mohammed*⁴, *S.P Naber*³, *D.J Jerry*². 1) Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Department of Veterinary & Animal Sciences, University of Mass. Amherst, MA; 3) Spectral Genomics, Houston, TX; 4) Department of Pathology Baystate Medical Center, Springfield, MA.

Breast cancer is the most common tumor type observed among women with Li-Fraumeni syndrome (LFS). Mammary tumors (MT) are also the most prevalent tumor type in BALB/c-Trp53-heterozygous female mice suggesting a genetic predisposition towards mammary tumorigenesis. The spectrum and histopathology of MT in this background is similar to the LFS patients, and therefore, presents a unique model for the study of breast cancer in LFS. The mechanisms of mammary tumorigenesis were examined in these p53-deficient mice. Loss of the wild type allele of Trp53 (LOH) was detected in the majority of mammary tumors from BALB/c-Trp53-heterozygous females (96%). LOH was also observed in 85% of the lymphomas and sarcomas arising in these mice which was similar to the rate of LOH for mammary tumors ($P=0.35$). To study the mechanism of LOH, normal tissues and tumors from 8 mice were karyotyped using short-term culture methods. FISH was used to further characterize the cytogenetic results. BAC CGH microarrays were applied to corroborate the cytogenetic results and to identify genomic regions undergoing frequent loss and gain. The mammary tumors contained a hypodiploid population of cells lacking one copy of chromosome 11 as well as a near-tetraploid population of cells. The BAC CGH data also indicated loss throughout chromosome 11. These results demonstrate that loss of the wild type allele of Trp53 in these mammary tumors results from missegregation of chromosomes rather than deletions. Preliminary results suggest that recombination within chromosome 11 occurs frequently and precedes loss of heterozygosity.

Acute Promyelocytic Leukemia (APL) with cryptic t(15;17), and atypical morphology demonstrating PML/RAR Alpha-gene transcript by FISH Method. *H.O. Shah¹, L.I. Sheng¹, E. Seguerra¹, M. Macera², H. Shih¹, J.H. Lin¹.* 1) Pathology & Lab Cytogenetics, Nassau Univ Medical Ctr, East Meadow, NY. / SUNY at Stony Brook, Stony Brook, NY; 2) Wyckoff Heights Medical Center, Brooklyn, NY.

This 28-year-old black woman presented to our emergency room for rectal bleeding and heavy menses for past two weeks. The CBC showed WBC 12K/mm³, RBC 3.1 mil./mm³ Hb 9.3g/dl, Hct 27.6%, MCV 88.7 fl and platelet 16K/mm³. There were 7% myeloblasts and 34% of promyelocytes with reniform nuclei in the peripheral smear which showed positive myeloperoxidase stain. No Auer rods were identified. The peripheral blood chromosomal studies were carried out under impression of acute promyelocytic leukemia (FAB, AML-M3) on admission. Shortly after admission, she suddenly developed disseminated intravascular coagulopathy and went into coma with severe upper gastrointestinal bleeding and intracranial hemorrhage. The coagulation tests revealed fibrinogen, 99 mg/dl and D-Dimer, >8.0 microgram/ml < 16.0 micrograms/ml. The patient was then treated with Heparin infusion (300 u/hr) for two days. However, the condition deteriorated and she succumbed on the third hospital day.

Most classic APL shows PML-RAR alpha gene fusion with exceptional cases lacking this change. The resultant chimeric protein is very much responsible for a variety of clinical manifestations and inferences of specific therapeutic strategy for patients with APL. In rare cases, no apparent chromosomal abnormality is seen in chromosomes Nos. 15 or 17. In such cases, FISH study with t(15;17) probe (Vysis) can clinch the accurate diagnosis. In the present case with the apparently normal cytogenetic and atypical morphology on peripheral blood, the diagnosis of APL was confirmed by the FISH technique.

PA-1, a human ovarian teratocarcinoma cell line, demonstrates a single chromosome abnormality, t(15;20)(p11.2;q11.2): analysis with FISH, SKY, and BAC microarray analysis. S.A. Sarraf¹, R. Tejada¹, T. Dennis², M. Oberst¹, K.C. Simon¹, J.K. Blancato¹. 1) Oncology, Georgetown University, Washington, DC; 2) National Human Genome Research Institute, NIH, Bethesda, MD.

Chromosomal changes are associated with altered regulation of oncogenes and tumor suppressors. Cell lines derived from primary tumors contain numerous chromosomal aberrations, which are studied to delineate progressive steps in tumor evolution. The ovarian teratocarcinoma cell line, PA-1, demonstrates a single chromosomal aberration: a reciprocal translocation, t(15;20)(p11.2;q11.2) (Zeuthen et al. 1980). Chromosome 20q amplification is implicated in both breast and ovarian cancer as a poor prognostic marker; this region contains a number of oncogenes including AIB1, STK15, MDM2, ZNF217, and the ovarian tumor marker HE4 (Courjal et al. 1996; Tanner et al. 2000; Bingle et al. 2002). The PA-1 cell line was analyzed in our lab using fluorescence in situ hybridization (FISH), spectral karyotyping (SKY), and BAC microarray analysis. FISH revealed gene amplification of AIB1(20q12) and that STK-15 (20q13) was present in normal copy number. SKY analysis and rev ish after microdissection confirmed the presence of the consistent single change, t(15;20)(p11.2;q11.2). Immunoblot demonstrated 3.6-fold over-expression of the AIB1 protein product, but no elevation of the STK-15. BAC oncogene microarray analysis showed minimal gene amplification of TERC (3q26.3), PAK1 (11q13.5-q14), KRAS2 (12p12.1), ERBB2 (17q21.2), and JUNB (19p13.2). The regulation of AIB1 and/or other oncogenes in the 20q12-13 region, have been affected due to the translocation. This abnormality appears to cause overexpression of the AIB1 or other protein products and may provide a stabilizing or immortalizing effect on the cell line. Further studies are aimed at directed analysis of the translocation breakpoints in the PA-1 cell line. Bingle, L. et al. (2002). *Oncogene* 17(21): 2768-73. Courjal, F. et al. (1996). *British Journal of Cancer* 74: 1984-1989. Tanner, M. M. et al. (2000). *Clinical Cancer Research* 6(5): 1833-9. Zeuthen, J. et al. (1980). *International Journal of Cancer* 25(1): 19-32.

Characterization of Myoepithelial tumors using combined cytogenetic, microarray and immunohistochemical approach. *G.R.V.N. Velagaleti*^{1,2}, *H. Kuivaniemi*^{3,4}, *G. Tromp*⁴, *J. Palazzo*⁵, *K.M. Graves*², *M. Guigneaux*⁶, *T. Wood*⁶, *M. Sinha*⁶, *B. Luxon*⁶, *Z. Gatalica*². 1) Department of Pediatrics, University of Texas Medical Branch, Galveston, TX; 2) Department of Pathology, University of Texas Medical Branch, Galveston, TX; 3) Center for Molecular Medicine & Genetics, Wayne State University, Detroit, MI; 4) Department of Surgery, Wayne State University, Detroit, MI; 5) Department of Pathology, Thomas Jefferson University, Philadelphia, PA; 6) Department of Human Biological Chemistry & Genetics, University of Texas Medical Branch, Galveston, TX.

Myoepithelium is an integral part of the mammary ductal and lobular architecture, positioned between luminal cells and the basement membrane. Myoepithelial hyperplasia frequently accompanies luminal epithelial hyperplasia, but true myoepithelial neoplasms are distinctly rare. The gene expression profile of a benign, pure myoepithelial tumor carrying a reciprocal translocation involving chromosomes 8 and 16 [46,XX,t(8;16)(p23;q21)] was analyzed using Affymetrix® Gene chip®U95AV2. Differential analysis identified 857 genes with 2 or more fold mRNA change in comparison to pooled normal breast control. Expression results were grouped based on the chromosomal location of the genes and protein function. Immunohistochemical analysis (IHC) of 15 such protein products confirmed these results, both in normal and tumor tissues. The predictive value of 3 antigens (GH, ninjurin 1, and CK19) was tested in additional cases of benign and malignant myoepithelial mammary and salivary gland tumors and an identical pattern of protein expression was observed. Additionally, a 23-fold increase in growth hormone mRNA, and 32-fold increase in ionotropic glutamine receptor GluR2 in the tumor indicated the existence of two autocrine growth loops, which were confirmed by IHC. Our results reaffirmed the value of microarray analysis in rapid and comprehensive identification of diagnostically useful tumor markers and identified several potential pathogenetic mechanisms (autocrine and paracrine growth stimuli) in the development of myoepithelial tumors.

MICROMETASTASIS DETECTION IN PERIPHERAL BLOOD FROM BREAST CANCER PATIENTS BY CYTOGENETIC TECHNIQUES. *A.E. Rojas-Atencio¹, M.L Soto-Alvarez¹, K.M. Urdaneta¹, L. Gonzalez², G.R. Garcia¹, F. Alvarez - Nava¹, H. Acevedo².* 1) Unidad de Genetica, Universidad del Zulia, Maracaibo - Zulia, Venezuela; 2) Hospital Clinico, Maracaibo - Zulia, Venezuela.

The identification of micrometastasis in peripheral blood (PB) from cancer patient become an important tool in the management of neoplasia due to is a marker metastasis prognostic. The objective of this study was to investigate the presence of tumoral cells on PB from patient with breast cancer (BC), by standard cytogenetic techniques. Twenty-four and Twelve samples from tumoral tissue and PB from patient with invasive and in situ BC were analyzed, respectively. At least 20 and 50 100 metaphase in tumoral tissue and PB were screened, respectively. Chromosomal abnormalities in 61,11%; patients with invasive BC versus 25%; patients with in situ BC were found. By comparing the chromosomal abnormalities seen in tumoral tissue and PB, 63%; were same in both analyzed samples, this findings was significant statically. In conclusion the identification of chromosomal abnormalities in PB from breast cancer patients, could be considered as micrometastasis, since the presence of early metastasis on subject with this findings and in situ BC it has been reported of this manner, PB cytogenetic analysis in patients with BC could became in other tool to define recurrence risk and death in these patients.

Telomeric Fusion as a Mechanism for the Loss of Chromosome 1p in Meningioma. *J.R. Sawyer^{1,2}, M. Husain², J. Lukacs¹, R. Lichti-Binz¹, O. Al-Mefty³.* 1) Cytogenetics Laboratory, Arkansas Children's Hosp, Little Rock, AR; 2) Department of Pathology, University of Arkansas for Medical Sciences, Little Rock, AR; 3) Department of Neurosurgery, University of Arkansas for Medical Sciences, Little Rock, AR.

Chromosome aberrations in meningiomas are characterized by the primary aberration of monosomy 22 in benign tumors. The most common secondary aberration is the deletion of 1p, which is associated with the progression to atypical and malignant tumors. We report a detailed cytogenetic investigation of chromosome aberrations in a series of 88 meningiomas using Giemsa banding, and multicolor spectral karyotyping (SKY). Clonal chromosome aberrations were identified in 46 (52%) tumors by G-banding. Thirty-five tumors showing complex chromosome aberrations not fully characterized by G-banding were subsequently reanalyzed by SKY. The SKY technique refined the G-band findings in 18 (51%) of the tumors on which it was applied. The most common features of cytogenetic progression in the complex karyotypes were chromosome arm specific losses relating to the formation of deletions and dicentric chromosomes involving chromosome 1p. Part or all of chromosome 1p was lost in 19 tumors. Five tumors showed evidence for the loss of 1p in a progressive step-wise series of telomeric fusions involving the formation of unstable intermediates resulting from breakage-fusion-bridge (BFB) cycles. Five recurring dicentric chromosomes were identified, including dic(1;11)(p11;p11), dic(1;12)(p12~13;p11), dic(1;22)(p11;q12~13), dic(7;19)(p11;p11) and dic(19;22)(p11~p13;q11~q13). These findings provide evidence that chromosome behavior subsequent to telomeric instability plays a role in the formation of clonal deletions, dicentrics, and unbalanced translocations of 1p.

Spectral karyotyping (SKY) analysis for complex chromosomal abnormalities in adult non-endemic Burkitts lymphoma. *B.B. Wang¹, C.Y. Chung², C.S. Chang², L.J. Hsieh¹, H.M. Chang³.* 1) Ctr Medical Genetics, Changhua Christian Hosp, Changhua, Taiwan; 2) Division of Hemato-oncology, Department of Internal Medicine Changhua Christian Hosp, Changhua, Taiwan; 3) Department of Pathology Changhua Christian Hosp, Changhua, Taiwan.

Some non-Hodgkin lymphomas (NHL) have clonal chromosomal abnormalities with specific or non-specific changes. Such abnormalities are often difficult to identify by conventional G-banding, but relatively easy to refine by spectral karyotyping (SKY) analysis. SKY analysis is a new molecular cytogenetic method that is based on the hybridization of 24 fluorescently labeled painting probes to a chromosome spread, allowing the visualization of chromosomes in different colors in one experiment. We report a case of non-endemic Burkitts lymphoma with involvement of many chromosomal changes in a bone marrow specimen. By conventional G-banding, the analysis showed multiple numerical and structural chromosomal aberrations involving 2p, 3p, 6p, 8q, 9p, 14q, 18q and X chromosome, but with no further information about the breakpoints or interchromosomal changes. However, SKY analysis was able to refine all the aberrations, and even revealed further the presence of a hidden translocation between chromosomes 8 and 14, a frequently observed reciprocal translocation in Burkitts lymphomas. Thus, with combined use of G-banding and SKY analysis, we were able to refine all the complex chromosomal changes, confirmed the presence of a 8;14 translocation, and foremostly, redesignated the karyotype to be 51,XXX, t(2;9) (p23;p13), +der(3)t(3;18)(p25;q21), t(6;9)(q21;p22), t(8;14) (q24.1;q32),+12,+13, -18, +der(18) t(8;18) (q24.1;q32)x2.

Cytogenetic and FISH studies of five cases of solid tumor.. *C.W. Yu¹, Y. Yang¹, F. Shipkey², J. Keeton³, J. Wyatt-Ashmead².* 1) Dept. of Preventive Medicine; 2) Dept. of Pathology; 3) Dept. of Pediatrics, University of Mississippi Medical Center, Jackson.

Specific chromosomal anomalies are frequently associated with particular cancers. The analysis of chromosomes provides useful information for cancer classification and treatment. We report here the cytogenetic and FISH studies from two meningiomas, one ovarian and two renal tumors. **Case 1.** BG, a 56-year-old white female, was referred due to the gradual onset of decreased vision, headaches and overall slowing of mentation. CT scan found a large frontal meningioma. Cytogenetic and FISH studies of the tumor indicated a large pericentric inversion 7. **Case 2.** JT, a 44-year-old male, was referred because of moderate double vision and difficulty walking. CT scan revealed a left sphenoid wing meningioma. Cytogenetic study of the tumor revealed a 7/22 translocation and monosomy 22. **Case 3.** JP, an 18-year-old black female with a history of Wilm's tumor, was referred because of a sex-cord stomal tumor. CT scan revealed a pelvic mass that was found to be stage III-C ovarian cancer. Cytogenetic and FISH studies of the abdominal mass revealed a derivative chromosome 11 resulting from a deletion and a pericentric inversion. **Case 4.** LN, a 6-year-old black male was referred due to bowel pain. Renal ultrasound identified an echogenic mass on the anterior surface of the right kidney. Cytogenetic and FISH studies of the tumor revealed a derivative 15 consisting of chromosome 15 and the long arm of 7. **Case 5.** NS, a 4-year-old black male, was referred because of decreased activity. On evaluation, a left renal tumor was found. Cytogenetic study of the renal mass indicated a clonal evolution with chromosome number ranging from 53 to 55. Abnormality of chromosome 7, either structural or numerical, was seen in four of the five tumors that we studied. Structural rearrangement of chromosome 11 and either structural change of chromosome 22 or monosomy 22 were found in the ovarin tumor and the meningioma respectively.

TEL/ABL gene fusion shown by FISH using commercially available probes in a patient with CML, eosinophilia and a t(9;12)(q34;p13). *M.J. Pettenati*¹, *M. Beaty*², *Yi-K. Keung*³. 1) Depts Pediatrics/Medical Genetics; 2) Pathology; 3) Internal Medicine/Hematology and Oncology, Wake Forest Univ Sch Medicine, Winston-Salem, NC.

CML is a myeloproliferative disorder characterized by cytogenetic or molecular genetic evidence of a t(9;22). We identified a case of Ph- CML with eosinophilia and a t(9;12)(q34;p13) with a TEL/ABL gene fusion shown by commercially available FISH probes.

The individual presented with persistent leucocytosis after an episode of lobar pneumonia. The marrow was 100% cellular composed largely of neutrophilic and eosinophilic precursors and was pathologically consistent with CML. An initial RT-PCR analysis of BCR/ABL showed a positive gene rearrangement. Karyotypic analysis revealed a 46,XX,t(9;12)(q34;p13). FISH with BCR/ABL probes failed to detect any fusions. A repeat RT-PCR analysis failed to detect a bcr/abl fusion. A follow-up cytogenetic study was unchanged. There are 7 reported cases of TEL/ABL gene rearrangements by DNA analysis, one with a chromosome abnormality. By using commercially available FISH probes, LSI BCR/ABL and TEL/AML1, we were able to demonstrate fusion of the ABL and TEL at 9q34.

The TEL(ETV6) gene is a member of the E26 transformation-specific family of transcription factors located at 12p13. Its role of leukemogenesis has been shown as a fusion partner in cases of t(5;12)(q33;p13), t(12;22)(p13;q11) [MN1/ETV6], t(3;12)(q26;p13) [ETV6/EVI1], and t(12;21)(p13;q22) [ETV6/AML1]. TEL(ETV6) is a very promiscuous gene involved in with over 40 different chromosome rearrangements. TEL is the only non-BCR fusion partner for ABL in human leukemia reported to date. Cytogenetically, this 9;12 chromosomal translocation can be difficult to detect. One can demonstrate the fusion of ABL and TEL using commercially available FISH probes in combination. This combination of probes may prove useful in the cytogenetic evaluation of cases with a similar cytogenetic abnormality or CML cases lacking the 9;22 translocation/fusion.

Gain of Chromosomes 7/7q and 11p in neuroblastoma. *R.L. Stallings^{1,2}, M. Mullarkey¹, C. Breen¹, J. Howard¹, A. Dunlop¹, M. McDermott³, F. Breatnach³, A. O'Meara³.* 1) National Ctr Medical Genetics, Our Lady's Hosp Sick Children, Dublin, Ireland; 2) Faculty of Medicine, University College Dublin, Dublin Ireland; 3) Our Lady's Hospital for Sick Children, Dublin, Ireland.

Loss of chromosome 11q material is a common genetic abnormality of advanced stage neuroblastoma and represents a distinct genetic subtype of tumour. This abnormality is frequently accompanied by unbalanced gain of the 17q region (>90%) and loss of chromosome 3p material (~70%). Gain of 11p material has also been reported in neuroblastoma with 11q loss, but at a considerably lower frequency (~10%) than the losses and gains for the 3p and 17q regions. Results reported here, however, indicate that gain of 11p may occur more frequently in the 11q- neuroblastoma subtype than was previously realized. CGH analyses of neuroblastoma from eleven patients indicated that six out of eleven tumors (55%) with loss of 11q also possessed gain of chromosome 11p. The shortest region of 11p gain was 11p11.2 to p14. G banding and FISH analysis performed on tumor cells from primary and metastatic sites indicates that gain of the 11p region occurs secondary to an unbalanced t(11;17) that led to 11q loss (and 17q gain). Gain of chromosome 7 (17/43 tumours) or 7q (5/43 tumours) material is a very common abnormality in neuroblastoma, but unlike gain of 11p, it is not restricted to the 11q- subtype and is prevalent in both low and high stage tumours. The significance of chromosome 7 gain is underscored by the fact that it was the sole abnormality detected in one tumour. We conclude that gain of 7/7q and 11p material may contribute to either neuroblastoma tumorigenesis or progression.

Comparison of cancer cell lines by karyotype and comparative genomic hybridization. *S.L. Wenger¹, J.R. Senft², L.M. Sargent², S.G. Grant³*. 1) Dept Pathology, West Virginia Univ, Morgantown, WV; 2) NIOSH, Genetic Susceptibility Lab, Morgantown, WV; 3) University of Pittsburgh, Dept Environmental and Occupational Health, Pittsburgh, PA.

Two cancer cell lines, MCF7 and ISHIKAWA, were each obtained from two sources, which maintained cells in different culture media. MCF7 was derived from breast tumor: #1 was obtained from ATCC at passage 149 and passaged an additional 16 times; #2 was cultured in another laboratory for unknown passages and subcultured an additional 95 times. Cell line #2 had a baseline HPRT mutation frequency 10-fold higher than #1. ISHIKAWA was derived from an endometrial tumor: #3 was obtained from European Collection of Cell Cultures passaged more than 3 times, was ER positive, and subcultured 130 more times; #4 was subcultured unknown times in another laboratory, was ER negative, and subcultured an additional 132 times. Cell line #4 had a baseline HPRT mutation frequency 1400-fold higher than #3. MCF7 cultures had complex karyotypes, however, similarities included up to 83 chromosomes, additional chromosomes 2,3,4,5,6,7,8,9,10,12,13,14,15,17,19,20, structural abnormalities add(3)(p25),del(6)(q21),add(22)(q13), and at least 1 of up to 17 marker chromosomes in common. The ISHIKAWA cultures each had up to 60 chromosomes with 4-6 markers, but only a missing X in common. CGH studies were performed using different colored fluorochromes to label each of the two MCF7 or ISHIKAWA cell lines, which were then co-hybridized to normal metaphases. Differences seen between the pairs of MCF7 and ISHIKAWA cultures reflect karyotype differences. Some initial DNA polymorphic data for the ISHIKAWA cell lines (Dr. R. Bamezai, New Delhi, India) suggest that they may not be derived from the same established cell line. Our studies demonstrate the utilization of CGH for comparing cell lines originating from the same specimen, but undergoing karyotypic and mutation rate changes due to different culture conditions and passage numbers.

Is a 20-cell cytogenetic analysis necessary for neoplastic bone marrow specimens? *B. Roland*^{1,2}. 1) Dept Pathology & Lab Medicine, University of Calgary, Calgary, AB, Canada; 2) Calgary Laboratory Services.

Bone marrow specimens in neoplastic disorders sometimes have a minority of cells with a chromosome abnormality. In order to detect small abnormal clones, North American guidelines require analysis of 20 or more cells from bone marrow and neoplastic blood specimens when all cells are normal. The goal of this study is to determine the effect of analysing fewer than 20 cells on the rate of detection of abnormalities.

Records from 4081 bone marrow specimens that had been analysed in one laboratory between 1991 and 2001 were examined retrospectively. At diagnosis, 20 cells had been analysed routinely; at follow-up, 30 cells had been examined for previously-identified abnormalities. 890 samples had an abnormal karyotype, and 479 of those were mosaic, with both normal and abnormal cells present. For each mosaic abnormal specimen, the following data were recorded: referring and final diagnosis, new diagnosis vs. treated, % abnormal cells, the cell at which an abnormality was first detected, and the cell at which the abnormality was confirmed as clonal.

Of the 479 mosaic abnormalities, 6 were first detected after cell #15. Therefore 6/479 (1.2%) of mosaic abnormalities, or 6/890 (0.7%) of all abnormalities that were detected by a 20-cell analysis would have been missed by a 15-cell analysis. Subgroups of data were also analysed, with similar results for samples at diagnosis, after treatment, and for most referring diagnoses and final diagnoses.

In conclusion, a 15-cell analysis of bone marrow specimens will detect 98.8% of the mosaic abnormalities and 99.3% of all abnormalities that are detected by a 20-cell analysis. These data should be considered when reviewing guidelines for the extent of cytogenetic analysis of bone marrow specimens. For some specimens at the time of diagnosis, a 15-cell analysis may be adequate, if additional cells are checked to confirm the clonality of any single-cell abnormalities that are detected.

Chromosomal imbalances and RET rearrangements in radiation-induced thyroid tumors. *H.E. Richter¹, A. Walch², J. Smida², L. Hieber¹, E. Lengfelder³, E.P. Demidchik⁴, H.-U. Weier⁵, H. Zitzelsberger¹.* 1) GSF-National Research Center for Environment and Health, Institute of Molecular Radiobiology, Neuherberg, Germany; 2) Institute of Pathology, Technische Universitaet Muenchen, Germany; 3) Radiobiological Institute, University of Munich, Germany; 4) Center for Thyroid Tumours, Minsk, Belarus; 5) Department of Subcellular Structures, Life Sciences Division, University of California, E.O. Lawrence Berkeley National Laboratory, Berkeley, CA, USA.

The aim of this study was to investigate cytogenetic changes in radiation-induced papillary thyroid tumors from children exposed to the radioactive fallout following the Chernobyl nuclear accident in 1986. The control group was comprised of tumors without radiation history. Methods used were comparative genomic hybridization (CGH) and RT-PCR analysis for RET expression. Results of this study were expected to provide leads to molecular cytogenetic mechanisms involved in radio-carcinogenesis. Frozen and micro-dissected paraffin-embedded tissues were available for CGH analyses. Ligation-mediated PCR was performed for amplification of whole genomic tumor DNA. Additionally, the specimen RNAs were analyzed by RT-PCR for specific rearrangements of the RET proto-oncogene (RET/PTC1, RET/PTC3) and general expression of the RET tyrosine kinase domain. For cases with insufficient RT-PCR amplification Southern blot analysis of PCR products were performed with radioactive labeled oligonucleotide probes. CGH analysis showed chromosomal imbalances in 23% (8 of 35) of the childhood tumors involving mostly chromosomes 1, 2, 5, 19, 20 and 22. In the non-irradiated control group from Munich, we detected copy number changes in 5/8 cases. At present specific RET rearrangements or expression of the RET domain was found in 9 of 16 childhood and 1 of 3 of the control tumors. Only one radiation-induced thyroid tumor with a rearranged form of the RET proto-oncogene (PTC1) showed additionally chromosomal imbalances detected by CGH suggesting an involvement of additional genes in the carcinogenic process. The authors gratefully acknowledge support from the US NIH (1R01 CA80792, 1R33 CA88258).

Multiple factors influence aneuploidy-driven chromosomal instability in oral squamous cell carcinoma. S.

*Reshmi-Skarja*¹, *W.S. Saunders*^{2,3,4}, *D.M. Kudla*¹, *S.M. Gollin*^{1,3,4}. 1) Department of Human Genetics, University of Pittsburgh Graduate School of Public Health, Pittsburgh, PA; 2) Department of Biological Sciences, University of Pittsburgh, Pittsburgh, PA; 3) The Oral Cancer Center at the University of Pittsburgh, Pittsburgh, PA; 4) University of Pittsburgh Cancer Institute, Pittsburgh, PA.

Oral squamous cell carcinoma (OSCC) arises through a complex, multistep process of genetic alterations. Previous studies have shown that OSCC cells exhibit near-triploid karyotypes and contain various clonal structural and numerical abnormalities. We hypothesized that in OSCC cells, chromosomal instability (CIN) is influenced by the state of aneuploidy within a cell. To test this hypothesis, we isolated six clones from two of our OSCC cell lines. Using a panel of centromere probes specific for chromosomes 4, 6, 7, 9, 11, 17, 20, and X, fluorescence *in situ* hybridization (FISH) was carried out on each of the clones. Variations in chromosome number both within clones and between clones of the same cell line were observed. However, despite similar chromosomal copy number, 'homologs' of a chromosome were structurally distinct from cell to cell ("marker chromosome evolution"). Spectral karyotyping (SKY) analysis revealed the segmental origin of these structurally aberrant chromosomes in cells within a clone. Our findings suggest that the aneuploidy observed in OSCC cells may be the result of both intrinsic chromosomal factors and extrinsic cytoskeletal factors, and that CIN is driven by their combined effects.

B-cell prolymphocytic leukemia with translocation 11;14: is it B-PLL or is it a leukemic variant of mantle cell lymphoma? C.A. Tirado, V. Golembiewski-Ruiz, J.O. Moore, P.J. Buckley, B.K. Goodman. Depts of Pathology and Medicine, Duke University Medical Center, Durham, NC.

B-cell prolymphocytic leukemia (B-PLL) is a very rare disease affecting the blood, bone marrow and spleen. It is characterized by a lymphocytic count greater than 100,000 consisting of medium to large round lymphoid cells with prominent nucleoli (prolymphocytes), marked splenomegaly, and median age of 70. Our patient presented with a fairly rapid onset of symptoms including weight loss, night sweats and dysnea or exertion. His WBC was 200,000 with 50% lymphocytes. He had massive splenomegaly and was referred to our institution for further evaluation. His white count continued to climb. Bone marrow and peripheral blood samples were sent for pathologic and cytogenetic evaluation. He had a B-cell neoplasm consisting of greater than 55% of peripheral blood cells, with prominent nucleoli, consistent with prolymphocytes. The cells expressed monoclonal surface immunoglobulin, were moderately CD5+, dimly FMC7+ and CD23 negative. Chromosome analysis showed 40-43 chromosomes with a complex karyotype including translocation 11;14, loss of chromosomes 3, 8 and 13 and iso 17q. FISH analysis showed the CCND1/IGH rearrangement with a variant pattern indicating either a breakpoint upstream of the CYCLIN D1 major translocation cluster or deletion of sequences upstream of this region. These results pose the question whether to consider this case as a B-PLL mimicking mantle cell leukemia/lymphoma or a mantle cell lymphoma (MCL) with an atypical blastoid presentation. About 1/3 of B-PLL cases and most MCL cases are CD5 positive. Both B-PLL and MCL are CD23-, FMC7+ and express IgM. While 75% of MCL are 11;14 positive, the translocation is seen in only about 20% of B-PLL cases. Deletions of chromosome 13 and the TP53 locus at 17p have been reported in both entities. Prognosis and treatment differ for these two disorders. It is critically important to fully characterize complex cases of hematologic malignancy such as this one, that share specific cytogenetic or molecular rearrangements, in order to generate criteria that will significantly affect clinical prognosis and treatment options.

The use of sub-telomere FISH and paint probes to clarify the origin of derivative chromosomes in bone marrow studies. *J.L. Smith, J.P. Cook.* Dynagene, Houston, TX.

Cytogenetic interpretation of bone marrow studies may be complicated by the presence of derivative or marker chromosomes whose identity cannot be conclusively determined by G banding. The ideal methodology for determining the exact composition of such chromosomes is by 24 color FISH; however, not every laboratory has access to this technology. We present two patients on whose samples paint probes and/or telomere FISH were useful in clarifying the composition of a derivative chromosome. Patient 1 was a 79 year old male referred for pancytopenia. The stemline and sideline had a supernumerary derivative chromosome which was very similar in appearance to the t(1;19)(q23;p13) commonly observed in lymphocytic disease. Due to the patient's age and recent reports of a t(1;19)(p13;p13.1) in myeloid disease, FISH analysis was performed. Telomere FISH (Vysis) showed one end of the derivative chromosome to hybridize with 1q and the other end to hybridize with 19p, supporting the probability that this was the 1;19 translocation consistent with myeloid disease. Since there was some question as to whether the derivative chromosome arose through centric fusion of 1q and 19p, the CEP1 a satellite probe was also hybridized to metaphase cells; both number 1 chromosomes and the derivative chromosome had CEP 1 signals. FISH analysis using paint probes for 1 and 19 from the OctoChrome panel (Cytocell) showed most of the derivative to paint with chromosome 1 and a small portion of one end to paint with 19, further supporting the interpretation of a supernumerary der(1)t(1;19) (p13;p13.1). Patient 2 was a 46 year old male referred for anemia; his condition was further complicated by a lung mass. He had a very complex karyotype which included a chromosome originally designated as der(1;19)(q10;p10). However, the derivative chromosome hybridized only with 1p and 1q subtelomeric probes indicating a deletion of 1p not a translocation involving 19p. In both patients, the clarification with telomere probes (and paint probes in one patient) allowed more accurate interpretations of the cytogenetic abnormalities which led to more accurate clinical significance statements.

Telomeric Association between Chromosomes 14 and 19 at bands p13 and q13.4 in a case of MDS/AML. *K.H. Ramesh, V.R. Pulijaal, C.T. Harrison, T. Zhou, S.K. Gogineni, D.S. Xu, L.A. Cannizzaro.* Dept Pathology, Montefiore Medical Ctr/AECOM, Bronx, NY 10461.

A 91 year old caucasian male with a 10 year history of well-differentiated adenocarcinoma of the prostate, now presenting with pancytopenia was referred for unstimulated peripheral blood cytogenetic analysis to rule out Myelodysplastic syndrome (MDS)/Myeloproliferative disease (MPD). Bone marrow biopsy showed a hypercellular marrow with left shifted granulopoiesis, 1-2 % myeloblasts and diffuse increase in reticulin fiber. Immunohistochemical studies for cytokeratin and prostate specific antigen were negative. Flow cytometry was not performed. Based on these findings the patient was diagnosed with secondary refractory anemia. The patient was put on supportive treatment and subsequently died. Cytogenetic analysis revealed a 45,XY,del(2)(q23q33),del(5)(q13q33),-7,tas(14;19)(p13;q13.4) karyotype in 35 % of the cells with the rest being normal. The abnormal clone showed loss of chromosome 7, and the structural anomalies included interstitial deletions of chromosomes 2 and 5 at bands q23q33 and q13q33 respectively, and telomere association (tas) between chromosomes 14 and 19 at bands p13 and q13.4. Fluorescence in-situ hybridization (FISH) analysis with painting probes for chromosomes 2, 5, 14 and 19, and telomere probes for 2q, 5q and 19q was performed to confirm the cytogenetic findings. A diagnosis of MDS evolving to AML was suggested based on the findings of deletion 5q and monosomy 7 and the secondary changes which included tas(14;19)(p13;q13.4). The occurrence of clonal tas in MDS/AML is a rare cytogenetic phenomenon in which there is fusion of terminal ends resulting in unstable dicentric, multicentric and ring chromosomes. Chromosomes 14 and 19p are frequently involved in tas. These are considered to be secondary changes when they occur with other characteristic anomalies that are frequently associated with MDS/AML. The identification and characterization of specific chromosomal anomalies is critical, especially when a hematological diagnosis is pending or inconclusive. This has important implications in the classification, treatment and prognosis of MDS/AML.

Chromosomal imbalances in flat and exophytic lesions of the human colon. *H. Zitzelsberger¹, H.E. Richter¹, A. Walch², P. Slezak³, M. Werner².* 1) GSF-National Research Center for Environment and Health, Institute of Molecular Radiobiology, Neuherberg, Germany; 2) Institute of Pathology, Technische Universitaet Muenchen, Germany; 3) Endoscopy Unit, Department of Gastroenterology, Karolinska Hospital, Stockholm, Sweden.

The aim of the study is to compare CGH results from flat and exophytic lesions of the human colon to study whether there are different avenues for colorectal cancer formation. Microdissected paraffin-embedded tissues were used for CGH analysis of histologically defined areas of colorectal lesions. Ligation-mediated PCR was performed for amplification of whole genomic tumour DNA. No aberrations were detected in normal epithelium (n=9). CGH analysis showed chromosomal imbalances in 71% (22 of 31 cases) of flat lesions and in 46% (13 of 28 cases) of exophytic lesions. In flat adenomas, DNA losses are frequently detected on chromosomes 16p, 17p, 20q and DNA gain is frequent on chromosome 8q. In carcinomas, gains on 8q, 20q as well as losses on 8p, 17p and 18 are recurrently observed. Exophytic adenomas showed preferentially DNA losses and gains of whole chromosomes indicating aneuploidy in these tumors. Distinct differences in chromosomal aberrations are detected in flat and exophytic lesions of the human colon. This indicates that there might be more than one avenue for colorectal cancer formation which is in accordance with morphological characteristics of polypoid cancers and cancers arising de novo, i.e. without any adenomatous component.

The Relationship between TOP2A Gene Copy Number and Topoisomerase IIa Protein Levels in Human Breast Tumors. *R.E. MUELLER¹, R. PARKES¹, F.P. O'MALLEY^{2,3}*. 1) Samuel Lunenfeld Research Inst, Toronto, Ontario, Canada; 2) Department of Pathology and Laboratory Medicine, Mount Sinai Hospital, Toronto; 3) Department of Laboratory Medicine and Pathobiology, University of Toronto.

Background: Clinical studies have suggested that tumors with HER2 gene amplification are particularly sensitive to anthracycline drugs used in adjuvant breast cancer therapy. The TOP2A gene, located adjacent to the HER2 gene on human chromosome 17q21-22, encodes topoisomerase IIa and is frequently altered in conjunction with HER2. Topoisomerase IIa is a direct molecular target for anthracycline drug action. Changes in the TOP2A gene copy number may result in altered levels of topoisomerase IIa in breast tumor cells and could contribute to differences in patient response to anthracycline therapy. **Design:** We evaluated a group of 43 formalin fixed, paraffin embedded, invasive breast tumor samples for topoisomerase IIa protein expression and cell proliferation using immunohistochemical staining, and for the copy number of TOP2A, HER2 and chromosome 17 (where both these genes normally reside) using fluorescence in situ hybridization. **Results:** Thirty-two samples had HER2 gene amplification. Of these, 11 samples (34.4%) had amplification of both genes while 16(50%) had a normal TOP2A gene copy number. Five samples (15.6%) were amplified for HER2 but showed deletion of TOP2A relative to the number of copies of chromosome 17. One sample had deletion of both HER2 and TOP2A genes. Ten tumor samples had no amplification of either gene. There was no evidence of a difference in the mean topoisomerase IIa protein level for TOP2A amplified (23.4%) vs unamplified (22.4%) cases ($p=.80$). **Conclusions:** Unlike HER2 where gene amplification is tightly linked to protein overexpression, no association was seen between the amplification of the TOP2A gene and protein expression levels of topoisomerase IIa in breast tumor cells. Protein levels of topoisomerase IIa determined by immunohistochemistry were not correlated with gene copy number in these samples suggesting that the analysis of TOP2A gene amplification in breast tumors will not identify all patients with high expression levels of topoisomerase IIa.

Evaluation of mouse telomere length with optimized Primed In Situ (PRINS) labeling technique. *J. Lavoie¹, M. Bronsard¹, M. Lebel², R. Drouin¹.* 1) Unite de recherche en genetique humaine et moleculaire, Universite Laval, Hop St-Francois d'Assise, CHUQ, Quebec, PQ, Canada; 2) Centre de recherche en Cancerologie, Universite Laval, Hop Hotel-Dieu de Quebec, CHUQ, Quebec, PQ, Canada.

Telomeres are chromosomal elements composed of (TTAGGG) DNA repeats. Telomeres are required for genomic stability; they protect chromosomes from degradation or end-to-end fusion, and are implicated in regulating the replication and senescence of cells. The gradual loss of telomeric DNA repeats has been linked to cellular aging and tumorigenesis. It is now thought that the shortening of specific telomeres at certain chromosome ends may be critical to cellular function. Therefore, methods that allow the estimation of the length of specific telomeres are of considerable interest. Individual telomeres can be analyzed using one of two methods: (i) the quantitative fluorescence in situ hybridization (Q-FISH) method, which uses the peptide nucleic acid probe and is the most popular, and (ii) the primed in situ (PRINS) labeling reaction, which produces a labeled copy of the telomeric DNA repeats in situ. We tested different conditions for DNA denaturation, labeling temperature, and other variables to optimize the PRINS reaction for detection and quantification of mouse telomeric DNA repeats. The specificity, efficiency and uniformity of staining were evaluated using digital fluorescence microscopy. Uniform staining is of paramount importance if PRINS is to provide telomere fluorescence intensity values that are sufficiently accurate for measurement of telomere length. Staining uniformity is measured by comparing the values of sister chromatids, as they are expected to contain essentially the same number of telomeric DNA repeats. Optimization of the labeling reaction resulted in an average detection efficiency of 99% and a good correlation between the values derived from sister chromatids was observed. We conclude that PRINS is a reliable method for telomere length evaluation and, compared to FISH, presents some advantages including a higher cost efficiency and less technical time. These advantages may encourage wider use of the PRINS technique for detection and quantification of telomeres in situ.

***In vitro* immediate and delayed cytogenotoxic effects of environmental concentrations of cadmium(II) in human lymphocytes.** M. Cojocaru^{1,3}, F. Fortin¹, S. Chakrabarti², N. Lemieux^{1,3}. 1) Dept. Pathologie et Biologie Cellulaire, Université de Montréal; 2) Dept. Travail et Hygiène du milieu, Université de Montréal; 3) Centre de recherche, Hôpital Sainte-Justine, Montréal, Qc, Canada.

Cadmium is a known carcinogenic metal, but its mechanism of action and the range of doses at risk for humans are not clarified. Our purpose is to study the immediate and delayed cytogenotoxicity of environmental concentrations of cadmium chloride (CdCl₂) in human lymphocytes, after an acute exposure (2hrs). The techniques used were the electron microscopy *in situ* end-labeling (EM-ISEL) and the sister-chromatid exchanges (SCE). We also investigated the induction of apoptosis and the effect on the cell cycle kinetics. The viability study showed that initially non-cytotoxic high concentrations (>150µM) have a delayed cytotoxicity, manifested after a 24 hour recovery. The cytogenotoxicity study revealed that concentrations equal or superior (0,01; 0,06; 0,1 and 1µM) to the cadmium blood concentration in smokers have a significant clastogenic effect, when measured immediately after exposure. On the other hand, the lowest tested concentration (0,002µM), equivalent to the cadmium plasma level in non-smokers, seems to act in a phase-dependent manner, producing a significant clastogenic effect only in interphase chromatin but not in chromosomes. Furthermore, a non-threshold delayed clastogenic effect was observed: while certain concentrations (0,002; 0,06 and 0,1µM) allow the recovery of the DNA integrity, other concentrations (0,01 and 1µM) significantly increase the frequency of DNA single-strand breaks at a delay of 48 hours after exposure. This last effect is associated with a delayed induction of apoptosis only in the case of the 0,01µM dose. Contrary to EM-ISEL, the SCE test has lead to negative results even at the highest doses. On the other hand, a significant slowing down in the cell cycle kinetics, dependent on the dose and on the delay after exposure, was observed. In conclusion, cadmium is a clastogenic agent at environmental concentrations. Furthermore, our study has provided more relevant information on its genotoxicity and on the related outcome by showing the persistence of induced lesions.

Inactivation of Rrb1p, a yeast nucleolar protein involved in ribosome biogenesis, results in chromosomal instability. A. Killian¹, N. Le Meur¹, P. Hieter², J-M. Flaman¹, T. Frebourg¹. 1) INSERM EMI 9906, Faculty of Medicine, 76183 Rouen, France; 2) Center for Molecular Medicine and Therapeutics, University of British Columbia, Vancouver, Canada.

Recent data have indicated that alteration of the spindle checkpoint, which controls the correct attachment of chromosomes to the spindle, might be involved in cancer. SAGE (Serial Analysis of Gene Expression) has previously been used to determine the yeast transcriptome in response to the activation of the spindle checkpoint induced by nocodazole. We have initiated functional analysis of genes induced by the activation of the spindle checkpoint and identified by SAGE. One of the genes, *ymr131c/RRB1*, is an essential gene encoding a nucleolar WD repeat protein which has recently been shown to bind the ribosomal protein rpl3 and to be involved in the assembly of the 60S ribosomal subunit. We have generated a temperature sensitive (ts) *RRB1* mutant yeast strain in which chromosomal instability was detected by a sectoring phenotype. The ts *RRB1* mutant strain demonstrated at semi-permissive temperature an abnormal sensitivity to benomyl suggesting that mutation of *RRB1* alters the spindle checkpoint. Screening of a yeast genomic library in the ts *RRB1* mutant strain led us to identify a genetic interaction between *RRB1* and *RPL3*. This study shows that inactivation of a protein involved in ribosome biogenesis may alter chromosomal segregation through an alteration of the spindle checkpoint.

Cancer incidence in first-degree relatives of a population-based set of cases of early-onset breast cancer with a known BRCA1 and BRCA2 mutation status. *H.L. Olsson, N. Loman, A. Bladstrom, O. Johannsson, A. Borg.* Dept Oncology, Univ Hosp, Lund, Sweden.

We have studied relative and cumulative cancer incidence in relatives of a population-based set of early onset breast cancer patients (N=203) with a known BRCA1 and BRCA2 germline mutation status. Among first-degree relatives (FDRs) of BRCA1 and BRCA2-mutation carriers (N=79), the standardized incidence ratio of breast cancer SIR=8.0 (95% CI=3.4-15.7) and ovarian cancer SIR=14.7 (95% CI=3.0-43.0) were elevated. In FDRs of women without a BRCA1 or BRCA2 mutation (N=705) the incidence of breast cancer was increased SIR=2.3 (95% CI=1.6-3.3). In addition, SIR of prostate cancer was elevated SIR=1.6 (95% CI=0.97-2.6). In a subgroup of women with at least two FDRs with breast cancer, but without an identified BRCA1 or BRCA2 mutation in the family (N=180), incidence of breast cancer was increased SIR=5.5 (95% CI 3.0-9.2). Cumulative incidence of breast cancer up to age 50 and 70 were calculated for FDRs of index-women with a BRCA1 or BRCA2 mutation: 19.1% (95% CI 8.8-41.8%) and 35.3% (95% CI 17.5-62.8%) respectively, translating to 36.8% (95% CI 21.0-52.6%;) and 65.3% (95% CI 42.2-88.4%) risks in BRCA1 or BRCA2 mutation carriers; for FDRs of index individuals without an identified BRCA-mutation: 3.6% (95% CI 1.3-5.7%;) and 12.8% (95% CI 6.5-15.7%); and finally for a subgroup of FDRs of index individuals without a BRCA1 or BRCA2 mutation but with at least one additional first- or second degree relative with breast cancer: 8.4% (95% CI 3.1-16.6%) and 27.7% (95% CI 13.4-46.2%) at ages 50 and 70. In FDRs of index-individuals with breast cancer <36 years of age without BRCA1 or BRCA2 mutations breast cancer risk is increased three-fold; if the index-individual was 36-41 the risk was only doubled. In addition to breast cancer, the incidence of prostate cancer is elevated among individuals with a FDR with breast cancer before age 36 but no BRCA1 or BRCA2 mutation in the family.

HY558, a novel cell cycle inhibitor, induces G1/G2 arrest and apoptosis in the human cancer cells. *C. Lee, H. Lim, M. Kim, Y. Cho.* Department of Medical Genetics, Hanyang University, Seoul, Seoul, Korea.

Proliferative disorders, cancer, are recognized as diseases of the cell cycle. In the course of screening for a novel cell cycle inhibitor, a novel CDK 1 inhibitor, HY558, was found from *Penicillium minioluteum* F558. This study reports on the biological properties of HY558 as a cell cycle inhibitor and apoptosis inducer in cancer cells. Inhibition of cancer cell proliferation: The antiproliferative effects of HY558 were assessed in six human cancer cell lines and normal lymphocytes as the control. The growth of all of the cancer cells tested, except for A549 and the normal lymphocyte cell, was inhibited in a dose-dependent manner by HY558. The estimated IC₅₀ in these cancer cell lines ranged from 0.25 to 0.33 mM. Interestingly, HY558 demonstrated no antiproliferative effect on the normal lymphocyte cells, and a low level of inhibition on the A549. Inhibition of cell cycle regulation: Flow cytometric analysis in HepG2 cells revealed an appreciable arrest of cells in the G1 and G2/M phase after treatment with 0.46 mM of HY558. Furthermore, HY558 has little effect on the expression levels of CDK 4/6, cyclin D1, and E, but decreases the levels of CDK2, and CDK1, as well as cyclin A/B1 in the HeLa cells, in which only G2/M phase arrest has been detected in flow cytometric analysis. Induction of apoptosis: To investigate the apoptotic induction by HY558, the DNA fragmentation of HeLa cells due to apoptosis was measured by a TUNEL assay. When HeLa cells were incubated with 0.46 mM of HY558 for 24 h, an apoptotic DNA fragmentation was observed. To understand the mechanism of HY558-induced apoptosis, we examined the change of the level of intracellular proteins related to apoptosis, such as Fas-L, Fas, Bcl-2, Bax, caspase-8 and caspase-9 in the HeLa cells. HY558 induced up-regulation of Bax, and activation of pro-caspase-9. However, there were no significant changes in expression of Fas, Fas-L, and Bcl-2. Furthermore, HY558 induced proteolytic cleavage of inactive pro-caspase-3 into its active form, and subsequent cleavage of its substrate PARP. The activation of caspase-9 in the HeLa cells is likely to occur via the mitochondria pathway.

Incorporating cytochrome P450 3A4 genotype expression and FT-IR/ Raman spectroscopy data as means of identification of breast tumors. *S.O. Miller¹, G.P. Gideon¹, C.M. Howard³, H. Tachikawa³, S.A. Bigler², W.H. Barber¹, M. Angel¹, D.O. McDaniel¹.* 1) Surgery, Univ of MS Medical Ctr, Jackson, MS; 2) Dept Medicine, Univ of MS Medical Ctr, Jackson, MS; 3) Depts Biology and Chemistry, JSU, Jackson, MS.

This study first seeks to determine importance of cytochrome P450s (CYPs) in breast cancer and second it utilizes the application of Fourier transform-infrared (FT-IR) and Raman spectra as a diagnostic tool in evaluating breast tissues. Making a diagnostic decision in early stage of breast cancer relies in part on biological presentation of breast tissue components. CYPs are involved in the production of potentially carcinogenic estrogen metabolites and the activation of environmental carcinogens and organic solvents. Such contaminants have been associated in the developmental pathways of mammary tumorigenesis. Thus in parallel studies we designed experiments to compare by RT-PCR, the CYPs 1A2, 1B1, 2E1 and 3A4 mRNA transcript levels and by FT-IR the relative level of carotenoids, lipids and heme-containing components with the pathology of the breast tissues. The CYP 1A2 and 2E1 mRNA transcripts were expressed in normal breast and tumor tissues. The mRNA CYP1B1 was in the order of 10-fold higher in some tumor tissues as compared with normals, but it was also detected in one breast reduction sample, with normal pathology. The CYP 3A4 mRNA transcript (380-bp fragment) was increased in the order of 10-fold in breast tumor as compared with normal tissues. In addition a 260-bp truncated fragment of 3A4 mRNA was detected in normal and reduction samples particularly in samples that the larger fragment was absent. Raman spectra of breast tumor tissue were demonstrated by an increase of heme-protein related peaks as evidenced by the peaks at 341, 674 and 1360cm⁻¹. The appearance of the heme band may imply a high level of red blood cells due to a vasculature where tumor is developing. The spectra for lipid were remarkably decreased in the same region. In summary, a combined genotype analysis and Raman spectra approach could have an ideal diagnostic value in decision making during the early stage of breast cancer.

Program Nr: 333 from 2002 ASHG Annual Meeting

A Mathematical Programming Approach for Gene Selection and Tumor Classification. *M. Sun*¹, *M. Xiong*². 1) Dept Business, Univ Texas, San Antonio, San Antonio, TX; 2) Human Genetics Center, School of Public Health, University of Texas.

A mathematical programming approach is proposed for gene selection and tissue classification using gene expression profiles. A new mixed integer programming model is formulated for this purpose. The objective is to use a minimum number of genes to classify normal and tumor tissue samples as accurately as possible. Very good results were obtained for two data sets from the literature. These results show that the mathematical approach can rival or outperform more traditional classification methods.

Computational screening and experimental validation of tumor related alternative splicing in human genome. Z. wang, S. Lo, H. Yang, S. Gere, Y. Hu, K. Buetow, M. Lee. Laboratory of Population Genetics, National Cancer Institute, Gaithersburg, MD 20877.

Alternative RNA splicing plays an important role in the normal development of eukaryotic organisms and its abnormal regulation has been frequently associated with human diseases and cancers. The purposes of this research are: 1) to develop a new algorithm to identify as many splicing variants as possible; (2) to identify the alternative splicing sites that are unique to tumor; (3) to validate the tumor related RNA splicing by experiments. We used RefSeq NM as a standard splicing model, and 11,014 NM sequences were compared with 3,471,822 EST sequences by BLAST analysis. A total of 21,345 alternative splicing sites were detected genome-wide. We mapped EST to each of the splicing site and identified 4,932 alternative splicing sites that were unique to tumors. A list of all these potentially tumor related alternative splicing sites were available at: http://ncicblion.nci.nih.gov:8080leelab/jsp/as_info/AS_Tumor.html. To validate the computation result, RT-PCR experiments were performed to evaluate aberrant RNA splicing in four tumor tissues (breast, liver, lung and prostate) as well as their matched normal tissues. 65% of predicted aberrant splicing products were verified in at least one of four tissues. Our results showed that some aberrant splicing sites were tissue specific. We also found that some aberrant RNA splicing products were absent in normal tissue but were present in various of tumor tissues. Such aberrant RNA splicing products can potentially serve as valuable molecular markers for tumor diagnosis. A web enabled alternative splicing database was created for public querying by using key words such as gene symbol, locus link ID, UniGene ID or accession number (NM_*), and is available at: http://ncicblion.nci.nih.gov:8080/leelab/jsp/as_info/LPG_ASDB.jsp.

Genetic fingerprinting of patients after allogeneic bone marrow transplantation using recipient mouthwash samples. *M. Shahrooei*¹, *A. Aleyasin*¹, *K. Alimoghadam*², *A. Ghavamzadeh*². 1) National Research Center for Genetic Engineering and Biotechnology, Tehran, Iran; 2) Cancer and Hematology Research Center, Shariati Hospital, Tehran, Iran.

Serial monitoring of chimerism after allogeneic hematopoietic stem cell transplantation (HSCT) can be performed rapidly using PCR-based assays analyzing informative tandem repeat genetic markers. Prerequisite for this type of analysis is knowledge of donor and recipient pretransplantation genotypes. In some cases, recipient cells prior to BMT are not available for genotyping of recipient's VNTRs before transplantation. Our study was to evaluate the feasibility of mouthwash samples that contains mouth epithelial cells as BM recipients only after their genotype in blood cells. Of 19 patients who had undergone BMT, DNA was isolated from mouthwash cell pellets obtained from mouthwashes. PCR analysis of six STR loci on six chromosomes was performed. Even though the mouthwash cell pellets contained about 75% epithelial cells (presumably of recipient origin) and only about 25% leukocytes (presumably of donor origin), three of nineteen patients showed recipient genotype and the rest exhibited chimeric DNA patterns from 5.0% to 60.0%. It means that this DNA contained donor and recipient material in different ranges. From our results it appears that blood cells serve as preferential DNA source in mouthwash samples which can be obtain before BMT.

Implication of 9p deletion in 1p/19q-deleted oligodendrogliomas. *C. Godfraind¹, E. Rousseau^{1,2}, M.M. Ruchoux³, F. Scaravilli⁴, M. Vikkula².* 1) Division of Neuropathology, Université catholique de Louvain, Brussels, Belgium; 2) Laboratory of Human Molecular Genetics, Christian de Duve Institute of Cellular Pathology and Université catholique de Louvain, Brussels, Belgium; 3) Department of Neuropathology, Hôpital R. Salengro, Lille, France; 4) Institute of Neurology, London, UK.

Oligodendroglioma is a tumour originating from oligodendrocytes, the myelin forming cells in the central nervous system. This glioma preferentially occurs in adults. It is mostly located in cerebral hemispheres with a predilection to the frontal lobe. This lesion accounts for 5-33% of all gliomas. The wide range reported for tumour occurrence reflects inter-observer discordance in histological diagnosis. Genetic analysis of oligodendroglioma has associated 1p/19q-deletions to chemosensitivity. Recently, we and others have linked a specific histological definition to this subgroup of tumors, allowing the diagnosis to be made on histological criteria prior to any genetic analysis. Now, we have studied 9p deletions, p14, p15 and p16 methylation as well as p14 and p16 mutations in a series of 21 1p/19q-deleted oligodendrogliomas. On 8 1p/19q-deleted oligodendrogliomas, presenting angiogenesis and/or necrosis, 6 had a heterozygous and 2 a homozygous deletion of 9p. Three of them also had methylation of p16, which in one case was associated with a p16 mutation and in another to p14 methylation. These results illustrate the implication of 9p-deletion in angiogenesis and tumor necrosis of 1p/19q-deleted oligodendrogliomas and the putative role of p16 in these tumours. (vikkula@bchm.ucl.ac.be) (<http://www.icp.ucl.ac.be/vikkula>).

Homozygosity Mapping in familial glioma. *B.S. Malmer¹, H. Gronberg¹, S. Haraldsson², R. Henriksson¹, D. Holmberg².* 1) Dept Radiation Sci, Oncology, Umea Univ Hosp, Umea, Sweden; 2) Umea center for Molecular Medicine, Umea University Hosp, Umea, Sweden.

Background: The aetiology of primary brain tumours is in most cases unknown. Previous studies have identified a familial aggregation of glioma apart from the well characterised hereditary glioma-prone syndromes as Li-Fraumeni and Neurofibromatoses. About 5% of all glioma patients have a family history of gliomas in the family. In many of these families, siblings are described and we have previously performed a segregation analyses indicating an effect of an autosomal recessive gene. Material and Methods: Seven families from Northern Sweden were included in a homozygosity-mapping project. The families came from the same area in Sweden so the pedigrees were extended back to the 17th century to investigate if there were a common ancestor. Results: Three families were remotely related in several branches of the pedigrees indicating a possible founder mutation. Since autosomal recessive inheritance was suspected a homozygosity mapping project was initiated. The project is still ongoing and closer results will be presented at the meeting. Conclusions: Previous studies of hereditary cancer have focused on an autosomal dominant inheritance and mutation spectra in tumour suppressor genes. We have initiated a first study of familial cancer searching for autosomal recessive genes as a cause of hereditary cancer.

p14, p15 and p16 are frequently and differentially methylated in ependymal tumours. *E. Rousseau*^{1,2}, *M.M. Ruchoux*³, *F. Scaravilli*⁴, *F. Chapon*⁵, *C.A. Maurage*³, *C. Godfraind*², *M. Vikkula*¹. 1) Laboratory of Human Molecular Genetics, Christian de Duve Institute of Cellular Pathology and Université catholique de Louvain, Brussels, Belgium; 2) Laboratory of Neuropathology, Université catholique de Louvain, Brussels, Belgium; 3) Laboratory of Neuropathology, Hôpital Roger Salengro, Lille, France; 4) Department of Neuropathology, Institute of Neurology, London, UK; 5) Laboratory of Neuropathology, CHU Caen, France.

Several studies implicate numerical abnormalities of chromosome 9 in the pathogenesis of ependymal tumors, yet the three important tumor suppressor genes located in this chromosome, p16 (p16, CDKN2a, MTS1), p14 (p14ARF) and p15 (p15, CDKN2b, MTS2) are thought not be involved in the pathogenesis of these tumors. However, no promoter methylation analysis of these genes have been reported for ependymal tumors up to now, and because methylation is an important mechanism of gene silencing, we decided to study promoter methylation of p14, p15 and p16 in a series of 152 ependymal tumors by methylation-specific polymerase chain reaction. We observed that at least 76% of the studied ependymal tumors showed methylation for one of these three genes, and most tumors were methylated for only one gene. Low grade tumors present a high rate of methylation whatever the gene, implicating that methylation could be an early event in the development of ependymal tumors. There was a decrease in the percentage of methylated tumors when their grade increased for p15 and p14, and there were variations in the patterns of methylation for p14 and p15 regarding tumor location. The high frequency of methylation observed, and the variation in the patterns of methylation for tumors according to grade and location point to an important role of these three genes in the development of ependymal tumors, a fact which was not evident from the previous studies of these genes in ependymal tumors. (vikkula@bchm.ucl.ac.be) (<http://www.icp.ucl.ac.be/vikkula>).

Loss of heterozygosity in normal tissue adjacent to primary breast carcinomas. *D.L. Ellsworth¹, R.E. Ellsworth¹, B. Deyarmin¹, V. Mittal¹, S. Lubert¹, C.D. Shriver², R.I. Somiari¹.* 1) Clinical Breast Care Project, Windber Research Institute, Windber, PA; 2) Clinical Breast Care Project General Surgery Service, Walter Reed Army Medical Center, Washington, D.C.

Morphologically normal cells adjacent to breast carcinomas are known to harbor genetic abnormalities commonly observed in malignant tissues. It is unclear, however, whether genetic changes in adjacent normal cells reflect random mutational events or coordinated patterns of genetic change characteristic of the neighboring tumors. In this study, laser capture microdissection of paraffin embedded breast tissue samples was used to define patterns of loss of heterozygosity (LOH) in different classes of breast cancer, including ductal carcinomas in situ, lobular carcinomas in situ, papillary carcinomas, and infiltrating ductal carcinomas, as well as in surrounding morphologically normal stromal and epithelial cells. High-throughput fluorescent genotyping of 52 anonymous microsatellite markers was conducted to survey 26 chromosomal regions commonly deleted in breast cancer. In situ carcinomas showed rates of LOH greater than those in more advanced invasive tumors, and a higher prevalence of LOH was observed in normal cells adjacent to in situ carcinomas (63%) than in cells adjacent to invasive lesions (38%). LOH in adjacent normal cells was most prevalent on chromosomes 2, 3, 5, 6, and 13. Interestingly, patterns of LOH in normal stromal and epithelial cells differed from those in the neighboring tumors in ~50% of the cases examined. Patterns of chromosomal alterations in normal tissue adjacent to breast carcinomas may identify molecular events underlying the early stages of breast cancer development and help define tissues prone to cancer recurrence.

HPV18 Preferentially integrates at or near c-myc in HPV18-positive cervical tumors. *M.J. Ferber*^{1,2}, *W.F. Wu*³, *A. Brink*⁴, *E. Thorland*^{1,2}, *D.I. Smith*². 1) Biochemistry/Molec Biol, Mayo Foundation, Rochester, MN; 2) Division of Experimental Pathology, Mayo Foundation, Rochester, MN; 3) The Chinese University of Hong Kong, Hong Kong; 4) Leiden University Medical Center Department of Molecular Cell Biology Wassenaarseweg 72 2333 AL Leiden The Netherlands Leiden University Medical Center Department of Molecular Cell Biology Wassenaarseweg 72 2333 AL Leiden The Netherlands Leiden University Medical Center Department of Molecular Cell.

Virtually all cervical cancers are associated with human papillomavirus (HPV) infection. In addition, HPV integration is temporally associated with the development of invasive cervical cancer. We previously demonstrated at the molecular level that integration of one of the high risk HPV subtypes, HPV16, occurs preferentially within common fragile site (CFS) regions of instability (Thorland et al., *Cancer Research* 2000; 60:5916-5921). We then subsequently examined many more HPV16 integrations and found that 50% of the integrations occurred within a CFS region, and that there were several regions that contained multiple HPV16 integrations. We have now analyzed 20 HPV18-positive cervical tumors and again used restriction site oligonucleotide (RSO) PCR to rescue human sequences flanking the sites of HPV18 integration. The sites of integration were distinct from those observed with HPV16-positive cervical tumors. In addition, we found that 25% of the integrations occurred at 8q24 at or near the c-myc oncogene. Due to the previous association between HPV integrations and CFS regions, we examined the c-myc region in greater detail. C-myc is actually flanked by two CFS regions, FRA8C (8q24.1) and FRA8D (8q243). Using a FISH-based assay to characterize these two CFS regions and BAC clones that span c-myc, we have found that c-myc is localized in the region between these two CFSs. We are currently defining these two flanking CFS regions to determine their size and their structure. The presence of two CFS regions around c-myc may offer an explanation as to why c-myc is such a frequent target of amplification in cancer.

High-Throughput TRAP/PCR analysis of telomerase using capillary electrophoresis. *D.H. Atha¹, K. Miller², A.D. Sanow², J. Xu², J.L. Hess², O.C. Wu¹, W. Wang³, S. Srivastava³, W.E. Highsmith².* 1) Biotechnology Division, National Institute of Standards and Technology, Gaithersburg, MD; 2) Department of Pathology, University of Maryland School of Medicine, Baltimore, MD; 3) Division of Cancer Prevention, National Cancer Institute, Rockville, MD.

The enzyme telomerase is expressed in (85-90%) of all human cancers, but not in normal, nonstem cell somatic tissues. Clinical assays for telomerase, particularly in easily obtained body fluids, would have great utility as non-invasive, cost-effective methods for the early detection of cancer. The most commonly used method for the detection and quantification of telomerase enzyme activity is the polymerase chain reaction (PCR) based assay known as the telomeric repeat amplification protocol or TRAP assay. Most of the TRAP assay systems use a slab-gel based electrophoresis system to size and quantify the PCR-amplified extension products. We are developing high-throughput capillary electrophoresis (CE) methods for the analysis of TRAP/PCR products. The TRAP assay was conducted on lysates of the human lung cancer cell line A-549 in reactions containing 5 to 100 cells. Trap/PCR products were generated using a fluorescent (4,7,2'4'5'7',-hexachloro-6-carboxyfluorescein)-labeled TS primer and analyzed on the Applied Biosystems Model 310 CE system using POP4 polymer. After analysis with GeneScan and Genotyper software, the total peak area of the TRAP ladder extension products were computed using Microsoft Excel. Results were compared with unlabeled TRAP/PCR products analyzed on the Bio-Rad BioFocus 3000 CE system using 6% high molecular weight polyvinylpyrrolidone (HMW PVP) polymer and SYBR Green I dye. Both CE systems were able to resolve the TRAP ladder products with high reproducibility and sensitivity (5-15 cells). With the appropriate multi-capillary and robotic sample handling systems, these CE methods would streamline clinical validation of the telomerase TRAP assay with increased sensitivity, reproducibility and automation over slab-gel methods.

Supported in part by NIST(EDRN)- NCI Interagency Agreement #CN-0103-02(DHA) and NCI/EDRN grant #UO1CA84988(WEH).

Molecular characterization of a constitutional t(5;6)(q21;q21) in a patient with bilateral Wilms' tumor. C.D.

Day¹, S-I. Matsui¹, P. Liang¹, N.J. Nowak¹, S. Jani-Sait², J.K. Cowell¹, M.J. Higgins¹. 1) Dept Cancer Genetics, Roswell Park Cancer Inst, Buffalo, NY; 2) Dept Cytogenetics, Roswell Park Cancer Inst, Buffalo, NY.

Wilms' tumor, one of the most common pediatric tumors, is believed to arise from persistent metanephric blastema cells that fail to differentiate. Although the *WT1* gene (11p13) was identified more than a decade ago, it remains the only tumor suppressor gene known to be involved in Wilms tumor; furthermore, *WT1* is mutated in less than 10% of cases. Analysis of chromosomal rearrangements, particularly translocations, has been extremely useful in the identification of genes involved in cancer. Our lab has been investigating a balanced constitutional translocation in a patient with bilateral Wilms' tumor. The breakpoints of this t(5;6)(q21;q21) have been previously mapped between *D5S495* and *D5S433* on chromosome 5 and between *D6S301* and *D6S447* on chromosome 6, genetic distances of 4 cM and 3 cM, respectively (Hoban et al., J Med. Genet. 34:343-345, 1997). Using BAC clones selected from the interval between these flanking markers as FISH probes, we have narrowed the breakpoint region to approximately 100 kb by identifying BACs from both chromosomes 5 and 6 that span the translocation breakpoints. The derivative chromosomes have also been segregated into somatic cell hybrids to facilitate molecular analysis of the chromosome rearrangements. Three candidate transcripts, a known gene, an EST, and a predicted gene, map within the breakpoint regions. These genes are being assessed for changes in structure and/or expression resulting from the translocation. Analysis of our large Wilms tumor tissue collection and other tumor types will establish the involvement of one or more of these genes in human cancers. Funded by NCI/NIH CA63333 to MJH.

The Association of Cytoplasmic Overexpression of Cyclin D1 and Tumor Metastasis in Hepatocellular

Carcinoma. *L. Hu¹, J.M. Wen², W.S. Wang³, J.S.T. Sham¹, Y. Wang⁴, M.C. Wu⁴, D. Xie¹, D.J. Tang¹, X.Y. Guan¹.* 1) Clinical Oncology, Univ Hong Kong, Hong Kong, China; 2) Department of Pathology, Sun Yat-sen University, Guangzhou, China; 3) Department of Hepatobiliary Surgery, First Affiliated Hospital, Sun Yat-sen University, Guangzhou, China; 4) Eastern Hepatobiliary Surgery Hospital, The Second Military Medical University, Shanghai, China.

Hepatocellular Carcinoma (HCC) is one of the worldwide most common malignant tumors with poor prognosis. In the present study, a marker chromosome containing a homogeneously staining region (HSR) in a recently established metastatic HCC cell line (H4-M) was characterized by comparative genomic hybridization and chromosome microdissection. The result showed that the HSR was composed of DNA sequence from 11q13 and amplification of cyclin D1 (CCND1) in H4-M was confirmed by fluorescence in situ hybridization (FISH) using a BAC clone containing CCND1 gene. Amplification and overexpression of CCND1 in H4-M has been demonstrated by Southern blot, Northern blot, and Western blot analyses. Immunohistochemical staining showed that the overexpression of CCND1 was located in cytoplasm in H4-M. Further study using a tissue microarray with 320 HCC samples showed that cytoplasmic overexpression of CCND1 was significantly higher in HCC with metastasis (19/56 cases, 34%) than that in HCC without metastasis (23/186 cases, 12%) ($P < 0.001$). This finding strongly suggested that the cytoplasmic overexpression of CCND1 may play an important role in the metastasis of HCC.

Genome-wide search for homozygous deletions in oral cancer. *H. Kayahara*¹, *H. Yamagata*^{2, 3}, *T. Miyoshi*¹, *M. Abe-Ochi*³, *J. Nakura*³, *I. Kondo*², *T. Miki*³, *H. Hamakawa*¹. 1) Dept Oral and Maxillofacial Surgery, Ehime Univ Sch Medicine, Onsen-gun, Ehime, Japan; 2) Dept Hygiene, Ehime Univ Sch Medicine, Ehime, Japan; 3) Dept Geriatric Medicine, Ehime Univ Sch Medicine, Ehime, Japan.

To date, in head and neck cancer including oral squamous cell carcinoma (OSCC), loss of heterozygosity (LOH) has been identified on chromosomes 2q, 3p, 4q, 7q, 8p, 9p, 10q, 11q, 13q, 14q, 17p, 18q and 22q. These findings suggest that some of these regions may contain a tumor suppressor gene. However, the most studies failed to isolate the candidate genes, except for DPC4 in colon cancer and PTEN in breast cancer that came from the mapping of homozygous deletions. To identify the putative tumor suppressor gene locus, we analyzed 6 cell lines from OSCC with 811 microsatellite markers (ABI PRISM Linkage Mapping Sets LMS-HD5) covering the entire chromosome except Y for allelic changes. Multiplex PCR products were electrophoresed on an ABI PRISM 3100 Genetic Analyzer and the fluorescent signals from the different sized alleles were recorded and analyzed by Genotyper and GeneScan. Homozygous deletions were found in 38/811 markers (4.7%) on average. Among them, 26 markers were screened for further studies in 12 OSCC cell lines. We identified three homozygously deleted regions in 12 cell lines. The candidate gene loci were as follows: D6S292 (6q23.2), D10S192 (10q24.32), and D18S68 (18q22.1). At present, no gene deletions have been identified in the centromeric and telomeric boundary of these loci.

Study of chromosomal abnormalities in esophageal squamous cell carcinoma by comparative genomic hybridization. *A.L.S. Tai, D.L.W. Kwong, J.S.T. Sham, X.Y. Guan.* Clinical Oncology, The University of Hong Kong, Hong Kong, China.

Esophageal carcinoma ranks among the nine most common cancer worldwide. In China, its incident rate is particularly high compare to the western countries. Squamous cell carcinoma is the dominant histological type found in the Asian populations. In this study, comparative genomic hybridization was used to screen for the genomic alterations among 60 primary esophageal squamous cell carcinoma cases globally. Chromosomal aberrations were detected in 52 cases. The frequent chromosomal gains were detected in 3q (67.3%), 8q (57.7%), 5p (51.9%), 7q (28.8%), 15q (28.8%), 20q (28.8%), 20p (21.1%), 1q (26.9%), 7p (26.9%), 2p (23.1%) and 12p (23.1%), where the chromosomal losses involved 3p (46.2%), 4q (26.9%), 4p (23.1%), 3q (19.2%), 9p (17.3%) and 13 (15.4%). High copy number amplifications were found in 3q and 8q among 10 and 8 cases, respectively, with minimum overlapping regions of 3q26.1-26.2 and 8q24.1-24.2. Interphase-FISH, using BAC clones was used to study the expression of eIF-5A2 and myc. Amplification of both eIF-5A2 and myc was found. In summary, genomic changes are common in esophageal squamous cell carcinoma.

Molecular FISH markers for metastasis in ductal breast carcinoma. *H. Zhao, J.G. Jones, H.P. Klinger, B. Vikram, P.M. Achary.* Albert Einstein College of medicine, Bronx, NY.

The objective of this project is to construct a panel of molecular genetic markers for detecting those 13% of breast cancer patients with negative lymph nodes, so that they could be treated more aggressively. Representational Difference Analysis was used to compare the DNA of cells from archival normal tissue or primary ductal tumor with that of the metastatic lymph node of the same patient in order to isolate those sequences that were lost in the course of tumor metastasis. The tumor cells were recovered by laser capture microdissection. We isolated 11 sequences that are candidates for metastasis associated genes (MAGs) because they were lost in metastatic cells. To-date three of these 11 sequences were used to screen normal, primary and metastatic cell DNA samples. MAGS-XI was found to be lost in the metastatic cells of 3 out of the 5 tumors. MAGS-IX was found to be lost in metastases from 2 out of 5 primary tumors, and MAGS-IV was lost in 1 out of 3 tumors. RH mapping and homology search results indicated that MAGS-IX was located on the long arm of chromosome 10 where the PTEN, a known metastasis suppressor gene is also located. To determine if MAGS-IX is perhaps a part of the PTEN gene we PCR screened the above mentioned five tumor cell DNA samples and a breast carcinoma cell line, HCC-1937, which has homozygous loss of the PTEN gene. The results indicated that MAGS-IX is a novel gene sequence. Presently we are isolating partial and/or full-length sequences of these MAGS to use as fluorescence in situ hybridization (FISH) probes to screen a larger number of tumor samples. A 2Kb sized MAGS-IX has been generated and localized to the q21 region of human chromosome number 10 by FISH. Screening of MAGS-IX as fish probe in the primary tumor tissue sections of a breast carcinoma which metastasized to lymph nodes showed nuclei with signals indicating normal, heterozygous and homozygous losses of MAGS-IX in the ratio of 11:13:1 respectively. We conclude that the MAGS-IX could possibly be used as a FISH probe to identify primaries that are prone to develop metastasis.

***MLH1* exon 3 deletion in cDNA associated with 213_215delAGA: Probable exon splicing enhancer mutation as a cause of HNPCC.** G. Chong^{1,2,5}, G. Ouellette⁶, B. Lemieux⁶, V. Marcus³, I. Thiffault¹, E. MacNamara^{2,3,5}, W.

We describe a new mutation in *MLH1* in an Amsterdam criteria I-fulfilling HNPCC kindred. The proband is a 53 yr old woman who was diagnosed with colon cancer at age 49. Her brother was diagnosed with rectal cancer at 39 and died at age 48. Her son died of colon cancer at 28. IHC showed loss of MLH1 protein in the two available colon cancers. PTT revealed an abnormal truncated protein. RT-PCR analysis of her cDNA revealed a shortened product, which on sequencing was found to be caused by the entire in-frame deletion of exon 3. Sequencing of the genomic DNA did not detect any splice site variant which might have explained the deletion of exon 3 in the cDNA. However, a 3 bp deletion at nt 213, predicted to result in DE71, was detected. The same deletion was found in the tumor from her son, with LOH. These findings suggest that the exon 3 deletion has resulted from the 213_215delAGA genomic alteration. The sequence around the mutation is purine-rich (AAAGAAGAT), and as these have been associated with exon splicing enhancers (ESEs), we postulate that 213_215delAGA has removed an ESE for exon 3. An in-frame deletion in exon 7 of SMN has been previously associated with aberrant splicing of this exon¹ and is thought to be disease-causing. Similar ESEs (-AAGAAGA-) have also been identified in the genes for human fibronectin (exon ED1)² and calcitonin (exon 3)³. As the significance of our mutation would not have been appreciated without examination of both DNA and RNA, this finding illustrates one benefit of multi-modal molecular screening for mutations in mismatch repair genes.

INK4/ARF germline mutations and additional neoplasia in pancreatic cancer patients and their families. L. Bonelli¹, P. Ghiorzo², L. Pastorino², R. Cusano¹, A.M. Nicora¹, S. Zupo¹, P. Queirolo¹, M.R. Sertoli², V. Pugliese², G. Bianchi-Scarrà². 1) Clinical Epidemiology Unit, Natl Inst for Cancer Research, Genova, Italy; 2) Dept Oncology Biol. Genetics, Univ. of Genova, Genova, Italy.

Roughly 40% of germinal mutations in melanoma families (MF) affect p16INK4a (p16) and p14ARF (p14). We previously found an excess of pancreatic cancer (PC) in MF carrying the G101W founder mutation. We now look at: the role of mutations in p14 among non-p16 MF; the role of p16 and p14 in sporadic PC (SPC) patients; the incidence of other tumors in SPC patients' families. We studied 49 MF enrolled between '95 and '01 at the Medical Genetics Service, 66 PC patients diagnosed at the NCI in Genoa between '98 and '01 and 54 controls. The MF consisted of 967 relatives, with 118 melanoma and 10 PC patients. The 18 G101W MF had an increased risk of developing PC (RR=9.4; 95%CI 2.7-33.4), unlike the 31 wt (non-p16, non-p14) families (RR=2.2; 95% CI 0.8-5.7). Median age at onset of PC in mutated families was 57.5 yrs (mean 61, range 49-78) vs. 77.5 in wt kindreds (mean 77, range 65-88), the same as found in the local Cancer Registry (mean 77, range 75-79). Sixty-one SPC patients and 54 controls were eligible; an in-person interview was conducted with 46/61 patients and 52/54 controls, for the others a kin was interviewed. Incidence of tumors in 836 blood relatives of patients vs. 711 of controls showed no significant difference. Tumor clusterings were identified in 17 branches from as many families of PC patients vs. 7 of controls. Some showed part of the tumor spectrum associated with family cancer syndromes. In particular, 2 showed a melanoma-PC association in concert with G101W p16 mutation, although no member displayed an atypical mole phenotype. No mutation was found in controls. The increased risk of PC in G101W carriers but not in wt families and cases does not rule out that coexisting alterations in p16 and p14 may be involved in the development of PC in those patients. The presence of G101W in 2/46 SPC patients confirms the prevalence of our founder mutation and suggests that relatives of PC patients may benefit from melanoma surveillance programs. Supported by Ministry of Health NICS0701/RF99.63 to GBS.

Hypermethylation of the CpG islands in the promoter region flanking GSTP1 gene is a candidate plasma DNA biomarker for screening or monitoring prostate carcinoma prognosis. *D. Chu*^{1, 3}, *C. Chuang*², *J. Fu*³, *S. Huang*², *R. Chia*³, *C. Sun*³. 1) School of Medical Technology, Chang Gung University, Tao-Yuan, Taiwan; 2) Division of Urology, Department of Surgery, Chang Gung Memorial Hospital, Lin-Kou, Taiwan; 3) Laboratory of Molecular Diagnosis, Department of Clinical Pathology, Chang Gung Memorial hospital, Lin-kou, Taiwan.

Purpose: to investigate whether our newly developed methylation-sensitive real-time PCR protocol could be used to detect cancer genome in prostate cancer patients' circulations. **Study design:** Serum or plasma DNA samples were collected from twenty-nine prostate cancer patients and thirty-six benign prostate hyperplasia (BPH) cases. After extensive methylation-sensitive restriction enzyme, *HpaII*, digestion, the DNA samples were subjected to the real-time PCR amplification. The amplification curves were adopted to know if hypermethylation occurred in the promoter region flanking the GSTP1 gene among these prostate cancer patients. **Results:** If we use the previously used cut-off cycle of threshold (Ct) value of 35, 11 of 29 prostate cancer patients could be correctly identified. However, none of the 36 BPH cases showed positive (Ct<35) results. To our attention, there were 15 prostate cancer cases did not have detectable cancerous genome in the plasma or serum. **Conclusions::** We have successfully analyzed prostate cancer genome in the peripheral blood in prostate cancer patients with the highly sensitive protocol. Due to the fact that the analytical results depended on whether enough cancer genomes presented in the plasma or serum sample, this protocol performed on plasma or serum is more suitable for mass-screening of prostate neoplasm or for follow-up after treatments.

Detection of *BRCA1* rearrangements in breast-ovarian cancer families using Quantitative Multiplex PCR of Short Fluorescent Fragments (QMPSF). *F. Casilli*^{1, 2}, *I. Tournier*¹, *Z.-C. Di Rocco*², *S. Gad*³, *D. Stoppa-Lyonnet*³, *T. Frebourg*¹, *M. Tosi*¹. 1) INSERM EMI 9906, Faculty of Medicine, Rouen, France; 2) Department of Experimental Medicine, University L'Aquila, 67100 Coppito, Italy; 3) Department of Genetics, Institut Curie, 26 rue d'Ulm, 75005 Paris Cedex 5, France.

Twenty different *BRCA1* rearrangements have already been described and the contribution of this type of defects is considered to be significant in breast-ovarian cancer families with high probability of *BRCA1*- or *BRCA2*- linked predisposition. The difficulty of detecting such heterozygous exon deletions or duplications has stimulated the development of several new screening methods. Quantitative Multiplex PCR of Short fluorescent Fragments (QMPSF) is based on simultaneous amplification of multiple short target sequences under conditions that allow rapid and reliable quantitative comparison of the fluorescence of each amplicon in test samples and in controls. We have developed, as a routine screening test, QMPSF for *BRCA1*. All *BRCA1* coding exons are analysed using four multiplexes. Analysis, using QMPSF of families without point mutations in the exons or splice-sites of *BRCA1* and *BRCA2* and selected because of high probability of a *BRCA1*- or *BRCA2*- linked genetic predisposition allowed us to identify several rearrangements including two novel deletions, which respectively involved exons 15-16 and exons 1-22. The 1-22 deletion is the largest exonic deletion found so far within the *BRCA1* gene. This rapid, sensitive and cost-effective method is also being adapted to the screening of *BRCA2* and may be included into the routine molecular analysis of breast-ovarian cancer predispositions.

Detection of the first complete heterozygous deletion of the *TP53* gene in a family with Li-Fraumeni syndrome. G.

*Bougeard*¹, *F. Charbonnier*², *C. Martin*², *G. Raux*¹, *L. Brugieres*³, *B. Bressac de Paillerets*⁴, *T. Frebourg*^{1, 2}. 1) INSERM EMI 9906, Faculty of Medicine, Rouen; 2) Department of Genetics, CHU de Rouen, 76031 Rouen, France; 3) Department of Pediatrics, Institut Gustave Roussy, 94805 Villejuif, France; 4) Molecular Genetics, Institut Gustave Roussy, 94805 Villejuif, France.

The Li-Fraumeni syndrome (LFS) represents one of the most devastating genetic predispositions to cancers and is characterized by a wide spectrum of early-onset malignancies including bone and soft-tissue sarcomas, brain tumours, adrenocortical tumours and pre-menopausal breast cancers. The absence of detectable germline *TP53* mutation in some LFS families has suggested the involvement of other genes, but this remains controversial. The density of *Alu* repeats within the *TP53* gene led us to screen for genomic rearrangements of *TP53* in families without detectable *TP53* mutation. To this aim we adapted the QMPSF (Quantitative Multiplex PCR of Short fluorescent Fragments) to the analysis of the 11 exons of *TP53*. We analyzed 100 families, either fulfilling or partially meeting the criteria for LFS and in which classical methods had revealed no *TP53* alteration. We identified, in one extended family fulfilling the criteria for LFS, a complete heterozygous deletion of *TP53*. Additional QMPSF analyses of genes surrounding the *TP53* locus showed that the deletion, estimated to 30-40 kb, involved only the *TP53* locus. This study shows that the occurrence of germline rearrangement of *TP53* is a rare event but must be considered in families fulfilling the original criteria for LFS and without detectable *TP53* mutation.

Conventional and Tissue MicroArray Immunohistochemical Expression Analysis of Mismatch Repair in Hereditary Colorectal Tumours. A. Bröcker-Vriends¹, Y. Hendriks¹, P. Franken¹, J.W. Dierssen², W. de Leeuw², J. Wijnen¹, C. Tops¹, M. Breuning¹, H. Vasen³, R. Fodde¹, H. Morreau². 1) Depts. of Human and Clinical Genetics; 2) Pathology, Leiden Univ. Medical Center; 3) Foundation of Hereditary Tumours, Netherlands.

Background and aims HNPCC is caused by germline mutations in the DNA mismatch repair (MMR) genes. IHC of MMR proteins and MSI in HNPCC related tumours can be used as pre-screening methods. Aims of the study: 1) Determination of the sensitivity and specificity of IHC for MLH1, MSH2 and MSH6 mutations, 2) Evaluation of the validity of IHC-TMA (Tissue MicroArray) compared with IHC-WS (Whole Slide).

Methods IHC-WS was performed in crc of 45 carriers of a MLH1, MSH2 or MSH6 mutation. The TMA cohort consisted of these 45 tumours and 84 crc from patients with S-HNPCC.

Results IHC-WS showed abrogation of at least one of the three MMR proteins tested in 86% (18/21), 100% (12/12), and 75% (3/4) of tumours from carriers of a MLH1, MSH2 and MSH6 mutation resp. Mismatch repair deficiency would thus have been detected in 89% (33/37) of the cases. MSI analysis was slightly more sensitive than IHC (25/27, 93%). For MLH1, MSH2 and MSH6, IHC-WS would have correctly predicted a mutation in 48%, 92% and 75% of the cases resp. Comparison of the IHC results based on whole slides versus TMA, showed a high level of concordance for MLH1 (85%) and MSH2 (95%), a slightly lower level for MSH6 (75%).

Conclusions The results of our study show that both IHC and MSI are sensitive pre-screening methods in identifying patients for MMR mutation analysis. IHC has the additional advantage of identifying the respective MMR gene involved. We propose a scheme for the diagnostic approach of families with (suspected) HNPCC. This study also shows that high-throughput IHC analysis performed by Tissue Micro Arrays can be reliably employed to simultaneously screen a large number of tumours from (suspected) HNPCC patients for MMR protein alterations.

Demographics and phenotype of familial Barrett's esophagus and esophageal adenocarcinoma series. C.M.

Drovdlic¹, K.A.B. Goddard², W. Brock³, W.M. Grady⁵, A. Chak³, J. King⁶, J. Richter⁴, G. Falk⁴, C. Eng¹. 1) OSU Med Ctr, Columbus, Oh; 2) CWRU; 3) Univ. Hosp. of Cleveland; 4) Cleveland Clinic, Cleveland, OH; 5) Vanderbilt Univ., Nashville, TN; 6) Mercy Med Ctr, Canton, OH.

Barrett's esophagus (BE) is a metaplastic columnar lined esophageal epithelium thought to be the result of a continual reparative process in response to chronic gastric reflux. BE is often a precursor of esophageal adenocarcinoma (EAC) and is most often diagnosed in males over age 50. Familial factors in development of BE/EAC have long been recognized. It is likely that inheritance of a BE/EAC predisposition follows the autosomal dominant model of most inherited cancer syndromes, but no causative gene has yet been identified. Our consortium has compiled the largest series of families with BE/EAC yet reported. Families were recruited from consortium sites and self-referral from advertisement. Family histories were taken through interview with the proband and considered positive if two or more individuals were diagnosed with BE/EAC. Available pathology and/or endoscopy reports and tissue samples were reviewed. Pedigrees were drawn and data entered for a total of 65 families comprising 156 affected and 390 unaffected individuals. Mean ages of diagnosis of BE and EAC among females were 48.7 and 60.2 years, and among males were 51.7 and 55.6 years, respectively. In contrast, typical ages at diagnosis for sporadic BE and EAC are approximately 63 and 64 years, respectively, for both sexes. Ten percent of affected and 15.2% of unaffected individuals were diagnosed with a cancer other than EAC. Power simulations were performed to estimate the expected lod score using typical pedigree structures in this data and four different autosomal dominant models that are consistent with the previously reported BE/EAC population prevalence and sibling risk ratio. Assuming at least two loci, a PIC of 0.7 at the marker locus, and theta = 0.05 in a 400 marker genome scan, 120 families are needed to achieve a lod score of 3.0 for a linked locus. Identification of a causative gene would enable predictive testing for BE/EAC, and is likely to give clues to the molecular pathogenesis of BE and EAC as well as other cancers.

Program Nr: 354 from 2002 ASHG Annual Meeting

B-RAF as a melanoma susceptibility candidate gene. *B. Bressac-de Paillerets, K. Laud, M-F. Avril, A. Chompret, G. Lenoir and French Hereditary Melanoma Study Group.* Inst Gustave Roussy, Villejuif, France.

The mitogen-activated protein (MAP) kinase cascade are membrane-to-nucleus signaling modules involved in multiple physiological processes. The Ras-RAF-MEK-ERK-MAPKinase pathway mediates cellular responses to growth signals. In a melanocyte-specific signaling pathway, B-RAF mediates the c-AMP-activation of ERK. As B-RAF somatic missense mutations have been shown to occur in 66 percent of malignant melanoma with 80 percent of mutations being a single substitution (exon 15, V599E), we hypothesize that B-RAF could be a melanoma susceptibility gene. Therefore, we searched for B-RAF germline mutations by direct sequencing of the entire B-RAF coding region (18 exons) for 12 highly selected melanoma-prone families. We also screened exons 11 and 15 in a large series of 45 melanoma-prone families or individuals. Results of our analysis will be presented.

Prevalence of BRCA1 and BRCA2 mutations in ovarian cancer patients from the French-Canadian population.

*F. Guenard*¹, *S. Klappenberger*¹, *Y. Labrie*¹, *M. Plante*², *B. Tetu*³, *F. Durocher*¹. 1) Cancer Genomics Laboratory, CHUL Research Centre, Quebec, Canada; 2) Department of Oncology and; 3) Department of Pathology, Centre de recherche de l'Hotel-Dieu de Quebec, Canada.

Studies on high-risk breast and ovarian cancer families have established the spectrum of BRCA1 and BRCA2 mutations present in the French-Canadian population. Two founder mutations have been reported in this population, one in each of the two BRCA genes. As ovarian cancer is the second leading cause of death from cancer in women, a better understanding of molecular alterations should contribute to improve prevention strategies and treatment, therefore reducing mortality due to ovarian cancer. To evaluate the incidence of BRCA1 and BRCA2 mutations in ovarian cancer, eighteen different mutations (10 in BRCA1 and 8 in BRCA2), reported at least once in French-Canadian ancestry, have been sequenced in a series of nearly 70 ovarian tumors not selected on the basis of a family history, from the Ovarian Cancer Clinic at Hotel-Dieu de Quebec, Canada. We identified two tumors bearing the BRCA1 founder mutation R1443X and one with the BRCA2 founder mutation 8765delAG. Both R1443X mutations were found at a homozygous state in the tumor, consistent with loss of heterozygosity. Another previously reported mutation was found, the 2953del3+C in BRCA1. In addition to these three mutations, two other changes have been found in two different tumors, a deletion of 13 and 7 nucleotides at position 1078 and 3721, respectively. To our knowledge, these two changes have not been reported previously and we are currently characterizing these two deletions in normal tissues coming from the same patients. In conclusion, alterations in BRCA1 or BRCA2 have been identified in approximately 9% of ovarian tumors, while the two most frequent BRCA1 and BRCA2 French-Canadian founder mutations have been found in approximately 5% of ovarian tumors. These findings could thus have clinical implications for adequate follow-up of ovarian cancer patients from the French-Canadian population.

Prevalence of BRCA1 and BRCA2 mutations on full sequence analysis of women with invasive breast cancer diagnosed in their fifties. C.A. Frye, H.L. Shappell, A.M. Deffenbaugh, L.A. Burbidge, T.S. Frank. Myriad Genetic Laboratories, Salt Lake City, UT.

An individual's age at diagnosis of invasive breast cancer is regarded as one of the primary factors in the risk assessment of hereditary breast and ovarian cancer syndromes. The earlier the diagnosis of invasive breast cancer the more likely the cancer is due to a *BRCA1/2* mutation. Questions remain regarding the appropriateness of *BRCA1/2* testing in individuals presenting with invasive breast cancer in their fifties. The aim of this study was to address the prevalence of mutations identified by full sequencing of the *BRCA1* and *BRCA2* genes in women diagnosed with invasive breast cancer after the age of 50, and to correlate the presence of such mutations with features of the family history. Overall deleterious mutations were identified in 121 of 1,327 (9.1%) women diagnosed with breast cancer between ages 50 and 59, including 54 in *BRCA1* and 68 in *BRCA2*. One individual had two deleterious mutations, one in *BRCA1* and one in *BRCA2*. Mutations were identified in 52 of 497 (10.5%) probands who indicated at least one first or second degree relative with invasive breast cancer diagnosed before the age 50, and in 15 of 155 (9.7 %) who indicated at least one first or second-degree relative with ovarian cancer at any age. In contrast, mutations were identified in 10 of 248 (4.0 %) probands who indicated at least one first or second degree relative with invasive breast cancer diagnosed after the age 50. Women diagnosed with invasive breast cancer in their fifties should be offered the option of genetic testing for *BRCA1/2* mutations, especially if their family history includes a diagnosis of breast cancer before age 50, or ovarian cancer at any age, in a first or second degree relative.

Identification of inactivating large scale deletions or other gene rearrangements in the BRCA1 gene by VNTR analysis coupled with Long-Range PCR. *S. Fard, B. Fraser, P. Ainsworth.* Mol Dx Lab, LHSC and Dept. Biochem, Univ. Western Ont, London, Ontario, Canada.

Larger genomic rearrangements have been reported to constitute a substantial proportion of BRCA1 gene mutations^{1,2}. These types of mutations may be identified by loss of heterozygosity (LOH) analysis using variable number tandem repeats (VNTRs). To determine the frequency of BRCA1 deletion events in at risk samples, a series of VNTRs spaced across the BRCA1 gene have been characterised. 5 of 20 di-, tri-, and tetra-nucleotide repeats within the BRCA1 gene were shown to be polymorphic. The relatively low frequency of informative VNTRs identified precluded the direct use of these markers to effectively define hemizyosity resulting from a gene deletion. We have therefore used the VNTRs (as markers of heterozygosity) in conjunction with Long-Range PCR (LR-PCR) to identify smaller deletion and/or duplication events within the BRCA1 gene. The BRCA1 gene (~120 kbp) was amplified by LR-PCR in overlapping fragments ranging from 5 to 20 kbp, each encompassing at least one of the polymorphic VNTRs noted above. The PCR amplicons were sized by 0.8% agarose gel electrophoresis. For amplicons of a normal size, confirmation of heterozygosity of the VNTR(s) within the amplified LR-PCR product demonstrated amplification of both alleles and ruled out a genomic deletion. A series of DNA samples, from S.W. Ontario individuals at a high risk for familial breast/ovarian cancer, had been screened by the protein truncation test (PTT). From this series 50 samples which were non-positive by PTT, as well as a subset of samples that were screen positive by PTT, but in which the causative mutation was not identified, have been subjected to the VNTR/LR-PCR screen described above. A preliminary analysis of results, consistent with more recent literature³, appears to confirm that deletion events at the BRCA 1 gene locus are not a common cause of inactivation of the function of this gene in the South Western Ontario population. References: 1. Puget N. et al. (1999) *Cancer Research* 59:455-61 2. Swensen J. et al. (1997) *Hum Mol Genet* 6:1513-7 3. Lahti-Domenici J. et al. (2001) *Cancer Genet Cytogenet* 129:120-3.

Development of a Targeted *BRCA1/BRCA2* Mutation Screening Panel for African-American Women. *L. Gayol*¹, *M.E. Ahearn*¹, *L. Fernandez*¹, *E. Estrella*¹, *R. Mirhashemi*², *J.F. Arena*², *L. Baumbach*¹. 1) Pediatrics/Genetics, Univ.of Miami School of Medicine, Miami, FL; 2) FOBCC, Univ.of Miami School of Medicine, Miami, FL.

Recent evidence from our laboratory, as well as others, suggest that certain *BRCA1/BRCA2* mutations and other genetic variants appear to be either at increased frequency, or specific, for African-American (AA) women at-risk for breast cancer. We recently completed *BRCA1* and *BRCA2* mutation scanning in twenty-five at-risk AA families. *BRCA1* and *BRCA2* germ-line alterations were detected first using a series of exon-specific PCR primers for SSCP analysis, followed by DNA sequencing of SSCP variants. In this cohort, only one protein-truncating mutation was detected in either *BRCA1* or *BRCA2*, however, splice mutations, missense mutations, and a number of polymorphic variants were detected in both *BRCA1* and *BRCA2*, with a higher frequency occurring in *BRCA2*. Many of these variants were both novel, and specific to AA patients, as well as present in the absence of another disease-causing mutation. These results agree with previous observations that deleterious mutations in *BRCA1* or *BRCA2* are uncommon in at-risk AA patients, and suggest that additional benign variants should be further evaluated for their potential role in the disease process in AA patients. These observations have lead to the development of an screening panel for such *BRCA1* and *BRCA2* mutations/variants for AA women. This panel consists of thirteen mutations and thirteen unclassified variants in *BRCA1* and five mutations and six variants in *BRCA2*, either detected in our laboratory or found in a thorough review of all published English literature. The screening strategy is based on a combination of PCR and multiplex SSCP, as well as *GENESCAN* technology using an ABI 3100. Site-directed mutagenesis has been used to synthesize mutation-positive controls for each variant to be analyzed. We will present our latest progress in panel development and mutation screening. Implementation of this panel will contribute significant new information regarding the frequencies and conferred risks of mutations and variants in the African-American population.

Sequence variation in the MC1R gene and melanoma risk. *J.A. Douglas¹, J. Davis¹, T.R. Rebbeck², M. Berwick³, S.B. Gruber¹.* 1) Depts Hum Genet, Epid, & Int Med, Univ Michigan, Ann Arbor, MI; 2) Dept Biostat & Epid, Univ Penn, Philadelphia, PA; 3) Dept Epid & Biostat, Memorial Sloan-Kettering Cancer Center, New York, NY.

The purpose of this investigation was to evaluate the relationship between genetic variation in the MC1R gene and melanoma risk in an initial sample of 100 Caucasian Americans (75 cases and 25 spouse controls) by sequencing the entire 953 bp coding region. Sequencing showed variation in 15 sites: 14 single nucleotide substitutions (12 non-synonymous and 2 synonymous) and 1 insertion/deletion. MC1R variants were found in 80% of cases and only 52% of controls. Two variants, R151C and R160W, were significantly associated with melanoma risk ($p=0.013$ and $p=0.028$, respectively) and were observed in cases only at frequencies of 11% and 9%, respectively. The strength of linkage disequilibrium (LD) between R151C and R160W (as measured by D') was only 12% of its theoretical maximum and was expectedly non-significant via a likelihood ratio test ($p=0.516$). These results are consistent with recent epidemiological and functional findings demonstrating a reduction in melanin synthesis for both variants, although adjusted case-control analyses suggest that the effects of these variants are not entirely mediated by pigmentation, i.e., by differences in eye, hair, or skin color. There were no significant differences in allele or genotype frequencies for the remaining 13 sites, although only 3 had minor allele frequencies $>5\%$. Given exceptionally short inter-marker distances, few common alleles, and a small sample size, a majority of our sites were in complete pair-wise LD ($|D'|=1$), with relatively few site pairs in significant LD. These results underscore the importance of sample size and marker/mutation frequency on the power to detect LD and illustrate that less common variants (minor allele frequencies $<20\%$) may be important functional predictors of risk. With our relatively small sample size analyzed thus far, it is not possible to exclude a melanoma role for many of the less common MC1R variants, but our data are consistent with the hypothesis that R151C and R160W are predictors of melanoma risk.

From Research to Service: Analysis of Mutation Yield Comparing the Population-Based OFBCR and the Ontario Cancer Genetics Program's BRCA1/2 Genetic Testing Eligibility Criteria. *G.D. Glendon¹, S. Taylor², W. Meschino³, J. Allanson⁴, I. Andrulis⁵ and Ontario Cancer Genetics Program Implementation Committee & Ontario Cancer Genetics Network.* 1) OCGN, Cancer Care Ontario, Toronto, ON, Canada; 2) Kingston Gen. Hosp., Kingston, ON, CA; 3) Dept. Genetics, North York Gen. Hosp. Toronto, ON, CA; 4) Dept. Genetics, Children's Hosp. of Eastern Ontario. Ottawa, ON, CA; 5) Samuel Lunenfeld Inst., Mount Sinai Hosp., Toronto, ON, CA.

From 1996 to April 2000 the Ontario Cancer Genetics Network (OCGN) provided genetic testing for the BRCA1/2 genes on a research basis. At that time, the Ontario Ministry of Health and Long Term Care (MOHLTC) began providing support for BRCA1/2 genetic testing as a clinical service. The Clinical sub-group of the Cancer Genetics Program Implementation Committee developed the service testing eligibility criteria aiming to identify families with a 10% or greater probability of carrying a BRCA1/2 mutation. The Ontario Familial Breast Cancer Registry (OFBCR) is an incident population-based familial breast cancer registry created to foster familial breast cancer research. It is administrated by the OCGN and is one of six sites that comprise the NIH funded Breast Cancer Family Registries. BRCA1/2 mutation analysis utilizing protein truncation analysis with 5' DNA sequencing (PTT) was performed on a wide variety of OFBCR participants meeting specific personal and family history criteria. Thirty-one of the 315 (9.8%) OFBCR eligible participants tested in the 1996 ascertainment period had BRCA1/2 mutations. An analysis applying the service eligibility criteria to this cohort yielded 250 of the 315 as eligible for service testing, of which 28 (11.2%) would have had BRCA1/2 mutations. Of the 6 Ashkenazi Jewish individuals that the service criteria would have excluded due to late age at onset, 2 carried the 6174delT BRCA2 mutation. Results from the service program's actual BRCA1/2 testing (PTT) from Sept. 1, 2000 to Sept. 1, 2001 revealed that 120 of 988 (12.1%) families had BRCA1/2 mutations thereby meeting their stated goal. A total of 19 mutations were identified more than once and 55.5% of the mutations identified were in BRCA1.

Approximately 25% of non-syndromic, non-familial pheochromocytoma patients carry germline mutations.

H.P.H. Neumann¹, B. Bausch¹, S.R. McWhinney², G. Franke¹, A. Januszewicz³, C. Eng². 1) Medizinische Univ, Freiburg, Germany; 2) Human Cancer Genetics Prog, Ohio State Univ, Columbus; 3) Warsaw Inst Cardiology, Poland.

When a patient has an operational >10% a priori probability of a germline mutation which gives cancer susceptibility, clinical gene testing is offered. It has been assumed that >90% of all pheochromocytoma (PC) cases are sporadic. Genetic testing is not offered to such patients unless syndromic features or family history are present. In order to test the hypothesis that germline mutation in 1 of 4 PC susceptibility genes in apparently sporadic pheochromocytoma would occur >10% of the time, we analyzed 280 non-syndromic patients without a family history from the population-based German-Polish Registries presenting with symptomatic PC for germline mutations in RET (multiple endocrine neoplasia type 2), VHL (von Hippel-Lindau syndrome), SDHD (familial glomus tumors/paraganglioma) and SDHB (familial glomus tumors/paraganglioma). Comprehensive clinical studies performed include personal and family histories, physical exam, biochemical studies and imaging (eg, MRI) studies of the neck, thorax and abdomen. Of the 280 unrelated apparently sporadic cases, 67 (24%) were found to have germline mutation. Of the 67, 13 had RET, 31 VHL, 11 SDHD and 12 SDHB mutations. While the expected younger age and multifocal presentations were associated with germline mutations, 46 cases with single tumor presentations were mutation carriers and 11 presented after age 40. The youngest presentations (mean 17.7 y) were the most common with VHL (14y) and SDHB mutations (26y). We found that extra-adrenal tumors, eg paragangliomas and glomus tumors, were associated with germline mutation, in particular those in SDHD. Overall, 43 (64%) of the patients were identified solely by molecular testing for RET, VHL, SDHD and SDHB. In summary, because one fourth of apparently sporadic PC were found to carry germline mutations in 1 of 4 genes, routine genetic testing should be offered to all presentations of PC in order not to miss occult hereditary cases. The features at presentation might help suggest which gene to initiate testing.

Searching the germline *LKB1/STK11* mutation in the only known family affected with Peutz-Jegher Syndrome from the São Miguel island (Azores, Portugal). L. Mota-Vieira¹, F. Melo-Bento¹, C.C. Branco¹, J.M. Cabral¹, N. Nunes¹, Z. Rego¹, H. Brum¹, J. Gonçalves¹, H. Mehenni², A. Andrade¹. 1) Hospital of Divino Espirito Santo, Azores Islands, Portugal; 2) Laboratory of Human Molecular Genetics, Geneva University Medical School, Switzerland.

Peutz-Jeghers syndrome (PJS) is a rare autosomal dominant disorder with variable expression and incomplete penetrance. It is characterized by hamartomatous polyposis of the gastrointestinal tract and melanin pigmentation of both skin and mucous membranes. PJS patients also show a predisposition to a wide spectrum of cancers. To date, 78 germline mutations in the *LKB1/STK11* tumour suppressor gene (19p13.3) have been reported as the cause of PJS. Most of them occurred in only one or a few families, of which several have arisen *de novo*.

Here, we report a large PJS family from the Azorean island of São Miguel (Portugal). This family is the only PJS family registered in our Hospital (Azores central hospital). The family history revealed 13 patients (6 deceased), spanning 5 consecutive generations. Among the remaining 7 patients, 4 are adults with aged 30-35y (3rd and 4th generations) and 3 are children aged 4-6y (5th generation). They were all evaluated according to clinical protocols adjusted to patient's age (imagingologic, endoscopic and histologic exams- of the polyps or the necessary resections). Surprisingly, after a routine thorax X-ray exam, a neoplasia - a neuroendocrine tumor of T cells of the mediastinum - was found in one adult patient. This is the first case reporting the presence of this kind of tumor in PJS patient. In order to identify the causative germline mutation segregating in this family, DNA were isolated from blood samples of the selected 7 patients and 6 unaffected relatives. Evidence of linkage was identified with markers located on 19p13.3. We are carrying out the sequencing of the 9 exons and adjacent intronic sequences of *LKB1/STK11* gene. These patients are undergoing a clinical surveillance program. The 3 affected children are also undergoing clinical follow up adjusted to age. (lmv.hospdelgada@mail.telepac.pt).

Contribution of *MSH2*, *MLH1*, *MSH6* and *TGFBR2* Germline Mutations to Colorectal Cancer Susceptibility and its Prevalence. A.E. Lagarde^{1,2,3}, E. Baumann¹, L. Danis¹, H.S. Stern^{1,2,3}. 1) Ottawa Health Research Institute, Ottawa, Ontario, Canada; 2) Department of Surgery, University of Ottawa; 3) Ottawa Regional Cancer Centre.

Early onset HNPCC is mostly attributed to predisposing mutations in DNA-mismatch repair genes. *MSH2* and *MLH1* are more often implicated than *MSH6*, *MLH3* or *EXO1*. *TGFBR2*, the gene encoding the TGF- β type II receptor has rarely been linked to HNPCC. The proportion of colon cancers attributable to mutations in all these genes is unclear, so that the identification of at-risk individuals remains confined to patients presenting with either very strong family histories or with highly microsatellite unstable (MSI) tumors. We addressed the possibility that some patients may be carriers of mutations in *MSH2*, *MLH1*, *MSH6* or *TGFBR2* that are not as penetrant as in HNPCC. A series of 84 colorectal patients diagnosed in Eastern Ontario were screened for MSI (15 markers) and for mutations in *MSH2/MLH1* (79/84 by SSCP), *MSH6* (38/84 by sequencing) and *TGFBR2* (31/84 by sequencing). Allele-specific PCR assays were developed for relevant sequence variations. Germline mutations, not detected in >90 control subjects, and other than common polymorphisms, were found in 3.8% (*MSH2,MLH1*), 5.2% (*MSH6*) and 2.8% (*TGFBR2*) of tested patients respectively, and overall in 5% of patients younger than 50 years of age. Five mutations were missense, and one was the recurrent a(IVS5, +3)t splice site alteration in *MSH2*. Only this and Met373Ile *TGFBR2* were associated with demonstrated loss of the normal allele in tumors. All were associated with patients having at least one first-degree relative affected by cancer, and all but IVS5 *MSH2* led to low/very low MSI. Both IVS5 *MSH2* and Val878Ala *MSH6* carriers were 2 out of the 6 HNPCC patients present in this series. Furthermore, Gly322Asp *MSH2* heterozygotes accounted for 5.9% of colon cancer patients and 4.9% of controls, but for 16% and 3% of young vs old (>50) patients respectively. After excluding 2 presumed non-penetrant missense mutations, we estimate the carrier frequency in the general population of Ontario to be 1:1400 (*MSH6*), 1:1400 (*TGFBR2*), 1:700 (*MSH2,MLH1*) and 1:280 (*Gly322Asp*).

Two novel *BRCA1* mutations in breast and ovarian cancer patients from Brazil. *J.J. Lourenco, F.R. Vargas, J. Bines, E.M. Santos, C.P. Lasmar, C.H. Costa, E.M. Teixeira, M.C.M Maia, F. Coura, C.H.D. Silva, M.A.M Moreira.* Genetics, Instituto Nacional do Cancer, Rio de Janeiro, RJ, Brazil.

It is well known that 5-10% of all breast cancers are attributable to germline mutations in *BRCA1* or *BRCA2* genes. Identification and characterisation of these mutations are important for genetic counselling and for implementing adequate measures aimed at early diagnosis. DNA sequencing of *BRCA1* and *BRCA2* was carried out in a sample of 40 Brazilian patients with breast and/or ovarian cancer who were selected by our Genetic Counselling Group either because of familial history of breast/ovarian cancer, age at diagnosis or tumour bilaterality. All *BRCA1* and *BRCA2* exons and splicing sites were sequenced. *BRCA1* or *BRCA2* germline mutations were found in 8 patients. Two not previously described mutations were found in *BRCA1*: a transversion (IVS17+2 T>C) in intron 17 at the splicing site and a transition in codon 1,135 (1135C>T; exon 11) resulting in a stop codon (CAG®TAG; GlnStop). Three previously described mutations were also found: (1) a rare *BRCA2* mutation (IVS21+4 A>G) in one Italian patient; (2) *BRCA1* 5382insC in exon 20 in 4 patients; and (3) a 4-nucleotide deletion in *BRCA1* exon 11 in codon 1,111 (3450del4) in one patient. The two novel mutations contribute to the characterisation of the mutational spectrum of *BRCA1* and *BRCA2*.

Analysis of Fanconi Anemia Gene Inactivation in Sporadic Squamous Cell Carcinoma of the Head and Neck. *B. Haider¹, M. Tischkowitz¹, J. Jones², M. McGurk², C.G. Mathew¹, S.V. Hodgson¹.* 1) Division of Medical and Molecular Genetics, Guy's Hospital, London, London, UK; 2) Department of Oral and Maxillofacial Surgery, Guys Hospital, London, UK.

Fanconi Anemia (FA) is a chromosomal breakage syndrome characterised by congenital abnormalities, bone marrow failure and an increased risk of leukemia and some solid tumours, notably squamous cell carcinomas of the head and neck (SCCHN). Given the high incidence of SCCHN in FA homozygotes, we investigated whether inactivation of the FA genes plays a causal role in sporadic SCCHN. Loss of heterozygosity (LOH) analysis was performed on DNA from tumour/normal tissue paired samples from sporadic SCCHN cases using microsatellites flanking the six cloned FA genes (FANCA, C, D2, E, F and G). LOH was found at the FANCD2 locus in 8 of 25 patients (36%) informative for D3S1597 and 2 of 29 patients (7%) informative for D3S1560. LOH was also found at the FANCG locus in 2 out of 31 (6%) patients informative for D9S1874. Quantitative Fluorescent PCR (QF-PCR) was performed on samples showing LOH to assess whether intragenic deletions were present; exons 1,5 and 44 were tested in FANCD2 and exons 1,2,10,14 were tested in FANCG. Two out of the 9 samples that showed LOH at the FANCD2 locus had deletions of all FANCD2 exons tested and both of the FANCG LOH samples had deletions of all FANCG exons tested. Analysis of the methylation status of the CpG island in the promoter region of FANCD2 and FANCG in LOH samples was performed by sodium bisulfite sequencing. None of these samples showed evidence of methylation. Correlation with clinical details showed that patients with FANCD2 LOH in their tumours were on average 10 years younger, there was a lower incidence of heavy smokers and a higher frequency of metastatic disease compared with patients showing no LOH. In summary, these findings suggest that FANCD2 and FANCG may be deleted in some cases of SCCHN. However, there was no evidence to suggest that inactivation of the remaining allele occurred by methylation. These results provide evidence of possible involvement of FANCD2 and FANCG in the etiology of SCCHN.

A 20 year perspective of the International Fanconi Anemia Registry (IFAR). *D.I. Kutler^{1,2}, B. Singh^{1,2}, J. Satagopan², M. Berwick², P.F. Giampietro¹, S.D. Batish¹, A.D. Auerbach¹.* 1) The Rockefeller University, New York, NY; 2) Memorial Sloan-Kettering Cancer Center, New York, NY.

Fanconi anemia (FA) is characterized by a cellular hypersensitivity to DNA crosslinking agents and cancer predisposition in patients. Recent studies demonstrate interactions among *ATM*, *BRCA1*, *BRAC2* (putative *FANCD1* gene) and *FANCD2*, suggesting a function for the FA proteins in DNA repair/recombination, cell cycle control and transcription. The IFAR, a prospectively collected database of FA families registered over the past 20 years (1982-2001), allows us the unique opportunity to analyze the natural history of this rare heterogeneous disease, to perform genotype/phenotype correlations, and to study cancer epidemiology in FA families. We report here on 754 subjects with a diagnosis of FA confirmed by cytogenetic studies at RU. Of these 754 patients, 601 (79.7%) experienced the onset of bone marrow failure (BMF) and 173 (23%) developed a total of 199 malignancies. Of these 199 malignancies, 120 (60%) were hematologic and 79 (40%) were non-hematologic. Twenty-one patients developed more than one neoplasm. The most common solid tumors were squamous cell carcinomas (SCC) of the head and neck, anogenital region and skin. There was no increased risk of SCC in FA patients after hematopoietic stem cell transplant (HSCT) vs. non-transplanted patients. The risk of developing BMF, hematologic and solid neoplasms increased with advancing age, with a 90% 33% and 28% cumulative incidence by 40 years of age, respectively. Univariate analysis revealed significant earlier onset of BMF for group FA-C compared to groups A and G, however there was no significant difference in the time to tumor development between the different groups. Multivariate analysis of overall survival time shows that *FANCC* mutations ($p=0.004$, early hematological onset ($p < 0.0001$)) and HSCT ($p < 0.0001$) define a poor-risk subgroup with significantly worse survival. This study of IFAR patients over a 20-year period enables us to define the natural history of this rare heterogeneous disorder. This information will allow us to better predict outcome and aid clinicians with decisions regarding major therapeutic modalities.

Role of *Cyp17* and *ERb* genes in Hereditary Nonpolyposis Colorectal Cancer. *S.A. Kuismänen*¹, *S. Bala*², *P. Peltomäki*¹. 1) Department of Medical Genetics, 00014 University of Helsinki, Finland; 2) Human Cancer Genetics, Comprehensive Cancer Center, Ohio State University, Columbus, OH 43210.

Two of the most common cancers in the hereditary nonpolyposis colorectal cancer (HNPCC) spectrum are cancer of the colon and of the endometrium. Observations that link the sex hormones in the development of these cancers in the general population prompted us to study the possible modifying roles of the hormone-related *Cyp17* and *ERb* genes. Both of these genes exhibit a nucleotide change that causes variants which may have involvement in the increased risk to cancer. The *Cyp17* gene, which regulates androgen biosynthesis, has a T to C change in the promoter region and gives rise to an A2 variant that may be associated with elevated levels of circulating sex hormones. *ERb*, encoding an estrogen receptor that regulates ovulation as well as being observed to be the primary ER in the colon, has a G to A substitution in exon 8. We analyzed the allele distribution against clinical parameters in a series of 173 affected carriers of 10 MLH1 and 4 MSH2 mutations and 183 mutation negative cases (controls). Individuals carrying an ancestral founding mutation in MLH1 ("mutation 1") constituted the majority of the cases and formed a subgroup with a homogenous background.

The observed genotypes of mutation positive individuals showed some interesting associations relative to age and location of colon cancer in the "mutation 1" group. The variant A2 allele of *Cyp17* (genotype A2/A2) showed significant association with lower age of onset of colon cancer in males (41 vs. 45 years) and an even more striking difference in females (39 vs. 50 years), as compared to genotype A1/A1. Furthermore, the presence of the A2 allele was also associated with distal location of the CRC in females. In *ERb*, homozygosity for the variant allele (A) was found to have a strong association with late onset of colon cancer in "mutation 1" males but not females. We conclude that the *Cyp17* T>C polymorphism may modulate the age at onset and location of colon cancer in HNPCC, especially in the female gender and that *ERb* G>A polymorphism may in turn modulate the age of onset in male HNPCC patients.

Familial prostate cancer in Tasmania. *J.D. McKay¹, J.L. Dickinson¹, D.A. Mackey², M.M. Sale³, D. Shugg¹, M. Ring¹, S. Inglis¹, A. Edwards¹, S. Easta¹*. 1) Menzies Centre for Population Health Research, Uni of Tasmania, Hobart, Tasmania. Australia; 2) Royal Hobart Hosital, Tasmania, Australia; 3) Center for Human Genetics, Wake Forest Uni. School of Medicine, Wiston-Salem, USA.

9% of prostate cancer is thought to be of familial origin. The search for potential susceptibility genes in familial prostate cancer (fPC) has been hindered by the existence of significant genetic heterogeneity, a high phenocopy rate and the late onset of the disease influencing the availability of genetic material in older generations. The Australian island state of Tasmania has a stable population and a high patient participant rate, making an ideal environment to study the aetiology of fPC. From the period of 1978-1998, in excess of 3650 prostate cancer cases have been identified in the Tasmanian cancer registry. By using a novel approach of identification of over-represented names in the Tasmanian cancer registry relative to the phone directory, fPC pedigrees in Tasmania have been identified. Thus far, this technique has identified over 65 families in Tasmania with fPC, with between 2 and 16 affected patients and 6 pedigrees containing more than nine cases. This is therefore, a significant resource for the study of the molecular genetics of fPC and work has commenced to determine the significance of the RNASEL and ELAC2 genes and the known prostate susceptibility loci in the Tasmanian population.

Cancer screening practices following genetic counseling/testing in families with HNPCC. *D. Hadley¹, J. Jenkins², M. DeCarvalho², E. Dimond², I. Kirsch², C.G.S. Palmer³.* 1) NHGRI/NIH, Bethesda, MD; 2) CCR/NCI/NIH, Bethesda, MD; 3) Dept Psychiatry, UCLA.

Little is known about cancer screening practices following genetic counseling and the receipt of genetic test results for cancer susceptibility genes. One goal is to focus cancer-screening in individuals identified at increased risk due to the presence of a familial mutation. A second goal is to reduce cancer-screening to general population levels in those not carrying familial mutations. Data on cancer screening behaviors following the receipt of genetic test results is limited. We report on cancer-screening practices of unaffected individuals receiving results in families with newly identified mutations in Hereditary Non-Polyposis Colorectal Cancer (HNPCC) genes. Individuals in families with an HNPCC mutation were recruited for a study assessing outcomes of genetic counseling/testing. Participants received genetic counseling followed by the offer of gene testing. Those choosing testing received results in a second counseling session. Verbal and written cancer screening recommendations following published guidelines were provided in both sessions. Data on cancer screening practices, psychological variables, attitudes, and beliefs were collected prior to testing and at 6 & 12 months post-test. For each cancer screening behavior, compliance/noncompliance was determined according to the guidelines. Analyses were performed to identify factor(s) associated with compliance. We report on colonoscopy screening behaviors. Of the 60 at-risk individuals with no personal history of cancer, 39 were negative and 21 were positive for an HNPCC mutation. Among the mutation negative, 10.3% were not compliant; half engaged in hyper-vigilance and half engaged in hypo-vigilance. Among the mutation positive, 38.1% were not compliant; 75% engaged in hyper-vigilance and 25% in hypo-vigilance. The data suggest that mutation positive individuals are more likely to be non-compliant for colonoscopy than mutation negative individuals. Furthermore, the predominant form of non-compliance in the mutation positive group is to undergo the procedures more frequently than is generally recommended.

Impact of MC1R variants on melanoma risk in pedigrees with familial and/or multiple melanomas associated with CDKN2A mutations. *S. Majore*¹, *C. Catricala*², *F. Binni*³, *L. Eibenschutz*², *G. Minozzi*³, *P. De Simone*², *A. Amantea*², *P. Grammatico*^{3,1}. 1) Medical Genetics, Az. Osp. S. Camillo-Forlanini, Rome, Italy; 2) S. Gallicano Dermatological Institute, Rome, Italy; 3) Medical Genetics, Experimental Medicine and Pathology Dept., University of Rome La Sapienza, Italy.

The MC1R gene, located in 16q24.3, encodes the melanocytes-stimulating hormone receptor (MSHR), is highly polymorphic in whites (Valverde et al. 1995; Box et al. 1997; Smith et al. 1998) and its variants have been found to be associated with skin phototype. Some recent studies (Van der Velden et al. 2001; Box et al. 2001) seem to evidence a significant association between particular MC1R alleles and an increase of melanoma risk, particularly in families with CDKN2A mutations. CDKN2A mutations predispose subjects to melanoma susceptibility due to an imbalance between functional p16 and cyclin D causing an abnormal cell growth but it is now clear the incomplete penetrance of CDKN2A mutations and the involvement of MC1R polymorphisms in modulating the onset of the disease in subjects belonging to a melanoma-prone family linked to CDKN2A. To better understand the significance of CDKN2A and MC1R variants in pathogenesis of melanoma as well as the weight of the molecular results in genetic counseling of familial and multiple melanomas, we analyzed 90 Italian patients, and several healthy subjects from the same families, by direct sequencing of these two genes. We identified CDKN2A germline mutations in more than 15% of the cases, including the IVS2-105 A/G intronic variant, previously described only in English families (Harland et al. 2001) and some new mutations: a 1bp deletion at nucleotide position 201 (codon 67) (CACGGcGCG) that produces a stop codon (145) by frameshift (Grammatico et al. 2001), a Pro48Thr missense change and a IVS1+2(T-C)/+ mutation interfering with RNA splicing. The analyses conducted on MC1R polymorphisms in patients and in several apparently healthy subjects from families with CDKN2A mutations confirmed the significance of these variants in modulating melanoma onset and age of occurrence.

Penetrance in molecularly proven BRCA1/2 Carriers: Moderate breast cancer risk is increasing in recent cohorts. *E. Levy-Lahad*^{1,2}, *S. Simchoni*^{1,2}, *B. Kaufman*³, *U. Beller*¹, *T. Safra*¹, *P. Renbaum*¹, *R. Catane*³, *A. Lahad*². 1) Medical Genetics, Shaare Zedek Medical Ctr, Jerusalem, Israel; 2) Hebrew University, Jerusalem, Israel; 3) Sheba Medical Center, Tel Aviv, Israel.

Objective: To accurately assess penetrance of the three common BRCA1/2 mutations in the Ashkenazi Jewish (AJ) population, using only molecularly proven carriers. Previous estimates of BRCA1/2 penetrance are extremely variable, ranging from 85% for breast cancer and 56% for ovarian cancer in directly tested high-risk families, to 56% for breast cancer and 16% for ovarian cancer using theoretical models in population-based studies. **Subjects and Methods:** Subjects were BRCA1/2 carriers proven either by direct testing or as obligate carriers per family structure and genotype. Families were ascertained through an affected proband or in our Cancer Genetics clinic. After excluding probands, analysis included 162 non-proband women from 74 families. Breast and ovarian cancer penetrance were analyzed using Kaplan-Meier survival and Cox regression. **Results:** Risk for breast cancer by age 70 was 63% for BRCA1 carriers and 51% for BRCA2 carriers (HR=2.3, p=0.04). Later birth year significantly increased breast cancer risk in BRCA1/BRCA2 carriers (HR=1.04 per year, p=0.009, or HR=1.48 for a 10 yr. difference in birth year). Ovarian cancer risk by age 75 was 63% (SE=9%) for all carriers, not significantly different for BRCA1 or BRCA2 carriers. There was also a trend for increased ovarian cancer risk in later birth cohorts. **Conclusions:** Breast cancer risk for BRCA1/2 carriers in Israel is similar to that estimated for low risk populations, with significantly lower risk for BRCA2 carriers (HR=0.4 vs. BRCA1), whereas ovarian cancer risk is as high as in high-risk families. Cancer risk is increasing significantly in more recent birth cohorts, suggesting a role for environmental and/or reproductive effects.

A *CHEK2* variant with increased breast cancer risk. O. Kilpivaara¹, P. Vahteristo¹, K. Syrjäkoski², H. Eerola^{1,3}, J. Bartkova⁴, K. Aittomäki⁵, P. Heikkilä⁶, J. Bartek⁴, K. Holli⁷, C. Blomqvist^{3,9}, O.-P. Kallioniemi⁸, H. Nevanlinna¹. 1) Dept. of Obstetrics and Gynecology, Helsinki University Central Hospital (HUCH), Finland; 2) Lab. of Cancer Genetics, Inst. of Medical Technology, Tampere University and Tampere University Hospital, Finland; 3) Dept. of Oncology, HUCH, Finland; 4) Inst. of Cancer Biology, Danish Cancer Society, Copenhagen, Denmark; 5) Dept. of Clinical Genetics, HUCH, Finland; 6) Dept. of Pathology, HUCH, Finland; 7) Dept. of Oncology, Tampere University Hospital, Finland; 8) Cancer Genetics Branch, National Human Genome Research Institute, Bethesda, MD; 9) Oncology, Uppsala University Hospital Sweden.

Cell cycle checkpoint kinase 2 (*CHEK2*) is a key mediator of cellular responses to DNA damage. Once activated it phosphorylates various substrates including p53, BRCA1 and CDC25A. Previously, we have identified two *CHEK2* germ line genetic variants in Finnish breast cancer patients and families, I157T in exon 3 and 1100delC in exon 10. The protein truncating mutation 1100delC was previously shown to strongly associate with family history of breast cancer, acting as a low penetrance susceptibility allele. The I157T mutant protein is deficient in binding and phosphorylating p53 and CDC25A. Here, we found that the frequency of I157T was significantly higher among an unselected population-based cohort of 1035 breast cancer patients (77/1035, 7.4%, OR 1.43 95% CI 1.06-1.95) and especially among family history negative patients (53/677, 7.8%, OR 1.52 95% CI 1.07-2.14), as compared to 1885 population controls (5.3%). The frequency in a cohort of 507 familial cases (5.5%) was similar to controls suggesting lower impact of this variant in patients with familial disease. Screening of the whole coding region of the *CHEK2* for novel germ line mutations in 75 breast cancer families revealed four carriers of the 1100delC mutation and five carrying the I157T, however, no additional coding variants were identified. In conclusion, our results indicate that *CHEK2* genetic variants with functional significance are associated with increased breast cancer risk and the I157T is likely to have a contribution to breast cancer at the population level.

Phenotype of *MSH6* versus *MLH1* and *MSH2*: Lower penetrance and higher age of onset . *Y. Hendriks*¹, *A. Wagner*², *H. Vasen*³, *F. Menko*⁴, *A. Stormorken*⁵, *P. Möller*⁵, *M. Genuardi*⁶, *L. Sandkuijl*⁷, *H. van Houwelingen*⁷, *C. Tops*¹, *H. Morreau*⁸, *W. de Leeuw*⁸, *H. Meijers-Heijboer*², *M. Breuning*¹, *R. Fodde*¹, *J. Wijnen*¹, *A. Bröcker-Vriends*¹.
1) Clinical and Human Genetics, Leiden University Medical Center, The Netherlands; 2) Clinical Genetics, Dijkzigt Hospital, Rotterdam; 3) Netherlands Foundation for the Detection of Hereditary Tumours, Leiden; 4) Clinical Genetics, Free University of Amsterdam; 5) Unit of Medical Genetics, University Clinic the Norwegian Radium Hospital, Oslo, Norway; 6) Institute of Medical Genetics, Università Cattolica del Sacro Cuore, Rome, Italy; 7) Medical Statistics, Leiden University Medical Center; 8) Pathology, Leiden University Medical Center.

Background In 50-70% of the families fulfilling the clinical criteria for HNPCC (Hereditary Non Polyposis Colorectal Cancer) a germline mutation is found in *MLH1* or *MSH2*. In 1997 the first germline mutations in *MSH6* were described. Wijnen et al. described 9 pathogenic *MSH6* mutations in 10 families. They found a higher age of onset and lower penetrance compared with *MLH1* and *MSH2*. **Purpose** To further delineate the tumourspectrum and penetrance of pathogenic *MSH6* mutations and to determine a protocol for periodic surveillance. **Methods** We studied 20 families with a mutation in *MSH6*. We performed mutation analysis in 78 clinically affected and 190 at risk carriers. We collected clinical data and performed microsatellite instability analysis and immunohistochemistry on 49 and 41 tumours respectively. **Results** We identified 146 carriers of a pathogenic *MSH6* mutation. We found a lower penetrance for colorectal cancer and a higher penetrance for endometrial cancer when compared with *MLH1* or *MSH2*. We found an average age of onset for both colorectal cancer and endometrial cancer of 55 years. In case of colorectal cancer this is more than 10 years higher than the average age of onset in carriers of a *MLH1* or *MSH2* mutation. **Conclusion** In carriers of a *MLH1* or *MSH2* mutation the current surveillance protocol advises a colonoscopy every 1 to 2 years from the age of 20 to 25 years. We suggest to start with colonoscopies from age 30 in carriers of a *MSH6* mutation.

Some germ-line mutations in mismatch repair genes in HNPCC patients may confer an increased risk for additional germline defects. P. Hutter¹, J. Wijnen², G. Chong³, C. Ray-Berthod¹, I. Thiffault^{3,4}, S. Thibodeau⁵, J. Burn⁶, N. Wong⁴, P. Chappuis⁷, A. de la Chapelle⁸, W. Foulkes⁴. 1) Unit of Genetics, ICHV, Sion, Switzerland; 2) Human and Clinical Genetics, Leiden Univ. Medical Centre, the Netherlands; 3) Diagnostic Medicine, SMBD-Jewish General Hospital, McGill Univ., Montreal, Canada; 4) Human Genetics, McGill Univ., Montreal, Canada; 5) Molecular Genetics, Mayo Clinic, Rochester, MN, USA; 6) Inst. of Human Genetics, Univ. of Newcastle, UK; 7) Div. Oncology/Genetics, Hopital Univ. Geneve, Geneva, Switzerland; 8) Cancer Genetics, Ohio State Univ., OH, USA.

Hereditary non-polyposis colorectal cancer (HNPCC) is thought to account for 2-5% of all colorectal cancer cases. The autosomal dominant syndrome, characterized by colorectal and/or endometrial cancers in the fourth or fifth decade is caused by germline mutations in DNA mismatch repair (MMR) genes. We have identified a number of patients who carry 2 different genetic alterations in MMR genes. Twenty-three probands were found to harbor 2 germline variants in *MLH1*, *MSH2* or *MSH6*. Double heterozygotes corresponded to 27 alterations in *MLH1*, 16 alterations in *MSH2* and 3 alterations in *MSH6*. Noticeably, 8 out of these 46 mutations (17%) involved either codon 618 or 716 of *MLH1*, both of which appear to be among the most frequently altered codons in *MLH1*. We estimate that at least 3% of MMR mutation carriers harbor 2 distinct germline alterations in the above 3 genes.

On further analysis of the *MLH1* haplotype associated with the A/G polymorphism at IVS14-19, it was notable that 25 out of 38 (66%) chromosomes from heterozygotes carried the G haplotype. This haplotype was recently shown to be over-represented on chromosomes bearing *MLH1* mutations, compared with ethnically-matched control groups. These findings may reflect a possible difference in MMR efficiency between A and G haplotypes (Hutter et al. J Med Genet. 39:323-327, 2002).

We hypothesise that some MMR mutations have a weak dominant negative effect which predisposes to other germline defects. This effect may have been overlooked as many centers tend to interrupt their mutation screen once a pathogenic defect is identified.

The Retinoblastoma Gene Mutation Spectrum: Analysis of 240 Independent Mutations. *S.T. May¹, M. Eppstein², M.E. Tang¹, D.W. Yandell¹*. 1) Molecular Diagnostics Lab, Vermont Cancer Center, Burlington, VT; 2) Department of Computer Science, University of Vermont, Burlington, VT.

Tumor suppressor genes provide a unique opportunity to compare in vivo mutation spectra in human genes in both somatic cells and the germline at a single locus. However, reported mutation spectra are often based on compilations of data from multiple studies that have used different detection methods. We report the results of comprehensive mutation analysis in a large series of retinoblastoma cases which identified 240 independent RB gene mutations. The physical characteristics, site and sequence context of these mutations were analysed to define the predominant mechanisms by which spontaneous mutations occur at this locus. We have also compared the physical characteristics of these mutations with clinical and phenotypic features including penetrance and expressivity. Nonsense mutations predominate (74%) with a subset of missense or splicing mutations recurrently associated with low penetrance. 74% of all base substitution mutations were transitions. C to T transitions at CGA arginine codons account for 12 of 16 sites of recurrent mutation and almost 30% of all observed mutations (45% of substitutions); there is a 70-fold bias toward the sense (versus antisense) strand in the occurrence of C to T transition mutations at CpG sites. The ratios of 1) missense to nonsense, and 2) insertion/deletion to base-substitution are different in somatic versus germline mutations. Local sequence context plays an important role in both substitution and insertion/deletion mutation, with regions near potentially stable stem-loop structures and repeated sequences particularly susceptible to mutation. Further analysis of these data is underway to determine whether rules defining the empirical mutation spectrum we have observed can be defined, and might be used to inform strategies to search new or unstudied human sequences for natural polymorphisms and pathogenic mutations.

How BRCA1/2 test results affect risk perception and beliefs among members of Hereditary Breast and Ovarian Cancer (HBOC) Families. *A.M. McInerney-Leo¹, B.B. Biesecker¹, D. Hadley¹, R.G. Kase^{2,3}, T.R. Giambaresi^{2,3}, E. Johnson⁴, C. Lerman⁵, J.P. Struewing².* 1) NHGRI/NIH Bethesda, MD; 2) NCI/NIH Bethesda, MD; 3) Westat Research, Rockville, MD; 4) Johns Hopkins Biostats Center, Baltimore, MD; 5) Univ of Pennsylvania Cancer Center, PA.

Members of HBOC families often have long-held beliefs about their carrier status and the advantages and disadvantages of testing. The extent to which these beliefs affect the decision to undergo testing and the consequences of the receiving results consistent or inconsistent with these beliefs is not known. Within a randomized trial of breast cancer genetic counseling methods, 212 members of 13 HBOC families were offered BRCA1/2 testing for a known family mutation. Risk perception and beliefs about the advantages and disadvantages of testing were assessed at baseline and again at 6-9 months following the receipt of test results, or at the equivalent time for those who declined testing. Comparisons were made between testers and non-testers and as well as between those who tested positive or negative. One hundred eighty-one participants elected to undergo genetic testing (85%) and 47 (26%) were identified as carriers. All individuals who participated believed themselves to be at "a little" to a "much" higher risk for breast cancer as compared to the general population and all felt it was "very likely" or "definite" that they had a mutation, with no difference between testers and non-testers ($p=0.518$). All participants felt that the most important reason to undergo testing was to learn information about their childrens risk. Both groups also felt that the most reason for not wanting testing was worry about losing insurance and non-testers were also worried about confidentiality. Individuals who tested negative had a significant decrease in their perceived risk for breast cancer, ovarian cancer and their chances of carrying an altered gene ($p<0.001$ for all). Those who tested positive had no change in their perceived risks. Conclusion: Perceived risks did not influence the decision to undergo testing. A negative result was followed by a significant decrease in all areas of perceived risk thus changing prior-held beliefs.

Overexpression of the Fanconi anemia protein FANCD2 induces apoptosis. *J. Hejna, D. Bruun, R. Moses.* Dept. of Molecular and Medical Genetics, Oregon Health and Science University, Portland, OR.

Fanconi anemia is a rare, autosomal recessive disease characterized by pancytopenia, and at the cellular level by genomic instability manifested by a hypersensitivity to DNA crosslinking agents. Patients are at elevated risk for certain cancers, including myelodysplasia, acute myelogenous leukemia, and solid tumors. One Fanconi protein, FANCD2, is modified in response to DNA damage and co-localizes with BRCA1 to nuclear foci after DNA damage, implying recruitment to the sites of damaged DNA. We have shown that FANCD2 cDNA constructs under the control of the strong constitutive CMV promoter are toxic to immortalized fibroblasts. By 20 hours after electroporation, most of the transfected cells have either lysed or have rounded up and shrunken, consistent with an apoptotic morphology. We have developed two assays to quantitate the toxicity of constructs carrying the FANCD2 toxic domain. The first is based on co-transfection of subclones of the toxic domain fused to an ECFP reporter, with a second plasmid carrying a non-toxic fluorescent reporter. Toxicity is determined from the ratio of doubly-transfected cells to the total number of fluorescent cells, 24 hours post-transfection. Toxic constructs result in virtually no doubly-transfected cells (only singly-transfected, red-fluorescent cells survive), while non-toxic constructs result in up to 85% co-transfected cells. A second assay, involves subclones of the toxic domain in pIRES constructs, measuring toxicity by a colony-forming assay: since the FANCD2 subclone and the selectable marker for puromycin resistance are co-transcribed, only non-toxic constructs allow colony formation under puromycin selection. Toxicity was determined relative to non-toxic controls. The two assays define the minimal toxic domain to about 85 aa including part of exon 11, all of exon 12, and part of exon 13. Caspase-3 assays also indicate that cell death induced by overexpression of the FANCD2 toxic domain is apoptotic. One possible function of FANCD2 under certain conditions may be to trigger apoptosis.

Multiple primary melanomas in a CDKN2A mutation carrier exposed to ionizing radiation. *S.A. Leachman^{1,2}, C. Hansen^{1,2}, L. Wadge², P. Porter-Gill^{1,2}, S.R. Florell^{1,2}, L. Swinyer¹.* 1) Dermatology, University of Utah Salt Lake City, UT; 2) Huntsman Cancer Institute, University of Utah Salt Lake City, UT.

The development of melanoma involves complex interactions between inherited genetic susceptibility and exposure to environmental risk factors. These interactions are beginning to be explored at the molecular level. Patients with more than five primary melanomas are unusual and can be serendipitous for cellular and molecular investigation. We have investigated a patient with eight primary melanomas in an effort to identify risk factors that may contribute to an exaggerated manifestation of disease. Germline mutations in the gene encoding cyclin dependent kinase inhibitor 2A (CDKN2A, p16, INK4a) are present in 8-15% of patients with multiple primary melanomas and in as many as 75% of patients with 5 or more primary melanomas. However, family members with the CDKN2A mutation do not usually demonstrate multiple primary melanomas and it is unclear why particular individuals suffer an increased risk. Although increased exposure to ultraviolet light is believed to increase penetrance of the CDKN2A gene, the role of additional environmental risk factors in the penetrance of CDKN2A has not been studied. Sequence analysis of CDKN2A in our identified patient revealed a previously reported -34 (G>T) 5' UTR germline mutation that creates an alternative start site and frame shift relative to normal CDKN2A. Cytogenetic evaluation, including fluorescent in situ hybridization, failed to identify additional chromosomal abnormalities in lymphocytes or cultured skin fibroblasts. However, the patient was exposed to ionizing radiation from nuclear testing in Nevada in the 1950s. Radioactive dust deposited preferentially on the right side of her body where six of the eight melanomas arose. Exposure to ionizing radiation in a genetically predisposed individual offers a potential hypothesis to explain the number and distribution of melanomas in this patient. The clinical implications of this potential association would be important to other carriers of p16/CDKN2A mutations because radiotherapy is frequently considered as a treatment option in melanoma patients.

Biallelic Inactivation of BRCA2 in Fanconi Anemia. *N.G. Howlett¹, T. Taniguchi¹, S. Olson², B. Cox², Q. Waisfisz³, C. de Die-Smulders⁴, N. Persky¹, M. Grompe², H. Joenje³, G. Pals³, H. Ikeda⁵, E.A. Fox¹, A.D. D'Andrea¹.* 1) Pediatric Oncology, Dana-Farber Cancer Institute, Boston, MA; 2) Department of Molecular and Medical Genetics and Department of Pediatrics, Oregon Health Sciences University, Portland, OR; 3) Department of Clinical Genetics and Human Genetics, Free University Medical Center, Amsterdam, The Netherlands; 4) Department of Clinical Genetics, Academic Hospital Maastricht, Maastricht, The Netherlands; 5) Department of Pathology, Sapporo Medical University School of Medicine, Sapporo, Japan.

Fanconi Anemia (FA) is an autosomal recessive cancer susceptibility syndrome characterized by multiple congenital anomalies and progressive bone marrow failure. FA patients often develop acute myeloblastic leukemia, but also develop squamous cell carcinomas. FA cells are hypersensitive to crosslinking agents, e.g. mitomycin C (MMC). At least eight distinct complementation groups of FA have been defined, and six FA genes have been cloned (A,C,D2,E,F,G), but the gene(s) corresponding to subtypes B and D1 remains unidentified. Many lines of evidence suggest genetic interactions among the breast cancer susceptibility genes, BRCA1 and BRCA2, and the FA genes. First, assembly of the multisubunit nuclear FA complex (A,C,E,F,G), in response to DNA damage or during S phase of the cell cycle, activates the monoubiquitination of the D2 protein, targeting D2 to BRCA1-containing nuclear foci. Second, BRCA(-/-) tumor cells exhibit MMC hypersensitivity and chromosome instability, similar to FA cells. Third, targeted disruption of the 3' region of the murine *Brca2* gene results in viable mice with an FA-like phenotype. To further investigate the relationship between the BRCA genes and FA, we sequenced BRCA1 and BRCA2 in cells derived from FA-B and FA-D1 patients. While no BRCA1 mutations were detected, biallelic mutations in BRCA2 were observed in the FA-D1 cell lines HSC62 and EUFA423, as well as the FA-B cell line HSC230. BRCA2 western analysis revealed expression of full length BRCA2 protein in HSC62, while only C-terminus truncated BRCA2 proteins were evident in EUFA423 and HSC230.

Localization of genes predisposing to acute leukemia in Down syndrome-A Childrens Oncology Group Study.

V.N. Rao, P.K. Rogan. Children's Mercy Hospital, Kansas City, MO.

In COG-B957, we are examining the possibility that predisposition to acute leukemia in Down syndrome is the result of increased disomic homozygosity at one or more loci on the non-disjoined chromosome 21 (reduction to homozygosity from heterozygous carrier). If the gene(s) acts as a tumor suppressor, a somatic event would be expected to unmask recessive alleles on the non-disjoined chromosome 21 (Am J Med Genet; 59:174-181). Microsatellite loci spanning the entire length chromosome 21 (n=50) were genotyped at diagnosis and remission and compared with parental genotypes for 22 patients (13 with AML, 9 with ALL). Linkage analysis of markers from D21S369, near the centromere, to D21D49, the most telomeric locus, revealed two genetic intervals (I and II) with high frequencies of disomic homozygosity. Within interval I, a locus at ~11 million base pairs (Mb) in the sequence of chromosome 21 had a maximum 2-point lod score of 4.82 for patients with at least one reduced locus. Z_{\max} was 5.30 at ~12.5Mb, when all 22 patients were analyzed. In interval II, the maximum lodscore was 3.31 between 25 -28 Mb, which includes the region containing AML1, the gene mutated in Familial Platelet Disorder. When all patients were considered, $Z_{\max} = 6.92$ for interval II. Somatic mutations confined to the diagnostic marrow were observed at 12.5 Mb in 2 individuals on the normally disjoined chromosomes, consistent with a possible second hit at these loci. Loss of heterozygosity (LOH) was evident for markers in 4 patients in the 11-13 Mb interval, as well as the 28-30 Mb (n=3) and 17-18 Mb (n=4) intervals. Three patients exhibited LOH for markers in 2 different intervals. Thus, at least 2 different genes on chromosome 21 appear to contribute to the predisposition to leukemia in Down syndrome. Linked somatic mutations suggest the possibility that a tumor suppressor gene in interval I may be inactivated. Potential gene candidates in interval I for sequence analysis include those involved in cell proliferation (BTG3), signal transduction (Metrin A), a tyrosine kinase (SAMS1), and chaperonin (STCH), and in interval II, a ser/thr kinase (HUNK), and a cell cycle regulator (TIAM1).

Putative common origin of two *MLH1* mutations in Quebec hereditary non-polyposis colorectal cancer (HNPCC) families. I. Thiffault¹, G. Chong^{1,2,5}, N. Wong¹, V. Marcus³, E. MacNamara^{2,3,5}, P. Radice⁶, P. Hutter⁷, W. Foulkes^{1,4}. 1) Department of Human Genetics; 2) Department of Medicine; 3) Department of Pathology; 4) Program in Cancer Genetics, McGill University, Montreal, QC, Canada; 5) Department of Diagnostic Medicine, SMBD-Jewish General Hospital, Montreal, QC, Canada; 6) Department of Experimental Oncology, Istituto Nazionale Tumori, Milano, Italy; 7) Unit of Genetics, Institut Central des Hopitaux Valaisans, Sion, Switzerland.

Hereditary non-polyposis colorectal cancer (HNPCC) is one of the most common inherited cancers accounting for 3-5% of all cases of colorectal cancer. In most HNPCC families, the disease is caused by a germline mutation in *MLH1* or *MSH2*. In some populations, founder mutations appear to explain a substantial fraction of HNPCC. Founder mutations in *MLH1* have been identified in Finland and Switzerland. A germline mutation that may also be a founder mutation (1.8-kb deletion involving exon 11 of *MLH1*) has also been reported in two HNPCC kindreds in China. We report here the identification and preliminary characterization of two putative *MLH1* founder mutations. The mutation *MLH1*:1831 delAT was shown to segregate in two Quebec families of Italian origin who fulfilled the Amsterdam criteria for HNPCC. Haplotype analysis using 5 intragenic micro-satellite/SNP markers spanning *MLH1* on chromosome 3 showed that these two unrelated families share an identical haplotype. By contrast, two other Italian kindreds whose affected members carry *MLH1*:IVS6+3 A>G did not share a common haplotype, suggesting that the latter mutation has arisen independently. The second probable founder mutation involves a deletion of the whole of exon 13 from the cDNA of *MLH1* in several affected members of two unrelated French Canadian kindreds. This out-of-frame deletion results in a premature stop codon 19 bp downstream. The mutation was shown to segregate on a common haplotype in both families, supporting the notion that this is a founder mutation. These two mutations are the first putative founder *MLH1* mutations to be identified in North American HNPCC kindreds.

Germline mutations in the PTCH gene in Italian Gorlin Syndrome patients. *L. Pastorino¹, R. Cusano¹, F. Faravelli², M. Barile¹, P.L. Santi¹, L. Lo Muzio³, A. Tel⁴, G. Bianchi-Scarra¹.* 1) Dept Oncology Biol. Genetics, Univ. of Genova, Genova, Italy; 2) EO Ospedali Galliera, Genova, Italy; 3) Institute of Dental Sciences, Univ. of Ancona, Ancona, Italy; 4) Ospedale S.Martino, Genova, Italy.

Gorlin Syndrome (GS), alternatively called Nevoid Basal Cell Carcinoma Syndrome, is a rare autosomal dominant disorder. GS is characterized by predisposition to basal cell carcinomas (BCC) of the skin, medulloblastomas and other tumors. A variety of malformations is another feature of the syndrome including pits of the palms and soles, odontogenic keratocysts and skeletal alterations. GS is noted for its interfamilial and intrafamilial clinical variability, and no evident genotype-phenotype correlation has been established. The disease is known to result from mutations in the PTCH gene located at chromosome 9q22.3, which causes loss of function in the patched protein. In order to verify the involvement of PTCH among Italian patients we provide a molecular characterization of 5 unrelated Italian probands who met the criteria for GS (keratocysts of the jaw, calcification of the falx cerebri and multiple BCCs), and 7 patients with multiple BCCs presenting at least 3 BCCs before 50 years or 1 before 20 years and no other major criteria. Screening was performed using combined standard SSCP and DHPLC analysis (WAVE DNA fragment analysis system, Transgenomic, Santa Clara, CA). Sequencing of the variants revealed 5 different mutations, 2 missense (L479R, T1194S), and 3 non-sense (2011_2012insC, 2535_2536insG, 2577_2583delTGACAGT), in the 5 GS cases. With the exception of 2011_2012insC, none of these mutations have been previously described. Although none of the 7 BCC patients were found to be mutated, some showed variations of uncertain significance in the introns and exons of the gene. The importance of genetic analysis in Italian GS patients lies in the possibility to provide more accurate pre- and post-natal diagnosis and implement strategies for prevention of UV- and radiation therapy-induced BCC.

IGF-1 and insulin-induced expression of HIF-1 through activation of PI3K/Akt signaling in ovarian cancer cell lines. *H.D. Skinner, J.Z. Zheng, N. Gao, X.S. Zhong, L.A. Lopez, B.H. Jiang.* MBR Cancer Center, Dept. of Microbiology, Immunology and Cell Biology, WVU School of Medicine, Morgantown, WV.

Ovarian cancer continues to be one of the most prevalent female cancers. The gene coding for p110 α , the catalytic subunit of phosphatidylinositol 3-kinase (PI3K), is frequently amplified in ovarian carcinoma. Hypoxia-inducible factor 1 (HIF-1) is a basic helix-loop-helix transcription factor that is induced by hypoxia, growth factors and oncogenes. HIF-1 plays an important role in angiogenesis and tumorigenesis. Insulin and IGF-1 have been shown to be mitogenic in a number of human carcinomas. In this study we determined whether activation of PI3K/Akt mediated the expression of HIF-1 in several ovarian carcinoma cell lines. We demonstrated that increased expression of HIF-1 α is mediated through PI3K/Akt. We also showed that IGF-1 and insulin specifically induced HIF-1 α , but not HIF-1 β protein. The induction of HIF-1 α expression by insulin and IGF-1 was inhibited by the addition of the PI3K inhibitors LY294002 and Wortaminin, which indicates that the induction of HIF-1 α expression was mediated by PI3K signaling. These results suggest that HIF-1 may play an important role in ovarian carcinoma tumor progression due either to the amplification of PI3K or the increased expression of growth factors.

Investigation of candidate genes located within the chromosome 6q24.1-25.2 cytogenetic location in adenoid cystic carcinoma of the salivary gland. *S. Rutherford*¹, *C.A. Rumpel*¹, *H.F. Frierson Jr*¹, *C.A. Moskaluk*². 1) Dept of Pathology, University of Virginia, Charlottesville, VA; 2) Depts of Pathology and Biochemistry and Molecular Genetics, University of Virginia, Charlottesville, VA.

Deletion of chromosome 6q has been described in adenoid cystic carcinoma (ACC) of the salivary gland, consistent with targeted inactivation of a tumor suppressor locus. In order to identify possible tumor suppressor genes, we previously conducted comparative genomic hybridization (CGH) and loss of heterozygosity (LOH) analyses to characterize regions of genetic deletion on chromosome 6 in ACC. The results from these ACC studies show the greatest loss occurring within the 6q24.1-6q25.2 cytogenetic location which also harbors the tumor suppressor genes *pleomorphic adenoma of the salivary gland gene like 1 (PLAGL1/LOT1/ZAC)* and *large tumor suppressor gene-1 (LATS1)*. We therefore evaluated both *PLAGL1* and *LATS1* as possible candidate tumor suppressor genes in ACC. In this study, we performed a sequencing based mutation analysis for *PLAGL1* and *LATS1* in 5 ACC samples with monoallelic deletion in this area. In each of the 5 tumor samples, DNA was extracted from microdissected paraffin embedded tumor tissue. All exons of *PLAGL1* and *LATS1* were PCR amplified and sequenced using the Applied Biosystems 377 Prism DNA Sequencer that employs BigDye terminator chemistry with Taq DNA polymerase. No mutations were identified in *PLAGL1* and *LATS1* in the 5 ACC samples tested, suggesting that these genes are not common targets of biallelic genetic inactivation. Further studies using gene transfer and gene expression analysis are required in order to determine if these tumor suppressor genes play a role in ACC progression.

Germline mutations and uncertain variants of the BRCA1 and BRCA2 genes in a hospital-based series of breast cancer patients

. R.B. van der Luijt¹, R.P.M. Jansen¹, P.H.A. van Zon¹, M. Oostra¹, N. Smakman¹, V.C.M. Kuck-Koo², C.C. Wárlám-Rodenhuis³, M.G.E.M. Ausems¹. 1) Department of Biomedical Genetics, University Medical Center Utrecht, Utrecht, The Netherlands; 2) Department of Epidemiology, Comprehensive Cancer Center Utrecht, Utrecht, The Netherlands; 3) Department of Radiotherapy, University Medical Center Utrecht, Utrecht, The Netherlands.

Germline mutations in either of two tumor suppressor genes, BRCA1 and BRCA2, predispose to breast and/or ovarian cancer. The study presented here is part of a prospective study on genetic risk factors in 1,000 breast cancer patients receiving adjuvant radiotherapy for their treatment. We performed mutation analysis of the BRCA1 and BRCA2 genes in 137 patients fulfilling the selection criteria for referral to the Family Cancer Clinic of our hospital. A mutation screening protocol aimed at the analysis of regions of both genes containing recurrent deleterious mutations was used. This partial analysis of BRCA1 and BRCA2 employed the protein truncation test (exon 11 of BRCA1; exon 10 and 11 of BRCA2), denaturing gradient gel electrophoresis (DGGE; exon 2 and 20 of BRCA1), and a PCR-based deletion test (exon 13 and 22 of BRCA1). In addition, the entire coding region of BRCA1 and BRCA2 was analyzed by DGGE in a subset (n=37) of the patients. In 18 patients, germline alterations of the BRCA1 and BRCA2 genes were identified. Nine of the sequence alterations are clear deleterious mutations. As expected, these include several known founder mutations present in the Dutch population. The other nine genetic changes were variants of uncertain clinical significance. They included aminoacid changes as well as single base substitutions in intronic sequences. The prevalence of BRCA1 and BRCA2 mutations (7%) is low compared with breast cancer patients referred to our department outside this study (16%), but is in accordance with mutation prevalences observed in other hospital-based series of breast cancer patients. Correlations between risk factors and the mutations detected are currently being investigated.

Cancer Risk in NBS Heterozygotes from the Czech Republic. *K. Sperling¹, E. Seemanova², R. Varon¹, P. Jarolim², J. Pelz¹*. 1) Institute of Human Genetics, Charite, Humboldt University, Berlin, Germany; 2) Dept. of Medical Genetics, Charles University, Prague, Czech Republic.

The chromosomal instability disorder Nijmegen Breakage Syndrome (NBS) is associated with extreme susceptibility to lymphoid malignancies due to a defect in DNA double strand break repair. Based on familial data it has been suggested that NBS heterozygotes have an elevated cancer risk (Seemanova, E., 1990). Here, we present 1. the results of a cohort study (index-test method) based on the histories of 251 persons from 21 Czech pedigrees. Each individual was personally interviewed and detailed information was collected. The items of relevance comprised: reproductive history, X-ray history, working place history, former and current health status and possible confounding factors. Of the 251 persons analysed for the 657del5 founder mutation, we found 108 heterozygotes and 143 normal homozygotes with almost identical mean age. There were 13 cases of cancer among the heterozygous subgroup, as opposed to 3 cancer cases found among the normal homozygotes ($p < 0.01$). Amongst others, the heterozygotes developed the following type of tumours: carcinoma coli, - ventriculi and - mammae, myeloma multiplex and lymphoma malignum. 2. In addition, we have interviewed and genotyped 60 grandparents from 16 families (ascertainment is almost complete). Ten out of the 30 NBS heterozygotes but only one out of the 30 normal homozygotes developed cancer. Both groups showed no difference in age distribution and socio-economical status. These studies confirm the earlier suggestion that NBS gene carriers have an elevated cancer risk.

Atypical Li-Fraumeni-like syndrome due to a novel exon 6 TP53 germline mutation. *M.W.G. Ruijs¹, S. Verhoef¹, G. Wigbout¹, A. Floore¹, R. Pruntel¹, L.J. van 't Veer¹, F.H. Menko².* 1) Family Cancer Clinic, The Netherlands Cancer Institute, Amsterdam, The Netherlands; 2) Family Cancer Clinic, Department of Clinical Genetics and Human Genetics, VU University Medical Center, Amsterdam, The Netherlands.

Li-Fraumeni syndrome (LFS) and Li-Fraumeni-like syndrome (LFL) are autosomal dominant cancer predisposition syndromes with high penetrance, in which susceptible individuals may develop a wide variety of early-onset malignancies, including sarcoma, brain tumor and breast cancer. In many of the LFS/LFL families, germline mutations in the TP53 gene have been identified; the majority missense mutations. We present an extended Dutch kindred with clustering of a variety of cancers, in which a TP53 mutation was found in exon 6, Arg213Gln. The tumors observed in 7 proven or obligate mutation carriers are atypical with respect to tumor type and age at diagnosis. They include breast cancer in three patients (mean age at diagnosis 60 yrs), renal cell carcinoma (1 patient, 48yrs), melanoma (1 patient, 46yrs), oesophagus-cardia carcinoma (1 patient, 71yrs) and mesothelioma (1 patient, with asbest exposure, 55 yrs). The missense mutation found in this family has not previously been identified as a germline mutation in LFS or LFL families. Several observations suggest that this novel missense mutation is the underlying causative factor, including its identification as a somatic mutation in different tumors, e.g. bladder, breast, and colon, the occurrence of other codon 213 germline mutations associated with LFS/LFL and co-segregation of the mutation with the disease in this family. In a functional yeast-based assay, with a p53 inducible promotor, it could be shown that the mutated allele lacks biological transcriptional activity. Ongoing studies include characterization of genetic alterations in tumor tissue and screening of 250 healthy controls for this TP53 Arg213Gln mutation. In summary, we observed an atypical spectrum of tumors with an unusual age of onset in an extended LFL kindred with a novel TP53 mutation. Our observations contribute to gaining insight into genotype-phenotype correlation of TP53 germline mutations.

Spectrum of Mutations Detected in the RET Proto-oncogene Associated with Multiple Endocrine Neoplasia Type

2. *W. Sun¹, A. Buller¹, R. Fenwick², F. Hantash¹, S. Huang¹, M. Peng¹, J. Redman¹, C. Strom¹.* 1) Molec Gen Dept, Nichols Inst, Quest Diagnostics Inc, San Juan Capistrano, CA; 2) Molec Endocrine Dept, Nichols Inst, Quest Diagnostics Inc, San Juan Capistrano, CA.

Multiple endocrine neoplasia type 2 (MEN2) is an autosomal dominant disease characterized by medullary thyroid cancer, pheochromocytoma, parathyroid adenoma and mucosal neuromas. Detection of disease-causing mutations in the RET proto-oncogene confirms the clinical diagnosis of MEN2 and familial medullary thyroid cancer (FMTC). Moreover, detection of such mutations in at-risk family members allows pre-symptomatic diagnosis and treatment, thereby reducing morbidity and mortality. In this study, we determined the frequency of RET mutations detected in 1993 consecutive samples (3986 alleles) received at Quest Diagnostics Nichols Institute for RET proto-oncogene mutation testing. Using PCR amplification and automated DNA sequencing of exons 10, 11, 13, 14, and 16, we detected 254 mutant alleles. After eliminating all but the probands of the affected kindreds, the following mutation frequencies were observed: 24.7% for C609Y, 16.4% for C634R, and 12.8% for V804M. Five novel missense mutations and one novel trinucleotide deletion were also detected. C609Y, the most common mutant allele in our samples, occurred at a greater frequency than that reported by others. On the other hand, mutations at codon C634 represent only 29.2% of all mutations detected in our study, less than what would be expected based on previous reports. For example, Muligan et al (1995) found codon C634 mutations accounted for 85% of RET mutations in MEN2A patients (or over 50% of MEN patients). Nevertheless, C634 is still a mutation hotspot in our test population, along with C609, C618, C620, and V804. Nucleotide substitutions altering amino acid coding at these locations collectively accounted for over 83% of disease-causing mutations in our test population. The unexpected high prevalence of mutations outside of C634 in our test population may suggest under ascertainment in previous studies.

Identification of cyclin D1 (CCND1) and other novel targets for the VHL tumour suppressor gene (TSG) and investigation of CCND1 genotype as a modifier in VHL disease. *M. Zatyka¹, N.F. da Silva¹, S.C. Clifford¹, M.R. Morris¹, M.S. Wiesener², K.U. Eckardt², R.S. Houlston³, F.M. Richards¹, F. Latif¹, E.R. Maher¹.* 1) Med & Molec Genetics, University of Birmingham, UK; 2) Charit, Humboldt-University, Berlin, Germany; 3) Section of Cancer Genetics, Institute of Cancer Research, Sutton, UK.

Germline mutations in the VHL TSG are associated with a high risk of retinal and cerebellar hemangioblastomas (HABs), renal cell carcinoma (RCC) and pheochromocytoma. pVHL has a critical role in regulating proteosomal degradation of the HIF transcription factor and VHL inactivation results in overexpression of a wide range of hypoxia-inducible mRNAs including VEGF. In order to identify novel pVHL target genes we investigated the effect of wild type pVHL on the expression of 588 cancer related genes in two VHL-defective RCC cell lines. Expression array analysis identified 9 genes which demonstrated a >2-fold decrease in expression in both RCC cell lines following restoration of WT pVHL. Three of the 9 genes (VEGF, PAI-1 and LRP1) had previously been reported as pVHL targets and are known to be hypoxia-inducible. In addition 6 novel targets were detected: cyclin D1 (CCND1), cell division protein kinase 6 (CDK6), collagen VIII alpha 1 subunit (COL8A1), CD59 glycoprotein precursor, integrin beta 8 (ITGB8), interleukin 6 precursor (IL-6, interferon beta 2). We found no evidence that CCND1, CDK6, CD59 and ITGB8 expression was influenced by hypoxia suggesting that pVHL downregulates these targets by a HIF-independent mechanism. Other studies have suggested that (a) genetic modifiers influence the phenotypic expression of VHL disease and (b) polymorphic variation at a CCND1 codon 242 A/G SNP may influence cancer susceptibility or prognosis in some situations. We therefore analysed the relationship between CCND1 genotype and phenotypic expression of VHL disease. There was an association between the G allele and multiple retinal angiomas ($p=0.04$) and risk of CNS haemangioblastomas ($p=0.05$). These findings suggest that polymorphic variation at pVHL target genes may influence phenotypic expression of VHL disease.

Family characteristics associated with nonreferral of relatives for HNPCC genetic counseling and testing. *S.K. Peterson¹, B.G. Watts¹, P.M. Lynch¹, S.W. Vernon², S. Kapoor¹, E.R. Gritz¹.* 1) UT MD Anderson Cancer Ctr, Houston, TX; 2) UT School of Public Hlth, Houston, TX.

Despite potential benefits of cancer genetic counseling and testing (GCT), uptake has been lower than expected. Because individuals act as gatekeepers in disseminating genetic information to their relatives, willingness to refer one's relatives for GCT may affect uptake of these services. Using pedigree data, we evaluated characteristics associated with at-risk relatives who were not referred for HNPCC GCT services that were offered free as part of a research study. Of 35 HNPCC mutation-positive probands, 33 chose to receive their results. After results disclosure, probands were invited to refer their at-risk relatives to the study. When we received permission to contact probands' at-risk relatives, GCT was offered using a standard method. As additional carriers were identified in the families, GCT was subsequently offered to their at-risk relatives in the same manner. Of 471 adult relatives who were at 25% or 50% risk of carrying a known mutation and were eligible for GCT, only 52% (n=247) were referred for GCT by probands or other mutation-positive family members. Two probands (with n=23 total eligible relatives) referred no relatives for GCT. In multivariate analysis, at-risk relatives were less likely to be referred if they had no children. In non-White families (n=4 families), men were less likely to be referred. In White families (n=29 families), relatives were less likely to be referred if the family member relating them to the mutation carrier was deceased or if they were in the oldest living generation on the pedigree. Relatives' personal cancer history or mutation risk were not associated with referral for GCT. Data from a companion qualitative study on family communication about HNPCC also support these findings; namely, that probands and other mutation-positive family members may be less likely to take an active role in referring more distant at-risk relatives for GCT, particularly if intervening relatives are deceased. Future research should evaluate strategies that facilitate greater diffusion of HNPCC GCT services through extended high-risk families.

Novel and founder mutations in mismatch repair genes in HNPCC families from Newfoundland. *M.O. Woods*^{1,2}, *J.S. Green*², *J.D. Robb*³, *A. Pollett*¹, *B. Younghusband*¹, *P.S. Parfrey*⁴, *J.R. McLaughlin*⁵, *B. Bapat*¹. 1) Dept of Lab Medicine & Pathobiology, University of Toronto, Toronto, ON, Canada; 2) Dept of Genetics, Memorial University of Newfoundland, St. John's, NF, Canada; 3) Dept of Pathology, Memorial University of Newfoundland, St. John's, NF, Canada; 4) Dept of Nephrology, Memorial University of Newfoundland, St. John's, NF, Canada; 5) Dept of Public Health Sciences, University of Toronto, Toronto, ON, Canada.

Hereditary non-polyposis colorectal cancer (HNPCC) is the most common heritable form of colon cancer. Mutations in five known susceptibility genes involved in mismatch repair (MMR) have been identified in causing HNPCC. Alterations in two, *MLH1* and *MSH2*, make up approximately 90% of all mutations causing HNPCC. The island of Newfoundland has a relatively homogenous population, composed of multiple genetic isolates which have been valuable in genetic research. Due to the population structure of the island, founder mutations are anticipated. A cohort of 27 high-risk Newfoundland HNPCC families has been collected in order to determine their putative genetic defect, assess their cumulative cancer risk and evaluate genotype-phenotype correlations. Of the 27 kindreds, 15 meet Amsterdam criteria I (AC1) and 12 AC2. Of the 15 AC1 families, individuals in 13 have multiple primary cancers (MPC). For the 12 AC2 kindreds, individuals in 9 have MPC.

Automated sequencing of *MLH1* and *MSH2* was used for initial screening of sequence alterations. When available, DNA from tumours was analyzed for microsatellite instability, a hallmark of MMR involvement. All tumours also underwent immunohistochemical analysis to determine MLH1 and MSH2 expression. Southern blot analysis was employed to identify large genomic deletions. Only one family had an alteration in *MLH1* upon sequencing. This putative mutation, V94E, is a novel substitution. A novel mutation, the deletion of exon 8, was identified in *MSH2* and was shown to segregate in two unrelated families. Affected females in these families had an increased predilection for endometrial cancer. Additional HNPCC-like Newfoundland families are being tested for other MMR defects, including *MSH6*.

Empiric risk of prostate cancer for relatives of a prostate cancer patient. *M.P.A. Zeegers¹, A. Jellema¹, H. Ostrer².*
1) Maastricht University, Netherlands; 2) New York University School of Medicine, New York.

Although narrative reviews have concluded that there is strong support for familial clustering of prostate cancer, the association has never been quantified systematically in reviews. The purpose of this meta-analysis was to summarize and quantify the recurrence risk ratio with emphasis on the degree of relatedness, the relationship of the family member, the number of affected family members and the age at diagnosis. The authors included 32 population-based studies and calculated summary recurrence risk ratios (SI) by random effects meta-regression analyses. They also evaluated changes in summary estimates according to differences in study methodology. SI was 2.46 (95% CI: 2.14-2.82) for first-degree family members. The SI appeared to be higher for men with an affected brother (3.28, 95% CI: 2.84-3.78) than for men with an affected father (2.18, 95% CI: 1.89-2.51). Whereas the recurrence risk ratio for men with second-degree relatives with prostate cancer was only slightly elevated (1.68, 95% CI: 1.07-2.64). The nature of this familial clustering is such that SI rises with decreasing age of the patient and family members, with increasing genetic relatedness of the affected relative and with an increase in the number of individuals affected within the family. No significant differences were observed in studies that analysed familial recurrence risks based on ethnicity. These studies demonstrate consistently that family history is a significant risk factor for developing prostate cancer. This meta analysis provides precise quantitative estimates that can be used for providing genetic counselling to the male family members of men with prostate cancer.

Origins of neurofibromas in NF1. *T. Tucker, C.J. Brown, J.M. Friedman.* Medical Genetics, University of British Columbia, Vancouver, B.C., Canada.

Neurofibromas are benign tumours arising from peripheral nerves. These tumours are comprised largely of Schwann cells but may contain numerous fibroblasts, perineural cells, endothelial cells and mast cells. Neurofibromas are generally assumed to be neoplasms, but there is evidence that at least some neurofibromas are actually dysplastic or hyperplastic lesions. If neurofibromas are true neoplasms, they would be expected to arise clonally by a "two-hit" mechanism, with one inherited and one acquired mutation of NF1 the locus. On the other hand, if some neurofibromas arise by hyperplasia or dysplasia as a result of NF1 haploinsufficiency, they would not be expected to be clonal or to exhibit NF1 loss of heterozygosity. The purpose of this study is to determine if clonal proliferation of the Schwann cells is necessary and sufficient for the development of discrete dermal neurofibromas in patients with NF1 and if these cells exhibit loss of expression of neurofibromin, the protein product of the NF1 gene. Schwann cells and fibroblasts in discrete dermal neurofibromas from women with NF1 are identified using appropriate membrane markers. Following cellular identification, slides are stained with neurofibromin, to identify Schwann cells and fibroblasts expressing the protein. Schwann cells and fibroblasts expressing neurofibromin and those that lack neurofibromin are isolated using laser microbeam microdissection and laser pressure catapulting and tested for clonality using X-linked polymorphic markers. Fibroblasts are used as a negative control because any skewing of their X-inactivation pattern is likely to be a result of small sample size. Almost all people with NF1 develop multiple discrete dermal neurofibromas, and the number of tumours usually increases with age. Better understanding of the pathogenesis of these benign but ubiquitously tumours may provide insights into development of more severe tumours that also occur in people with NF1.

The genetics of breast cancer in Newfoundland. *T.-L. Young^{1,2}, J.S. Green², S. Snook¹, M. Connolly-Wilson², M. Crowley², K. Laing², K. Dalikashvili¹, R.K. Kim¹, M.C. King¹.* 1) Medical Genetics, University of Washington, Seattle, WA; 2) Memorial University of Newfoundland.

A well-recognized problem associated with the broad mutation spectrum of breast cancer mutations is that information critical to implementation of screening programs, like the age of onset of breast/ovarian cancer, spectrum of associated cancers and the lifetime risk of developing cancer are difficult to assess because the number of cases per mutation is low. Newfoundland, a genetically isolated population of mostly English and Irish extraction, is characterized by large families with a traditional lifestyle and close family ties. Founder mutations have been identified in several cancer syndromes in this population. We have collected DNA samples from women with breast and/or ovarian cancer in 150 Newfoundland families with a history of breast/ovarian cancer. We have completed conventional screening (SSCP, PTT, sequencing) in 90 of these families and identify 7 probands with mutations in BRCA1 and 5 probands with mutations in BRCA2. We have also identified 4 women with the 1100delC mutation in CHK2. We will report on the occurrence of breast cancer, associated cancers, and age-related penetrance in these extended families.

Molecular genetic analysis of archival ovarian tumors confirm probable deleterious nature of an in-frame 15 bp deletion (8457del15) in *BRCA2*. *J.N. Weitzel, S.L. Martinez, J. Herzog.* Clinical Cancer Genetics, City of Hope Cancer Center, Duarte, CA.

Mutations in *BRCA1* or *BRCA2* account for the majority of families with HBOC syndrome. Most clearly deleterious mutations are small insertions or deletions, causing a protein-truncating frame shift. However, minor alterations such as missense mutations or small in-frame deletions in the coding regions of *BRCA1* and *BRCA2* have been reported and are a clinical dilemma because of their classification as variants of unknown significance. It has been suggested that somatic allelic deletion of the wild-type allele in the tumor sample, as detected by loss of heterozygosity (LOH) analysis can be used to determine if these mutations are likely to be deleterious. *BRCA* gene sequencing in a 50-year-old ovarian cancer patient with a family history of breast and ovarian cancer revealed a 15bp in-frame deletion in exon 18 of *BRCA2* (8457del15), classified as a variant of unknown significance. Her deceased mother was diagnosed with breast cancer at 57 and ovarian cancer at 62. Alignment of *BRCA2* amino acid (aa) sequences from five species indicated significant evolutionary conservation (39/50 aa identity in the region, including all five aa in the deletion). To investigate whether the mutation tracked with disease in the family we extracted DNA from paraffin-embedded tumor tissues from the proband and her deceased mother. Primers flanking the 15 bp deletion locus were used to PCR amplify the respective segment of exon 18 from blood DNA for the proband, two unaffected siblings, one offspring and from the tumor blocks. Easily discerned on an 8% acrylamide gel, the mutated allele was detected in both the proband and her mother. However, the unaffected siblings and the daughter were all negative for the mutation. In addition, there was clear LOH of the wild-type allele in both tumors. Analysis of six markers along chromosome 13 (D13S742, D13S218, D13S171, D13S267, D13S263, and D13S248, listed in physical map order) revealed LOH at all informative markers in both cases. Coupled with the data on evolutionary conservation we conclude that the *BRCA2* 8457del15 mutation is highly likely to be deleterious.

Analysis of MLH1 promoter hypermethylation in MSI versus MSS tumors arising in patients with confirmed HNPCC or familial colorectal cancer. V. Pethe^{1,3}, A. Saka^{1,3}, A. Pollett¹, M. Aaronson², H. Rothenmund², M. Redston^{1,3}, S. Gallinger^{2,3}, B. Bapat^{1,3}. 1) Pathology, Mount Sinai Hospital, Toronto, ON, Canada; 2) Surgery, Mount Sinai Hospital, Toronto, ON, Canada; 3) Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, ON, Canada.

Hereditary nonpolyposis colorectal cancer (HNPCC) is recognized by a dominant inheritance pattern of early-onset CRC and an increased frequency of certain extra-colonic cancers. Defects in mismatch repair (MMR) pathway cause HNPCC and also account for ~15% of sporadic CRC. MMR deficient tumors exhibit a mutator phenotype known as microsatellite instability (MSI). Among MMR genes, inactivation of MLH1 via promoter hypermethylation is shown to be the principal mechanism of MMR deficiency in MSI + sporadic CRC, however, its specific contribution to inherited CRC is largely unknown. We investigated MLH1 hypermethylation in CRC tumors from individuals with confirmed HNPCC (N=20; 10 each with germline MSH2 and MLH1 mutations) or familial CRC (N=28). Families were identified through population-based (OFCCR) or hospital-based (FGICR) CRC registries. Fifty-nine tumors (43 MSI+, 16 MSS) from 48 patients were investigated for MLH1 hypermethylation by methylation-specific PCR (MSP) [nts: 721-597 upstream from transcription start site, GenBank # U83845), MLH1/MSH2 protein expression by IHC and germline MLH1/MSH2 mutations by sequence analysis. 13/43 (30%) MSI+ and 6/16 (37%) MSS tumors were methylated for MLH1. Interestingly, 4/20 (20%) HNPCC patients with known germline MMR mutation (2 MSH2 and 2 MLH1) exhibited MLH1 hypermethylation. Of 13 MSI+ and methylated tumors, 11 were MLH1 immunodeficient indicative of biallelic inactivation, while none of the methylated MSS tumors showed absence of MLH1 protein expression, suggesting either partial methylation or monoallelic inactivation. Our results suggest that MLH1 promoter hypermethylation occurs at a comparable frequency among individuals with either confirmed or suspected HNPCC and may contribute to a distinct pathway of colorectal tumorigenesis.

Association of the C677T and A1298C polymorphisms in the MTHFR gene with breast cancer risk in Turkish women. A. SAZCI¹, E. ERGUL¹, Z. UTKAN², Z. CANTURK², M. MUSLUMANOGLU³, A. IGCI³ and Cancer Research Study Group. 1) Department of Medical Biology & Genetics, Kocaeli University, Kocaeli, Turkey; 2) General Surgery Department, Faculty of Medicine, University of Kocaeli, Kocaeli, Turkey; 3) General Surgery Department, Faculty of Medicine, University of Istanbul, Istanbul, Turkey.

The C677T and A1298C mutations in the methylenetetrahydrofolate reductase (MTHFR) gene are involved in upto 65%; reduced enzyme specific activity, hyperhomocysteinemia, increased risk for venous thrombosis and atherosclerosis in homozygotes as well as in the compound heterozygotes. The C677T mutation in homozygotes is associated with bilateral breast cancer or combined breast and ovarian cancer. We investigated the frequency of C677T and A1298C mutations and their association with disease pattern in 87 Turkish breast cancer women and 103 controls. Population frequencies for the MTHFR C677C, C677T, and T677T genotypes were 50.6%, 33.3%, and 16.1% in the cases and 53.4%, 40.8%, 5.8% in the controls, respectively. The allelic frequency of C677T was 32.76% in the cases and 26.21% in the controls. Population frequencies of MTHFR A1298A, A1298C, and C1298C genotypes were 42.5%, 39.1%, and 18.4% in the cases and 48.5%, 45.6%, and 5.8% in the controls. The allelic frequency of A1298C was 37.93% in the cases and 34.47% in the controls. The MTHFR T677T/A1298A genotype was higher among 87 breast cancer patients compared with 103 controls, conferring a 26.90-fold increase in risk for breast cancer (OR = 9.685; 95% CI = 2.135-43.924, $X^2 = 12.245$, $P = 0.000$). We also observed a 10.44-fold increase in risk for breast cancer in individuals with the MTHFR C677C/C1298C variant allele (OR = 3.759; 95% CI = 1.296-10.905, $X^2 = 6.618$, $P = 0.010$). Individuals with the MTHFR C677C/A1298A genotype have a 2.36-fold protection against breast cancer ($X^2 = 6.226$, $P = 0.013$). In conclusion, folic acid metabolism appears to be important in breast cancer. Both individuals with the MTHFR T677T/A1298A, and C677C/C1298C genotypes provide susceptibility to breast cancer. However, individuals with the MTHFR C677C/A1298A genotype have protection against breast cancer.

Minimal expression of von Hippel-Lindau disease. *M.L. McMaster¹, G.M. Griffith², P.L. Choyke³, G.M. Glenn¹, W.M. Linehan².* 1) Genetic Epidemiology Branch, DCEG/NCI/NIH, Bethesda, MD; 2) Urologic Oncology Branch, CCR/NCI/NIH, Bethesda, MD; 3) Diagnostic Radiology Department, Warren Grant Magnuson Clinical Center, NIH, Bethesda, MD.

Introduction: In a family with a history of von Hippel-Lindau disease (VHL), an affected first degree relative clearly indicates the need for genetic and clinical screening studies, including CT and MRI. If the manifestations of VHL are mild, or even absent, there may be no suspicion of the risk of VHL in either the index or other generations. We report a series of patients with molecular documentation of VHL disease who have clinically silent or "minimal expression of VHL" -- a presentation that may delay diagnosis in the patient and forestall screening of their at-risk family members. **Methods:** Between 1989 and 2000, 756 patients from 215 kindreds with VHL underwent screening. Affected patients over 26 years were categorized as minimally, moderately or severely affected with VHL disease. A patient with minimal disease was defined as one being more than 26 years old, having a confirmed genetic diagnosis of VHL, and absent or mild clinical findings of VHL disease (limited to asymptomatic small lesions in two or fewer target organs). **Results:** Eight patients fulfilled the criteria for minimal expression of VHL disease. These patients ranged in age from 30 to 70 years, and five of the eight were female. Three of these patients had descendants with moderate or severe manifestations of VHL and five had no offspring. **Conclusion:** Minimal expression of VHL underscores the need for genetic testing of relatives of individuals with VHL disease, including asymptomatic family members who may be silent carriers.

Estradiol and tamoxifen stimulate lymphangiomyomatosis-associated angiomyolipoma cell growth. *J.J. Yu, A.G. Aristotelis, S. Howard, E.P. Henske.* Human Genetic Program, P-3045, Fox Chase Cancer Ctr, Philadelphia, PA.

Lymphangiomyomatosis is a progressive and often-fatal lung disease characterized by diffuse pulmonary smooth muscle cell proliferation and cystic degeneration of the lung parenchyma. Lymphangiomyomatosis occurs in women with tuberous sclerosis complex, and also in women without tuberous sclerosis complex (sporadic lymphangiomyomatosis). Renal angiomyolipomas occur in 50%-60% of sporadic lymphangiomyomatosis patients. We report here the establishment of a primary cell culture from a sporadic lymphangiomyomatosis associated renal angiomyolipoma. The angiomyolipoma cells contain somatic mutations inactivating both alleles of TSC2: a missense change in one allele (Arg611Gln), and loss of heterozygosity of the remaining allele. The cells expressed estrogen receptor alpha, estrogen receptor beta, and androgen receptor. The growth of these cells was stimulated by estrogen, associated with an increase in c-myc expression, suggesting that estrogen stimulates the growth of angiomyolipoma cells through transcriptional activation of estrogen responsive genes. Tamoxifen citrate also stimulated growth of the cells, indicating that tamoxifen has agonist effects on angiomyolipoma cells. These data provide the first in vitro evidence that estrogen stimulates the growth of angiomyolipoma cells. The smooth muscle cells of angiomyolipomas and pulmonary lymphangiomyomatosis appear to be closely related. Therefore, estrogen responsiveness could be related to the many reports of worsening of angiomyolipoma and lymphangiomyomatosis symptoms during pregnancy, and to the underlying reasons that lymphangiomyomatosis affects primarily women.

A Genome-Wide Analysis of Allelic Loss In Rhabdoid Tumor. *T.T-L. Chen¹, P. Grundy², J.A. Biegel³, G.E. Tomlinson^{1,4} and Hamon center, UT Southwestern Medical Center.* 1) Hamon Center , UT Southwestern Medical Center, Dallas, TX; 2) Cross Cancer Institute, Edmonton, AB; 3) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania; 4) Department of Pediatrics, UT southwestern Medical Center, Dallas, TX.

Rhabdoid tumor of the kidney is a rare but highly aggressive malignant neoplasm of kidney. The development of rhabdoid tumor is associated with mutation of hSNFs/INI1 gene, which may be germline or acquired. In order to determine the extent and spectrum of other genetic change in rhabdoid tumors, we performed high-resolution genome-wide allelotyping for sixteen primary rhabdoid tumors and their matched genomic DNAs. DNAs was analyzed using 399 fluorescent microsatellite markers from the ABI Prism linkage mapping set v.2 on an ABI 377 sequencer/genotyper. Loss of heterozygosity(LOH) was observed in 31% of tumors in 22q11-12 region. Seven other regions with more than 10% of LOH were identified. The chromosomal arms with LOH were 1q42(12.5%), 2q24(12.5%), 4p16(18.75%), 4q12(12.5%), 11q14(12.5%), 15q26(12.5%), 16p12(12.5%), 22q11-12(31.25%). In one of primary tumor, there was discontinuous allele loss at several sites. We conclude that: Chromosome 22q11-12 allele loss is the primary recurring event in rhabdoid tumor corresponding to the loss of hSNF5/INI1 gene. Other losses were seen at chromosome 1q,2q,4p,4q,11q,15q,16p that might have a lesser role to play in rhabdoid tumor development.

Pooled analysis of loss of heterozygosity in breast cancer provides comparative evidence for multiple tumor suppressors in a genomewide scan and identifies novel candidate regions. *F.A. Wright¹, B.J. Miller², D. Wang¹, R. Krahe³.* 1) Dept of Biostatistics, Univ North Carolina, Chapel Hill; 2) College of Medicine, The Ohio State University, Columbus; 3) Section of Cancer Genetics, Dept of Molecular Genetics, University of Texas M. D. Anderson Cancer Center, Houston.

Somatic loss of heterozygosity (LOH) has been widely reported in breast cancer as a means of identifying putative tumor suppressor genes. However, individual studies have rarely spanned more than a single chromosome, and the varying criteria used to declare LOH complicate efforts to formally differentiate regions of consistent vs. sporadic (random) loss. Here, we report the first compilation of an extensive database from 151 published LOH studies in breast cancer, with summaries of over 15,000 tumors and 4,300 primary allelotypes. Allelic loss was evaluated at 1,173 marker loci, with large variation in marker density across the genome. An initial genome-wide analysis of the summarized loss data was performed, accounting for heterogeneity across studies and seeking direct evidence for preferential loss at each locus compared to nearby loci. A full likelihood-based approach using a chromosomal breakpoint and selection model was also performed, using studies in which primary allelotype information was available. The approach enables the direct comparison of candidate regions across the genome. Striking and significant evidence of preferential loss was observed on chromosomes 7q, 16q, 13q, 17p, 8p, 21q, 3p, 18q, and other regions, in many cases coinciding with previously identified candidate genes or known fragile sites. We report strong evidence for several tumor suppressor genes, but suggest that some previously-reported LOH results may not be systematic or reproducible.

PTEN is Targeted for Loss During Melanoma Tumor Development. *J. Stahl¹, M. Cheung¹, A. Sharma¹, S. Shanmugam¹, G.P. Robertson^{1,2,3}.* 1) Department of Pharmacology; 2) Pathology and Dermatology; 3) The Foreman Foundation for Melanoma Research, The Pennsylvania State College of Medicine, Hershey, PA 17033.

Malignant melanoma is the seventh most common cancer in the United States, affecting 1 in 71 Americans. Statistically one American dies from melanoma every hour; with an estimated 47,700 new cases and 7,700 deaths anticipated this year. Currently, there is no effective long-term treatment for patients suffering from the metastatic stages of this disease. Deletion or alteration of chromosome 10 occurs in 30-60% of sporadic human melanomas. The PTEN gene, located at 10q23, has been suggested to be a key factor on chromosome 10 involved in melanoma development. However, no biologically relevant model demonstrating suppression of melanoma tumor formation by PTEN or dissection of the mechanism underlying this process in melanomas has been reported. To investigate the functional involvement of PTEN in melanoma tumorigenesis, we have created an in vivo model in which a wild-type chromosome 10 was transferred into melanoma cells, and tumor development measured. We observed that tumor formation would not occur unless the cells first eliminated PTEN in order to relieve the growth suppressive effects of this gene. This has led to the establishment of a relevant model for studying PTEN involvement in melanoma since the chromosomally expressed gene is not overexpressed; rather it is produced at normal physiological levels even though only a single copy of the gene is present. Furthermore, it undergoes appropriate processing, and is under normal regulatory control. This approach has also been useful for creating isogenic cell lines to dissect the biological consequences of PTEN expression on tumor development as well as for determining the mechanism by which PTEN inhibit melanoma development. Different genetic targeting mechanisms such as deletion and epigenetic silencing were found to eliminate functional PTEN protein prior to tumor formation. Since these genetic events mirror those occurring in clinical tumor samples for targeting the PTEN gene, we believe that this is a relevant model for studying PTEN signaling and functioning in melanoma tumorigenesis.

DNA integrity as a potential apoptotic marker for the detection of colorectal cancer by analyzing stool DNA. *K.A. Boynton¹, I. Summerhayes², D.A. Ahlquist³, A.P. Shuber¹*. 1) Applied Research, EXACT Sciences, Maynard, MA; 2) Department of Urology, Lahey Clinic, Burlington, Massachusetts, 01805; 3) Division of Gastroenterology and Hepatology, Mayo Clinic, Rochester, Minnesota 55905.

Dysregulation of apoptosis is an important factor in the progression of colorectal cancer (CRC). As there may be less degradation of tumor DNA in CRC cells due to abrogated apoptotic dynamics, we have developed a methodology to analyze the integrity of DNA fragments purified from stools of CRC positive and colonoscopically negative patients to determine if DNA integrity is associated with the presence of disease. We analyzed the integrity of DNA purified from the stools of 27 CRC patients and 77 colonoscopically negative patients using this method. Stool DNA was purified by performing oligonucleotide-based hybrid DNA captures and long PCR was used to analyze the integrity of genomic DNA at four unique human genomic loci. Analysis of PCR amplicons indicates that DNA isolated from patients with CRC contains high molecular weight fragments, while DNA from colonoscopically normal patients contains significantly less or lacks high molecular weight DNA fragments. High molecular weight DNA fragments were found in 15 CRC stools (15/27, 56% sensitivity) and two colonoscopically negative stools (2/77, 97% specificity). These data suggest that fecal DNA integrity can be used to discriminate between individuals with cancer and those that are disease free. DNA integrity was also analyzed in a model system consisting of culture cells treated with Genistein, an apoptosis inducer. DNA fragment length was found to decrease when culture cells were exposed to Genistein. Integrity of DNA purified from stool as a novel marker may provide a sensitive method for the detection of apoptotic changes in the colon providing a means for the detection of CRC.

Identification of novel genes with somatic frameshift mutations within coding mononucleotide repeats in colorectal tumors with high microsatellite instability. *M. Ravnik-Glavac*^{1,2}, *U. Potocnik*^{1,3}, *D. Glavac*¹. 1) Department of Molecular Genetics, Institute of Pathology, Medical Faculty, Korytkova 2, Ljubljana, Slovenia; 2) Institute of Biochemistry, Medical Faculty, Ljubljana, Slovenia; 3) Laboratory of Genomic Diversity, NCI-FCRDC, Frederick, MD.

We have systematically retrieved genes with coding mononucleotide repeats from sequence databases and analysed them for mutations in MSI-H tumors. We found somatic frameshift mutations in 7/13 (77%) genes previously not analysed in MSI-H tumors. According to frequency of mutations in MSI-H tumors these genes could be divided into genes with high coding mononucleotide repeat instability (CMRI-H) and genes with low coding mononucleotide instability (CMRI-L). CMR-H genes were mutated in more than 24%; and CMRI-L in less than 11(%); of MSI-H tumors. Four genes in our study were CMRI-H and were therefore suggested to play a role in development of MSI-H tumors: TFE3(24%), TEF4(32%), RGS12(29%) and TCF132%). Our study suggests that systematic identification of genes with CMR in the sequence databases and determination of mutation frequency in MSI-H tumors might be powerful tool for identification of new molecular targets in development of MSI-H tumors.

Role of SV40 insertion site in the immortalization of human fibroblasts: Cloning and analysis of disrupted loci.

R.S. Athwal, J. Liu. Fels Inst Cancer Research, Temple Univ Sch Medicine, Philadelphia, PA.

Normal human diploid fibroblasts (HDF) multiply for finite generations and then enter senescence. Spontaneous transformation and immortalization have never been observed in HDF. Cells transformed with oncogenic DNA viruses such as SV40, Adv, and HPV can multiply for additional 20-30 doublings and give rise to immortal clones, albeit at a very low frequency. These studies suggest that alterations in cellular genes are essential for a cell to gain indefinite proliferation. Viral proteins are known to sequester p53 and Rb proteins and abrogate growth regulatory pathways controlled by these genes. We hypothesize that site of viral integration is another event that plays role in the regulation of normal cell growth. Following the identification of cell lines carrying a single copy of the ori SV40 viral genome, we applied inverse PCR to rescue human genomic sequences flanking the insertion site. PCR primers designed from the nucleotide sequence of the 500bp rescued fragment were used to screen a BAC library. The results of these studies identified a 150Kb BAC clone located at 1q21. The sequence of this region is available in the human genome database. We have developed a high-resolution physical, genetic and expression map of the region surrounding the BAC clone. This genomic region contains four cDNAs with open reading frames, which translate into hypothetical proteins. Experiments are underway to test BAC and full length cDNA clones for function in cell lines lacking the expression of these cDNAs. Rearrangements at 1q21 in breast tumors and abnormal expression of genes located in this region in transformed cells suggest a role for this region in the immortal growth of cells.

Identification of A Cell Senescence Gene at 6q16.3 for Ovarian Cancer. *V.K. Zhawar¹, N. Rane¹, A. Sandhu², G.P. Kaur¹, R. Athwal¹.* 1) Fels Inst Cancer Research, Temple Univ, Philadelphia, PA; 2) Wistar Institute, University of Pennsylvania, Philadelphia, PA.

Applying a Functional Positional approach, we have identified a genomic clone that carries a cell senescence gene, SEN6A, for ovarian tumor cells. The introduction of chromosome 6 or 6q into human (SKOV.3) and rat (ROSE199 and ROV12) ovarian tumor cell lines led to the restoration of normal cell growth phenotypes and senescence. Analysis of spontaneous revertant clones, which occurred due to deletions in the donor chromosome, allowed us to map the location of SEN6A locus within a 1cM genetic interval at 6q16.3. Precise localization of the deletions allowed us to identify three overlapping Yeast Artificial Chromosome (YAC) clones, corresponding to the smallest deletion, shared among independent revertant clones. Functional testing of candidate YAC clones identified a YAC that restored normal cell growth and senescence in ovarian tumor cells. Following the library screen, we assembled a contig of 17 BAC clones corresponding to the complementing YAC. Candidate BAC clones were tested for function by introduction into ovarian tumor cells. In these experiments two BAC clones were identified to carry SEN6A gene. The sequence of this 1cM region is now available in the human genome database. 25 ESTs, 11 unigenes and one full length cDNA, located in the candidate region have been assembled into a high resolution expression map. In an effort to identify candidate cDNAs, we have performed Southern blot analysis of tumor cell line, for a 1Mb region, using cDNA probes. These data revealed chromosomal rearrangements in a breast cancer cell line, MCF.7 and a hepatoma cell line, FOCUS for one of the cDNAs. Northern blot analysis of a multi-tissue blot with same cDNA identified transcripts of 6Kb and 4.5Kb size, expressed in skeletal muscle, pancreas and placental tissue. Our effort is directed to analyze the entire 1Mb region in tumor tissues for possible deletions or alteration in expression. A full-length candidate cDNA has been cloned into a mammalian cell expression vector for functional analysis.

Detection of *RB1* Mutations in Retinoblastoma patients. *E. Braggio*^{1,2}, *C.R. Bonvicino*^{1,3}, *H.N. Seúanez*^{1,2}. 1) Genetics Department, Instituto Nacional de Câncer, Rio de Janeiro, Brazil; 2) Genetics Department, Universidade Federal do Rio de Janeiro, Brazil; 3) Tropical Medicine Department, IOC-Fundação Instituto Oswaldo Cruz, Rio de Janeiro, Brazil.

Retinoblastoma is the most common intraocular tumor in children arising almost exclusively under 5 years of age. Both copies of *RB1*, the gene responsible for this tumor, must be functionless for the development of this malignancy. To detect mutations in the *RB1* gene in 27 patients (15 with bilateral and 12 with unilateral retinoblastoma) we isolated DNA from formalin-fixed, paraffin-embedded tissue and screened the entire coding region (exons) and nearby intronic regions by PCR-mediated SSCP analysis followed by direct DNA sequencing. We identified 2 novel mutations and 8 previously described in 10 patients, all of which consisting of single base substitutions. One of the novel mutations involved a G→A transition in the last, invariant base of intron 13 (G76429A) affecting mRNA splicing. The other, a T→C transition in exon 20, was a T156795C resulting in L679P. Both were described in unilaterally affected patients and we confirmed the germ-line origin of the first mutation in DNA extracted from a blood sample. The eight others were C→T transitions that changed CGA-arginine codons to TGA-stop codons and were localized in exon 10 (C64348T; R320X), 14 (C76430T; R445X), 17 (3 mutations C78238T; R552X and C78250T; R556X), and 18 (2 mutations C150037T; R579X). Although specific mutation hot spots have not been identified in the literature 8 of 10 mutations occurred in CGA codons and 7 in E1A binding domains, with 5 mutations affecting CGA codons within E1A binding domains (codons 393-572 and 646-772). These sites are apparently more frequent mutational targets and should be initially screened in patients with retinoblastoma.

Is age of onset in breast cancer families heritable? *Y. Yao*^{1,2}, *D. Markakis*¹, *B. Doan*¹, *K. Helzlsouer*¹. 1) Epidemiology, Johns Hopkins Univ, Baltimore, MD; 2) Center for Inherited Disease Research, Johns Hopkins Univ, Baltimore, MD.

The goal of this study is to test whether age of onset in breast families is heritable. We recently performed a correlation study of age of onset involving 629 breast cancer families from the Johns Hopkins breast and ovarian surveillance service (BOSS). The analyses were performed with the FCOR2 program of SIBPAL2 only including relative pairs with documented age of onset and verified cancer status. The correlation coefficients (CC) for different types of relatives are 98.9%, 38.1%, 23.5%, 66.7% and 39.3% for father:son, father:daughter, mother:daughter, sister:brother and sister:sister pairs. Interestingly, grandmother:granddaughter pairs correlated differently in the pairs connected through father and the ones connected through mother (-29.6% vs 11.6%). CC for paternal aunt:niece and maternal aunt:niece were 20.3% and 21.6%, respectively. These results support the hypothesis that age of onset is heritable. The confirmation of this finding using different high-risk breast cancer registries is necessary and updated results will provide further motivation to look for genetic modifiers that interact with BRCA1 and BRCA2 mutations and help distinguish families with various level breast cancer risk in genetic counseling.

Detecting genetic modifier involved in extracolonic manifestations in Familial Adenomatous Polyposis (FAP) families: Power to detect linkage in 22 eligible families. *B. Doan*^{1,2}, *F. Giardiello*³, *Y. Shugart*^{1,2}. 1) Department of Epidemiology, Bloomberg School of Public Health Johns Hopkins Univ, Baltimore, MD; 2) Dept ICM/CIDR, Johns Hopkins Univ, Baltimore, MD; 3) Department of Medicine, Johns Hopkins Univ, Baltimore, MD.

FAP is caused by germline mutations in the adenomatous polyposis coli (APC) gene on 5q21. Although the hallmark of FAP includes innumerable adenomatous polyps, the disease phenotype often includes the presence of one or more extracolonic symptoms. With genetic testing available for identified at risk patients to undergo rigorous screening and prophylactic colectomy, the presence of some extracolonic symptoms have become the leading cause of further morbidity and mortality. This study is designed to search for new genes associated with these extracolonic manifestations based on the assumptions that these genes act in concert with the APC mutated gene to contribute to the phenotype variability. This first step is to identify eligible families from the Johns Hopkins University Hereditary Colorectal Cancer Registry. Patients were originally recruited from a 5 state area (MD, VA, DE, PA, WV) and D.C. The Registry includes: 1) family histories and medical records on patients and 2) families with a history of familial aggregation of colorectal cancer. We have identified 22 FAP families with at least 3 affected siblings, each carrying APC mutations and having at least one extracolonic manifestation. To determine the strategy for gene mapping, we performed simulations, followed by lod score analyses, considering heterogeneity. Results showed that the power to detect linkage is 72% with an ELOD of 4.2 if 80% families are linked; the power is 45% with an ELOD of 3.02 if 70% pedigrees are linked and the power reduces to 25% with an ELOD of 2.10 if only 50% pedigrees are linked. Our results indicate that we have collected a set of eligible families with reasonable power for a stage I genome scan although more families are being identified to improve power. Further, we will try to collect important information such as age of onset and smoking status, which will lead to parametric and non-parametric linkage analysis with covariates.

SNP500Cancer database and candidate SNP approach to genetic association studies. *M. Yeager*^{1, 2}, *B. Packer*², *E. Miller*², *R. Welch*², *M. Kiley*², *M. Burke*², *R. Strausberg*³, *N. Rothman*⁴, *S. Chanock*¹. 1) Section on Genomic Variation, Pediatric Oncology Branch, NCI, Bethesda, MD; 2) Intramural Research Support program, SAIC Frederick, NCI-FCRDC, Frederick, MD; 3) Office of Cancer Genomics, NCI, Bethesda, MD; 4) DCEG, NCI, Bethesda, MD.

SNP500Cancer, an integral part of the long-term Cancer Genome Anatomy Project, is a new database designed to publicly address the immediate needs for candidate SNP and candidate gene approaches to mapping complex diseases. SNP500Cancer provides bi-directional sequencing information on a set of control DNA samples derived from anonymized subjects (102 Coriell samples representing 4 self-described ethnic groups: African/African-American, Caucasian, Hispanic and Pacific Rim). All SNPs are chosen from public databases and reports, and the choice of genes includes a bias towards nonsynonymous and promoter SNPs in genes that have been implicated in one or more cancers. The website (<http://snp500cancer.nci.nih.gov>) is searchable for SNPs by gene, chromosome and by known dbSNP ID. The database currently contains over 1100 SNPs, and as of June 1, 2002, 531 SNPs have been sequenced. For each analyzed SNP, gene location and over 200 bps of surrounding annotated sequence (including nearby SNPs) are provided, with frequency information in total and per sub-population. A calculation of Hardy-Weinberg Equilibrium is included. Moreover, genotyping assays (5-exonuclease, hybridization-triggered fluorescence, and/or MALDI-TOF) are developed for SNPs with minor allele frequencies > ~5%. These assays are performed on the same 102 samples and the results are compared for concordance with the sequencing results. The website will soon post the conditions (including sequences for probes, primers, etc.) for validated genotyping assays. Estimation of haplotypes is currently provided for select genes, with the goal of expanding this effort rapidly. SNP500Cancer provides an invaluable resource for investigators world-wide to select SNPs for analysis, design genotyping assays using validated sequence data, choose selected assays already validated on one or more platforms, and provide reference standards for genotyping assays of interest.

Second primary cancers in men with prostate cancer: An increased risk for male breast cancer - a key to identify BRCA2 families? *C. Thellenberg, B. Malmer, B. Tavelin, H. Grönberg.* Department of Radiation Sciences, Oncology, University of Umeå Sweden.

Background: Studying second primary cancers can give valuable insight in etiology, as genetic factors in common and shared risk factors for the first and the primary cancer. Second primary cancers following prostate cancer have been studied earlier and most studies have found decreased overall risks for second primary cancers, however increased risks have been found for urinary bladder cancer and kidney cancer. The aim in this study is to examine the risk for second primary cancers following prostate cancer, in a large population based cohort in order to find clues to etiological factors in common. **Method** All prostate cancer cases in the Swedish Cancer Registry from 1958 to the end of 1996 constituted the study base, (n = 135.713) were included. The risk (Standardized Incidence Ratio, SIR) of second primary cancers was calculated as the ratio between observed and expected number of cancers. Two-tailed 95% confidence intervals (CI) were used to test the significance. **Results:** The most interesting finding was an increased risk (SIR 2.01 95% CI 1.44-2.74) for developing male breast cancer. The risk was more pronounced in younger ages indicating at least partly a genetic explanation to the increased risk. An overall increased risk (SIR 1.17, 95 % CI 1.15-1.19) for second primary cancers were found, but the risk was only seen in the first six months of follow-up (SIR 3.45, 95% CI 3.32-3.57). **Conclusions:** There is an increased risk for second primary male breast cancer following prostate cancer. This association might be due to BRCA2 mutation and have not been reported earlier. A more detailed investigation is essential to confirm this finding.

Program Nr: 412 from 2002 ASHG Annual Meeting

Candidate Gene Linkage Analysis in a Prostate Cancer Affected Sib Pair Population. *G.P. Larson, T.G. Krontiris.*
Div Molecular Medicine, Beckman Res Inst City of Hope, Duarte, CA.

Prostate cancer is the second leading cause of cancer mortality in American males. Epidemiological studies of twins suggest a strong inherited genetic component to disease susceptibility; however, genome-wide linkage analysis approaches have found few loci implicated in disease. Recently low-penetrance risk variants in this disease (RNASEL, HPC2) and diseases such as inherited ovarian fibroid disease have been identified. In these cases, mutations in genes involved in routine aspects of metabolism were identified and suggest that a candidate disease approach utilizing genes integral to such processes as DNA integrity, steroid metabolism, and cell-cycle control will be successful in identifying low-penetrance disease alleles. We present results that support linkage for multiple candidate genes and their regions including 10q21 and 3p14 by utilizing a physically dense spectrum of markers throughout the candidate interval. The maximum NPL identified utilizing GENEHUNTER is approximately 2.3 for the 10q21 region. This result is further supported by single-point IBD analysis in SIBPAL over a physically distinct, subcentimorgan interval. We are refining the region utilizing a dense set of SNP markers to identify areas of linkage disequilibrium in this cohort with the ultimate goal of identifying disease variants in our candidate gene(s).

Linkage analysis of prostate cancer susceptibility: Confirmation of linkage at 8p22-23. *F. Wiklund, B.A. Jonsson, I. Goransson, H. Gronberg.* Oncology, Radiation Science Univ Umea, Umea, Sweden.

BACKGROUND: Evidence for a prostate cancer susceptibility locus at the short arm of chromosome 8 was reported in a recent study. They performed linkage analysis, using 21 densely spaced markers spanning ~35 cM at 8p22-23, in 159 pedigrees affected by hereditary prostate cancer (HPC). In the present report we replicate the linkage analysis in 61 Swedish pedigrees with HPC.

AIM: To confirm linkage to 8p22-23 in 61 Swedish pedigrees with HPC.

METHODS: Thirteen microsatellite markers spanning ~35 cM at 8p22-23 were genotyped in 61 Swedish pedigrees with HPC. Both parametric and nonparametric multipoint linkage analyses were performed, implemented by the computer program GENEHUNTER-PLUS.

RESULTS: Both parametric and nonparametric analyses confirmed evidence for linkage between a prostate cancer susceptibility locus and markers on chromosome 8p in the complete 61 HPC pedigrees. The highest parametric HLOD was 0.58 ($P = 0.050$) with $a = 0.22$, observed at D8S1731. The nonparametric analyses yielded a peak allele-sharing LOD of 0.67 ($P=0.038$) at marker D8S1731. When the analyses were stratified by pedigree characteristics, the evidence of linkage was seen in pedigrees with early onset and in pedigrees with small number of affected. The peak allele-sharing LOD was 1.07 ($P=0.013$) at D8S552 in the 16 pedigrees with mean age at onset < 65 years, and 1.39 ($P=0.006$) at D8S1731 in the 47 pedigrees with less than five affected pedigree members.

CONCLUSIONS: Our study confirms previously reported evidence of prostate cancer linkage at 8p22-23 in an independent population. These results, together with the identification of frequent somatic alterations of 8p loci in prostate cancer cells and the discovery of mutations in some tumor-suppressor genes in the region, warrant further studies.

A conserved domain within Snm1 is required for the repair of DNA interstrand cross-links. X. Li¹, L. Thrun¹, D. Bruun¹, S. Jones², R. Moses¹. 1) Dept. of Molecular & Medical Genetics, Oregon Health & Science University, Portland, OR; 2) Dept. of Cell Biology, University of Massachusetts Medical Center, Worcester, MA.

DNA interstrand cross-links (ICLs) block transcription, replication and segregation of DNA. *SNM1* of yeast is required for normal ICL repair and homologs exist from yeast to human. The function of Snm1 is unknown. *SNM1* shows some homology to *Artemis*, acting in V(D)J recombination. Mutations in *Artemis* cause human radiosensitive severe combined immune deficiency (RS-SCID). In response to treatment with psoralen plus UVA radiation, *snm1* mutant yeast cells were similar to wild type cells in inducing chromosomal breaks as analyzed by pulsed-field gel electrophoresis (PFGE), but they were defective in the subsequent repair of such breaks, suggesting Snm1 is required for processing of ICL-induced chromosomal breaks. Double-stranded breaks (DSB) are thought to be an intermediate in repair of ICLs, but we found Snm1 is not required for the repair of mating type switch endonuclease HO-induced DSBs. These results suggest that ICL-induced DNA breaks (as repair intermediates) are structurally different from DSBs induced by HO, or that SNM1 is not involved in the DSB repair step. A recent report (Ma et al. Cell 108: 781-94) showed that both Snm1 and Artemis contain b-lactamase motifs and that Artemis possesses a single-strand exonuclease activity, possibly acting in processing intermediates in recombination. We find that a point mutation in motif-2 of the b-lactamase domain abrogates functional complementation for ICL repair in a *snm1* deletion mutant, indicating this motif is important for the action of Snm1. We have made SNM1^{-/-} mice in which the gene was disrupted upstream of all of the lactamase motifs. Results show *snm1*^{-/-} fibroblast cells are sensitive to the ICL agent CDDP. However, FACS studies with T-cell and B-cell-specific markers indicate no abnormality. Our results do not support a role for *SNM1* in immunocompetence, but do indicate the b-lactamase domain is required for function in ICL repair.

Heterogenous Expression of beta-Catenin, p16, E-cadherin, and C-myc in Multistage Colorectal Carcinogenesis Detected by Tissue Microarray. *D. Xie¹, W.F. Zeng², J.S.T. Sham¹, H.L. Lin², L.H. Che², Y. Fang³, J.M. Wen², L. Hu¹, X.Y. Guan¹.* 1) Dept. of Clinical Oncology, The University of Hong Kong, Hong Kong, China; 2) Department of Pathology, Sun Yat-Sen University, Guangzhou, China; 3) Cancer Institute, Sun Yat-Sen University, Guangzhou, China.

Most colorectal carcinomas (CRCs) arise from adenomas through an archetypal pathogenic pathway, the adenoma-carcinoma-metastasis sequence. Aberrant expressions of b-catenin, p16, E-cadherin, and c-myc have played important roles in carcinogenesis of CRC, but their distribution pattern and associations in different pathological loci along CRCs tumorigenetic progress is not fully understood. In this study, a tissue microarray (TMA) containing 85 advanced CRCs in different Dukes stages was constructed. In all 85 cases, tissue specimens from normal mucosa, primary carcinomas in different layers of the bowel wall were included in the TMA. Tissue specimens from matched adenoma, lymph node metastases, and distant metastases were recruited from 22, 21, and 21 cases, respectively. Expression pattern of b-catenin, p16, E-cadherin, and c-myc in multistage colorectal carcinogenesis and progression was evaluated by immunohistochemistry. The results revealed 1) Nuclear overexpressions of b-catenin, p16, and c-myc was increased apparently from normal mucosa to adenoma, primary carcinoma, and lymph node metastatic tumor; 2) The frequencies of nuclear overexpression of b-catenin and p16 in lymph node metastases were significantly higher than that in distant metastases ($p < 0.05$). This result implies that nuclear overexpression of b-catenin and/or p16 might be associated with CRCs local lymph node metastasis but probably not distant blood-bore metastasis; 3) A well correlation of nuclear expressions of b-catenin and c-myc either in primary carcinomas at subserosa layer or lymph node metastases was observed ($p < 0.05$), suggesting overexpression of c-myc could be transcriptionally activated by nuclear b-catenin in both primary CRC and its nodal metastases.

Comparative Expression Profiling of the Mouse Cytochrome P450 Gene Family. *I. Stoilov¹, D. Choudhary², I. Jansson², J.B. Schenkman², M. Sarfarazi¹.* 1) Molecular Ophthalmic Genetics Laboratory, Surgical Research Center, University of Connecticut Health Center, Farmington, CT; 2) Department of Pharmacology, University of Connecticut Health Center, Farmington, CT.

Expression profiles for 48 mouse genes representing all known cytochrome P450 families were developed with the assistance of multiple tissue cDNA panel Mouse I (Clontech). This panel contains normalized cDNA samples from 4 embryonic stages (days 7, 11, 15 and 17) and 8 adult tissues: heart, brain, spleen, lung, liver, skeletal muscle, kidney and testis. Individual gene-specific PCR assays were uniformed with respect to their primer T_m, amplicon size, reaction conditions and number of cycles used. The amplification reactions were analyzed by agarose/EtBr gel electrophoresis. Low-mass DNA ladder (Invitrogen) was used for band sizing and as a quantitative reference. Gel images were digitized and quantitative densitometry analysis was performed with Scion Image software program. The level of expression of each gene was translated into ng of RT-PCR product. Mouse P450s were detected in the gastrulation phase and number of expressed genes steadily increased during somitogenesis and organogenesis phase of development. In adult tissues, the largest number of P450s was detected in liver (n=34) followed by kidney (n=33), lung (n=27) and testis (n=26). Heart had the fewest number (n=12) of P450s. Of special interest was the expression profile of P450 genes belonging to sub-family Cyp1 because the mutant forms of Cyp1b1 ortholog in human cause Primary Congenital Glaucoma. Both Cyp1a1 and Cyp1b1 showed a complex non-overlapping pattern of expression during embryonic development. Cyp1a1 was detected only at embryonic day 7 while Cyp1b1 was detected on days 11, 15 and 17. In adult tissues, the highest Cyp1a1 expression was in lung and liver. Interestingly, Cyp1b1 was not detected in liver but was present in all other tissues. On the contrary, Cyp1a2 was detected only in the adult liver. This data suggests that Cyp1a1 and Cyp1a2 are not able to compensate for Cyp1b1 deficiency during embryonic development. Supported by AHAF-National Glaucoma Research grant to I.S. and NIH (EY-11095) grant to M.S.

Loss of heterozygosity in premalignant lesions and invasive tumors of the breast: examination of 26 commonly deleted chromosomal regions. *R.E. Ellsworth¹, C.D. Shriver², D.L. Ellsworth¹, B. Deyarmin¹, V. Mittal¹, S. Lubert¹, R.I. Somiari¹.* 1) Windber Research Institute, Windber, PA; 2) Walter Reed Army Medical Center Washington, D.C.

Despite tremendous efforts towards the elucidation of the genetic events involved in breast cancer etiology, the majority of molecular dysfunctions associated with breast cancer are still unknown. The successful sequencing of the Human Genome has revealed that tumor suppressor genes (TSGs) are often found clustered together in small chromosomal regions. We have taken a high-throughput genotyping approach to examine 26 chromosomal regions, including the BRCA1, BRCA2 and TP53 gene regions, frequently deleted in breast cancer tumors to identify TSGs and TSG gene clusters involved in a variety of breast cancers. Approximately 100 tumor samples have been studied, including cases of atypical hyperplasia, in situ carcinoma and infiltrating carcinoma (stages 0-3). DNA was extracted from relatively homogenous cell populations using laser microdissection technology. First-pass genotyping on a 96-capillary electrophoresis sequencer equipped with an ultra-high throughput genotyping software involved the use of two microsatellite primer pairs per chromosomal region for the development of a global LOH map. Fine mapping was then carried out on the subset of samples showing specific chromosomal loss using large, custom panels of microsatellites from each region. Of note, ~60% of cases of DCIS show a loss of heterozygosity on chromosome 8p22 with a commonly deleted region encompassing the deleted in liver cancer 1 (DLC1) gene. Development of this large map, representing 26 loci on 17 chromosomes, will greatly facilitate the identification of novel tumor suppressor genes and/or surrogate markers for breast cancer.

A common haplotype of CYP1B1 is associated with prostate cancer risk in Caucasians. *B. Chang¹, S.L. Zheng¹, S.D. Isaacs², K.E. Wiley², A.R. Turner¹, G.A. Hawkins¹, E.R. Bleecker¹, P.C. Walsh², D.A. Meyers¹, W.B. Isaacs², J. Xu¹.* 1) Center for Human Genomics, Wake Forest Univ Sch Med, Winston-Salem, NC; 2) Department of Urology, Johns Hopkins Medical Institutions, Baltimore, MD.

Cytochrome P450 1B1 has been hypothesized to play an important role in carcinogenesis because it catalyzes the conversion of 17- β -estradiol (E2) to the catechol estrogen metabolite 4-OH-E2, the most carcinogenic estrogen which induces DNA single-strand breaks. As recent epidemiological and animal studies suggest that estrogen metabolism is involved in prostate carcinogenesis, we hypothesize sequence variants of CYP1B1 affect estrogen metabolism and in turn affect prostate cancer risk. To test this hypothesis, we systematically genotyped 14 single nucleotide polymorphisms (SNPs) of CYP1B1 in 159 probands of hereditary prostate cancer (HPC) families, 245 sporadic prostate cancer cases, and 211 unaffected controls. These SNPs well cover the gene and include two SNPs in the promoter region (-1549G/A and -1001T/C), five nonsynonymous changes (R48G, A119S, V432L, D449E, and N453S), four in introns (IVS1-13T/C, IVS1-263A/G, IVS2+3015G/A, and IVS2+3653C/A), and three in the 3'UTR (+5359T/A, +5639G/A, +7072A/T). Because the majority of study subjects are Caucasians, all the hypothesis tests were limited to Caucasians. Significantly different allele frequencies between sporadic cases and unaffected controls were observed for five consecutive SNPs in the promoter region, intron 1, and exon 2 ($P < 0.05$). Due to strong linkage disequilibrium (LD) within these five SNPs, only two major haplotypes were observed (all other possible haplotypes were either not observed or observed in $< 1\%$). The haplotype of C-C-G-C-G of SNPs -1001T/C, IVS1-13T/C, IVS1-263A/G, R48G, and A119S were observed in 75% of sporadic cases, compared with 68% of controls ($P = 0.038$). These results suggest that sequence variants in CYP1B1 may be associated with prostate cancer risk.

Isolation of expressed sequences from a genomic segment carrying senescence gene (SEN16) for breast tumor cells. *G.P. Kaur, R. Athwal.* Fels Cancer Research Inst, Temple Univ Sch Medicine, Philadelphia, PA.

Escape from replicative senescence has been postulated to be a prerequisite for progressive tumor growth. Cells cultured from many tumors exhibit immortal cell growth in culture while all normal human cell types that can be grown in culture undergo cellular senescence after a definite life span. Cellular senescence is expressed as dominant phenotype over immortal cell growth, which indicates that immortal phenotype arises due to recessive genetic mutations in the senescence pathways(s). More than ten human chromosomes have been identified to carry senescence genes by complementation of immortal phenotype of a variety of cultured tumor cells. However, cloning of senescence genes has been a challenging task so far. We have applied an approach that combines functional complementation with traditional positional cloning to isolate human genes that induce senescence in immortal tumor cell lines. Using this functional-positional approach, we have identified a cell senescence gene, SEN16, located at chromosome 16q24 to a 85 kb genomic segment (Reddy et al.1999, Oncogene 18:5100, Reddy et al. 2000, Oncogene19: 217). A high-resolution map of the candidate region was constructed with YAC and BAC clones. Functional testing of these clones identified a genomic segment of 85 kb that could induce replicative senescence in human and rat mammary tumor cells. In following experiments, we isolated expressed sequences from the complementing BAC clone by exon trapping. Twelve exons were identified and their sequence comparison with databases identified five partial cDNA clones. Two of these cDNAs have been characterized in detail with respect to their transcript size and expression in different tissues. Both of these cover 55 kb of the complementing genomic region. One of these cDNA is rearranged in two breast tumor cell lines, SKBR3 and T47D, thus promises to be a more likely candidate. This cDNA has been cloned into LACII inducible expression system. Cloned cDNA will be expressed in tumor cells and resulting phenotype studied.

Novel germline mutations in the gene coding for α -Methylacyl-CoA Racemase may associated with prostate cancer risk. *S. Zheng¹, B.L. Chang¹, S.D. Isaacs², K.E. Wiley², A.R. Turner¹, G.A. Hawkins¹, E.R. Bleecker¹, P.C. Walsh², D.A. Meyers¹, W.B. Isaacs², J. Xu¹.* 1) Center for Human Genetics, Wake Forest Univ Sch Med, Winston-Salem, NC; 2) Department of Urology, Johns Hopkins Medical Institutions, Baltimore, MD.

The enzyme α -Methylacyl-CoA Racemase (AMACR) plays an important role in peroxisomal β -oxidation of branched-chain fatty acid and C27-bile acid intermediates, and therefore is relevant to carcinogenesis. The involvement of AMACR in prostate carcinogenesis is further implicated by the following several observations: 1) two recent studies independently found that AMACR is consistently over-expressed in prostate cancer at both the mRNA and protein level; 2) multiple epidemiological studies have found that red meat and dairy products, major sources of branched-chain fatty acid, are associated with prostate cancer risk; and 3) chromosomal region 5p13, the location of the AMACR gene, is linked to a prostate cancer susceptibility gene by two genome-wide scans. In this study, we hypothesize that sequence variants in AMACR may alter the risk for prostate cancer. To test for this hypothesis, we sequenced all 5 exons, exon-intron junctions, the promoter region, and both 5' and 3' UTR of AMACR in germline DNA samples of 96 probands from hereditary prostate cancer (HPC) families ascertained at the Johns Hopkins Hospital. We found 17 sequence variants, including 5 novel (R118Q, V185A, P238S, Q239H, L250R) and 5 known (V9M, S52P, G175D, S201L, K277E) nonsynonymous changes. Six of these are at the residues that are conservative among the rat and mouse Amacr. To assess whether these sequence variants are associated with prostate cancer risk, we genotyped a subset of these variants among an additional 63 HPC probands, 245 sporadic cases, and 211 unaffected controls. Several nonsynonymous changes were observed more frequently in cases than in controls. In particular, the nonsynonymous change S52P was only observed in two Caucasian cases (one each in HPC probands and sporadic cases), and never observed in 189 Caucasian unaffected men. These results suggest that sequence variants in AMACR may be associated with prostate cancer risk.

No association between germline sequence variants in Angiopoietin-2 gene and prostate cancer risk. *J. Xu¹, B.L. Chang¹, S. Zheng¹, S.D. Isaacs², K.E. Wiley², A.R. Turner¹, G.A. Hawkins¹, E.R. Bleecker¹, P.C. Walsh², D.A. Meyers¹, W.B. Isaacs².* 1) Center for Human Genomics, Wake Forest Univ Sch of Med, Winston Salem, NC; 2) Department of Urology, Johns Hopkins Medical Institutions, Baltimore, MD.

A gene or genes on chromosome 8p22-23 have been implicated in prostate carcinogenesis by the observation of frequent deletions of this region in prostate cancer cells, and by two recent linkage studies in hereditary prostate cancer (HPC) families. Angiopoietin-2 (Ang-2) is a good candidate gene in this region because of its role in angiogenesis, which is critical in tumor growth and metastasis. Multiple studies have shown that higher activity of Ang-2 may lead to enhanced tumor angiogenesis and growth. The Ang-2 gene consists of 9 exons and spans about 61 kb. So far, only two sequence variants have been reported in the coding sequence of Ang-2, and both are synonymous changes (Q245 and Y369). To identify additional sequence variants in prostate cancer patients, we sequenced all 9 exons, exon-intron junctions, the promoter region, and both 5' and 3' UTR of Ang-2 in germline DNA samples of 96 probands from hereditary prostate cancer (HPC) families ascertained at the Johns Hopkins Hospital. We found 26 sequence variants, including 4 variants in the 5'UTR, 4 variants in the 3'UTR, and 3 synonymous changes (T294, N365, and Y369). To assess whether these sequence variants are associated with prostate cancer risk, we genotyped a subset of these variants (n=12) among an additional 63 HPC probands, 245 sporadic cases, and 211 unaffected controls. There was no significant difference in the allele frequencies between prostate cancer cases and controls for any of these variants. These results suggest that sequence variants in Ang-2 are unlikely play a major role in affecting prostate cancer risk.

Genome wide screening for prostate cancer susceptibility loci: Results from the Mayo Clinic Familial Prostate Cancer Study. *J.M. Cunningham, R. Berry, J.J. Schroeder, A.J. French, A.F. Marks, S.J. Hebring, B.R. Koch, S.A. Anderson, S.K. McDonnell, B.J. Peterson, S.L. Slager, S.N. Thibodeau, D.J. Schaid.* Mayo Clinic, Rochester, MN.

Prostate cancer is one of the most common human cancers and has long been recognized to occur in familial clusters, with family members sharing an increased risk of cancer development. Genetic linkage is a powerful technique for identifying disease susceptibility loci, although it can be confounded by factors that are present in prostate cancer, such as late age of onset and a high phenocopy rate. Nonetheless, several putative loci have been identified on chromosomes 1 (HPC1, PCAP and CAPB), X (HPCX), 17 (HPC2) and 20 (HPC20), with genes for two, HPC1 and HPC2, being tentatively defined. We report herein on a genome-wide scan in 161 prostate cancer families, using the ABI Prism Linkage Mapping Set version 2 of 400 microsatellite markers. The most significant linkage was found for chromosome 20, with an Hlod (recessive model) of 4.70 ($\alpha = 0.30$), and an NPL of 3.58 for the whole group. Linkage was most prominent among families with a late age of onset (>66 years), with <5 affected family members and with no male to male transmission (MMT) of disease (Hlod = 3.94, $\alpha = 1.0$, NPL = 3.62). No other chromosome showed significant evidence for linkage within the entire group. However, chromosome 6 demonstrated some linkage potential, with an Hlod of 1.93 (recessive model) and an NPL of 1.8 for the whole group. Age appeared to influence this somewhat, with Hlod of 1.99 and an NPL of 2.8 in those with an older age of onset. Within the subsets described above, another region showing potential evidence for linkage was chromosome 5, in those families without the presence of MMT of disease (Hlod 3.28, dominant model, and an NPL of 3.61). Data for the entire genome wide scan will be presented along with appropriate subset information.

CYP3A and GST genotypes in treatment response in pediatric leukemia. *R. Aplenc*^{1, 2}, *K. Meredith*², *B.J. Lange*², *T. Rebbeck*¹. 1) CCEB, Univ Pennsylvania, Philadelphia, PA; 2) Children's Hospital of Philadelphia, Philadelphia, PA.

Acute lymphoblastic leukemia (ALL) is the most common pediatric cancer. Present day therapies stratify patients according to clinical criteria and cure approximately 80% of patients. Despite risk stratification based on clinical criteria, some patients relapse. The risk of relapse in pediatric ALL may be related to polymorphisms in drug metabolizing enzymes. We evaluated polymorphisms in cytochrome P450 3A5 (CYP3A5) and glutathione-s-transferase (GST) and relapse and toxicity risk in pediatric ALL. CYP3A5 may be the primary Phase I enzyme involved in the metabolism of several chemotherapy agents to active Phase I metabolites. GST may be responsible for a majority of glutathione conjugation and deactivation of Phase II metabolites of chemotherapy agents. To date, no studies of CYP3A5 have been reported in pediatric ALL and controversy exists on the role of GST polymorphisms. We hypothesized that patients with deactivating SNPs in CYP3A5 would have less active chemotherapy metabolites and therefore a decreased risk of toxicity but an increased risk of relapse. Conversely, we hypothesized that patients with GST deactivating SNPs would have higher Phase I chemotherapy metabolite exposure with more attendant toxicity but a lower rate of relapse. The Children's Cancer Study Group (CCG) national ALL study, CCG-1891, enrolled 1204 standard risk patients from 1989 to 1992 of whom 222 patients relapsed. Archived bone marrow slides from patients enrolled on CCG-1891 were obtained. DNA was extracted by standard protocols. CYP3A5 genotype was determined by a Pyrosequencing assay. GST mu and theta genotypes were determined by a previously described assay. Approximately 100 relapse patients and 380 non-relapse patients were genotyped for each SNP. GSTM1, GSTT1, and CYP3A5*3 genotypes were not associated with statistically significant changes in relapse risk. (GST M1 OR = 1.25, 95% CI 0.76-2.08; GST T1 OR 0.59, 95% CI 0.24 - 1.29; CYP3A5*3 OR = 1.36, 95% CI 0.50 - 3.33). No interaction between CYP3A5 and GST genotypes was observed. We conclude that CYP3A5 and GST genotypes do not significantly modify the risk of relapse in children treated for standard risk ALL.

Expression profiling of normal breast fibroblasts from *BRCA1* mutation carriers following induced DNA damage: identification of genes predictive of the presence of mutation. Z. Kote-Jarai¹, N. Cattini², M. Copeland¹, I. Giddings², R. te Poele², R. Wooster², C. Campbell³, G. Gui⁴, J. Peacock⁵, R. Eeles^{1,4}. 1) Translational Cancer Genetics, Inst. Cancer Research, Sutton, Surrey, UK; 2) Molecular Carcinogenesis, Inst. Cancer Research, Sutton, Surrey, UK; 3) Computational Intelligence Unit, Bristol University, Bristol, UK; 4) Royal Marsden NHS Trust, London, UK; 5) Radiobiology Team, Institute of Cancer Research, Sutton, Surrey, UK.

Germline mutations in the *BRCA1* gene predispose women to develop breast and ovarian cancer. *BRCA1* has been implicated in many cellular processes including transcription regulation, DNA repair and recombination. We employed high-density cDNA microarray technology in order to identify different responses to DNA damage in heterozygous mutation carrier cells when compared to wild type cells. We used normal primary breast fibroblasts cultured from prophylactic mastectomy specimens of women carrying a germline mutation in the *BRCA1* gene. Control breast fibroblast cells were obtained from women undergoing reduction mammoplasties. Cells were subjected to 15 Gy of gamma-irradiation using a ⁶⁰Co source. Our cDNA arrays were produced from 5604 IMAGE clone cDNAs. The clone set includes specifically chosen genes such as the currently known *BRCA1* interacting genes and genes with known function in DNA repair. The PCR products were gridded onto poly-L-Lysine coated glass microscope slides. After hybridisation the slides were scanned using an Axon Genepix 4000A scanner and the images were analysed with GenePix Pro 3.0. Data mining was performed using GeneSpring 4.2 (Silicon Genetics). Based on the Class Prediction model we have identified a set of genes differentially expressed in *BRCA1* heterozygous mutation carriers when compared to non-carriers. These predictor genes represent transcription regulators, cell cycle control genes and genes with function in chromatin remodelling. We are currently extending our study to establish the significance of these predictor genes. This result shows that gene expression profiling may be applied to distinguish *BRCA1* carriers from non-carriers.

Prediction of edema using pharmacogenomic analysis in a clinical trial of CML patients treated with

Gleevec™/Glivec®. *L.A. McLean¹, M. Dressman¹, I. Gathmann², R. Capdeville², M.H. Polymeropoulos¹.* 1) Novartis Pharmaceuticals Corporation, Gaithersburg, MD; 2) Novartis Pharma AG, Basel, Switzerland.

Gleevec™/Glivec® (imatinib, STI571), an inhibitor of the bcr-abl tyrosine kinase, has been shown to be highly effective in the treatment of chronic myelogenous leukemia (CML). However, a common adverse event associated with Gleevec™ treatment is that of fluid retention, particularly periorbital and other peripheral edema, which occurs in approximately 50% of patients. In an effort to develop predictive markers of edema, we evaluated blood samples collected at baseline (pre-treatment) for 105 CML patients enrolled in a Phase III clinical trial that were subsequently treated with Gleevec™. Patients were identified as having edema if they had at least one occurrence of peripheral edema or other fluid retention event following treatment with Gleevec™ for a minimum of six months. Gene expression data for more than 12,000 genes were generated from each blood sample using Affymetrix oligonucleotide microarrays. Using a subset of the patients (the predictor set), we utilized a leave-one-out strategy to identify a set of predictor genes that could differentiate between those patients who developed edema and those that did not. A second, independent subset of patients (the test set) was utilized for validation of the findings. Overall, the set of predictor genes was able to correctly predict the development of edema in 89% of all the edema cases (40 of 45). To determine the relative risk of developing edema, we compared an individual's expression of the predictor genes to the mean expression profiles from the predictor set. Patients that displayed an expression pattern that was more similar to the mean Edema profile and less like the mean No Edema profile were found to be 7.2 times more likely to develop edema (95% confidence interval: 2.4 - 21.4; $p < 0.001$). Application of these findings could provide a useful tool in the clinical setting.

Genomic profiling of primary breast cancers and cell lines using array CGH. *T.L. Naylor¹, J.D. Greshock¹, S.H. Cleaver¹, B.J. Baxter¹, A. Margolin¹, M.L. Liebman¹, R. Wooster², P.A. Futreal², M.R Stratton², B.L. Weber¹.* 1) AFCRI, University of Pennsylvania, Philadelphia, PA; 2) Wellcome Trust Sanger Institute, Hinxton, UK.

Previous strategies to identify oncogenes and tumor suppressor genes have been limited by absence of the complete human genome sequence and methods for rapid, genome-wide analysis. Array comparative genomic hybridization (aCGH) measures relative copy number by competitive differential hybridization of labeled genomic DNA to DNA microarrays. The use of densely-spaced, sequence-mapped BACs for aCGH provides a high-throughput whole genome approach to identifying genes amplified or deleted in cancers. Thus aCGH circumvents many previous limitations in identifying oncogenes and tumor suppressor genes. We have constructed arrays of 5000 human BAC clones with 1 Mb average resolution. We have characterized 30 invasive breast carcinomas and 10 breast cancer cell lines using these arrays and have developed software to analyze these data. All cell lines have been genotyped at 10 Mb resolution (or greater) across the genome (Cancer Genome Project, Wellcome Trust Sanger Institute). Genotyping data correlate closely with the aCGH profile, with the aCGH data providing additional mapping information. All primary tumors were verified as >80% tumor. We identified recurrent copy number gains in primary tumors and cell lines on chromosomes 1, 8, 17, 18 and 20 that do not contain known oncogenes. These regions range from chromosome arm duplication to complex amplification of a region represented by a single BAC. Single copy losses are less frequent than gains overall and less frequent in primary tumors than cell lines. We identified recurrent single copy losses on chromosome 6 and 8 in the primary tumors that do not contain known tumor suppressor genes. To date, homozygous losses have been seen only in cell lines. We are expanding the number of primary tumors analyzed by aCGH and identifying genes located within the regions of gain/loss. We also are incorporating histopathology and outcome data into the analysis, to evaluate correlations between genomic profiles and clinical characteristics.

Monitoring telomere sequence content in sub-nanogram quantities of DNA from primary stem-like cells. *R.D. Learish¹, G. Coppola², R.F. Bulleit¹, M. Kent-First¹*. 1) Cellular analysis, Promega Corporation, Madison, WI; 2) University of Napoli, Department of Animal Science and Food Inspection, 80055 Portici, Italy.

Studies of telomere length have been carried out in diverse areas of research such as stem cells, aging, cancer, and animal cloning. However, current methods to measure telomeres are cumbersome and require microgram quantities of DNA. Using a coupled pyro-phosphorolysis/ trans-phosphorylation reaction, we have developed a sensitive assay to quantitate telomere repeat sequence content (TRSC) in a single tube or 96-well format. The standard reaction uses a telomere-specific oligonucleotide probe to interrogate nanogram quantities of DNA without PCR amplification and is coupled to the luciferase enzyme reporter system. Primary neural progenitor cells were isolated from rat embryos and cultured in media containing 1% serum and growth factors until senescence at 30-50 days, and DNA was isolated at various time points. Southern blot analysis showed decreasing telomere restriction fragment length (TRFL) corresponding with time in culture. This observation correlated with a loss in TRSC using 10 ng aliquots of the same DNA samples in the new assay system. We subsequently tested the sensitivity of the new method using limiting amounts of genomic DNA from cultured cells, primary neural progenitor cells, or bovine blastocysts. The DNA was isolated using a magnetic resin and eluted into an appropriate buffer. Preliminary results indicate the sensitivity limit for rodent or bovine cells is approximately 300 pg of DNA-- the equivalent of approximately 100 cells. This raises new possibilities in basic and clinical research, such as monitoring global changes to telomeres in blastocysts, small colonies expanded from single cells in vitro, or limiting numbers of cells isolated by FACS.

Genotype-phenotype correlations for presenile cataracts in neurofibromatosis 2. *M.E. Baser¹, J.M. Friedman², H. Joe³, A.J. Wallace⁴, R.T. Ramsden⁵, D.G.R. Evans⁴.* 1) Los Angeles, CA, U.S.A; 2) Department of Medical Genetics, University of British Columbia, Vancouver, B.C., Canada; 3) Department of Biostatistics, University of British Columbia, Vancouver, B.C., Canada; 4) Department of Medical Genetics, St. Mary's Hospital, Manchester, U.K; 5) Department of Otolaryngology, Manchester Royal Infirmary, Manchester, U.K.

Neurofibromatosis 2 (NF2) is an autosomal dominant disease that is characterized by nervous system tumors and other abnormalities. Genotype-phenotype correlations have been studied for NF2-related tumors, but have not been evaluated for non-tumor manifestations of NF2, the most common of which is presenile cataracts. We used data from the United Kingdom NF2 registry to examine genotype-phenotype correlations for cataracts in 261 people from 191 families (160 new mutations and 101 inherited cases) who had been screened for constitutional *NF2* mutations using SSCP. Cataracts were evaluated by slit lamp. There were 82 people with nonsense or frameshift mutations (including 15 known somatic mosaics), 50 with splice-site mutations, 16 with missense mutations, 32 with large deletions, and 83 with unidentified mutations. Logistic regression was used to calculate relative risks (RR). The RR of cataracts was not significantly associated with age at diagnosis of NF2 or current age. People with nonsense or frameshift mutations were the reference group in comparisons between types of mutations. In new mutations, the RR of cataracts in people with splice-site mutations was 0.94 (95% confidence interval (CI), 0.31-2.80); with missense mutations, 0.96 (95% CI, 0.14-6.47); with large deletions, 0.39 (95% CI, 0.07-2.14); with somatic mosaicism, 0.29 (95% CI, 0.07-1.17); and with unidentified mutations, 0.30 (95% CI, 0.13-0.68). In inherited cases, the RR of cataracts in people with splice-site mutations was 0.42 (95% CI, 0.13-1.29); with missense mutations, 0.18 (95% CI, 0.03-1.06); with large deletions, 0.60 (95% CI, 0.18-1.91); and with unidentified mutations, 0.46 (95% CI, 0.12-1.84). In future work, we will evaluate age at diagnosis of cataract, which may be a more sensitive measure than presence of cataract.

DNA REPAIR GENE POLYMORPHISMS AND DNA-ADDUCT LEVELS IN BLADDER CANCER. S. POLIDORO^{1, 2}, S. GUARRERA^{1, 2}, L. DAVICO², S. CARTURAN¹, M. PELUSO³, A. MUNNIA³, A. PIAZZA¹, P. VINEIS², G. MATULLO^{1, 2}. 1) Dip di Gen, Biol e Bioch, Università di Torino; 2) Serv di Epidemiol dei Tumori, Dip di Sc Biomediche e Onc Umana, Università di Torino; 3) CSPO, Lab di Biol Mol, Firenze.

The repair of DNA damage has a key role in protecting the genome of the cell from the insults of cancer-causing agents. In industrialized countries cancer of the bladder is the fifth most common cancer in men. Although development of bladder cancer is associated with exposure to tobacco (about 50%) and occupational exposure (about 20%), only a proportion of exposed individuals will develop cancer, suggesting that there is a genetic predisposition. Polymorphisms in several DNA repair genes have been identified; however the impact on repair phenotype has not been elucidated. We analyzed the relationship between 9 DNA repair gene polymorphisms belonging to different repair pathways (XRCC1-28152A/G, XRCC1-26651A/G, XRCC1-26304T/C, XPD-35931-A/C XRCC2-31479G/A, XRCC3-18067C/T XRCC3-17893A/G, ERCC4-30147A/G, PCNA-6084G/C) and DNA damage as measured by WBC 32P-postlabeling DNA-adduct levels in about 225 individuals with bladder cancer and 175 controls. No significant difference has been observed in the genotype distribution between cases and controls for all the polymorphisms, except for XRCC3-18067C/T ($p=0.008$). Significant differences exist between cases and controls for DNA-adduct levels (0.47 ± 0.04 vs 0.20 ± 0.03 , $p<0.001$) and smoking ($p<0.00001$, 89.4% vs 55.3%, respectively). Notwithstanding we have not observed a significant difference in genotype distributions and DNA-adduct levels between smokers and non-smokers, we have found an interesting higher DNA-adduct level in individuals with XRCC1-R399H GG-AG vs AA genotypes (0.49 ± 0.05 vs 0.34 ± 0.07 , $p=0.15$; maximum values are 2.5 and 0.9, respectively) in smoker cases but not in non-smoker cases. No difference in DNA-adduct levels has been observed between genotypes in smokers and non-smokers controls. Our results mainly suggest XRCC3 involvement as a bladder cancer genetic risk factor, being possibly relevant for risk assessment. Work is in progress to analyze additional polymorphisms in the same and other genes, including linkage disequilibrium data.

Microarray Analysis of Disease Relapse in Childhood Acute Lymphoblastic Leukemia (ALL). *K.M. Brown¹, R. Pillai³, E. Perez², G.H. Reaman², D.A. Stephan¹.* 1) Research Center For Genetic Medicine, Children's National Medical Center, Washington, DC; 2) Department of Hematology and Oncology, CNMC, Washington, DC; 3) Genomic Collaborations Group, Affymetrix Inc., Santa Clara, CA.

Acute lymphoblastic leukemia (ALL) is the most common childhood malignancy and the second leading cause of deaths from childhood cancer in the United States. Over the past four decades, the fraction of children whose treatment results in long-term, disease free survival (LTDFS) has increased from less than 5% in 1960 to approximately 70% in 1994. Despite this progress, approximately 900 children with ALL relapse every year in the United States. Treatment of patients who relapse is significantly more difficult than initial treatment of ALL, in large part because relapsed leukemia cells are much more likely to be resistant to one or more chemotherapy agents. Currently, salvage therapy for relapsed disease is only able to provide LTDFS for about 40% of these children. We hypothesize there is a common mechanism underlying therapy resistance (i.e. relapse) in ALL. Identification of genes mediating therapy resistance could 1) facilitate design of novel, targeted therapy protocols, and 2) identify patients with high risk of relapse at the time of diagnosis for targeted and/or intensified therapy protocols. To this end, we expression profiled bone marrow samples from 25 similarly-treated patients with relapsed ALL using Affymetrix oligonucleotide arrays. This collection includes samples from both the time of diagnosis and relapse for each patient. Expression profiling of these diagnosis/relapse pairs on the Affymetrix U95Av2 chip (~12,600 genes) and subsequent permutation testing based on the paired t-test statistic has identified several genes whose expression is consistently different within pairs of diagnosis and relapse samples. We are currently validating these genes on an independent set of diagnosis/relapse pairs at both the RNA and protein levels. Additionally, we will use both expression profiling and flow cytometry on an independent set of diagnosis samples to determine whether differences in expression of these genes detectable at the time of diagnosis correlate with risk of disease relapse.

The Cancer Genetics Network: Recruitment Results and Pilot Studies. *H. Anton-Culver^{1, 2}, A. Ziogas^{1, 2}, D. Finkelstein², C. Griffin², J. Hanson², C. Isaacs², C. Kasten-Sportes², G. Mineau², P. Nadkarni², J. Potter², B. Rimer², J. Schildkraut², L. Strong², B. Weber², D. Winn², R. Hiatt², S. Nayfield².* 1) University of California, Irvine, CA; 2) The Cancer Genetics Network.

In 1998 the National Cancer Institute established the Cancer Genetics Network (CGN) to support collaborative investigations into the genetic basis of cancer susceptibility, explore mechanisms to integrate this new knowledge into medical practice, and identify ways of addressing the associated psychosocial, ethical, legal, and public health issues. Eight recruitment centers and an Information Technology Group (ITG) were established. Four centers use population-based cancer registries to contact and enroll patients and their family members. In the four clinic-based centers, physicians and health care professionals directly refer patients to CGN Centers. The ITG is responsible for developing and maintaining a registry and providing the statistical and computer informatics infrastructure necessary to perform the investigations. This resource is available to approved researchers and can provide clinical, environmental and family cancer history data on CGN enrollees, and access to the patients and their families for special studies. The CGN is conducting a variety of pilot studies: Ovarian Cancer Screening, Inherited Colon Cancer Among Sibling Pairs, Families with Prostate Cancer, Genetic and Environmental Modifiers of Cancer Risk Among Women With BRCA1/2 Mutations, Comparison of Models to Estimate Risk of Being a BRCA1/2 Carrier, Factors Affecting Participation Rates in the CGN, and the Breast Screening Study. As of May 2002, the CGN contained data on 15,045 participants and 241,948 family members. The distribution of participants in the CGN by cancer site is: prostate (2,823), breast (4,588), melanoma (533), lung (217), colorectal (1,074), ovarian (477), and other (3,489). Many of the families have familial or hereditary cancers, including 2,331 breast cancer families, 942 ovarian cancer families, 857 prostate cancer families, and 349 colon cancer families. The CGN is now a rich resource for collaborative studies on cancer genetic susceptibility, translational research and behavioral research.

BRAF and RAS mutations in human lung cancer and melanoma. *M.S. Brose^{1,2}, P. Volpe², M. Kumar², I. Rishi², E. Einhorn³, R. Gerrero¹, M. Herlyn⁴, J. Minna⁵, R. Wooster⁶, M.R. Stratton⁶, P.A. Futreal⁶.* 1) Dept Med, Hematology/Oncol, Hosp Univ Pennsylvania, Philadelphia, PA; 2) Abramson Family Cancer Research Institute, Philadelphia, PA; 3) Philadelphia VA Medical Center, Philadelphia, PA; 4) The Wistar Institute, Philadelphia, PA; 5) University of Texas Southwestern Medical Center, Tx; 6) The Wellcome Trust Sanger Institute, Hinxton, UK.

The relationship between signaling pathways and cancer is a focus of investigation because of the role of these pathways in malignant transformation and their potential as therapeutic targets. The RAS-RAF-MEK-ERK-MAP kinase pathway is one such pathway. Activating mutations in BRAF have recently been identified in 70% of melanomas as part of a genome-wide search for cancer-related mutations. BRAF mutations also were found in several other human primary cancers, including lung carcinomas. In order to extend the observation on BRAF mutations, we screened 150 adenocarcinomas and 100 squamous cell carcinomas of the lung for mutations in the kinase active site (exon 15) and glycine loop (exon 11) using capillary-based heteroduplex analysis. We are screening the same samples for the most common mutations in codon 61 of NRAS and codon 12 of KRAS, in order to determine whether mutations in BRAF occur in combination with other mutations in the same pathway, as suggested by the initial observation. We also have screened 50 primary melanoma and melanoma cell lines. To date we have identified mutations in BRAF in 7% of squamous cell carcinomas and confirmed the previous observation of BRAF mutations in more than 50% of primary melanomas. Analysis is still ongoing and final results will be presented. Mutations in BRAF may explain the increase in active (phosphorylated) forms of MEK and ERK in lung carcinomas present in a significant number of lung cancers in the absence of RAS mutations. In addition, mutations in BRAF also may be important in combination with RAS mutations, challenging the previous paradigm that only one defect in a molecular pathway is relevant in carcinogenesis.

A novel transcription factor, FTCTF, is fused to PPAR γ in follicular thyroid carcinoma. *W.O. Lui¹, T.G. Kroll², I. Leibiger¹, J. Liden³, B. Leibiger¹, S. Thoppe¹, A. Höög⁴, L.O. Farnebo⁵, J.A. Fletcher⁶, C. Larsson¹.* 1) Dept Molecular Medicine, Karolinska Hosp, Stockholm, Sweden; 2) Pathology and Laboratory Medicine, Emory University School of Medicine, Atlanta, USA; 3) Dept of Biosciences, Huddinge, Sweden; 4) Dept of Oncology-Pathology, Karolinska Hosp, Stockholm, Sweden; 5) Dept of Surgical Sciences, Karolinska Hosp, Stockholm, Sweden; 6) Dept of Pathology, Brigham and Women's Hosp, Boston, USA.

Both papillary thyroid carcinoma (PTC) and follicular thyroid carcinoma (FTC), derive from the thyroid follicular epithelial cells. However, they display distinct differences in biological and clinical behaviors. Interestingly, a common mechanism of fusion oncogene resulting from chromosomal rearrangements has been observed in these tumors. In PTC, somatic rearrangements commonly involve RET and NTRK1 genes, in which the tyrosine kinase domain of the gene is fused to the N-terminus of another gene. To date, only one fusion oncogene is reported in FTC, involving PAX8, which encodes a paired domain transcription factor essential for thyroid development, and the peroxisome proliferator-activated receptor gamma (PPAR γ) gene. In the previous study, it was suggested that the abrogation of normal PPAR γ function may play a critical role in thyroid follicular tumorigenesis.

In this study, we cloned a second PPAR γ rearrangement, from our previously reported FTC involving t(3;7). We identified a novel transcription factor, which is fused to the N-terminus of PPAR γ gene, and demonstrated the expression of the fusion product in RNA and protein levels. In addition, we characterized the expression distributions of the novel gene identified. Finally, we compared the transcription program regulated by this fusion gene and the PAX8-PPAR γ .

IDENTIFICATION OF CANDIDATE TRANSCRIPTS AT CHROMOSOMES 10q25-q26 AND 9p21 IN ENDOMETRIAL CANCER (EC) AND MALIGNANT MELANOMA (MM). A. Manca¹, P. Baldinu¹, A. Cossu², M.P. Satta¹, M.C. Sini¹, S. Tore¹, M. Casula¹, M. Pisano¹, C. Rozzo¹, S. Dessole³, A. Pintus², A. Lissia², A.A. Carboni², F. Tanda², G. Palmieri¹. 1) Istituto Genetica Popolazioni, C.N.R., Alghero; 2) Istituto di Anatomia Patologica, University of Sassari; 3) Ostetricia e Ginecologia, University of Sassari; Italy.

Loss of heterozygosity (LOH) at chromosomes 10q25-q26 and 9p21 has been reported in EC and MM, respectively. We previously identified two consensus regions of LOH: one, between D10S610 and D10S542 markers in EC; and the second, between D9S1748 and D9S126 markers in MM. To assess the existence of candidate gene(s) in these regions, bioinformatic approaches allowed to identify ESTs, which were confirmed by both RT-PCR assays and Northern blot hybridization on tissue mRNAs. RACE method was used to further extend the cDNA ends. Germline and tumor DNA from patients was used for mutation analysis. In EC, a 160 kb consensus region of allelic deletion between D10S1236 and WIAF3299 markers was defined and a putative transcription unit was predicted by computer-assisted analysis. Exons were confirmed by RT-PCR analysis and candidate proteins were also predicted. RNA expression analysis revealed at least two main transcripts (about 1.8 and 4.8 kb). Candidate transcripts share the first three exons with different genomic location and length of the fourth exon. Mutation analysis of the first three exons identified a nucleotide substitution in 1/9 (11%) tumor DNAs at exon 2 and in none of 102 normal controls. Additional cases are being investigated in order to define the role of such transcripts in EC. In MM, the allelic deletion at the D9S171 locus was firstly confirmed by both PCR analysis on primary tumor cell lines from MM patients (D9S171 was found homozygously deleted) and FISH analysis on MM tissue sections [a single signal was detected in 2/19 (11%) MM samples using a PAC clone corresponding to D9S171]. Five candidate ESTs between D9S962 and D9S1679 markers were isolated through bioinformatic approaches and transcription has been confirmed by RT-PCR; full-length cDNAs are being defined. Work was funded by Regione Autonoma Sardegna and A.I.R.C.

APC D1822V and the risk of colorectal cancer. *B.L. Niell¹, G. Rennert², L.P. Tomsho¹, J.D. Bonner¹, S.B. Gruber¹.*
1) Depts Int Med/Epidemiol, Univ Michigan, Ann Arbor, MI; 2) Technion University, Haifa, Israel.

Low penetrance colorectal cancer (CRC) susceptibility alleles may contribute significantly to the remaining risk not explained by other known risk factors. *APC* D1822V is a common SNP that has recently been suggested as a candidate susceptibility allele that reduces the risk of colorectal cancer in specific risk groups. We investigated the relationship between D1822V and colorectal cancer in the Molecular Epidemiology of Colorectal Cancer (MECC) study, a large population based case-control study of colorectal cancer in northern Israel. Eligible cases for this planned, interim analysis included 715 individuals diagnosed with incident CRC in northern Israel between March 1998 and March 2001. Controls were 715 age, sex, ethnicity, and clinic-matched individuals without CRC. Genotyping for D1822V was performed by allele specific oligonucleotide hybridization. Conditional logistic regression was performed to adjust for potential confounders. The D1822V allele frequency was 24% in the control population, and homozygous valine/valine individuals accounted for 6.2% of the control population. No strong associations were found between colorectal cancer and D1822V heterozygous genotype (OR= 0.9, 95% CI 0.7-1.1) or homozygous variant (valine/valine) genotype (OR= 0.9, 95% CI 0.5-1.5) when compared to homozygous (aspartic acid/aspartic acid) genotype in matched, unadjusted analyses. Adjustment for family history of colorectal cancer and I1307K (in addition to age, gender, and ethnicity) did not measurably influence the results. Codon 1822 is located between the fourth and fifth b-catenin binding and regulatory domains, but no known functional consequences of D1822V are known to date. These data suggest that D1822V is unlikely to be a strong susceptibility allele for colorectal cancer, although further analysis is required to evaluate whether there is any evidence of effect modification of environmental risk factors by D1822V.

Differential Gene Expression Between Tumorigenic and Non-tumorigenic Hybrid Clones of Human Ovarian Carcinoma Cell Line SKOV-3. *N. Wang¹, R. Abeysinghe¹, L. Li¹, B. Kim², R. Miller³, J. Xu¹.* 1) Dept Pathology, Univ Rochester Sch Medicine, Rochester, NY; 2) Department of Microbiology and Immunology, Univ Rochester Sch Medicine, Rochester, NY; 3) Department of Obstetrics and Gynecology, Univ Rochester Sch Medicine, Rochester, NY.

We have previously reported that the introduction of chromosome 11 suppresses tumorigenicity in the ovarian cancer cell line SKOV-3, indicating the presence of tumor suppression gene(s) (TSG) on chromosome 11. To identify these TSG, we performed cDNA microarray analysis on tumorigenic and non-tumorigenic hybrid clones derived from the parental cell line SKOV-3. Of the 30,000 genes investigated by microarray, 274 (0.9%) showed differential expression profiles between non-tumorigenic, slow-growing tumorigenic and fast-growing tumorigenic cells. Only 7 of the 274 differentially expressed genes, LDHA, KIAA 0750, FKBP2, CRYAB, THY1, THY1 co-transcribed and cDNA FLJ23593 (HS287749) are located on chromosome 11 in three minimal regions with high frequency of LOH in ovarian cancers. Five of these 7 genes, LDHA, CRYAB, THY1, THY1 co-transcribed and cDNA FLJ23593 (HS287749), were also analyzed by real time PCR which confirmed a suppressed expression of these genes in tumorigenic clones/cell lines. Among the 268 non-chromosome 11 differential expressed genes, CAV1, HPAC3, IGFBP7, and SPARC were putative tumor suppressor genes (PTSG) identified previously by others. The up-regulation of these genes via chromosome 11 transfer suggests the presence of a regulatory gene(s) on chromosome 11 for these PTSG. Indeed by abolishing the Thy-1 expression in one of the non-tumorigenic clone 11(c)9-8, through the transfection of Thy-1 antisense results in a significant suppression of the expression of both CAV1 and CDH6 indicating the regulating role of Thy-1 on these two genes. In summary, our findings provide fundamental information to better understand the molecular basis of ovarian carcinogenesis.

Analysis of mRNA Levels in Prostate Cancer; An Investigation of Endoglin as a Prognostic Marker of Tumor Progression. *C.L.T. Clelland¹, C. Bancroft¹, J.D. Clelland²*. 1) Dept Physiology & Biophysics, Mount Sinai Hospital, New York, NY; 2) Dept Movement Disorders and Molecular Psychiatry, Nathan Kline Institute for Psychiatric Research, Orangeburg, NY.

Endoglin, also called CD105, is a homodimeric membrane glycoprotein component of the transforming growth factor beta receptor complex, primarily associated with human vascular endothelium. Endoglin is also found on bone marrow proerythroblasts, activated monocytes, and lymphoblasts in childhood leukemia. Murine studies have shown that endoglin is critical for angiogenesis, and reduced levels of functional endoglin protein, caused by mutations in the human gene, result in Hereditary Hemorrhagic Telangiectasia (HHT), an autosomal dominant vascular dysplasia leading to telangiectases and arteriovenous malformations of skin, mucosa, and viscera.

Endoglin is highly expressed on endothelial cells during angiogenesis in tumors, with much lower expression detected in normal blood vessels. Significantly, vascular density has been proposed as a promising prognostic marker in a variety of tumor types and recently a study involving immunohistochemical staining of the endoglin protein in prostate tumor specimens, documented a strong association between the density of endoglin stained tumor microvessels and Gleason score, tumor stage, presence of metastasis at diagnosis, and cancer specific survival. We have further investigated the use of endoglin as both a diagnostic and prognostic marker of prostate cancer. In this preliminary study we have measured mRNA levels of the endoglin gene in leukocytes obtained from prostate cancer patients and healthy control subjects. Here we describe the preliminary findings of our study, and discuss their implications for staging and prognostic testing of patients with prostate cancer.

The Breast Cancer Family Registry:1997-2002. *J.C. Beck¹, J.L. Hopper², E.M. John³, J.A. Knight⁴, S.L. Neuhausen⁵, R.T. Senie⁶, I.L. Andrulis⁴, H. Anton-Culver⁷, S. Buys⁵, D. West³, A. Whittemore³, M.B. Daly⁸, D. Seminara⁹.* 1) Coriell Inst Medical Research, Camden, NJ; 2) U. of Melbourne, Melbourne, Australia; 3) Northern California Cancer Center, Union City, California; 4) CancerCare Ontario, Toronto, CA; 5) U. of Utah, Salt Lake City, Utah; 6) Columbia U., New York, NY; 7) U. of California, Irvine, CA; 8) Fox Chase Cancer Center, Philadelphia, PA; 9) National Institute of Health, NCI, DCCPS, EGRP, Bethesda, MD.

Breast cancer etiology is complex, involving interplays of genetic and environmental factors. Genetic risk may be due to mutations in high-risk genes and to common genetic variants in metabolic pathways. Complementary study designs are necessary to identify and characterize breast cancer susceptibility genes and address genetic and environmental modifiers of risk. The goals of the international Breast Cancer Family Registry (B-CFR) are to: characterize breast and ovarian cancer susceptibility genes for genotype frequency and penetrance; evaluate the roles of genetic and environmental modifiers of penetrance; map new susceptibility genes and assess putative candidate genes. The B-CFR enrolls population-based (PB) families, clinic-based (CB) multiple-case families and population-based controls (PC). Dual ascertainment allows flexibility in study design. Family history of breast and other cancers is collected and validated. A risk factor and diet questionnaire is completed, blood or mouthwash samples and tissue blocks are collected and lymphoblastoid cell lines are established. Anonymized data are stored/managed by a Central Data Base. As of 5/02, 5240 PB families, 2,575 CB families and 2379 PC have enrolled, 68% white, 16% Ashkenazi, 16% minorities. 236 CB and 622 PB families with 3 or more cases of BC, 731 early-onset cases (<36 years), 1,056 cases with multiple primary breast cancer, 557 affected sister pairs have enrolled. Testing of 8,449 participants for BRCA1 mutations and 6,650 for BRCA2 has identified 700 carriers of deleterious mutations. Strengths of the B-CFR are: focus on family data; dual ascertainment; emphasis on Ashkenazi and minorities recruitment and quality and completeness of data and biospecimens. For access information go to: <http://epi.grants.cancer.gov/BCFR/index.html>.

Program Nr: 439 from 2002 ASHG Annual Meeting

Linkage Analysis on Prostate Cancer Aggressiveness. *S.L. Slager, D.J. Schaid, J.M. Cunningham, S.K. McDonnell, A. French, B.J. Peterson, A.F. Marks, S. Hebring, B. Koch, S. Anderson, S.N. Thibodeau.* Mayo Clinic, Rochester, MN.

Prostate cancer is the most common cancer among men in the United States, yet the disease etiology is still not fully understood. Several studies have demonstrated that genetics plays an integral role in its etiology, but only recently has the genetic basis of prostate-cancer aggressiveness been investigated, with several putative regions identified on chromosomes 5q, 7q, and 19q (Witte et al., *AJHG* 67:92, 2000). Tumor aggressiveness can be assessed by a pathologist using the Gleason score, which is a cancer grading system based on architectural pattern and ranges between 2 (low grade) and 10 (high-grade). To confirm the findings of Witte et al., we analyzed 190 brother pairs from 161 families affected by prostate cancer using the Haseman-Elston linkage analysis method. With Gleason score as the quantitative trait, we regressed the squared trait difference, as well as the mean-corrected cross product, on the estimated proportion of alleles shared identical by descent at each marker position. Our analysis reproduced the results of Witte et al. for chromosome 19. Specifically, we found a significant association ($P=0.0001$) between marker D19S902 (at 67 cM) and the squared trait difference. However, the associations on chromosomes 5 and 7 were not as strong. On chromosome 5, the most significant result was at marker D5S436 ($P=0.025$), and on chromosome 7, it was at marker D7S516 ($P=0.036$). Full genome wide results will be presented. Our findings and the findings of Witte et al. strongly suggest that chromosome 19q harbors a susceptibility locus for prostate cancer aggressiveness.

Establishment of the physical map in the 17p11.2 critical region for BHD gene discovery. *V. Matrosova¹, M. Nickerson¹, M. Warren¹, N. Sharma¹, L. Schmidt², B. Zbar¹.* 1) Lab ImmunoBiology, NCI/NIH, Frederick, MD; 2) SAIC-Frederick, Inc., Frederick, MD.

Birt-Hogg-Dub syndrome (BHD), an inherited autosomal genodermatosis, characterized by benign tumors of the hair follicle (fibrofolliculomas), has been associated with renal neoplasia, lung cysts and/or spontaneous pneumothorax. Previously we localized the BHD gene locus to chromosome 17p11.2 by linkage analysis in several BHD kindreds. Chromosome 17p11.2 is an unstable genomic region harboring a number of low-copy repeats associated with several genetic disorders including Smith-Magenis Syndrome. The gene density (1 gene/37 kb) in this region is much higher than the average in the human genome (1 gene/90 kb). Genome assemblies using NCBI (<http://www.ncbi.nlm.nih.gov>), UCSC Genome Browser (<http://genome.ucsc.edu>) and Celera (<http://www.celera.com>) genome databases, and our FISH mapping data revealed discrepancies among available information. Our map agrees with the UCSC Genome Browser genomic organization (August 6, 2001 release) in the 17p11.2 region between D17S1857 and AGAT100 markers. Comparison of this region to other genomic assemblies reveals that Celera's contig is reversed in orientation and the public NCBI contig is improperly assembled. In this study using overlapping BACs, we combined molecular biological technique and cytogenetic analysis to make our map more reliable. Fourteen BACs and PACs were used to provide coverage throughout the region of interest. The analysis of 12 polymorphic markers and 11 known and predicted gene PCR products from the BHD interval was combined with fluorescent in situ hybridization (FISH) of BAC/PAC probes on interphase nuclei and metaphase spreads from human B-lymphocytes. We have generated a physical map of the BHD 1.8 Mb critical interval flanked by D17S1857, a polymorphic marker from the distal region and AGAT100, a proximal marker. The correct genomic organization of the BHD syndrome region is critical to narrow the field of search for candidate genes. A promising candidate gene was identified for mutation analysis in BHD patients.

Promoters of DAPK, CDH1 and RARB Genes are Frequently Methylated in Cervical Carcinoma and Show no Association with Clinical Outcome or Microsatellite Instability. *G. Narayan¹, H.A. Pulido¹, S. Koul¹, A. Schneider², V.V.V.S. Murty¹.* 1) Department of Pathology, College of Physicians & Surgeons of Columbia University, New York, New York; 2) Department of Obstetrics & Gynecology, Friedrich Schiller University, Jena, Germany.

Promoter hypermethylation is believed to play an important role in tumor suppressor pathways in cancer. Although much is known about the etiology and treatment of cervical carcinoma (CC), the role of epigenetic alterations in the multi-step pathway of cervical tumorigenesis is poorly understood. In our goal to understand the molecular basis of CC, we performed a comprehensive promoter hypermethylation profiling of 12 genes and microsatellite instability (MSI) in 49 primary CCs. Promoter methylation of at least one locus was found in 37 of 49 (75.5%) cases. The Death-Associated Protein Kinase (DAPK1) (55.1%), Cadherin 1(CDH1) (34.7%) and Retionic Acid Receptor Beta (RARB) (18.4%) genes were frequently methylated. Seventeen of 45 (37.8%) tumors showed MSI. No correlation was found between promoter hypermethylation of any gene and MSI, HPV type and stage of the disease, or clinical outcome after the treatment. The frequent methylation of DAPK, CDH1, and RARB in invasive CC, in the absence of clear associations with genetic changes or clinical parameters, suggests a major role for the epigenetic inactivation of these genes in CC development.

Analysis of methylation status of *RBI* promoter in retinoblastoma. *P.S. Lai*¹, *R. Rong*², *Y.F.L. Ling*³, *T.C. Quah*¹, *P.S. Low*¹. 1) Dept of Pediatrics, National Univ Singapore, Singapore, Singapore; 2) Dept of Pharmacology, State University of New York, Syracuse, NY; 3) Singapore National Eye Centre, Singapore.

Retinoblastoma is a retinal cancer caused by loss of function of both alleles of the retinoblastoma tumor suppressor gene, *RBI*. In retinoblastoma patients, the somatic mutations arising in retinal cells or their precursor cells that have been identified include loss of heterozygosity (LOH) at the *RBI* locus on chromosome 13, small nucleotide mutations within the gene and hypermethylation of the *RBI* promoter region. Previous reports on the methylation pattern of the CpG rich island in the *RBI* promoter indicated evidence of hypermethylation in 9-13% of unilateral sporadic retinoblastoma tumors. To further investigate the role of hypermethylation as an inactivating event for loss of *RBI* expression, we examined the methylation status of *RBI* promoter by bisulfite sequencing analysis. A total of 21 unilateral sporadic tumors were initially screened for LOH and point mutations in *RBI*. Fourteen out of 21 tumors showed LOH (66.7%) and a second truncating mutation was identified in 11 out of the 14 LOH-positive tumors. In the 6 non-LOH cases, there were 3 tumors in which no mutation could be detected despite DNA sequencing of the entire coding exons and flanking introns of the *RBI* gene. These six tumors were thus subjected to bisulfite treatment and both strands of DNA were then amplified by primers specific for both methylated and unmethylated segments of the *RBI* promoter. The amplified products were then sequenced to identify the methylation status. Our results show lack of hypermethylation in all six cases suggesting that this epigenetic change may not be a major mechanism in the development of retinoblastoma in our patients.

Promoter methylation of the TSLC1 gene in advanced lung cancer. *Y. Murakami¹, T. Fukami¹, H. Fukuhara¹, M. Kuramochi¹, T. Maruyama¹, K. Isogai¹, M. Sakamoto², R.H. Reeves³.* 1) Tumor Suppression & Functional Genomics Project, Natl. Cancer Ctr. Res. Inst., Tokyo, Japan; 2) Pathology Div., Natl. Cancer Ctr. Res. Inst., Tokyo, Japan; 3) Dept. of Physiology, Johns Hopkins University School of Medicine, Baltimore, MD.

TSLC1 is a novel tumor suppressor gene in human non-small cell lung cancer (NSCLC) on 11q23.2 that we recently identified by functional complementation (1). Loss or markedly reduced expression of the TSLC1 was frequently observed in NSCLC cells, where promoter methylation was strongly correlated with loss of expression. Here, we examined methylation status of the TSLC1 gene promoter in 48 primary NSCLC tumors as well as 64 cancer cell lines derived from various organs by bi-sulfite-SSCP. Bi-sulfite-SSCP of cloned fragments with known methylation status indicated that it could clearly distinguish the fragments that were unmethylated at all 6 CpG sites adjacent to the predicted TATA box sequence from those fully or partially methylated. These analyses revealed that the TSLC1 promoter was significantly methylated in 18 of 48 primary NSCLC tumors (38%), including 10 of 27 adenocarcinomas, 7 of 14 squamous cell carcinomas, and 1 of 5 large cell carcinomas. Promoter methylation was more likely to be observed in relatively advanced tumors of stage Ib, II, III, and IV with TNM classification of pT2, T3, or T4 (17 of 36, 47%) than in those of stage Ia with pT1 (1 of 12, 8.3%). Furthermore, promoter methylation was observed in 19 of 64 cell lines (39%) derived from cancers of the lung (NSCLC and small cell lung cancer), esophagus, stomach, colon, breast, uterus and ovary as well as osteosarcoma and frequently accompanied by LOH on 11q23.2. These results suggest that alteration of TSLC1 would be involved in the progression of NSCLC tumors as well as in the formation of a various human cancers. We also propose that bi-sulfite-SSCP is a sensitive and practical method to detect the overall status of the promoter methylation of the relevant gene. (1) Kuramochi et al., *Nat. Genet.*, 27, 427-430, 2001.

Frequent epigenetic inactivation of the RASSF1A tumour suppressor gene in testicular tumours plus methylation profiling of testicular tumours and relationship to clinicopathological features. *S. HONORIO¹, A.*

AGATHANGGELOU¹, N. WERNERT², P. ANDREWS³, E. MAHER^{1,4}, F. LATIF^{1,4}. 1) Department of Paediatrics and Child Health, Section of Medical and Molecular Genetics, University of Birmingham, BIRMINGHAM, UNITED KINGDOM; 2) Institute of Pathology, University of Bonn, 53011 Bonn, P.O. Box 2120, Germany; 3) Department of Biomedical Science, University of Sheffield, Western Bank, Sheffield S10 2TN, U.K; 4) CRC Renal Molecular Oncology Research Group, University of Birmingham, The Medical School, Birmingham, B15 2TT, U.K.

Testicular germ cell tumours (TGCTs) are rare heterogeneous neoplasms with differing histological patterns and malignant potential. Like other solid tumours, these may arise through multiple genetic/epigenetic changes in oncogenes and tumour suppressor genes (TSGs). We and others have recently shown that the 3p21.3 TSG RASSF1A is frequently inactivated in various tumour types including lung, breast and kidney. We have now investigated the role of RASSF1A inactivation in primary TGCTs. RASSF1A promoter hypermethylation was detected in 71% (17 of 24) TGCTs from the two major histological types, seminoma and non-seminoma. RASSF1A methylation was significantly less in seminomas versus non-seminomas ($P=0.0346$). We also determined the methylation status of 9 other genes known to be epigenetically inactivated in cancer. None of these genes were methylated in seminomas, whilst in non-seminomas methylation percentages were: MGMT, 47%; FHIT, 29%; APC, 24%; CDH13, 12%; CDH1, 11%; RARBeta, 5%; p16INK4A, 0%; GSTP1, 0% and DAPK, 0%. 61% of non-seminomas but no seminoma samples demonstrated promoter methylation at two or more genes ($P=0.0016$). In conclusion, we demonstrate that RASSF1A inactivation by promoter hypermethylation is the most frequent epigenetic event in TGCTs, suggesting that RASSF1A is a candidate 3p21.3 testicular TSG. Furthermore, our findings are consistent with a multistep model of pathogenesis in which RASSF1A methylation occurs early in tumourigenesis and additional epigenetic events characterize progression from seminoma to non-seminoma.

Methylation profiling of Wilms' tumour and adult renal cell carcinoma. *K.J. Wagner¹, N.V. Morgan^{1,2}, R.D. Lees^{1,3}, M.R. Morris^{1,2}, W.N. Cooper¹, R.G. Grundy^{1,4}, F. Macdonald³, T. Kishida⁵, M. Yao⁵, P. Schraml⁶, F. Latif^{1,2}, E.R. Maher^{1,2,3}.* 1) Section of Medical and Molecular Genetics, Department of Paediatrics and Child Health, University of Birmingham, Birmingham B15 2TT, UK; 2) Cancer Research UK Renal Molecular Oncology Group, University of Birmingham, Birmingham B15 2TT, UK; 3) West Midlands Regional Genetics Service, Birmingham Womens Hospital, Birmingham B15 2TG, UK; 4) Department of Paediatric Oncology, Birmingham Childrens Hospital; 5) Yokohama City University School of Medicine, Japan; 6) Institute for Pathology, University of Basel, Switzerland.

To investigate the role of epigenetic gene silencing in the pathogenesis of Wilms' tumour (WT) and adult renal cell carcinoma (RCC) we determined their methylation profile using a candidate gene approach. Thus 40 WT and up to 49 adult RCC were analysed by methylation-specific PCR for promoter methylation at *CASP8*, *CDH1*, *CDH13*, *DAPK*, *MGMT*, *p14^{ARF}*, *RASSF1A*, *p16^{INK4a}* and *RARb* in primary WT and *CDH1*, *CDH13*, *DAPK*, *MGMT*, *RASSF1A*, and *RARb* in primary RCC. WT demonstrated a high incidence of *RASSF1A* (56%), *CASP8* (43%) and *MGMT* (30%) methylation and intermediate frequencies at *p14^{ARF}* (15%), *p16^{INK4a}* (10%) and *DAPK* (11%). The frequency of *MGMT* methylation was higher in stage 1 and 2 tumours (50%) than in stage 3 and 4 tumours (17%) but this did not reach statistical significance ($p=0.06$). RCC were most frequently methylated at *RASSF1A* (25%), *DAPK* (24%), *CDH1* (16%), and *MGMT* (9%). Papillary RCC demonstrated a higher frequency of *DAPK* methylation (43%) than clear cell tumours (19%) ($p=0.14$). We have demonstrated that *de novo* promoter methylation is frequently implicated in the pathogenesis of WT and RCC but that methylation profiles differ between the two tumour types. Combining our results with data from previous studies, it appears that promoter methylation occurs frequently (>20% of primary tumours) at *CASP8*, *RASSF1A*, *H19* and *MGMT* in WT and at *RASSF1A*, *TIMP3*, *DAPK*, *CDH1* and *GSTP1* in RCC.

Mitochondrial DNA mutations in the buccal mucosal cells of smokers with lung cancer. *L.L Liu¹, P. Shields², L.J. Wong¹*. 1) Institute for Molecular and Human Genetics, Georgetown University Medical Center, Washington DC; 2) Lombardi Cancer Center, Georgetown University Medical Center, Washington DC.

Tobacco effects on buccal mucosal cell have been demonstrated in some studies. Smoking is the single greatest risk factor of lung cancer. It damages the DNA of buccal mucosal cell. The mitochondrial DNA (mtDNA) mutations scattered through coding and noncoding regions have been reported in lung cancer. The aim of this study was to determine whether mtDNA mutations could be detected in buccal mucosal cells of the patients with lung cancer and whether mtDNA mutations in buccal mucosal cells would provide an alternate source of tissue for lung cancer biomonitoring. Eight buccal mucosal cells were brushed, and their corresponding blood samples were drawn from the patients with lung cancer. The entire mitochondrial genome was amplified with 32 pairs of overlapping primers. MtDNA mutation was screened by temporal temperature gradient gel electrophoresis (TTGE) method. DNA fragments showing different banding patterns between buccal mucosal cell and paired blood mtDNA were sequenced to identify the mutations. All 8 (100%) samples had somatic mtDNA mutations. Seven of them had mutations in the hypervariable D loop region. Three buccal mucosal cells had one mutation each. Each of the remaining samples had multiple somatic mutations. Among a total of 19 somatic mutations, 7 were in mRNA (36.8%) and 12 (63.2%) in the hypervariable D loop region. All of the mRNA mutations are located in COX subunit encoding region. Fifteen DNA alterations were at the heteroplasmic state in buccal mucosal cell. The remaining 4 mutations were homoplasmic. Common 5 kb deletion of mtDNA was not detected in all samples by PCR. The high incidence of mtDNA mutations found in buccal mucosal cells in patients with lung cancer suggests that smoking causes mtDNA alterations that may play an important role in tumorigenesis of lung cancer. Further studies will be needed to determine the pathological effects of somatic mtDNA mutations and their relationship to lung cancer.

Genetic association of the UDP-glucuronosyltransferase (*UGT1A1*) gene polymorphisms with hepatocellular carcinoma in a Korean male population. C.S. Ki¹, K.A. Lee¹, J.H. Lee², S.S. Cho³, J.W. Kim¹. 1) Department of Laboratory Medicine, Samsung Medical Center, Seoul, Korea; 2) Department of Internal Medicine, Samsung Medical Center, Seoul, Korea; 3) Center for Clinical Research, Samsung Biomedical Research Institute, Seoul, Korea.

Although chronic infection with hepatitis B (HBV) or C virus (HCV) is a well-known risk factor for hepatocellular carcinoma (HCC), only about one fifth of chronic carriers are expected to develop HCC in their lifetime, suggesting that there may be an inter-individual variation in susceptibility to HCC. This study was designed to test a hypothesis that any functional polymorphisms in the genes related to lowering antioxidant capacity may be associated with genetic susceptibility to oxidative damage and HCC. Since bilirubin is a well-known physiological antioxidant and several functional polymorphisms in the *UGT1A1* gene explaining unconjugated hyperbilirubinemia have recently been reported, we performed an association analysis by comparing the genotype and allele frequencies of the *UGT1A1* gene polymorphisms between 212 male patients with HBV-associated HCC and 329 age- and sex-matched controls. Three functional polymorphisms in the *UGT1A1* gene were genotyped by direct sequencing; a -3263T/G polymorphism at the phenobarbital-responsive enhancer module, a TA repeat polymorphism (*UGT1A1**28) in a putative TATA box in the promoter region, and a 211G/A polymorphism (Gly71Arg; *UGT1A1**6) in exon 1. There was no statistical difference in the genotype and allele frequencies of the *UGT1A1* gene polymorphisms between HCC and controls. However, serum bilirubin concentrations were significantly different among controls with different *UGT1A1* genotypes ($p < 0.0001$). Based on this observation, HCC and controls were divided into two groups with low or high bilirubin genotypes. Reanalysis with these groups revealed that subjects with high bilirubin genotypes were significantly fewer in HCC than those in controls (11.7% vs. 19.1%; $c^2 = 5.19$, $p = 0.022$, OR = 1.79, 95%CI 1.05 - 3.08), which is consistent with our hypothesis. These data suggest that the *UGT1A1* gene polymorphisms may, in part, explain inter-individual susceptibility to HCC.

Novel chemotherapy resistance markers in osteogenic sarcoma. *M.B. Mintz^{1,3}, R. Sowers², R. Gorlick², D.A. Stephan¹.* 1) Dept Genetic Medicine, Childrens Hosp, Washington, DC; 2) Memorial Sloan-Kettering Cancer Center, New York, NY; 3) George Washington University, Department of Genetics, Washington, DC.

Osteosarcoma is a bone tumor that occurs predominately in adolescents and adults, with the average age of diagnosis being 15 years of age. Osteosarcoma accounts for approximately 6% of childhood tumors and is the most common malignant bone tumor in children. Current treatment for osteosarcoma involves multi-agent chemotherapy followed by limb salvage surgery. Drug resistance continues to be the major problem preventing long-term survival of many osteosarcoma patients. Tumors that do not respond to preoperative chemotherapy result in patients with poor survival rates due to the occurrence of metastases and relapse. Due to the lack of reliable markers predicting the response to chemotherapy at the time of diagnosis, risk assessment and subsequent treatment modification is not possible. The goal of this project is the identification of novel markers that are associated with poor prognostic outcome and low disease-free survival rates in osteosarcoma patients. 40 tumor samples from patients before chemotherapy treatment were studied. 20 tumor samples were obtained from patients who did not respond to chemotherapy, while the remaining 20 samples were obtained from patients who were responsive to chemotherapy. The gene expression profiles from these tumor samples was investigated through the use of using Affymetrix® U95Av2 GeneChips (~12,600 genes). Data extraction and normalization was conducted using Affymetrix® MicroArray Suite 5.0. Thereafter, genes were cropped in a systematic fashion to eliminate those that showed no expression or little variation across all of the tumors. Supervised clustering was used to identify expression correlates of therapy resistance, and these genes were expanded to encompass a pathogenic model. We are currently validating these markers on independent sample sets. We hope to begin prospective diagnostic trials as well as preclinical studies with compounds that target resistant tumors shortly.

SCREENING FOR GERMLINE MUTATIONS OF CANDIDATE GENES IN SARDINIAN CANCER

FAMILIES. *M. Colombino*¹, *G. Palomba*¹, *A. Cossu*², *M. Pisano*¹, *M.P. Satta*¹, *M.G. Sarobba*³, *A. Farris*³, *M.F. Dedola*⁴, *A.A. Carboni*², *A. Manca*², *F. Tanda*², *G. Palmieri*¹. 1) Istituto Genetica Popolazioni, C.N.R., Alghero; 2) Istituto di Anatomia Patologica, University of Sassari; 3) Oncologia Medica, University of Sassari; 4) Radioterapia, University of Sassari; Italy.

Sardinian population is genetically homogeneous and seems to be instrumental to better understand the genetic counterpart of a complex disease like cancer. To evaluate the role of disease-causing mutations in breast cancer (BC) as well as colorectal carcinoma (CRC), we screened tumor susceptibility genes (BRCA1 and BRCA2, for BC; MLH1 and MSH2, for CRC) in apparently unrelated Sardinian BC/CRC cancer families with at least three affected members. Paired normal and tumor samples from familial CRC patients were screened by PCR for microsatellite instability (MSI), followed by MLH1/MSH2 mutation screening on germline DNA. For BC, two deleterious BRCA1/2 germline mutations (BRCA2-8765delAG and BRCA1-Lys505ter) were found in 15 (23%) out of 64 BC families analyzed. BRCA2-8765delAG was detected in 13/15 (87%) BRCA1/2-positive families and demonstrated to be a founder mutation. Prevalence of BRCA1/2 mutations in BC families was significantly correlated to the total number of BC cases and increased by the presence of a) at least one case of ovarian or male-breast cancer; or b) three generations affected, or c) bilateral BC. For CRC, MSI was markedly higher in familial (18/27; 67%) than sporadic (32/193; 17%) cases among 220 patients investigated for family cancer history. To date, 1 (4%) and 10 (40%) out of 25 CRC families presented MLH1 and MSH2 germline mutations, respectively. Again, MLH1/MSH2 mutations were associated to the total number of either CRC or endometrial cancer (EC) cases in the family [7/12 (58%) families with at least 4 CRC/EC cases vs. 4/13 (31%) families with three or less CRC/EC cases]. BRCA2 and MSH2 mutations seem to be strongly correlated to cancer development in BC and CRC families from Sardinia, respectively. Presence of the above-described features should address BC/CRC patients and their families to genetic counseling and mutation analysis. Work was funded by Regione Autonoma Sardegna and A.I.R.C.

A population based study in Northern Sweden: cancer risks and mutation analysis of the *hMLH1*, *hMSH2* and *hMSH6* genes in patients with double primary tumours of the colorectum and the endometrium. *K. Cederquist*¹, *M. Emanuelsson*², *I. Goransson*², *R. Stenling*³, *I. Golovleva*¹, *H. Gronberg*². 1) Med Biosciences, Med Genetics, Umea University, Umea, Sweden; 2) Radiation Sciences, Oncology, Umea University, Umea, Sweden; 3) Med Biosciences, Pathology, Umea University, Umea, Sweden.

Hereditary non-polyposis colorectal cancer, HNPCC, is an autosomal dominant condition predisposing to cancers primarily of the colorectum and the endometrium. The aim of this study was to estimate the risk of colon and other HNPCC-associated cancers in relatives of persons with double primary (DP) tumours of the colorectum and the endometrium and to investigate the *hMLH1*, *hMSH2* and *hMSH6* mutation spectrum of the microsatellite instability (MSI) positive patients.

Family histories of cancer were obtained on 89 persons with DP cancers of the colon and the endometrium, identified through the Regional Cancer Registry at the University Hospital of Umea. The cancer risks in their 649 first-degree relatives and the MSI status of 78 proband tumours were analysed. The cancer risks were estimated in relation to MSI status and age at diagnosis in the proband (over or under 50 years) and the standardised incidence ratio (SIR) was calculated. The *hMLH1*, *hMSH2* and *hMSH6* mutation spectrum of 23 MSI positive patients was investigated by DHPLC analysis and direct sequencing.

The overall SIR was 1.69 (95% CI; 1.39-2.03). The highest cancer risk was seen in the ≤ 50 years age group (SIR=2.67), especially when MSI positive (SIR=3.17). 30 tumours (38.5%) were MSI positive. 14 MSI positive patients had sequence variants of *hMLH1*, *hMSH2* or *hMSH6*, likely affecting the function of these genes. The majority of the mutations (71%) were found in patients diagnosed before or at the age of 50. Four of the mutations detected were novel: one frameshift mutation affecting *hMSH2*, one nonsense mutation affecting *hMSH6* and two missense mutations affecting *hMLH1* and *hMSH6*. Notably, the *hMSH6* mutations were found in six different families originating from the same geographical area and therefore expected to be founder mutations.

RNASEL mutations are infrequent in hereditary prostate cancer families. *K.A. Cooney^{1,2}, K.A. Zuhlke¹, A. Griffin¹, Y.Q. Wu¹, L.P. Tomsho¹, S.B. Gruber^{1,3}, E.M. Lange⁴, H. Chen¹.* 1) Department of Internal Medicine, University of Michigan Medical School, Ann Arbor, MI; 2) Department of Urology, University of Michigan Medical School, Ann Arbor, MI; 3) Department of Epidemiology, University of Michigan School of Public Health, Ann Arbor, MI; 4) Department of Public Health Sciences, Wake Forest University School of Medicine, Winston-Salem, NC.

Recently, Carpten et al. have reported the identification of mutations in the RNASEL gene occurring in two out of eight multiplex prostate cancer families with evidence of prostate cancer linkage to chromosome 1q24-25 markers (Nat Genet 30: 181, 2002). To test the hypothesis that the RNASEL gene is the prostate cancer susceptibility gene HPC1 on chromosome 1q, we examined genomic DNA from 95 affected men in 75 multiplex prostate cancer families, including 19 families with evidence of linkage to 1q24-25 markers, from the University of Michigan Prostate Cancer Genetics Project for RNASEL mutations. Direct sequence analysis of the coding region revealed four rare missense/nonsense mutations (G59S, I97L, V247M, E265X) occurring in four unrelated families. All four of the families harboring RNASEL mutations are white, and two of the families exhibited evidence of linkage to chromosome 1q24-25 markers. However, the mutation co-segregated with disease status in only one family. None of four reported rare mutations (M11, G59S, V247M, and E265X) were observed in a panel of 75 control DNA samples or in any of the 103 cases and 323 control samples from a population-based study of prostate cancer in African Americans. Taken together, our results suggest that RNASEL mutations do not completely account for the HPC1 linkage evidence and additional studies of 1q24-25 candidate genes should be performed.

Automated construction of tissue microarrays from morphologically selected sites: a powerful method for studies of genetic heterogeneity of cancer. *G.H. Hostetter¹, J. Kakareka², G. Salem², J. Hubbell¹, J. Kononen¹, U. Wagner¹, R. Cornelison¹, T. Pohida², O-P. Kallioniemi¹.* 1) Cancer Genetics Branch, NHGRI, NIH, Bethesda, MD; 2) Center Information Technology, NIH, Bethesda, MD.

Tissue microarrays (TMAs) are an invaluable tool for the rapid in situ analysis of genetic alterations and molecular targets in tumors and precursor lesions. We developed a robotic tissue arrayer to facilitate large-scale and customized TMA studies. Digital images are first scanned from hematoxylin-eosin stained tissue sections and regions are selected for punching. The arrayer automatically acquires tissue cores from pre-selected donor sites and deposits the cores in the TMA blocks. Up to 21 TMAs can be constructed at a time using a computer-controlled, motorized stage that controls the X-Y-Z movements of the punching apparatus. The robotic arrayer has been used to array up to 2250 tumors including tumor specific arrays of melanoma (352 cores), testicular germ cell tumors (532 cores), prostate tumors (240 cores) and breast tumors (300 cores). Precision and accuracy of arraying compared favorably with the manual arraying method. A centralized database permits archiving and subsequent retrieval of sites sampled in clinical samples that are heterogeneous, including precursor lesions and invasive cancer. The application of TMAs of different stages of breast cancer (normal, ADH, DCIS, and invasive cancer) in FISH analysis with Her-2, c-myc, cyclin D, and EGFR-1 oncogene probes (Vysis, Inc.) demonstrates the utility of this method for studies of tumor heterogeneity. In summary, a robotic computer-controlled tissue arraying instrument with a block marking feature was developed and applied to construct tissue arrays for studies of genetic heterogeneity of cancer.

Comprehensive assay development for Hereditary Non-polyposis colon cancer. *M.R. Hegde, D. Odenbaugh, Y.P. Weng, C.S. Richards.* Baylor College of Medicine, Department of Molecular and Human Genetics, Houston, TX.

Colorectal cancer is the second leading cause of cancer related death in the United States accounting for more than 57,000 deaths per year. While the majority of colorectal cancer is not inherited, inherited CRC accounts for up to 10% of total cases, and primarily consists of familial adenomatous polyposis (1%), or hereditary non-polyposis colon cancer (HNPCC). Hereditary non-polyposis colon cancer (HNPCC) is an autosomal dominant disorder, which is genetically heterogeneous. Mismatch repair (MMR) genes, primarily MLH1, MSH2, and MSH6, are causative of this disorder. The challenge to the identification of the HNPCC is to separate sporadic tumors from HNPCC tumors. Additionally, the large size of these causative genes makes identification of mutations both labor intensive and expensive. We have developed a comprehensive assay, which includes microsatellite instability assay (MSI), methylation assay and mutation scanning for MMR genes using denaturing high performance liquid chromatography (dHPLC). The MSI assay includes NCI recommended panel and five additional microsatellites. Hypermethylation of the MLH1 promoter is screened using a PCR-based assay. Our criteria for selection of HNPCC candidates includes family history analysis using Bethesda criteria, a high level of MSI in the tumor and absence of methylation of the MLH1 promoter prior to mutation analysis by dHPLC. The dHPLC approach is an attractive option for clinical molecular laboratories because of its high throughput capability and cost effectiveness. Our assay consists of 51 sets of primers to amplify all exons of these genes. All PCR reactions were designed for a single set of conditions and are amplified simultaneously in a 96-well format. The amplified products are analyzed by dHPLC, using the optimum temperature and variations for partial denaturation based upon each specific fragment melting profile. We anticipate no false positive results of the assay, since all positive results obtained by dHPLC are confirmed by automated sequence analysis prior to reporting. The combination of the above mentioned approaches will allow for greater sensitivity and a more directed molecular analysis.

Identification of a novel 26 kb deletion in *BRCA1* by haplotype pair analysis. *B.D. Ward, B.C. Hendrickson, C.A. Gaglio, T. Scholl.* Myriad Genetic Laboratories, Salt Lake City, UT.

The identification of intragenic rearrangements is important for a comprehensive understanding of mutations that occur in clinically important genes. We report the identification of a novel, recurrent 26 kb deletion in *BRCA1*.

An algorithm employing expectation maximization statistics was used to derive *BRCA1* haplotypes from unphased coding nucleotide polymorphism data and then identify unusual haplotypes suggestive of intragenic deletions. Data for 5911 completely anonymized samples were processed through this algorithm. Six samples were observed with a genotype that did not match pairs of known canonical haplotypes, and which possessed strong family histories of breast and/or ovarian cancer and negative clinical full gene-sequencing tests for *BRCA1* and *BRCA2*. The genotypes for these samples closely resembled a combination of the consensus haplotype and a common, non-consensus haplotype defined by eight polymorphisms in exons 9, 11, 13 and 16. In these six DNAs, the exon 16 polymorphism was homozygous for the non-consensus base, whereas the remaining polymorphisms were heterozygous. This haplotype could be explained by intragenic deletions on the consensus chromosome that include exon 16 and with upstream breakpoints 3' of exon 13.

Long range PCR results from two of the six samples produced a fragment 26 kb shorter than the expected wildtype fragment (32 kb) when amplified with primers in exon 13 and exon 21. This suggested a deletion encompassing exons 14 through 20. The deletion region was further defined using restriction mapping of the mutant fragment. The breakpoint, which resulted from inter-*Alu* recombination was completely characterized by nucleotide sequencing. Because the deletion occurred on the consensus chromosome, a group of 417 completely anonymized samples with uninformative haplotypes was assayed for this new mutation. One additional sample with the same 26 kb deletion was identified, which strongly suggests its presence in unrelated families. Finally, an allele specific PCR assay was developed and currently detects this deletion as a part of the comprehensive clinical analysis of the *BRCA* genes.

A novel method to rapidly screen for large genomic deletions or duplications in the BRCA1 gene. *G. Pals¹, P.N. Nederlof², J.J.P. Gille¹, M. Grippeling¹, R. Pruntel², F.H. Menko¹, I. Kluijt³, C. Dommering¹, S. Verhoef^{2,3}, J. Schouten⁴, L.J. van 't Veer², F.B.L. Hogervorst².* 1) Clinical Genetics, VU medical center, Amsterdam, Netherlands; 2) Family Cancer Clinic, Netherlands Cancer Institute, Amsterdam, Netherlands; 3) Department of Clinical Genetics, Academic Medical Center, Amsterdam, Netherlands; 4) MRC Holland, Amsterdam, Netherlands.

The majority of the families seeking advice at a family cancer clinic are those with familial breast/ovarian cancer. Often they are offered mutation analysis of the BRCA1 and BRCA2 genes, which is usually restricted to the analysis of PCR fragments from genomic DNA. However, a wide variety of different exon deletions and duplications in the BRCA1 gene have been described. Here, we present a simple and reliable method to detect all possible single or multiple exon deletions and duplications in the BRCA1 gene. The method, called multiplex ligation-dependent probe amplification (MLPA), is PCR based and allows the relative quantification of many different sequences in a single tube. In a collaborative study, we have tested more than eighthundred individuals in which routine DNA-diagnostic analysis did not reveal a mutation in either BRCA1 or BRCA2. This study identified 5 different mutations in this gene among which are a deletion of exon 8 and duplications of exon 21-23 and 17-19 that are not reported before. Furthermore, all identified mutations were found only once, suggesting that there is no additional high frequency founder mutation like the genomic deletions of exons 13 or 22. The MLPA test for BRCA1 proved to be a very efficient and reliable test, which can easily be implemented in the DNA-diagnostic laboratory. Furthermore, it provides a means to screen all counselees for large genomic deletions/duplications and thus improves the diagnostic mutation screening.

Tampa Bay Ovarian Cancer Study - a population-based study of BRCA1/2 in ovarian cancer. *T. Pal^{1,2}, J.P. Krischer^{1,2}, T. Holtje², J.A. Betts², J. Permuth-Wey^{1,2}, J. Fiorica^{1,2}, E. Grendys^{1,2}, J. LaPolla³, H. Arango⁴, K. Wakeley¹, M. Hoffman¹, G. Wilbanks¹, S. Nicosia^{1,2}, R. Sutphen^{1,2}.* 1) Departments of Interdisciplinary Oncology, OB-GYN, Pathology and/or Pediatrics, University of South Florida College of Medicine, Tampa, FL; 2) H. Lee Moffitt Cancer Center and Research Institute, Tampa, FL; 3) Bay Front Medical Center, St. Petersburg, FL; 4) Morton Plant Mease Healthcare, Clearwater, FL.

BRCA1 and BRCA2 are believed to account for the majority of hereditary ovarian cancers. Current estimates of mutation likelihood among ovarian cancer patients range from 9.2% (Myriad data) to 11.7% (Ontario population data, the only published population-based data). To determine the prevalence, spectrum of mutations and genotype/phenotype correlations among ovarian cancer cases, we are conducting a population-based study of unselected incident cases of epithelial ovarian cancer in the geographic regions of Hillsborough and Pinellas counties, Florida (which includes Tampa, St. Petersburg, and Clearwater). Beginning in 2001, we have enrolled 100 women diagnosed with incident ovarian cancer, ascertained through their treating gynecologic oncologists. Medical records and tumor tissue have been reviewed and genetic counseling and DNA testing performed through full sequencing of the BRCA1 and BRCA2 coding regions and adjacent intronic base pairs. Of the first 100 women enrolled in the study, 15 (15.0%) had mutations in BRCA1 or BRCA2: 7 in BRCA1 and 8 in BRCA2. No mutations were found among the 6 cases with mucinous tumors. No mutations were found among the 5 cases with borderline tumors; thus, the mutation frequency among invasive tumors was 15.8% (15/95). These data suggest that 1) the frequency of BRCA1 and BRCA2 mutations among invasive ovarian cancer cases may be higher than previously reported, 2) previous studies may have underestimated the contribution of BRCA2 to ovarian cancer, especially mutations outside the ovarian cancer cluster region (OCCR). Preliminary data regarding risk factors, penetrance, associated cancers and tumor characteristics is being analyzed and will also be presented.

Mutation analysis of the *HCCS1* gene in medulloblastomas. F. Zhang¹, J.A. Biegel^{1, 2}. 1) Division of Human Genetics and Molecular Biology, The Children's Hospital of Philadelphia, Philadelphia, PA. 19104; 2) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, PA 19104.

Medulloblastomas and related primitive neuroectodermal tumors (PNETs) of the central nervous system are malignant, invasive embryonal tumors with predominantly neuronal differentiation that comprise 20% of pediatric brain tumors. Cytogenetic analysis has shown that alterations in chromosome 17, particularly the loss of 17p and the formation of an isochromosome 17q, are the most common changes among this group of tumors, implicating loss or inactivation of a tumor suppressor gene in 17p. A novel tumor suppressor gene, *HCCS1*, located at 17p13.3, was recently reported to have a high frequency of mutations in hepatocellular carcinoma (HCC) samples (Zhao, X et al, Cancer Res, 61:7383-7387, 2001), whereas no alteration was found in matched noncancerous liver tissues. The purpose of this study was to determine whether *HCCS1* is a candidate tumor suppressor gene for medulloblastoma. Forty-five medulloblastoma/PNET samples and fifteen normal control cDNAs from lymphocytes or normal brain tissues, were screened for mutations within a full-length *HCCS1* cDNA using RT-PCR and sequence analysis. Three tumors had deletions of one or more exons of the *HCCS1* gene, but matched blood samples or noncancerous tissue were not available for comparison. Four polymorphisms, including the 341-427 deletion reported as a liver tumor specific mutation, were found in tumor and/or normal cDNA samples. Further studies are needed to confirm the presence of the tumor associated mutations of the *HCCS1* gene in medulloblastoma/PNET before it should be considered a good candidate for a 17p13 medulloblastoma tumor suppressor gene.

Genetic risk factors for progression to lymphoma in AIDS patients. *U. Potocnik, M.P. Martin, B. Gold, X. Gao, M. Dean, M. Carrington.* Lab. of Genomic Diversity, NCI at Frederick, Frederick, MD, USA.

The frequency of B-cell non-Hodkin's lymphomas (NHL) is high in patients infected with HIV and account for a significant fraction of HIV-related mortality. AIDS lymphomas are particularly resistant to treatment. Immune surveillance is suggested to play an important role in lymphomagenesis. Previous studies demonstrated that the deletion allele in the CCR5 chemokine receptor gene (CCR5-delta 32 allele) is associated with 3-fold lower risk of NHL. In this study we used PCR-Taqman for SNPs detection in some genes involved in immune response, multidrug resistance and tumor suppression. The killer immunoglobulin-like receptor genes (KIR) which code for one family of natural killer cell receptors were typed by PCR-SSP. For typing of KIR genes coding for Natural killer cell receptors. HLA-class I typing was performed by PCR-SSOP. The genotypes were compared between AIDS patients with NHL and AIDS patients without NHL (controls). A significant difference between the two groups was observed in the frequency of inhibitory KIR genes, particularly 2DL2 and 2DL3 alleles ($p=0.0059$). Also the distribution of HLA class I alleles differed between groups. The combination of KIR 2DL3 and HLA-Cw*0701 which serves as a ligand for KIR 2DL3 was higher in NHL patients as compared to controls. Functional MDR1 polymorphisms (G2677T and C3435T) were less frequently found in NHL patients as compared with controls though these were only at the borderline of statistical significance. We found no correlation between polymorphisms within chemokine genes CCR2 and CX3CR1 and the tumor suppressor genes BRCA1 and BRCA2 with progression to NHL. These results suggest several genes contribute to the susceptibility for NHL in AIDS patients.

Identification of a Candidate Oncogene SEI-1 within a Minimal Amplified Region at 19q13.1 in Ovarian Cancer Cell Lines. *X-Y. Guan¹, T.C.M. Tang¹, J.S.T. Sham¹, D. Xie¹, Y. Fang².* 1) Dept Clinical Oncology, Univ Hong Kong, Hong Kong, China; 2) Cancer Institute, Sun Yat-Sen University, Guangzhou, China.

High-level amplification of DNA sequence at 19q13.1-q13.2 in ovarian cancer has been frequently detected by chromosome microdissection and comparative genomic hybridization (CGH). This strongly suggests that 19q13.1-q13.2 contains putative oncogene(s) which plays an important role in the development or progression of ovarian cancer. In an attempt to verify the nature of amplification events and identify minimal amplified region (MAR) at 19q13.1-q13.2, we surveyed the amplification status in this region in four ovarian cancer cell lines that have been confirmed containing amplification at 19q13.1-q13.2. Fluorescence in situ hybridization (FISH) with 30 cosmid clones and Southern blot hybridization with 19 DNA markers within the region from D19S425 to D19S907 (about 19.5 cM) were performed. Two separated overlapping MARS, MAR1 (200 kb) and MAR2 (1 Mb), were identified at 19q13.1. MAR2 contains two candidate oncogenes AKT2 and SEI-1. Amplification and overexpression of these two genes in four ovarian cancer cell lines were confirmed by Southern and Northern blot analyses. The proliferation-related function of AKT2 and SEI-1 suggests that both genes are likely to be biological targets of amplification event at 19q13.1 in ovarian cancer and play important roles in ovarian tumorigenesis.

Correlation between NF- κ B/GM-CSF expression and functional status of the p16 melanoma susceptibility gene.

P. Ghiorzo¹, C. Gramigni¹, M. Mantelli¹, L. Pastorino¹, S. Gargiulo¹, B. Banelli², M. Romani², B. Villaggio³, C. Garré¹, G. Bianchi-Scarrá¹. 1) Dept Oncology Biol. Genetics, Univ. of Genova, Genova, Italy; 2) National Cancer Institute, Genova, Italy; 3) Dept Internal Medicine, Univ. of Genova, Genova, Italy.

P16 loss of expression correlates with tumor progression in sporadic melanoma and the presence of germline mutations in a subset of melanoma families suggests that its inactivation could be an early step in melanomagenesis. Alternative targets for p16 other than CDK4 have been identified: p16 also binds and inhibits NF- κ B, which regulates the transcription of a variety of genes including p53, cyclinD1 and GM-CSF. NF- κ B protein dimers are mostly detected in the cytoplasm and are bound to I κ B via ankyrin domains. Several stimuli activate NF- κ B allowing it to translocate into the nucleus. We aimed to verify whether p16-impairing alterations affect the expression of NF- κ B and dependent genes. Five metastatic melanoma cell-lines, including 1 stabilized from a familial case, were used to evaluate expression of the p16/NF- κ B/GM-CSF genes by IHC. We then analyzed NF- κ B activation by EMSA with specific antibodies (p50, p65, c-rel), and positive responsive elements, both canonical and in the GM-CSF promoter. Most of the cell lines, as compared with NHEM, exhibited constitutive activation of the NF- κ B complex, which was found to correlate with NF- κ B/I κ B expression and subcellular localization by IHC. NF- κ B expression correlated with EMSA experiments and localization of I κ B and GM-CSF expression correlated with its receptor. Methylation affected p16 expression in 3 of the 5 melanoma cell lines. These results do not rule out that alteration of p16 expression may favor constitutive transcription of different cytokines and neoplastic growth via an autocrine pathway in a tissue-specific manner. Melanoma cell lines represent useful models for studying this correlation, but in vivo expression studies on melanoma lesions can help in discriminating between different stages of progression. This study was supported by Ministry of Health Grant ICS 030.1/RF99.32 to G.B.S. The last two authors contributed equally.

A role for the DNA mismatch repair proteins Msh2 and Msh6 in the response of MEFs and keratinocytes to UVB-induced DNA damage. *S.E. Andrew¹, L. Young¹, A.C. Peters¹, L.T. Leong¹, E. Chomey², V. Tron².* 1) Dept Medical Genetics, Univ Alberta, Edmonton, AB, Canada; 2) Dept Laboratory Medicine and Pathology, Univ Alberta, Edmonton, AB, Canada.

The DNA mismatch repair (MMR) system maintains genomic stability by repairing post-replicative DNA errors. It has also been shown to repair DNA damage inflicted by exogenous agents. Recent studies have shown that MMR is also required for apoptosis in response to alkylating agents, aromatic amines and polycyclic aromatic hydrocarbons. Thus MMR may protect cells from DNA damage by sensing damage and activating repair or apoptosis pathways. The MMR protein MSH2 has previously been shown to bind to UV-induced DNA adducts and complex with the nucleotide excision repair proteins that repair such adducts, however a role for MMR post-UV has been controversial. We propose that Msh2 and Msh6 play a role in mediating cellular responses post-UV treatment. Specifically, we ask if MMR participates in the decision to repair or apoptose. We show that the MMR proteins are induced by UVB irradiation in primary keratinocytes and MEFs and this induction is at least partially p53-independent. We demonstrate in primary cells from Msh2 proficient and deficient mice that repair of UVB-induced thymine dimers is significantly impaired without functional MMR. This involvement of Msh2 in thymine dimer repair also appears to be independent of p53. Msh2^{-/-} and Msh6^{-/-} cells demonstrate increased viability following UVB irradiation. We also demonstrate reduced levels of UVB-induced apoptosis in MMR deficient fibroblasts compared to wildtype. Furthermore, in vivo experiments will determine whether Msh2 and Msh6 deficient mice display an increased susceptibility to UV-induced skin tumours, which would strongly support a role for MMR in UV-induced tumorigenesis. Thus we suggest that the MMR proteins Msh2 and Msh6 are involved in the cellular response to UVB-induced DNA damage, including thymine dimer repair, apoptosis, and tumorigenesis, affirming the possibility that the MMR system acts as a broad spectrum DNA damage sensor.

Unusual pattern of age-related somatic mutation in cell lines derived from carriers of the BRCA1 and 2 genes. *R. Das, S.G. Grant.* Environmental and Occupational Health, University of Pittsburgh, Pittsburgh, PA.

Cancer, including breast cancer, is caused by the accumulation of somatic mutations in oncogenes, tumor suppressor genes and mutator genes. Most cancer-predisposing human diseases involve the loss of fidelity of DNA metabolism or repair. We have shown that these diseases are often characterized by elevated frequencies of in vivo bone marrow somatic mutation. Somatic mutation is an unavoidable consequence of cellular replication and metabolism, and the frequency of in vivo somatic mutation has been shown to significantly increase with age. We obtained immortalized lymphoblastoid cell lines from five carriers of mutations in the breast cancer predisposing BRCA1 gene, four carriers of mutations in the BRCA2 gene and nine normal individuals of widely varying age at time of blood donation. We then applied the clonogenic HPRT mutation assay to these cell lines to determine whether carrier status for these potential mutator genes affected their baseline mutation frequencies. First, we established that an aging effect indistinguishable from that observed in vivo could be demonstrated amongst the normal cell lines. The slope of the age regression indicates an increase of one new mutation per million cells every four years over lifetime. By first purging the input cell populations of pre-existing mutants we were able to demonstrate that at least two mechanisms contribute to this increase: an intrinsic increase in the mutation rate that may be related to an overall loss of cell viability, and an accumulation of mutants over time. When these same studies were repeated with cell lines established from BRCA1/2 mutation carriers, a much different pattern was evident. Cell lines from young mutation carriers had significantly higher HPRT somatic mutation frequencies than age-matched normal controls, but there was no evidence of any effect of donor age. Thus, by age 60 the frequency of somatic mutation in the cell lines from genetically normal individuals were indistinguishable from the mutation carriers. This is the first description of a distinctive cellular phenotype for carriers of BRCA1/2 mutations that could play a role in their susceptibility to breast cancer.

Qualitative and quantitative change of AIB1 in breast cancer cell lines. *P. Dai*¹, *R. Clarke*², *L.J.C. Wong*¹. 1) Inst Molec & Human Genetics, Georgetown Univ Medical Ctr, Washington, DC; 2) Department of Oncology, Georgetown Univ Medical Ctr, Washington, DC.

The amplifications of AIB1 (amplified in breast cancer) gene in breast cancer cell lines were studied by real time quantitative PCR analysis to determine their relationship to estrogen receptor status and drug (estrogen antagonist or agonist) treatment. Amplifications of AIB1 gene were found in ER positive cell lines, BT-20, ZR-75-1, BT-474, MCF-7 and T47D but not in the ER positive cell lines, BT483, MD-MB-361, MD-MB-468 and MDA-MB-330. Only MDA-MB-435 of the ER negative cell line (MD-MB-57, BT-549, MD-MB-134v, MDA-MB-231N, MDA-MB-436, HBL-100, MDA-MB-435, ZR-75-30, Hs 578T) was found to have AIB1 gene amplification. Most AIB1 amplifications occurred in the ER positive cells. Different passages of MCF-7 cell (MCF-7 p19, MCF-7 p72) and their variants (LCC-1, LCC-2, LCC-9, LY-2 and R27) all showed the feature of significant amplification of AIB1 gene. The higher amplification of AIB1 in LCC-1, LCC-9, LY-2 than in their original MCF-7 cells suggest that the gaining of estrogen independence may result in the higher level of amplified AIB1 gene. These data indicate that amplification of AIB1 gene is regulated by hormonal status. Sequencing analysis of poly Q encoding region of AIB1 gene showed that 26% of breast cancer cell lines had 3 or more poly Q repeat encoding sequence patterns. Among them, MD-MB-157, MD-MB-435 and BT-483 had 6, 4, 4 distinct poly Q sequence patterns respectively. LCC-6, the variant of MD-MB-435, even had 7 distinct poly Q sequence patterns. Although all MCF-7 cells and their variants had the same predominant poly Q encoding sequence pattern of (CAG)₃CAA(CAG)₉(CAACAG)₃(CAACAGCAG)₂CAA of the parental cell line, small percentage of altered poly Q sequences were found in all MCF-7 passages and variants. These data suggest somatic instability of AIB1 gene. In conclusion, the poly Q encoding DNA sequence of AIB1 gene is somatically unstable. Its amplification partially depends on the presence of ER and level of amplification may be affected by the estrogenicity of the cellular environment.

Human methylthioadenosine phosphorylase, a gene frequently co-deleted with p16, acts as a tumor suppressor gene. *W.D. Kruger¹, S.A. Christopher¹, P. Diegelman², C.W. Porter².* 1) Population Sci, Fox Chase Cancer Ctr, Philadelphia, PA; 2) Pharmacology and Therapeutics Department, Roswell Park Cancer Institute, Buffalo, NY.

The human MTAP gene is located on 9p21 and is frequently homozygously deleted, along with p16/ARF, in a wide variety of human tumors and human tumor derived cell lines. MTAPs function is to salvage methylthioadenosine (MTA) which is produced as a byproduct of polyamine metabolism. We have reintroduced MTAP into MCF-7 breast adenocarcinoma cells and have examined its effect on the tumorigenic properties of these cells. MTAP expression does not affect the growth rate of cells in standard tissue culture conditions, but severely inhibits their ability to form colonies in soft-agar or collagen. In addition, MTAP expressing cells are suppressed for tumor formation when implanted into SCID mice. This suppression of anchorage-independent growth appears to be due to MTAPs enzymatic activity, as a protein with a missense mutation in the active site does not exhibit this phenotype. MTAP expression causes a significant decrease in intracellular polyamine levels and alters the ratio of putrescine to total polyamines. Consistent with this observation, the polyamine biosynthesis inhibitor α -difluoromethylornithine (DFMO) inhibits the ability of MTAP deficient cells to form colonies in soft-agar, while addition of the polyamine putrescine stimulates colony formation in MTAP expressing cells. These results indicate that MTAP has tumor suppressor activity and suggest that its effects may be mediated by altering intracellular polyamine pools.

Epigenetic control of genomic stability in an endometrial cancer-derived cell line. *N. Joshi, S.G. Grant.*
Environmental and Occupational Health, University of Pittsburgh, Pittsburgh, PA.

It is widely assumed that genomic instability is an early development in carcinogenesis. In a survey of breast and endometrial cancer-derived cell lines, however, we found that baseline frequencies of mutation at the X-linked HPRT locus varied by over three orders of magnitude, from approximately normal frequencies of 10^{-6} to frequencies approaching 10^{-3} . Cell lines with mutation frequencies at the upper end of this range could not be induced with the alkylating agent ethylmethane sulfonate. The same broad range of mutation frequencies could be observed within sublines of the breast cancer cell line MCF7 and the endometrial cancer cell line Ishikawa. To determine whether the genomic stability phenotype of the Ishikawa-ECCA subline, with a mutation frequency of 2.6×10^{-6} , was subject to culture conditions, we grew these cells under conditions of restricted serum (1 and 2% vs. 5, 10 and 15%), which are selective for transformed cells. After one month of growth under these selective conditions the mutation frequency of these cells rose dramatically to 10^{-3} , similar to the frequency observed in the Ishikawa-UNC subline, 3.6×10^{-3} . Similarly, cells grown for 3 and 7 months under these conditions also exhibited mutation frequencies in the range of 10^{-3} or more. Perhaps more significantly, similar increases in uninduced mutation frequency were observed when the Ishikawa-ECCA cells were incubated for only one week in low serum medium, or if they were only selected in this medium. Finally, if the cells grown in 1% serum for one month were returned to 15% serum for one month, they reacquired their original genetic stability. It should be noted that growth in low serum resulted in long doubling times and low cloning efficiencies, even after months of culture under these conditions. One interpretation of these results is that genomic instability arose during the generation of the tumor this cell line was derived from, but that the full tumorigenic phenotype is not expressed under normal, i.e. high serum, culture conditions. These results have important implications for in vitro studies of the fundamental characteristics of the transformed phenotype.

The E2F binding partner DP-1 and its role in cancer progression and differentiation. *M.T. Tilli^{1,4}, M.S. Frech⁴, S.L. Hudgins¹, J-P. Renou³, I. Heletz¹, K.S. Hruska^{1,2}, L. Hennighausen³, J.A. Flaws², P.A. Furth^{1,4}.* 1) Graduate Program in Human Genetics, University of Maryland, Baltimore, Baltimore, MD; 2) Department of Epidemiology and Preventive Medicine, University of Maryland, Baltimore, Baltimore, MD; 3) Laboratory of Genetics and Physiology, NIDDK, NIH, Bethesda, MD; 4) Lombardi Cancer Center, Department of Oncology, Georgetown University, Washington, DC.

The aim of this study was to examine genetic events controlling cancer progression and regression using conditional transgenic mouse models. The T-Antigen (TAg) conditional carcinogenesis model with reversible (4 mo. TAg expression) and irreversible (7 mo.) stages of dysplasia in the salivary gland (SG) was utilized. Differential expression of genes needed for reversal was examined by probing a mouse oncochip cDNA microarray (NCI) of 2600 cancer pathway genes with SG RNA from 4 mo. and 7 mo. old tTA/TAg mice. Two-fold increased expression at 7 mo. was seen in 2 cell cycle regulatory genes, including DP-1, dimerization partner essential for activity of E2F transcription factor family, suggesting a role in reversal. DP-1 was localized to TAg-targeted SG cells in 4 and 7 mo. mice and in SG tumors. Western blot analysis comparing 4 mo. tTA/TAg mice treated with doxycycline revealed 3 closely migrating forms of DP-1. The forms of DP-1 may be due to differences in phosphorylation, with the highest form involved in cellular differentiation, the middle form in cell cycle progression, and the lowest form in cellular quiescence. PPAR γ induces phosphorylation of DP-1, leading to decreased DNA-binding activity of the E2F-DP complex due to a decrease in the ubiquitous serine-threonine phosphatase, PP2A. Treatment with PP2A altered the mobility of the highest form of DP-1, suggesting that DP-1 is differentially phosphorylated during tumorigenesis in this model. ERa's role in cancer was examined by introducing a novel mouse model with conditional dominant gain of ERa (tTA/ERa) into the TAg model. Three tTA/TAg/ERa females, but no tTA/TAg females, developed mammary gland (MG) tumors, suggesting that overexpression of ERa in this model may contribute to MG tumor development.

Somatic alterations of the mitochondrial genome in human hepatocellular carcinomas. *D.J. Tan¹, L. Agress¹, L.L. Liu¹, R.K. Bai¹, J. Chang², L.J. Wong¹.* 1) Institute for Molecular and Human Genetics, Georgetown University Medical Center, Washington, DC; 2) Changhua Christian Hospital, Taipei, Taiwan.

Mitochondria are not only the sites where the reactive oxygen species are generated but also the easy target for oxidative DNA damage. Recent reports have supported the concept that somatic mitochondrial DNA (mtDNA) alteration is a general phenomenon of cancer. In order to investigate the potential role of somatic mtDNA mutations in tumorigenesis, the occurrence of mutations in mtDNA of hepatocellular carcinomas was studied. Somatic mtDNA mutations of the entire mitochondrial genome were screened in 20 pairs of hepatic tumor and surrounding tissues using 32 overlapping PCR primer and temporal temperature gradient gel electrophoresis (TTGE). DNA fragments showing different TTGE banding patterns between normal and tumor mtDNA were followed by direct DNA sequencing to identify the mtDNA mutations. Our results showed that 12 out of 20 (60%) tumors had somatic mtDNA mutations. Eleven of them (55%) had mutations in the hypervariable D loop region, and One had mutation in mRNA. Nine tumors had one mutation, each of the remaining had multiple somatic mutations with a total of 27 mutations. All mutations, except one, 26/27(94.3%) were in the hypervariable D loop region. Among them, 21 were in H-strand origin area (80.7%). Eight were involved in np303-315 poly C region. Quantitative PCR analysis showed that the amount of mitochondrial DNA per cell in 7 tumors was below 50% of the mean. One tumor with a stretch of 12->13 Cs in np303-315 had a 2.7 fold elevation in mtDNA content. Twenty-two mtDNA alterations were at the homoplasmic state in tumor tissue, 5 of them were heteroplasmic state in the surrounding normal tissue. The remaining 5 mutations were heteroplasmic state in tumor. Our study suggests that there is a significantly higher incidence of D loop mtDNA mutations in hepatocellular carcinomas (94.3%) compared to breast cancer (81.5%) and oral cancer (40%). The high instability of poly C tract at np303-309 might play a role in tumorigenesis.

DNA repair gene SNPs as modifiers of BRCA1 and BRCA2 phenotypic expression. *G. Chenevix-Trench*¹, *A. Spurdle*(*kConFab*)¹, *X. Chen*¹, *J. Hopper* (*ABCFS*)², *C. Apicella* (*AJS*)², *B. Newman*³, *M. Cook*⁴, *S. Peock*⁴, *D. Easton* (*EMBRACE*)⁴. 1) Queensland Institute of Medical Research, Brisbane, Australia; 2) University of Melbourne; 3) School of Public Health, Queensland University of Technology, Brisbane; 4) CRC Genetic Epidemiology Unit, University of Cambridge, UK.

We are assessing the role of DNA repair gene variants as modifiers of BRCA1 or BRCA2 mutations, and as low-penetrance breast cancer genes. 552 female BRCA1 and BRCA2 mutation carriers from 337 families, collected through Australian (kConFab, AJBCS, ABCFS) and British sources (EMBRACE), have been screened for the Breakage Excision Repair APE Asp148Glu and XRCC1 Arg399Gln SNPs. Modification of disease presentation was assessed by analysis of shifts in genotype distribution with respect to affected status, and by comparison of age at onset of breast cancer for different genotypes. There was no evidence that the APE 148Glu variant modified disease presentation in the BRCA1 or BRCA2 carriers, for crude analyses or after adjustment for sample source, ethnicity and oophorectomy. However, there was evidence that the XRCC1 Gln allele modified disease presentation in BRCA1 carriers, with a lower frequency of heterozygotes and Gln homozygotes in affected vs unaffected carriers ($P=0.04$). Affected BRCA1 carriers with at least one Gln allele had a marginally older age at onset of breast cancer ($P=0.04$). The XRCC1 variant did not modify disease presentation amongst BRCA2 carriers ($P>0.6$). A population-based case-control-family sample of Australian women, over-sampled for early-onset disease, has been screened for the same BER variants. Results from 1455 cases and 793 controls suggest that the APE Asp148Glu is not associated with breast cancer risk, with ORs of 1.00 (0.81-1.25) and 1.02 (0.80-1.29) for the heterozygote and homozygote Glu genotypes, respectively. The XRCC1 Arg399Gln substitution also occurs at similar frequencies in cases and controls with ORs of 0.94 (0.78-1.14) and 0.98 (0.75-1.30) respectively, for the heterozygote and homozygote Gln genotypes. Analyses with stratification by exposure to environmental risk factors are pending, as are analyses of an additional 95 BRCA1 and BRCA2 carriers.

An investigation of the relationship between DNA repair genotype and histopathological subtype in breast cancer. A. Cox¹, S. Rafii¹, G. Xinarianos¹, I. Azmy², M. Reed², T. Stephenson³, M. Meuth¹. 1) Institute for Cancer Studies, University of Sheffield, UK; 2) Section of Surgical and Anaesthetic Sciences, University of Sheffield, UK; 3) Department of Histopathology, Royal Hallamshire Hospital, Sheffield, UK.

There is considerable evidence to suggest that defects in DNA damage repair, in particular the homologous recombination repair (HRR) pathway of DNA double strand break repair, contribute to breast cancer susceptibility. Recent studies from our own laboratory and others have shown that common polymorphisms in genes involved in HRR, including the *XRCC2* and *XRCC3* genes, have modest effects on sporadic breast cancer risk. To clarify the role of *XRCC2* and *XRCC3* polymorphisms in breast cancer in more detail, we investigated whether they were associated with particular histopathological subtypes. Women with histologically confirmed breast cancer were recruited from surgical out-patient clinics in Sheffield, UK, and detailed demographic, clinical, and histopathological data and a blood sample were obtained from each patient. Genotyping of the *XRCC2 R188H* and *XRCC3 T241M* polymorphisms was performed by 5' nuclease PCR (Taqman™) and PCR-SSCP. Histopathological data were available on 387 tumours; 376 of these were invasive lesions, the remainder were ductal carcinoma in situ. The majority (272, 72.3%) of the invasive tumours were of the ductal NOS (not otherwise specified) type, 40 (10.6%) were lobular, and 64 (17.0%) were ductal special types. The rate of carriage of the *XRCC2 188H* allele was raised in the lobular tumours compared to the ductal NOS tumours (27.5% vs 15.1%, $p=0.05$), with a similar trend for the rate of carriage of the *XRCC3 241M* allele (72.5% vs 58.5%, $p=0.09$). The allele carriage rates in the ductal sub-types were similar to those in the ductal NOS tumours (18.75% and 62.5% respectively). There was no association between either of the polymorphisms and tumour grade or oestrogen receptor status. Whilst these studies require confirmation, they raise the possibility that polymorphisms of the HRR pathway may be relevant to particular breast tumour subtypes.

African-Americans and Caucasians differ in polymorphisms of Glutathione S-transferases and Estrogen Receptor b genes correlated with prostate cancer. *K. Muralidharan, E. David.* Department of Pediatrics, Division of Genetics, Emory University School of Medicine, Atlanta, GA.

The incidence of prostate cancer is the highest among African-Americans. The reason for this increased incidence is not known. Differences in certain polymorphic genes involved in carcinogen detoxification in the prostate or in prostate development and differentiation could contribute to this difference. Polymorphisms in Glutathione S-transferase genes (GSTM1, GSTT1, and GSTP1 isotypes) have been correlated with prostate cancer susceptibility. We compared the frequency of GST variants in a group of African-Americans and Caucasians. Our results revealed that the genotype frequencies are statistically different between these two races, particularly for GSTM1 and GSTP1 variants [$p < 0.001$]. Estrogen receptor [ER] plays a critical role in prostate cancer apart. We studied the CA repeat polymorphism in ER b gene in the African-Americans and Caucasians. These two groups differ significantly in the range and distribution of CA repeats. African-Americans have an extended range of CA repeats compared to Caucasians. The allele with 23 repeats was the most common in African-Americans, while the allele of 27 repeats was most common in Caucasians. We conclude from our preliminary results that African-Americans and Caucasians differ significantly in these polymorphisms that have been correlated with prostate cancer.

Ornithine decarboxylase allele frequency distribution in Caucasians and African Americans. *T.G. O'Brien¹, A. Parlanti², Y. Guo¹, D. Boorman¹, K. Visvanathan³, K. Helzlsouer³, D. Watkins-Bruner².* 1) Lankenau Inst for Med Research, Wynnewood, PA; 2) Fox Chase Cancer Center, Philadelphia, PA; 3) Johns Hopkins Bloomberg School of Public Health, Baltimore, MD.

Differences in prostate cancer incidence and mortality between North American Caucasian and African American men are unexplained by known risk factors. Allelic variation at common, low penetrance cancer susceptibility/resistance loci may contribute to these differences in disease risk. A functional single nucleotide polymorphism (SNP) in the human ornithine decarboxylase (ODC) gene has been described that defines 2 allelic variants, termed A and G. Inheritance of one or two copies of the ODC A allele is associated with increased risk of prostate cancer in North American Caucasians who are cigarette smokers and in those men who carry an androgen receptor (AR) gene with less than or equal to 22 CAG repeats. We hypothesized that the frequency of the ODC A allele may be increased among African American compared to North American Caucasian men and that the mean number of AR CAG repeats may be decreased. In order to evaluate this, 150 African American men in the Prostate Cancer Risk Assessment Program (PRAP) at Fox Chase Cancer Center were genotyped for both AR CAG repeats and ODC. The results were then compared to those obtained from a population-based study from Washington County, MD, of 319 Caucasian men. The distribution of ODC genotypes (AA, AG, and GG) in African-Americans was significantly different ($P=0.0005$, Chi-square test) than the ODC genotype distribution in Caucasians: 13.3% of African-Americans had the AA genotype vs. 6.6% of Caucasians and 42% of African-Americans were AG vs. 35.7% of Caucasians. Thus, the allele frequency of the putative high-risk A allele in African-Americans (0.343) was 40% higher than in Caucasians (0.247). Consistent with other studies, the mean number of AR CAG repeats was 19.8 in African Americans compared to 22.0 in Caucasians. It is possible that the higher frequencies of risk alleles for both the ODC and AR genes in African Americans compared to Caucasians may account for some of the difference in prostate cancer risk between these two ethnic groups.

RNASEL variation does not account for the increased risk of prostate cancer in the Afro-Caribbean population of Tobago. *P.R. Shea¹, C.S. Ishwad¹, R.E. Ferrell¹, A.L. Patrick³, L.H. Kuller², C.H. Bunker².* 1) Human Genetics, Univ Pittsburgh, Pittsburgh, PA; 2) Epidemiology, Univ Pittsburgh, Pittsburgh, PA; 3) Tobago Regional Health Authority, Scarborough, Tobago, Tobago and Trinidad.

Recently, the Ribonuclease-L gene was implicated as a positional candidate gene for prostate cancer (PCa) susceptibility in the HPC1 region of chromosome 1q24-25. Two polymorphic missense variants, Arg462Gln and Glu541Asp, and a Glu265X truncation variant were reported to confer an increased risk of hereditary PCa. Afro-Caribbean males from Tobago have an elevated screening-detected prevalence of PCa (135/1000 in males > 49 years of age). However, only a small number of patients of African ancestry were included in previous studies of RNASEL. Because a number of African-American families were included in the original linkage study that localized HPC1, we tested the hypothesis that variation in RNASEL influences risk of prostate cancer in the population of African ancestry in Tobago. We genotyped 104 cases and 228 controls for the Arg462Gln and Glu541Asp variants identified in RNASEL. The 462Gln allele was found to be much less common in the Tobago population (12.4% compared to 63%) than in the previously reported European/European-American population. The 265X variant was not observed in 48 Tobago prostate cancer cases screened by direct sequencing. The Glu541Asp polymorphism was not significantly associated with risk of PCa in the Tobago population. Alternatively, homozygotes for the 462Gln allele were found to have an increased risk of borderline significance ($p=0.068$). Because of the low frequency of the 462Gln allele in Tobago, neither homozygosity for this allele nor variation at the Glu541Asp site can account for the increased risk of prostate cancer observed in this population.

Profiling SMAD4-mediated transcriptional regulation by TGF-beta on a global scale using high density microarrays. *P.J. Collins¹, T. Cheung², T.B. Doan¹, K.W. Shannon¹, X. Liu².* 1) Agilent Technologies, 3500 Deer Creek Road, 25U, Palo Alto, CA 94304; 2) Department of Chemistry and Biochemistry, UCB215, University of Colorado-Boulder, Boulder, CO 80503.

Transforming growth factor-beta is a multifunctional growth factor whose best-known function is to inhibit cell growth and suppress tumor formation. Loss of TGF-beta growth inhibition is one of the most common cellular events in the pathogenesis of human breast, pancreatic and colon cancers. TGF-beta signals through a heteromeric signaling complex consisting of Smad2, 3 and 4. Disruption of the Smad signaling complex often leads to tumor formation. We have used both 60-mer oligonucleotide and cDNA microarrays to investigate the consequences of Smad4 inactivation to the TGF-beta controlled transcription program in tumor cells. These high density DNA microarrays, generated using Agilent's SurePrint inkjet technology, were used to profile global transcriptional regulation in breast, colon and pancreatic Smad4-null tumor cell lines in response to TGF-beta. Data from both microarray types showed a high degree of correlation in demonstrating that TGF-beta induces transcriptional activation and repression of genes involved in signal transduction, cell adhesion and transcriptional regulation across the range of cell lines tested. Comparison with expression profiles from Smad4-positive cell lines indicates that inactivation of Smad4 does alter transcriptional programs of TGF-beta signaling but it is not absolutely required for TGF-beta signaling from cell surface to nucleus. The composition of the Smad signaling complex may control the specificity of TGF-beta signaling to control expression.

Transforming Growth Factor-beta Receptor type III expression levels are downregulated in cancerous tissues.
C.M. Stevens, M. Dressman, C.D. Wolfgang, C. Lavedan. Pharmacogenetics, Novartis Pharmaceuticals Corp, Gaithersburg, MD.

Transforming growth factor- beta (TGF-B), is a cytokine involved in many different cell growth and repair functions including cell differentiation, adhesion, and cell cycle progression. To date, three forms of the TGFB receptor have been identified. Even though TGFB binds to the type III receptor (TGFBR3), this receptor lacks a recognizable signaling domain and has no defined role in TGFB signaling. To better understand the expression of this receptor in different human tissue types, which may provide insight into its function, we examined the expression level of TGFBR3 in 50 different tissues using RNA expression profiling. While most non-cancerous tissues express TGFBR3 at some level, the expression of TGFBR3 is downregulated in all cancerous tissues with the exception of stomach. Reproductive tissues such as breast, cervix, ovary, and testes showed the most significant differences between normal and cancerous tissues. On average, the cancerous tissues showed 11.86 fold lower levels of TGFBR3 expression compared to their normal matched tissue. This downregulation in expression of TGFBR3 indicates that the gene may have tumor suppressor activities.

Androgen receptor (CAG)_n and (GGC)_n polymorphisms and breast cancer risk in a population-based case control study of young women. *N.M. Suter¹, K.E. Malone², J.R. Daling², D.R. Doody², E.A. Ostrander¹.* 1) Human Biology, Fred Hutchinson CRC, Seattle, WA; 2) Public Health Sciences, Fred Hutchinson CRC, Seattle, WA.

The androgen receptor (AR) is involved in the regulation of hormone responsive genes, and as such, has been suggested as a possible candidate gene for breast cancer susceptibility. The AR gene contains two polymorphic trinucleotide repeats within exon 1: (CAG)_n and (GGC)_n, encoding for polyglutamine and polyglycine tracts respectively. Few studies have assessed both repeats with respect to breast cancer risk in the general population, and none have done so in young women with breast cancer. Women diagnosed with breast cancer before age 45 and age-matched controls, all participants in a population-based case-control study of breast cancer before were therefore assessed for length variation in the (CAG)_n and (GGC)_n AR repeats.

Results were generated from 524 cases and 461 controls. Repeat lengths were analyzed as categorical variables and adjusted for age and reference year. Women with a cumulative (CAG)_n repeat size of 43 showed a modest increased risk for breast cancer (OR =1.3, 95% CI 1.0-1.7). Women with a (GGC)_n Long (L) allele and those with a 33 cumulative repeat size had a significantly decreased risk of breast cancer (OR=0.7, 95% CI 0.5-0.9). Among women homozygous for the (CAG)_n Short (S) allele, and among women with any (GGC)_n L allele, there was an increased risk of breast cancer in relation to ever use of oral contraceptives (OR=1.9, 95% CI 1.0-3.6 and OR = 1.7, 95% CI 0.9-3.5, respectively). Risk did not increase further with duration or recency of last use. Our analyses are the first to assess breast cancer risk in young women from the general population in relation to both (CAG)_n and (GGC)_n repeats in the AR gene, and suggest a reduced risk for those who possess (GGC)_n repeat lengths of 17 or greater. In addition, our results suggest AR repeat length may be partly responsible for the increased risk for breast cancer in women who use oral contraceptives. Further work is needed to confirm these findings.

Hereditary hemochromatosis in a large mexican family. *L.R. Cornejo^{1,2}, H. Romero¹, L. Oliver¹, G. Nava¹.* 1) Medicine Academic Area, Autonomous Hidalgo State Univ, Pachuca de Soto, Hidalgo, Mexico; 2) Childrens Hospital of Mexico Federico Gomez, Mexico City, Mexico.

Introduction. Hereditary hemochromatosis (HH) is one of the most common autosomal recessive disease. Its frequency has been estimated between 1/200 to 1/400 in Caucasian population. HH has been classified in three types regarding its clinical presentation. Its full phenotype keeps several questions because it is vary variable. To approach patients with HH include, (1) clinical data in liver, heart, pancreas, endocrine organs, skin and joints; (2) lab test such as serum iron, serum ferritin and transferrin saturation; and, (3) molecular biology studies for HFE and TFR2 genes. Geographic localization of Zimapan, Hidalgo Mexico has been highly associated with arsenic residues pollution. Objective. To present a large pedigree with HH where there are 36 relatives under risk to develop the disease. Material. Thirty-six people who are first and second degree relatives of an already dead 18 years old male proband. Methods. Clinical diagnosis and lab test in proband, as well as, clinical evaluation for his available relatives pictured from a three generation pedigree. Results. An eighteen years old male was studied, he presented the next clinical characteristics: cardiomyopathy, diabetes mellitus, hypogonadism, skin pigmentation, arthritis and hepatic cancer; and, lab test alterations. His pedigree shows a brother who dead previously because of the same liver disease. One of his sisters is developing hepatic alterations since 3 months ago. Three of his first degree relatives and 6 second degree relatives have skin pigmentation. Discussion. HH was thought as diagnosis because clinical aspects. It is show that develop of the disease is variable for male and female. There is a strong recommendation to establish a pathway to preserve an hepatic integrity, after enzyme restriction assay and sequencing in the relatives under risk. Conclusions. (a) A first large mexican family is presented; (b) to outline the major clinical date as hepatic cancer in young people; and, (3) it remains molecular biology test as support the correlation with arsenic pollution background where the family is living.

A variant of Tietz syndrome caused by a mutation in the basic domain of the MITF gene. *K.O. Welch¹, S.D. Smith², D. Hoover², K.S. Arnos¹, P.M. Kelley³, A. Pandya⁴, W.E. Nance⁴.* 1) Biology Dept, Gallaudet Univ, Washington, DC; 2) Ctr for Human Molecular Genetics, Univ of Nebraska Medical Ctr, Omaha, NE; 3) Ctr for Hereditary Communication Disorders, Boys Town National Research Hospital, Omaha, NE; 4) Dept of Human Genetics, Virginia Commonwealth Univ, Richmond, VA.

Tietz syndrome is a dominant form of profound sensorineural hearing loss (SNHL) with generalized hypopigmentation of the skin and hair, blue irides with hypopigmented fundi, and complete penetrance. The only family reported with these features has a missense mutation (Asp210Lys) in the basic domain of the MITF gene. Another missense mutation (Arg217del) in the basic domain was reported in a deaf mother and son. The mother had red hair with premature greying, fair skin and freckles, and blue eyes with hypopigmented fundi. Various mutations in other domains of MITF cause Waardenburg syndrome, type II (WS2), a dominant condition with SNHL of varying degrees that may be bilateral or unilateral, heterochromia irides, white forelock, patchy hypopigmentation of the skin, and variable expression. Our family has 28 members with features of both Tietz syndrome and WS2. All have blue eyes and generalized hypopigmentation of the skin and hair. Some have a white forelock and premature greying. Many have small pupils and photophobia; none have nystagmus. Several individuals have constipation, some severe. Fourteen are hearing. Fourteen have varying degrees of SNHL, including two with unilateral deafness. Sequencing of MITF revealed a T to G substitution in exon 6 in the basic domain, resulting in the missense mutation Ile212Met. This mutation was found in all 6 affected family members who were tested but not in the one unaffected family member tested nor in 96 controls. The mutation is in the same amino acid as the mouse Mi mutation that causes a dilute (as opposed to spotted) phenotype. Other mutations in this region are associated with diffuse hypopigmentation in mice and Tietz syndrome in humans. Spotted/WS2 phenotypes are associated with mutations in other regions or truncation mutations. While this family shows phenotypic overlap between the two syndromes, the generalized hypopigmentation and blue eyes are requisite features.

Characterization of osteogenesis imperfecta diagnosed in adulthood. *L.J. Kessler¹, M. Pepin², P.H. Byers², J. Farmer¹, R.E. Pyeritz¹.* 1) Medical Genetics, Univ Pennsylvania, Philadelphia, PA; 2) Dept Pathology, Univ Washington, Seattle.

Osteogenesis imperfecta (OI) syndromes share osteopenia due to a deficiency of the osteoid component of bone and osteoporosis, but are diverse in severity, prognosis and cause. Most OI is due to mutations in either COL1A1 or COL1A2. In the past 2 years, we established the diagnosis of OI in 5 adult patients (pts). Here we review their clinical, biochemical and genetic characteristics. All 5 pts were women (ages 34, 42, 52, 57 & 58 yr); 3 were postmenopausal. As children, 1 patient was diagnosed with rickets and 1 had probably been diagnosed with OI, but pediatric records were never transferred to adult physicians. Each was being evaluated for different medical problems, and was referred to genetics because of severe osteoporosis. 3 pts had no relatives with unusual fractures or osteoporosis and 1 had not had children. The fracture history was diverse, including 1 pt with 0, 1 with 2 after trauma as an adult, 1 with 3 as a child and 0 as an adult, 1 with 2 as a child and more than 10 as an adult, and 1 with many as a child and 0 as an adult. All were short-statured and had blue sclerae. 3 had dentinogenesis imperfecta (DI) and 1 who was edentulous probably did. The 4 who had DEXA scans had osteopenia (T scores -1.6 to -3.9). Collagen synthesis by dermal fibroblasts was assessed in 2 and was pending in 2. One pt synthesized normal type I collagen. One pt with an extensive pedigree of OI had a normal type I to type III collagen ratio; biochemical studies on the other pts and mutational analyses are pending. In conclusion, OI may present in adulthood, both in pts never diagnosed and in some without precise knowledge of past medical history. Women are particularly prone to be diagnosed because of general concerns about bone density, especially post-menopause. OI should be suspected in adults who present with moderate osteopenia, a history of fractures at any age or occult fractures, blue sclerae or DI. The role of collagen studies will vary among pts, but is especially useful in pts of child-bearing age to confirm the diagnosis and to offer prenatal and obstetrical counseling.

A new proximal mutation of the receptor tyrosine kinase gene *ROR2* associated with a severe form of brachydactyly type B. C. Carves-de La Rochebr^{1, 2}, V. Drouin-Garraud¹, N. Drouot¹, C. Martin¹, B. Bachy³, T. Frebourg^{1, 2}. 1) Department of Genetics, CHU de Rouen, 76031 Rouen, France; 2) INSERM EMI 9906, Faculty of Medicine, 76183 Rouen, France; 3) Department of Pediatric Surgery, CHU de Rouen, 76031 Rouen, France.

Heterozygous mutations of the orphan receptor tyrosine kinase *ROR2* gene are responsible for brachydactyly type B (BDB), an autosomal disorder characterized by terminal deficiency of fingers and toes. In a French family, we identified a new frameshift mutation, 1394delT, localized within the proximal mutations cluster, and responsible for a severe form of BDB. The index cases mother exhibited a supernumerary lumbar vertebra, which might be part of the BDB phenotype associated with *ROR2* mutations. The association of a mutation localized within the proximal region and a severe phenotype moderates the genotype/phenotype correlation previously suggested in BDB. This report suggests that the severity of the BDB phenotype depends more on modifying factors than on the location of the mutation itself.

Clinical Homogeneity and Genetic Heterogeneity in Weill-Marchesani Syndrome. *L. Faivre¹, MK. Wirtz², R.J. Gorlin³, A. Megarbane⁴, H. Dolffus⁵, S. Lyonnet¹, Y. Alembik⁵, A. Alswaid⁶, M. Le Merrer¹, A. Munnich¹, V. Cormier-Daire¹.* 1) Dept Genetics, Hopital Necker Enfants Malades, Paris, France; 2) Department of Ophthalmology, Oregon Health Sciences University, Portland, Oregon, USA; 3) Department of Oral Science, University of Minnesota Health Sciences Center, Minneapolis, Minnesota, USA; 4) Medical Genetics, Saint Joseph University, Beirut, Lebanon; 5) Medical Genetics, Hopital de Hautepierre, Strasbourg, France; 6) Clinical Genetics, Riyadh Armed Forces Hospital, Riyadh, Saudi Arabi.

Weill-Marchesani syndrome (WMS) is a rare disease characterized by short stature, brachydactyly, joint stiffness, and characteristic eye abnormalities including microspherophakia, ectopia of lens, severe myopia and glaucoma. Both autosomal recessive (AR) and autosomal dominant (AD) modes of inheritance have been described in association with WMS and one locus for AR WMS has recently been mapped to chromosome 19p13.3-p13.2. Here, we report on the exclusion of linkage to chromosome 19p13.3-p13.2 in a large AD WMS family using twelve microsatellite polymorphic markers (distant from 1.5 cM) encompassing the locus. In order to answer the question of whether or not genetic heterogeneity could be related to a clinical heterogeneity, we reviewed 128 WMS patients from the literature (including 57 AR, 50 AD and 21 sporadic cases), with a particular attention for clinical features. Statistical analyses using Fischer exact test were used to compare the proportions of 12 clinical parameters between AR and AD patients. There was no significant difference between both groups for myopia, glaucoma, cataract, short stature, brachydactyly, thick skin, muscular build and mental retardation. Significant results were found for microspherophakia (94% in AR, 74% in AD, Fischer 0.007), ectopia lentis (64% in AR, 84% in AD, Fischer 0.0063), joint limitations (49% in AR, 77% in AD, Fischer 0.010) and cardiac anomalies (39% in AR, 13% in AD, Fischer 0.004). Nevertheless, we failed to distinguish AR from AD inheritance in individual cases. These results support the clinical homogeneity but the genetic heterogeneity of WMS.

Quantitative ultrasound at the phalanges in a cohort of monozygotic twins: evaluation of affinities and environmental influences. *G. Guglielmi¹, F. De Terlizzi², I. Torrente³, R. Mingarelli³, M. Cammisa¹, S.B. Angeletti⁴, B. Dallapiccola⁵.* 1) Department of Radiology, IRCCS - CSS, S.Giov. Rotondo, Italy; 2) Laboratory of Clinical Biophysics IGEA, Carpi, Italy; 3) Mendel Institute, Rome, ITALY; 4) New York Accademy of Science, New York, NJ; 5) IRCCS-CSS, S.Giov.Rotondo and Mendel Institute, Rome, Italy.

In this study we have investigated the ultrasonographic characterisation of a cohort of 79 couples of Italian monozygotic twins: 56 couples of female twins and 23 couples of male twins. The 158 subjects were on an age range between 7 and 60 years and have been measured for ultrasonic evaluation of the bone tissue at level of the distal metaphysis of the first phalanx of the last four fingers of the non dominant hand by DBM Sonic Bone Profiler (IGEA, Italy). Data of Amplitude Dependent Speed of Sound (AD-SoS) and Bone Transmission Time (BTT) have been collected; in particular BTT was of great interest because of its complete independence on soft tissue thickness around the phalanx. Data have been analysed all together and separately for males and females couples. Extremely high correlation coefficients were found for AD-SOS and BTT when comparing all couples of twins. R values were: 0.91 for AD-SoS (0.89 for females only, 0.95 for males only) and 0.95 for BTT (0.92 for females only, 0.95 for males only). All correlation coefficients were statistically significant ($p < 0.0001$). Finally we investigated the influence of age in the progressive differentiation between twins, observed by ultrasound parameters. We classified twins into 5 groups according to their age and we calculated the mean difference between couples of twins for AD-SoS and BTT values in each group. For female groups ANOVA results show a statistical significance ($p < 0.05$) in the association between increasing differences in AD-SoS and BTT between couples of twins with increasing age. This result was not observed on the male group of twins, probably due to the low number of subjects. In conclusion these results support the evidence of an environmental influence on bone status in our studied group of MZ twins.

Genital anomalies in a boy with sporadic brachydactyly, type A2. *G.A. Bellus¹, J. Anderson²*. 1) Depts Dermatology, Pediatrics and Human Medical Genetics Program, Univ Colorado Health Sci Ctr, Denver, CO; 2) Genetic Services, The Children's Hospital, Denver, CO.

Brachydactyly, type A2 (BDA2) is an extremely rare genetic disorder characterized by a triangular middle phalanx in the index finger, often resulting in striking radial deviation, and mild fifth finger clinodactyly due to abnormal deviation of the distal phalanges. In the feet, the halluces are often short, broad and laterally deviated and the remaining toes, especially the second toes, have hypoplastic middle phalanges, resulting in medial deviation of their distal phalanges. There are very few reports of BDA2 in the literature and no mention of other associated findings. Our patient was the product of a G1 P0-1 mother. Triple screen revealed elevated AFP leading to fetal u/s and genetic amniocentesis. The ultrasound was suspicious for distal limb anomalies and the karyotype was 46, XY. He was delivered at 38 weeks by vaginal delivery and presented with classic features of BDA2 as well as severe hypospadias with a bifid scrotum and a perineal opening. Both parents have normal limbs and genitalia and rest of the family history was unremarkable. Brachydactyly and genital anomalies are observed in Hand-Foot-Genital syndrome (HFGS) which, is due to mutations in the Hox A13 gene. However in HFGS, it's always the first digits that are most obviously involved, resulting in short proximally-placed thumbs, hypoplastic thenar eminences and short medially-deviated halluces, with small pointed first distal phalanges and short first metacarpals/metatarsals. Our patient has normal thumbs, and his toes are broad and laterally deviated. In HFGS, there is often also hypoplasia of the middle phalanges, especially in the little and index fingers, and in toes 2 to 5, and this can result in fifth finger clinodactyly and ulnar deviation of the index fingers - but not the striking radial deviation demonstrated by our patient. The occurrence of severe hypospadias and BDA2 in this patient may be coincidental but could also represent a new association. The general similarities between HFGS and the findings in our patient suggest that mutations in another Hox gene may cause BDA2.

Mutation detection in *NOGGIN* in individuals with multiple synostosis syndrome. *K.G. Dawson, E. Sebald, J.M. Graham, Jr., D. Krakow.* Department of Pediatrics, Division of Medical Genetics, Cedars-Sinai Medical Center, UCLA School of Medicine, Los Angeles, CA.

Multiple synostosis syndrome (SYNS1; OMIM 186500) is an autosomal dominant disorder characterized by early, progressive joint fusions, characteristic facies, and deafness. The disorder was mapped to chromosome 17q21-22, the location of the disease gene for proximal symphalangism (SYM1; OMIM 185800). Subsequently, heterozygous mutations in *NOGGIN* (*NOG*) were identified in the allelic disorders. Noggin has been shown to be a bone morphogenetic protein antagonist, and mice homozygous for *Nog*-null alleles have several skeletal developmental defects, including a lack of normal articulating joints. To date, eleven *NOG* mutations have been published, all of which were within the single coding exon. We identified eight individuals with the clinical findings characteristic of multiple synostosis syndrome. Seven of these occurred as sporadic cases. To identify novel multiple synostosis syndrome mutations in the *NOG* gene we sequenced the entire coding region of *NOG* in both 5' to 3' and 3' to 5' directions. We were able to demonstrate a previously published mutation (W217G) in the individual from an affected family. In the remaining seven sporadic patients, however, we could not demonstrate a sequence alteration. Although *NOGGIN* mutations have been demonstrated to be responsible for both multiple synostosis and proximal symphalangism syndromes, these data suggest several possibilities: 1) an alternative gene locus, 2) an alteration in the noncoding portion of *NOGGIN*, and 3) a heterozygous gene deletion.

Arthrogryposis, gastroschisis and spinal cord atresia with dysmorphic features: a variant of dyssegmental dysplasia or a new syndrome? *D.K. Manchester, E.R. Elias.* Div Genetics Services, The Children's Hosp, Denver, CO.

Case History: This 8 mo old male was the 2 kg product of a 37 wk gestation to a healthy 23 yo G3P2 mother, born by Csection. Gastroschisis was detected on prenatal ultrasound along with short limbs, club feet, and muscular hyperechogenicity. Postnatal evaluation revealed dysmorphic facies with epicanthal folds, midface hypoplasia, high arched palate, low set and dysplastic pinnae, mandibular hypoplasia, short and hyperextended neck, small thorax, gastroschisis, ileal atresia, severe shortening of all limbs with ulnar deviation of the hands, bilateral equinovarus feet deformities, and 2-4 toe syndactyly. Additional studies revealed small optic nerve heads, ventriculomegaly and increased extra axial fluid on head MRI, spinal cord thinning from T1-6, normal heart with small PFO and PDA, and normal kidneys with mild right hydronephrosis. Karyotype in amniocytes and skin fibroblasts was normal, 46, XY.

His medical course has been complicated by severe, restrictive lung disease with oxygen dependency, feeding disorder with failure to thrive necessitating Gtube feeds, and severe developmental delay. His vision is intact and hearing is normal.

Discussion: The differential diagnosis of arthrogryposis is quite broad, but few syndromes also include gastroschisis, intestinal atresia and spinal cord lesions. The association of the latter 3 problems suggests the possibility of a vascular event prenatally, compromising blood supply to the mid thorax and abdominal region. The skeletal anomalies, facial features, cardiac and renal anomalies are similar to those reported in dyssegmental dysplasia, type Silverman-Handmaker. However, the xray findings are not identical, and no abdominal wall defects or spinal cord anomalies have been reported in this skeletal dysplasia.

Genotype and phenotype analysis in patients with achondroplasia mimicking clinical features. *G-H. Kim¹, Y-L. Shin², E-J. Seo¹, H-W. Yoo^{1,2}*. 1) Medical Genetics Clinic & Lab, Asan Medical Center, Seoul, Korea; 2) Department of Pediatrics, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea.

Achondroplasia(Ach) and hypochondroplasia(Hch) are autosomal dominant skeletal dysplasia characterized by disproportionate short stature with rhizomelic shortening of the limbs. These disorders are known to be allelic and caused by specific point mutations in the fibroblast growth factor receptor 3(FGFR3) gene. Hch resembles the clinical features of Ach, but are less severe. However, the phenotype in severe cases of Hch sometimes overlaps that of Ach. In this study, we analyzed the FGFR3 gene for the previously described Ach and Hch mutations in patients with achondroplasia mimicking features and compared the clinical and radiological findings to clarify whether or not each genotype has a distinctive phenotype. Twenty six patients(14 males and 12 females) with features of Ach, such as disproportionate short stature with shortening of the limbs and large head with a prominent forehead were included in this study. Initially, Ach mutations (G380R and G375C) were screened. If both mutations were not present, subsequently Hch mutations(N540K, N540T, D540S, I538V, K650Q, K652Q) were screened by PCR-RFLP analysis or DNA sequencing. For comparison of the phenotypes, auxological parameters and radiological findings were analyzed. We detected the G380R mutation in 13 patients(50%), the N540K mutation in 5 patients(19%), and no mutations in 8 patients(31%) of 26 patients. No significant differences were found in mean age at presentation, height SDS, head circumference SDS, and sitting height to standing height ratio among three groups. Common radiological features observed in all these groups include narrowing or unchanged lumbar interpedicular distances(L1/L4 ratio), squared shortened ilia, macrocephaly, shortening of long tubular bones, long fibula and brachydactyly. Frequencies of these radiological findings were not significantly different in each group. In conclusion, it is difficult to differentiate Hch from Ach based on clinical and radiological findings, especially when presented in early childhood. Therefore, genotype-based diagnosis is needed for proper genetic counselling.

GOING BEYOND THE MARFANOID HABITUS: THE WORK-UP OF 3 UNUSUAL PATIENTS WITH SIGNIFICANT STRUCTURAL AND DEVELOPMENTAL DEFECTS IN ADDITION TO MARFANOID FEATURES. *D. Kostiner, V. Cox, A. Zanko, N. Stewart, S. Cheng, M. Golabi.* Dept. Pediatrics, Div. Medical Genetics, UC San Francisco.

Tall, thin people are often referred to genetics for evaluation of possible Marfan syndrome (MS). The DX is often ruled in/out based on H&P, so fibrillin testing is rarely needed. We present 3 patients who were referred for rule-out MS, but whose concomitant features suggested possible fibrillin defects for which FBN1 or 2 analysis might be appropriate. Pt. #1 is a 19-yo female with mental retardation (MR), seizures, deafness, marfanoid habitus, proptosis, cleft lip/palate, webbed neck, arachnodactyly and camptodactyly. Bony defects include scoliosis, vertebral defects, Sprengel deformity and craniosynostosis. Skin defects include angiofibromas, Shagreen patch and hypopigmented macules. Karyotype with subtelomeric probes reveals 46,XX. Skin findings suggest tuberous sclerosis (TS), skeletal features suggest Klippel-Feil syndrome (KFS), but overall gestalt suggests Shprintzen-Goldberg syndrome (SGS). A contiguous gene sequence is possible, but the known genes for these conditions are not adjacent (TS genes are on 9q and 16p; KFS gene might be on 8q; SGS gene might be FBN1 on 15q). Work-up could include TS mutation analysis, FBN1 mutation analysis and array-based comparative genomic hybridization (CGH). Pt. #2, born of a father-daughter mating, is a 10-yo female with dysmorphism, MR, marfanoid habitus, abnormal cranium, severe myopia, downward dislocated lenses, high palate, MVP, significant scoliosis, vertebral defects, sacral meningoceles and arachnodactyly. Karyotype reveals 46,XX. DDX includes MS, SGS and homocystinuria plus possible effects of consanguinity. Work-up could include plasma homocysteine, FBN1 mutation analysis and CGH. Pt. #3 is a 12-yo female with profound scoliosis, pectus carinatum, contractures, thin habitus, high palate and restrictive cardiomyopathy. Congenital contractural arachnodactyly is suspected. FBN2 mutation analysis is underway. We conclude that FBN1 or 2 mutation analysis might be appropriate for patients whose features are more severe than/not consistent with typical MS and in whom other diagnoses have been excluded by more accessible tests.

Program Nr: 487 from 2002 ASHG Annual Meeting

Evaluating Clinical Efficacy and safety of Palmidronate in Patients with osteogenesis imperfecta. *J. Lin, S. Wang, J. Hou.* Genetic Div Pediatric Dept, Chang Gung Children's Hosp, Taoyuan, Taiwan.

Osteogenesis imperfecta (OI) is a rare genetic bone disease, which caused by the mutations within COL1A1 or COL1A2 genes. It caused osteoporosis, which would induce bone fracture and even mortality. In the past, surgical correction seemed to be the only treatment. Fifteen patients with OI had received Palmidronate 30 mg/m² every month by IV dripping for 4 hours in our hospital. They also received oral vitamin and calcium supplement once per day. Osteocalcin, alkaline phosphatase, procollagen I C-terminal peptide (PICP), collagen I telopeptide (ICTP) had been checked before treatment and every six months after treatment to evaluate the bone response and collagen fiber type I production and destruction rate. We check the bone density of every patient by DEXA in the same period as described above. It showed that every patient benefited from this treatment significantly.

Anomalies of the hand in Smith-Magenis syndrome: Evaluation by metacarpophalangeal pattern profile analysis.

A.E. Schlesinger^{1,2,5}, *J.R. Lupski*^{3,4,5,6}, *A.K. Poznanski*^{2,7}, *L. Potocki*^{3,5,6}. 1) Edward B. Singleton Department of Diagnostic Imaging; 2) Department of Radiology; 3) Department of Molecular and Human Genetics; 4) Department of Pediatrics; 5) Texas Children's Hospital, Houston; 6) Baylor College of Medicine, Houston, TX; 7) Children's Memorial Hospital and Northwestern University School of Medicine, Chicago, IL.

Smith-Magenis syndrome (SMS) is a multiple congenital anomalies, mental retardation syndrome associated with deletion of chromosome 17 [del(17)(p11.2p11.2)]. The clinical phenotype includes short stature, minor craniofacial anomalies, and neurobehavioral abnormalities. Brachydactyly has been described as a clinical manifestation of SMS, but measurement of the length of the bones of the hand in a large series of patients has not been performed to objectively confirm this finding. Metacarpophalangeal pattern profile analysis (MCPPPA), a method of graphic depiction of the relative size of the bones of the hand, had been used to objectively evaluate radiographs of the hand in a few patients with SMS. We measured the bones of the hand and performed MCPPPA in 29 patients with SMS. Our results demonstrated a different MCPPPA in patients with SMS than previously reported. The analysis confirmed brachydactyly and the previously described trend of more pronounced shortening of the distal bones relative to the more proximal bones, but also demonstrated a previously undescribed pattern: relative enlargement of the proximal phalanx of the thumb and middle phalanx of the fifth finger. It is interesting that our results demonstrate relative enlargement of the fifth middle phalanx, as that bone is frequently relatively shorter than the remaining bones of the hand in many syndromes. While our study objectively confirms brachydactyly in SMS and demonstrates a unique-appearing MCPPPA, statistical analysis reveals that the relative change in the size of the bones of the hand is small, implying that the MCPPPA is not highly characteristic, and correlation between the pattern for each patient and the mean pattern is not high. This suggests that MCPPPA analysis would be of limited utility in identifying patients with SMS.

Long-term survivor of malignant infantile autosomal recessive osteopetrosis with complete absence of osteoclasts and lack of response to M-CSF/RANKL. *G. Yoon*^{1,2}, *L.M. Ward*¹, *F.H. Glorieux*¹, *F. Rauch*¹. 1) Genetics Unit, Shriners Hospital for Children and McGill University Montreal, Canada; 2) Department of Medical Genetics, Alberta Children's Hospital, Calgary, Canada.

Malignant infantile osteopetrosis is an autosomal recessive disease which is usually lethal in the first decade of life. At the bone tissue level it is usually characterized by a large number of osteoclasts. We describe an unusual case of a boy with malignant infantile osteopetrosis due to lack of osteoclasts. Increased bone density, macrocephaly and hepatosplenomegaly were noted in the first year of life. A transiliac bone biopsy specimen was obtained at 10 months of age and revealed a complete absence of osteoclasts. Accordingly, serum levels of the osteoclast enzyme tartrate-resistant acid phosphatase were consistently decreased. The clinical course was further complicated by multiple fractures, blindness and compression of the left internal carotid artery. At 15 years he is severely debilitated, requires blood transfusions every 2 months and suffers from recurrent infections. Studies of the osteoclast differentiation pathways failed to reveal a treatable cause of the disease. Skin fibroblasts revealed normal production of macrophage colony-stimulating factor. The patient's peripheral blood mononuclear cells could not be stimulated to form osteoclasts in the presence of osteoprotegerin ligand and colony-stimulating factor-1. The fact that the clinical course in this patient without osteoclasts was less severe than that usually observed in children with malignant osteopetrosis suggests that the disease in these latter patients is not due solely to lack of osteoclast function.

The interparietal bone: An anatomic variation. *D.A. Staffenberg¹, J. Wu¹, A. Barkan¹, J.T. Goodrich², A. Shanske³.*
1) Plastic Surgery, Montefiore Medical Center, Bronx, NY; 2) Neurological Surgery, Montefiore Medical Center, Bronx, NY; 3) The Center for Craniofacial Disorders, Children's Hospital at Montefiore, Bronx, NY.

The interparietal bone, or Os Inca, is formed by the presence of the suture mendosa. The suture is a normal variation of the human skull with no known sequelae. It was first described in 1842 in Incan skulls from Peru. The incidence is rare with estimates ranging from 0.4% to 2.5% in all races. Neither the incidence nor its pathogenesis is known in children with craniofacial anomalies. A retrospective review of 35 consecutive patients with craniofacial anomalies was done. Only 20 3-D CAT scans of the skull were available for study. Two of these demonstrated an interparietal bone. The first patient had incomplete facial duplication (diprosopus). He had a duplicated maxilla, mandible, upper frenulum and tongue. The nose was bifid and the secondary palate cleft. There were 4 infraorbital foramina and bifurcation of the upper cervical spine. There were no other sutural abnormalities. The second patient was noted to have craniosynostosis at 6 weeks of age as a result of fusion of the sagittal suture. Imaging showed a normal brain and the presence of 2 interparietal bones. The interparietal bones remain separated in most mammals and in primates fuse with the occipital bone. In man, the occipital bone is made up of a supraoccipital portion and an interparietal portion separated by the mendosal suture. Ossification and fusion of the membranous interparietal portion is complete by 20 weeks and at birth the 2 segments are fused. The mendosal suture is obliterated by 2 years. Much progress has been made in suture biology. The future study of this suture in patients with craniofacial abnormalities will result in a further understanding of sutural biology as well as the significance of the parietal bone in these patients.

Ulnar/fibular ray defect and brachydactyly type E in a family: a possible new autosomal dominant syndrome.

K.A. Weissbecker¹, E. Morava², M. Czako³, J. Kárteszi², J.B. O'Connor¹, K. Méhes^{2,3}. 1) Dept. of Psychiatry and the Hayward Genetics Program Tulane Medical Ctr, New Orleans, LA; 2) University of Pécs, Department of Medical Genetics and Child Development, Pécs, Hungary; 3) University of Pécs, MTA-PTE Clinical Genetics Research Group, Pécs, Hungary;.

The ulnar-mammary syndrome (UMS) includes postaxial ray defects, abnormalities of growth, delayed sexual development, mammillar and apocrin gland hypoplasia. The TBX3 gene for ulnar mammary syndrome has been localized to chromosome 12q23-q24.1. A gene for Holt-Oram syndrome, which presents with mostly mild symmetrical radical ray defects, associated atrial septum defect (ASD), but no lower limb malformations, has been localized to the same region of chromosome 12. Mutations in the TBX5 gene, just proximal to the TBX3 gene, have been identified in some families with Holt-Oram syndrome. Brachydactyly type E, which has not been mapped, presents with shortening of the metacarpals/phalanges in the ulnar ray in association with round face and moderately short stature. We describe a three-generation Hungarian family with variable expression of ulnar/fibular hypoplasia, brachydactyly, ulnar ray defects and short stature. The proband had ulnar hypoplasia with missing IV-Vth fingers, fibular hypoplasia on the right, bilateral club feet, growth retardation, hypoplastic midface, ASD and hemangiomas. She had normal mamillary tissue and normal sweating. Her mother had short stature, midfacial hypoplasia, hypoplastic ulna and hypoplasia of the IVth metacarpal on the right without other associated malformations. A maternal grandfather had mild bilateral fibular hypoplasia and midphalangeal brachydactyly of the IV-Vth toes. His sister had short stature and shortening of the IVth metacarpus of the left hand. We hypothesized that this family may have a mutation in the region of chromosome 12 which contains the UMS and Holt-Oram syndrome genes. However, a two-point linkage analysis of microsatellite markers spanning the locus at 12q24 did not find evidence of linkage, and linkage could be excluded for up to 10 centiMorgans for some of the markers. This family may therefore represent a previously undescribed syndrome.

An Atypical Lethal Acrofacial Dysostosis Syndrome. *B.T. Tinkle, H.M. Saal.* Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Accurate diagnosis of the acrofacial dysostoses presents with a great challenge given their rarity, phenotypic variability, and genetic heterogeneity. We report a case of a female infant born at 33 weeks gestation who died within a few hours of delivery due to respiratory failure secondary to profound retromicrognathia. The pregnancy was complicated by ultrasound diagnosis of a skeletal dysplasia at 20 weeks gestation and later by IUGR and polyhydramnios. At birth, the infant had severe respiratory distress and was very difficult to intubate. The infant died at 3.5 hours of life. She had mandibulofacial dysostosis, predominantly postaxial defects, and phocomelia of the upper extremities. The mandibulofacial dysostosis was characterized by small dysplastic ears, narrow short palpebral fissures, U-shaped cleft palate, bilateral cutis aplasia congenital lateral to the mouth, and the profound retromicrognathia. Postaxial defect was seen radiographically as missing the 5th digital ray in both hands and feet with the exception of the right foot which had a very hypoplastic 4th digital ray. The thumbs and great toes were hypoplastic as well. In addition, she had radiographic evidence of a unilateral cervical rib, 11 pairs of thoracic ribs, thin ribs, and hypoplastic scapulae. The lower limbs with the exception of the feet were relatively spared with normal appearing pelvic girdle and long bones. Chromosome study was normal. The postaxial defects may be seen in a lethal form of Miller syndrome; however, the infant did not have a lid coloboma or an extra nipple commonly seen in Miller. Further, she had synostosis of the upper extremities involving the fusion of the humerus with a single forearm bone as seen in the Rodriguez type. OMIM lists six different acrofacial dysostoses. This patient may represent a new syndrome or a further phenotypic variation of Miller or Rodriguez types of acrofacial dysostoses. The phenotypic variability and genetic heterogeneity of the acrofacial dysostoses makes diagnosis difficult especially in cases such as this one, and impacts on the genetic counseling.

New syndrome with focal dermal hypoplasia, follicular hamartomas, polysyndactyly, microphthalmia, morning glory optic disc anomaly, agenesis of the corpus callosum and polymicrogyria. *P.F. Giampietro¹, D. Babu¹, M. Koehn¹, D.M. Jacobson¹, C. Moretti¹, S.F. Patten¹, L.G. Shaffer², R.J. Gorlin³, Y. Peng⁴, W.B. Dobyns⁴.* 1) Marshfield Clinic, Marshfield, WI; 2) Baylor College of Medicine, Houston, TX; 3) Department of Oral Pathology and Genetics, University of Minnesota, Minneapolis, MN; 4) Department of Human Genetics, University of Chicago, Chicago, IL.

Multiple small areas of skin hypoplasia have been described in several genetic syndromes, including focal dermal hypoplasia (FDH), microphthalmia with linear skin defects (MLS), oculo-cerebro-cutaneous syndrome (OCCS) and terminal osseous dysplasia and pigmentary defects (TODP). All but OCCS are X-linked with increased male lethality. We describe a 13-year-old girl with an apparently new syndrome that overlaps each of these disorders. On examination, she had mild mental retardation, macrocephaly, right microphthalmos and morning glory optic disc anomaly, palmar and lip pits, polydactyly and syndactyly, swirls of skin hypopigmentation, and papular hypopigmented and herniated skin lesions reminiscent of FDH that were most prominent over her face, head, hands and feet. Brain MRI showed diffuse polymicrogyria most severe in the perisylvian and mesial frontal regions, enlarged left lateral ventricle, severe partial agenesis of the corpus callosum, and an optic nerve tumor on the right. Dermatopathologic examination of the skin lesions was consistent with basaloid follicular hamartomas. High-resolution chromosome analysis and FISH with a complete set of subtelomeric probes and several probes from the MLS region in Xp22.31 were normal. The skin and digit anomalies observed in this patient overlap with FDH, but polymicrogyria, basaloid follicular hamartomas, optic nerve tumor and morning glory optic disc anomaly have not previously been described in FDH. The skin defects in MLS are linear and the microphthalmic eyes typically have sclerocornea. Polymicrogyria has not been described. The limb anomalies in TODP are reductions rather than polysyndactyly. The skin defects are localized to the face, and digital fibromas occur rather than follicular hamartomas.

TRENDS IN THE PREVALENCE OF NEURAL TUBE DEFECTS IN NORTHEASTERN FRANCE 1979 2001.

B. DOTT, Y. ALEMBIK, M.P. ROTH, C. STOLL. Medical Genetics, Hpital de Hautepierre, STRASBOURG, France.

Objective : To examine the total prevalence of neural tube defects (NTD) and the prevalence at birth of NTD during 1979 2001 in Northeastern France. **Methods :** Using data from our registry of congenital anomalies we identified all cases of NTD (anencephaly, spina bifida and encephalocele) including live-births (LB), stillbirths and termination of pregnancies (TOP) from 1979 to 2001. Comparisons were made during 3 periods of time : 1979 1986, 1987 1994 and 1995 2001. In our country an ultrasound scan in the mid-trimester of pregnancy is routine part of antenatal care since 1979 as well as a triple test including alpha-fetoprotein since 1997, and there is no upper limit for TOP. There was no food fortification with folic acid in the area under investigation and the uptake of periconception supplementation was low, around 20% during the third period of the study, very low during the second period, and nil during the first period. **Results :** The total prevalence rates for anencephaly, spina bifida, encephalocele and all NTD in the area under investigation were not significantly different during the study periods. However there was a dramatic decrease of the prevalence rates of liveborn with NTD. No anencephalic child was born since 1988 whereas the prevalence rate per 10,000 of LB with spina bifida dropped from 4.6 during 1979-1986 to 1.5 during 1987-1994 and 1.1 during 1995-2001. The decrease of the prevalence rate of LB with encephalocele was lower. **Conclusions :** This study demonstrate that the impact of prenatal diagnosis during pregnancy on prevalence at birth of NTD was very high for anencephaly, high for spina bifida and low for encephalocele.

ARX mutation in a familial lissencephaly with agenesis of the corpus callosum syndrome. *T. Fukuda^{1,3}, J. Tohyama², N. Sugiyama³, H. Yamagata¹, K. Morohashi³, K. Kitamura⁴.* 1) Dept of Hygiene, Ehime University School of Med., Ehime, Japan; 2) Dept of Pediatrics, Okinawa Child Developmental Center, Okinawa, Japan; 3) Dept of Developmental Biol., National Institute for Basic Biol., Okazaki, Japan; 4) Mitsubishi Kagaku Institute of Life Sciences, Tokyo, Japan.

A gene for the aristaless-related homeobox (ARX) is mainly expressed in brain and considerable function of ARX protein might be the maintenance of specific neuronal subtypes in the cortex and axonal guidance in the floor plate in mouse (Miura et al., 1997). Recently, two groups showed human ARX mutations in the X-linked mental retardation families, nonspecific forms and specific forms with infantile epilepsy, myoclonic seizures and dystonia, but the brain anomalies in MRI have not been observed in these patients (Stromme et al., 2002, Bienvenu et al., 2002). We previously reported a family with X-linked lissencephaly and agenesis of the corpus callosum (the 51th ASHG, 2001). Two boys had intractable seizures and severe growth retardation, but their mother had no anomalies, suggesting that patients had an X-linked recessive condition. We have searched a region of X chromosome derived from a maternal grandfather in two affected males, and a gene for this condition was mapped to Xpter-Xp22, DXS8039- DXS710 interval, where ARX is mapped. Then, we found a missense mutation (L343Q) in exon 2 of ARX in affected siblings and their mother, but not in maternal grandparents, indicating that a fresh mutation occurred in a sperm of maternal grandfather. Our results strongly indicate that the function of ARX protein is a neural migration guidance and maintenance of specific neural subtypes in cerebral cortex. Impairment of mental development in patients with ARX mutations might be due to disturbance in neuronal cell migration.

Reciprocal fusion transcripts of two novel genes associated with absence of corpus callosum in an individual with a t(2;9)(p24;q32) translocation. *I. Grinberg, M. Ramocki, J. Dowling, D. Ledbetter, K. Millen, W. Dobyns.* Human Genetics, University of Chicago, Chicago, IL.

Agenesis of the corpus callosum (ACC) is one of the most common brain malformations in humans. ACC is a heterogeneous phenotype that may occur as an isolated malformation or as one component of a number of genetic syndromes. ACC is associated with mutations in numerous identified genes, chromosome rearrangements, and metabolic disorders. We identified a female patient with a complex phenotype that includes complete ACC, bilateral periventricular nodular heterotopia (PNH), and bilateral chorioretinal and iris colobomas. Examination of the patient also showed frontal bossing, left ptosis, dysplastic left ear, right frontal hemangioma, capillary hemangioma on the right side of the vulva, strawberry nevi on the left knee and shoulder, bilateral leukocoria, hearing loss, ventricular septal defects, vesicoureteral reflux, and hyperreflexia of all four extremities. She was born to a diabetic mother and the identification of mild concentric left ventricular hypertrophy was attributed to this fact. Karyotype analysis on peripheral blood lymphocytes of the patient identified a balanced, reciprocal, de novo chromosome translocation t(2;9)(p24;q32) in the proband but not in her biological parents. Physical mapping by FISH analysis of the translocation breakpoint lead to the identification of two novel zinc-finger-encoding transcripts that are disrupted in this patient. One of these genes encodes an ASX-related transcription factor, the homologue of which has a role in Polycomb gene regulation in *Drosophila*. The other gene encodes GT4-2, a mouse homologue of which was initially isolated in one of the first gene trap screens in mouse ES cells. In mouse, both genes are ubiquitously expressed in the developing CNS. Interestingly, reciprocal fusion in-frame transcripts are generated from each gene in patient lymphoblasts. Thus, the patient phenotype is caused by either loss of one or both gene(s) and/or gain of function of one or both fusion transcript(s).

Hypogonadism in familial cerebellar ataxia with muscle coenzyme Q₁₀ deficiency. *R. Freeman¹, A. Naini², S.*

Shanske², S. DiMauro², A. Shanske³. 1) Department of Obstetrics and Gynecology, Albert Einstein College of Medicine, Bronx, NY; 2) Department of Neurology, Columbia University College of Physicians and Surgeons, New York, NY; 3) Center for Congenital Disorders, Children's Hospital at Montefiore, Albert Einstein College of Medicine, Bronx, NY.

Coenzyme Q₁₀ is a component of the electron-transport chain that transfers electrons from complex I and II to complex III. A recently described disorder, familial cerebellar ataxia with coenzyme Q₁₀ deficiency is characterized by familial ataxia associated with pyramidal signs, seizures, cerebellar atrophy and dementia. We recently identified a 41 year old woman with this disorder and hypogonadotropic hypogonadism. She developed normally until 2 years when she developed ataxia and nystagmus and began losing milestones. A seizure disorder began at 2 years. An MRI showed marked cerebellar and pontine atrophy and a diffuse disorder of myelination. A muscle biopsy showed normal mitochondrial enzyme activities and normal muscle morphology. CoQ₁₀ levels in muscle and serum were very depressed. An endocrine evaluation done at age 19 revealed hypogonadotropic hypogonadism. Pituitary function was normal including LH, TRH and ACTH stimulation testing. Her three sibs, 2 sisters and a brother, have had a similar clinical course. The parents are unrelated and the 3 of the 4 sibs who have been tested all have normal pituitary function. At the present time, she is non-verbal and non-ambulatory. Her 38 year old sister was noted to have a questionable response to therapeutic doses of CoQ₁₀. Idiopathic hypogonadotropic hypogonadism (IHH) is a genetically and clinically heterogeneous group of disorders. When associated with anosmia, it is known as Kallmann syndrome (KS). In its X-linked form, it is caused by mutations in the KAL gene. Mutations in the KAL gene occur in only 14% of familial cases of KS. The majority of familial cases are normosmic and are caused by at least 2 presently unidentified autosomal genes. We suggest that an error in metabolism of CoQ₁₀ might also be responsible for familial IHH. The complexity of CoQ₁₀ biosynthesis suggests that different enzyme defects may cause different clinical syndromes.

Further delineation of Stuve-Wiedeman Syndrome in survivors . *LI. Al-Gazali¹, A. Ravenscroft², A. Feng³, A. Shubbar⁴, A. Al-Saggaf⁵, D. Haas⁶*. 1) Paediatrics, FMHS, UAE University, Al Ain, Abu Dhabi, UAE; 2) Tygerberg Hospital and University of Stellenbosch, Department of Paediatrics and Child Health, Republic of South Africa; 3) Sheikh Khalifa Medical Center, Department of Paediatrics, Abu Dhabi, UAE; 4) Corniche Hospital, Department of Paediatrics, Abu Dhabi, UAE; 5) Al Jazeirah Hospital, Department of Paediatrics, Abu Dhabi, UAE; 6) Tawam Hospital, Department of Radiology, Al Ain, UAE.

Stuve-Wiedeman syndrome (SWS) is an autosomal recessive bone dysplasia characterized by camptomelia, contractures of the big joints and camptodactyly. The clinical course is complicated by hyperthermic episodes, respiratory insufficiency, feeding & swallowing difficulties and distinct radiological changes. It is usually lethal as most of the reported cases died in the first year of life. We report 3 children from 2 inbred Arab families with Stuve-Wiedeman syndrome who have survived the first 2 years of life (ages are 6 years, 2.8 years and 20 months). All exhibited a specific phenotype very similar to that described by Chen et al 2001. In all 3 children the skeletal abnormalities progressed to severe bowing of the long bones with prominent joints and severe spinal deformity. Neurological symptoms were present in all of them. These included temperature instability with excessive sweating, reduced pain sensation with repeated injury to the tongue and limbs absent corneal reflexes and smooth tongue. Mentality was normal in all of them. There were specific radiological changes which included undertubulation of the diaphyses, rarefaction and striation of metaphyses, destruction of the femoral heads and spinal deformity. We suggest that survival in this syndrome is possible and that prognosis improve immensely after the first year of life. This should be taken into consideration when counselling parents of affected children. This report further support the existence of a specific phenotype in SWS survivors which include, in addition to the skeletal abnormalities and distinctive radiological features, unique neurological symptoms reminiscent of dysautonomia.

Unilateral Epidermal Nevus, Epidermolytic Hyperkeratotic Type, Following Blascko Lines Associated with Contralateral Hemihypertrophy, Hemimegalocephaly, Pachygyria and Developmental Delay. *C. Gutierrez¹, F. Suarez¹, J.C. Prieto^{1,2}*. 1) Instituto de Genetica Humana, Universidad Javeriana, Bogota, Colombia; 2) Hospital la Victoria, Departamento de Genetica, Bogota, Colombia.

Epidermal nevus is a benign and congenital hyperplasia of epidermis that follows the Blaschko lines, characterized by located or systematized verrucous plaques that display histopathologic features typical of epidermolytic hyperkeratosis. Hemihypertrophy, hemimegalocephaly and ipsilateral gyral malformations are related with the nevus sebaceous of Jadassohn, not with the epidermal nevus alone. The central nervous system malformations are also related, if both kinds of skin lesion are found in the same patient (Solomon Syndrome). We report a 1 year old masculine patient, first child of a healthy no consanguineous parents, with a epidermal nevus, following the blaschko lines, confirmed with histopatological analysis that showed features of epidermolytic hyperkeratosis and discarding a nevus of Jadassohn, associated with other systemic malformations. The skin lesion consist of verrucous plaques in the left side of the lower face, neck, and thorax, following blascko lines, not crossing the middle line and a complete right body hemihypertrophy including face and head and a severe development delay. Cerebral magnetic resonance showed a completed right hemimegalocephaly, associated with a severe neuronal migration disorder presented as a pachygyria. To the best of our knowledge, no similar case observations have been recorded with the presented neurocutaneous disorder and the presence of epidermal nevus alone not associated with nevus sebaceous. This new case contributes with new clinic and radiological findings that have not been reported on previous cases.

Identification of the gelsolin Asp187Tyr mutation in a French family with familial amyloidosis of the Finnish type (FAF). *N. Chastan*¹, *S. Baert*², *P. Saugier-veber*¹, *D. Hannequin*^{1, 2}, *T. Frebourg*^{1, 2}. 1) Department of Neurology, CHU de Rouen, 76031 Rouen, France; 2) Department of Genetics, CHU de Rouen, 76031 Rouen, France.

Familial amyloidosis of the Finnish type (FAF) is an autosomal dominant disease resulting from the accumulation of a 71-amino acid amyloidogenic fragment derived from mutant gelsolin. FAF is characterized by corneal lattice dystrophy, progressive cranial and peripheral neuropathy, and skin changes. Two gelsolin mutations have been described so far : the most common, identified in all Finnish families, in two American and three Japanese families is a G654A transition leading to an Asp to Asn substitution at residue 187 of the protein. The second mutation is a G654T transition resulting in a Asp187Tyr substitution and was found in a Danish and a Czech family. Here we report the first case of a French FAF family which originated from Normandy. The index case developed at 55 years distal arm numbness, weakness of the facial muscle and tongue responsible for speech difficulties. Clinical investigation showed diminished touch and pain senses with reduced vibratory perception, atrophic tongue with fasciculations, right facial weakness, right impaired hearing, paresthesia of the fifth cranial nerve, dysphagia and dysarthry. The slit lamp examination showed bilateral corneal dystrophy. His mother and grand-mother were both affected, with bilateral blepharochalasis, abnormally slack and hanging skin over the face, pronounced bilateral facial weakness, atrophic tongue with fasciculations. Sequencing analysis of the gelsolin gene exon 4 identified the Asp187Tyr mutation in the proband and his mother. Investigations are under process to determine if this family shares a common haplotype with the Danish family, which would confirm the existence of a founder effect.

Evidence for Genetic Heterogeneity of the Walker Warburg Syndrome, a Disorder of Neuronal Migration. *S.*

Currier¹, D.B. Valero de Bernabe², S. Kim¹, A. Bodell¹, D. Huang¹, T.J. Cherry¹, W.B. Dobyns³, H.V. Bokhoven², H.G. Brunner², C.A. Walsh¹. 1) Neurology, Beth Israel Deaconess Medical Center and Harvard Medical School, Boston, MA, 02115, USA; 2) Department of Human Genetics, University Medical Centre Nijmegen, The Netherlands; 3) Department of Human Genetics, Neurology and Pediatrics, The University of Chicago, Chicago, IL, USA.

Human genetics has proven to be a powerful method for identifying genes involved in cortical neuronal migration. Walker Warburg Syndrome (WWS), characterized by hydrocephalus, agyria, retinal dysplasia, encephalocele and congenital muscular dystrophy demonstrates over migration of neurons through the pial surface. Cloning of the WWS gene or gene(s) should reveal mechanisms that arrest migrating neurons. With this aim we performed a genome-wide linkage analysis screen of ten consanguineous pedigrees with WWS. The screen revealed several promising loci including 16q12, 17q11, 9q34 and 14q24. Amplification of additional microsatellite markers at these loci confirmed identity by descent in a subset of patients. However none of these loci achieved a LOD score of greater than 3.0 and no single locus was identified as linked in all pedigrees. Our results strongly suggest that WWS is genetically heterogeneous. In collaboration with the lab of Dr. Han Brunner, we have been sequencing candidate genes for mutations and have preliminary evidence that, as with muscle eye brain disease, o-mannosyl transferase genes are mutated in WWS.

Action Myoclonus-Renal Failure Syndrome: Characterization of a novel autosomal recessive disease. A.

Badhwar^{1,2}, F. Andermann¹, S. Berkovic³, S. Carpenter⁴, M. Gonzales³, J. Dowling³, A. Brodtmann³, J. Caviness⁵, L. Berzen⁶, A. Rothdach⁷, O. HernandezCossio⁸, E. Andermann^{1,2}. 1) Dept Neurology & Neurosurgery, McGill Univ, Montreal, PQ, Canada; 2) Dept. of Human Genetics; 3) Epilepsy Research Center, Austin & Repatriation Medical Center, Melbourne, Australia; 4) Dept. of Pathology, Univ. of Porto, Porto, Portugal; 5) Movement Disorders Center, Mayo Clinic, Scottsdale, AZ; 6) Dept. of Psychiatry, British Columbia Hospital, Vancouver, Canada; 7) Clinical Neurophysiology, Univ. of Goettingen, Goettingen, Germany; 8) Neurology, Curitiba, Brazil.

Action myoclonus-renal failure syndrome (AMRF) is a distinctive form of progressive myoclonus epilepsy associated with severe renal dysfunction. The first and only description of AMRF was in 4 French-Canadian patients (*Adv Neurol*,1986). We describe 15 patients (11 new) in 9 families from 5 countries. Autosomal recessive inheritance was determined based on absence of affected cases in previous generation; multiple affected siblings (4 families); parental consanguinity (3 families); and parental origins from the same rural area (6 families). Initial presentation can be renal or neurological or both. Tremor (onset:17-26 years, mean:19.8), progressive action-myoclonus (onset:19-29 years, mean:21.7), infrequent generalized seizures (onset:20-28 years, mean:22.7) and cerebellar features are characteristic. Proteinuria was detected in all cases and was detected between 10-30 years, and progressed within 8 years to renal failure in 12 patients. Brain autopsy (2 patients) revealed extra-neuronal pigment accumulation. Renal biopsy showed collapsing glomerulopathy. Our study extends the original AMRF phenotype and demonstrates that it is not due to a private French Canadian gene. Independent progression of neurological and renal symptoms suggests pleiotropic effects of a unitary molecular lesion, differentially affecting the two organ systems. Treatment with anti-myoclonic drugs and effective dialysis and/or transplantation can improve quality of life. The renal lesion in AMRF is a recessive form of collapsing glomerulopathy. Genes identified for focal segmental glomerulosclerosis to date are thus good candidates.

Obsessive compulsive symptoms in parents of individuals with Autistic Disorder. *R.K. Abramson¹, K.M. Wieduwilt¹, S.A. Ravan¹, K.A. Decena¹, H.H. Wright¹, M.L. Cuccaro².* 1) Dept Neuropsych & Behav Sci, W.S. Hall Psychiatric Inst, Columbia, SC; 2) Center for Human Genetics, Duke University, Durham, N.C.

One area of impairment in Autistic Disorder (AD) is repetitive behaviors and stereotyped patterns. Gordon(1992), Bolton(1998) and Piven(1999) asked if restrictive and repetitive behaviors seen in persons with AD are related to symptoms of Obsessive Compulsive Disorder(OCD). Cook(1994)and Bolton(1998)found an increase in OC symptoms/OCD in family members.This study examines OC symptoms in parents of AD individuals as a first step in relating OC symptoms in parents and restrictive/repetitive behaviors in AD individuals. The Yale-Brown Obsessive Compulsive Behavior Scale(Y-BOCS;Goodman,1986) a self-report scale that identifies the nature and extent of OC symptoms was sent to parents in the Duke/USC AD research project. Males(n=28) were 45.2% of the sample and females(n=34)54.8%. Clinically significant Y-BOCS scores were present in 34% of parents, with moderate to severe scores in 13.2%. Family history data for 131 families at USC was similar: 34.4% of families had first/second degree relatives with probable/ confirmed OCD and 11.5% with confirmed OCD. Parents with clinical Y-BOCS scores differed significantly from those with subclinical Y-BOCS scores, endorsing certain obsessions and compulsions most or all of the time. Significant obsessions were fear of doing something embarrassing(p=0.014);fear of being responsible for something terrible happening(p=0.010); bothered by certain sounds/noises (p=0.005); and overly concerned with body parts and/or appearance(p=0.035). Significant compulsions were check locks, stove, appliances(p=0.001);check you did not make a mistake(p=0.001); and reread/rewrite things (p=0.035). Significant compulsions and rituals in this study compare to Cuccaro's (2000) Factor 2 derived from factor analysis of restrictive/repetitive behaviors from the Autism Diagnostic Interview-Revised. Factor 2 reflects problems with minor changes, compulsions and rituals in AD individuals. Future correlation of AD Factor 2 scores with clinical parent OC symptoms could clarify commonality of OC symptoms between parents and AD children and identify a subset of AD families.

Classic Rett syndrome in a boy with MECP2 mutation. *I. Kondo¹, T. Masuyama², S. Matsuo³, K. Kitsuki², Y. Kan², K. Ishii³, H. Yamagata¹.* 1) Dept. of Hygiene, Ehime Univ. School of Medicine, Ehime, Japan; 2) Saga Seishi Child Developmental Medical Center, Saga, Japan; 3) Dept. of Pediatr., Saga Medical School, Saga, Japan.

Rett syndrome (RTT) is a neurodevelopmental disorder affecting females in a sporadic manner and DNA mutations in methyl-CpG binding protein 2 gene (MECP2) have been detected in about 80% of the female patients with classical RTT. The existence of RTT males has been discussed extensively, because males with MECP2 mutations have severe encephalopathy in families with female RTT patients. In addition, MECP2 mutations have been detected in males with an X-linked recessive form of nonspecific mental retardation syndromes. Classic RTT was diagnosed in two boys with a somatic mosaicism of MECP2 mutation, 2 bp deletion within exon 3 and R133H. We report here a family with a missense mutation in MECP2, R133C. A female patient was diagnosed with RTT at age 3 and MECP2 mutation, R133C was confirmed at age 12. Developmental delay was noted in her young brother at age 12 months, and classic RTT symptoms were developed at age 3. MECP2 analysis was performed at the age 10. He had only a C133 allele indicating without somatic mosaicism. Their mother was a carrier for the R133C and she was slightly mentally retarded. The R133C mutation has been detected in female patients with classic RTT and preserved speech variant form of RTT, but not in male patients with nonspecific X-linked mental retardation syndromes. These results strongly suggest that a phenotype caused by DNA mutations in MECP2 is determined by position of mutation site and the R133 is a critical amino acid residue to introduce RTT symptoms in human.

A sibling of a patient with Smith-Lemli-Opitz syndrome was a heterozygote for DHCR7 mutation. *M. Mori, M. Komiyama, S. Kato, L. Hong, T. Yamagata, M. Mizuguchi, M.Y. Momoi.* Dept Pediatrics, Jichi Medical Sch, Tochigi, Japan.

SLOS is an autosomal recessive disorder that is caused by the reduced activity of 7-dehydrocholesterol B7-reductase(DHCR7). Low plasma and tissue cholesterol levels and increased plasma and tissue 7-dehydrocholesterol (7-DHC) are characteristic biochemical findings. Because of the importance of cholesterol in morphogenesis, the derangement of cholesterol metabolism causes varieties of congenital anomalies as observed in SLOS. An infant presenting with failure to thrive, generalized hypotonia, and developmental delay was diagnosed as having SLOS with the serum cholesterol level of 30mg/dl. Her anomalies included mild facial dysmorphism, prominent foreheads, syndactyly in her 2, 3 toes, ambiguous genitalia and pyloric stenosis. Sequence analyses of DHCR7 revealed that she was a compound heterozygote with G303R and R352Q. The former was a novel missense mutation found in SLOS. The patient's sister who had holoprosencephaly without associating other anomalies and with the normal level of serum cholesterol was a heterozygote with G303R. The SLOS is rare in Asian population and this is the first report that confirmed DHCR7 gene mutations in Japanese patient. The patient's clinical symptoms and biochemical characters were typical in SLOS. R352Q mutation that is located in the transmembrane domain (TM mutations) was related with the mildest clinical phenotype. A novel missense mutation, G303R, substitutes a highly conserved amino acid at 303 and is also located in TM domain. Considering the severe clinical and biochemical phenotype of our patient, this novel mutation can cause profound defect in the enzyme. Whether G303R detected in her sibling can cause holoprosencephaly or requires other gene mutation, the further studies is required.

Spinocerebellar ataxia type 2 (SCA2) presenting with ophthalmoparesis and developmental delay in infancy. *P. Moretti¹, M. Blazo¹, L. Garcia², F. Scaglia¹*. 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX 77030; 2) Pediatrics and Neurology, UT San Antonio, Mc Allen, TX 78503.

Autosomal dominant cerebellar ataxias are a heterogeneous group of neurodegenerative disorders that generally present in adulthood. SCA2 typically presents with progressive cerebellar symptoms and slow ocular saccades. An 11-year-old boy was evaluated for progressive ataxia, ophthalmoparesis, and developmental delay. Abnormal eye movements were noted at age two months. Developmental delay was noted at age six months. At seven years he was found to have poor balance and coordination and progressive cognitive deterioration. He has developed difficulty swallowing and loss of bladder function. The mother was unaffected and the father was not known. General physical examination was normal. On neurological examination he had bilateral external ophthalmoplegia, ataxic dysarthria, dysmetria and tremor in the upper extremities, and marked gait ataxia. There was no evidence of pigmentary retinopathy. Brain MRI demonstrated cerebellar, brainstem, and cerebral atrophy. Brain MR spectroscopy, plasma amino acids, and urine organic acids were normal. Alpha-fetoprotein and immunoglobulin levels were normal. An ataxia panel showed 62 repeats in one of the alleles of the SCA2 gene. The mother had normal SCA2 alleles with 22 repeats (normal size between 14 and 31 CAG repeats). The patient was diagnosed with SCA2 based on history, examination findings, and expansion of CAG repeats in one allele of the SCA2 gene. Most cases of SCA2 present between 20 and 40 years and affected individuals have between 34 and 57 CAG repeats. Ocular motor apraxia or ophthalmoparesis may be present in early stages of the disorder. Infantile and childhood cases of SCA2 have very rarely been described in the literature. The most severe case known was described in a neonate with over 200 CAG repeats. This case contributes to the characterization of the phenotypic spectrum of SCA2 and highlights the importance of considering this diagnosis in young children. Developmental delay in addition to abnormal eye movements appears to be an early clinical feature in this age group.

Outcomes of a genetic and neurological evaluation in 84 individuals with pervasive developmental disorders. *A.P. Marques-de-Faria¹, C.E. Steiner¹, M.M. Guerreiro²*. 1) Departamento de Genética Médica; 2) Departamento de Neurologia, FCM-UNICAMP, Campinas,SP, Brazil.

Pervasive developmental disorders (PDD) constitute a heterogeneous group of conditions comprising autism, atypical autism, Asperger syndrome, Rett syndrome, and PDD not otherwise specified. There is a wide range of phenotypic expression and its management presents particular challenges for clinicians. We studied 103 individuals with a preliminary diagnosis of autism using a protocol that included an initial assessment based on neuropsychological criteria, followed by a careful clinical evaluation with special attention to dysmorphic and neurological findings, screening for inborn errors of metabolism, chromosomal analysis, molecular study of FRAXA, FRAXE and FRAXF mutations, EEG, magnetic resonance and SPECT imaging. As 2 patients had the diagnosis of Rett syndrome, 6 had other functional neuropsychiatric diagnosis and 11 were excluded due to incomplete complementary investigation, the final sample comprised 84 individuals (71 males and 13 females) who met the DSM-IV criteria for PDD and were classified in 3 main clinical groups: autism (71.4%), atypical autism (15.5%) and Asperger syndrome (13.1%). A recognizable syndrome or genetic disorder was identified in 17 individuals (20.2%), of which 3 with Down syndrome (3.6%), 2 with untreated phenylketonuria (2.4%), 1 with fragile X syndrome (1.2%), 1 with tuberous sclerosis (1.2%), 5 with other monogenic conditions (6%) and 2 with balanced chromosomal rearrangements (2.4%), one maternal chromosome 9 pericentric inversion and one Robertsonian translocation (15q21q), besides 3 individuals with non-genetic etiologies. The relatively high prevalence of genetic causes corroborates previous data that pointed individuals presenting PDD should have a detailed clinical genetic evaluation, as well as chromosome analysis and tests for the fragile X mutations. Neuroimaging findings revealed low frequency and specificity among the groups and the value of these exams as routine in all patients with PDD seems secondary. Other aspects as sex ratio, familial recurrence and some findings as increased head circumferences are also discussed.

Neuronal intranuclear inclusions in a tremor/ataxia syndrome among fragile X premutation carriers. *P.J.*

*Hagerman*¹, *C.M. Greco*², *R.J. Hagerman*³, *F. Tassone*¹, *A.E. Chudley*⁴, *M.R. Del Bigio*⁵, *S. Jacquement*³, *L. Gane*³, *M. Leehey*⁶. 1) Department of Biological Chemistry, University of California, Davis, School of Medicine, Davis, CA; 2) Department of Pathology, University of California, Davis, School of Medicine, Davis, CA; 3) M.I.N.D. Institute, University of California, Davis, School of Medicine, Davis, CA; 4) Department of Pediatrics and Child Health, University of Manitoba, Winnipeg, Manitoba, Canada; 5) Department of Pathology, University of Manitoba, Winnipeg, Manitoba, Canada; 6) Department of Neurology, University of Colorado Health Sciences Center, Denver, CO.

Fragile X syndrome is generally regarded as a non-progressive neurodevelopmental disorder in which premutation carriers (~55 to 200 CGG repeats; FMR1 gene) are largely unaffected. However, neurological findings of progressive action tremor, ataxia, cognitive decline, and generalized brain atrophy have recently been described in some adult males with premutation alleles. Neurohistological studies on the brains of five adult (>50y) male carriers (range: 70-135 CGG repeats) who had the neurological findings reveal ubiquitin-positive intranuclear inclusions in both neuronal and astrocytic cells of all five males, with highest frequencies (~40% of neuronal nuclei) in the hippocampus. These observations strongly support the association of inclusions with the premutation alleles. Additional studies were also conducted on a 75y female with the premutation but without any neurological findings, a cognitively impaired adolescent female with the premutation, and a typically affected young adult male with the full mutation. None of these patients displayed inclusions or other neuropathologic findings. The basis for inclusion formation among premutation carriers is not known. The FMR1 protein (FMRP) is structurally normal and is present at near-normal levels in the low-mid premutation range. Moreover, the inclusions do not react to antibodies to tau protein, alpha-synuclein, or polyglutamine repeats, suggesting a novel pathogenic mechanism. FMR1 mRNA levels are elevated by 2 to 5-fold in this range, raising the possibility that altered message levels may participate in inclusion formation and neuropathology.

Monosomy 1pter Syndrome: A Case Report. *C. Li*^{1,2}, *C. Prasad*^{1,2}. 1) Section Genetics and Metabolism, Department of Biochemistry and Medical Genetics, University of Manitoba; 2) Pediatrics and Child Health, Health Sciences Center, Winnipeg, R3A 1R9, Canada.

We report a 20 year old male patient with inherited unbalanced karyotype 45,XY, der(1)t(1;15)(p36.3;q11),-15mat. The mother carries the balanced reciprocal t(1;15) and is phenotypically normal. The proband has lost a tiny segment of chromosome 15pter~q11. As loss of this segment of chromosome 15 is clinically inconsequential, our patient is primarily monosomic for 1p36.3 only. Hemizyosity for 1pter has the patient exhibiting profound mental retardation, no speech and severe physical handicap (wheel-chair bound, ambulatory only by means of crawling). He also has craniofacial dysmorphism with flat occiput, sloping forehead, prominent supra-orbital ridges, deep-set eyes, malar hypoplasia and prognathia. In addition, he has patches of discoloration of the scalp hair, although examination of the eyes and skin did not reveal heterochromia and hyper- or hypo-pigmented patches or streaks. Delineation of chromosomal disorders in patients with unbalanced karyotypes is often complicated by the fact that the patients are often monosomic for one chromosome segment and trisomic for another chromosome segment that are involved in an originally balanced rearrangement. Therefore, in those situations, it is very hard, if possible at all, to attribute observed phenotypes to a particular imbalance, be it segmental monosomy or segmental trisomy. Our case, therefore, may be valuable in correlating cytogenetic abnormality and clinical phenotypes. For example, certain features of del(1pter) described in the literature were observed in our patient. Unique features, however, were also appreciated. Furthermore, the nature of the chromosomal anomaly in our patient may be taken advantage of to elucidate the molecular basis of these patients' deviation from normal development: known cell cycle and neuro-transmitter receptor genes, e.g. CDC2L1(mim#176837), CDC2L2(mim#116951), and GABRD(mim#137163) are located at 1p36.3. Haplo-insufficiency and/or dominant negative effects of these genes may each, and in combination, have their influence on phenotypic expressions.

Identifying genetically informative phenotypes in autism spectrum disorders (ASD). *P. Szatmari¹, C. Merrette², M. Jones³, R. Palmour⁴, L. Zwaigenbaum⁵, M. Roy², M. Maziade².* 1) Dept Psychiatry, McMaster Univ, Hamilton, ON, Canada; 2) Dept of Psychiatry, Laval Univ, Quebec City, Quebec, Canada; 3) Dept of Behavioral Sciences, Penn State Univ College of Medicine, Hershey PA, USA; 4) Dept of Psychiatry, McGill Univ, Montreal Quebec, Canada; 5) Dept of Pediatrics, McMaster Univ, Hamilton ON Canada.

Even though autism is a highly heritable disorder, it has proven difficult to identify susceptibility genes. One possible reason for this is that genetically informative phenotypes have not been used in current studies. Autism is a clinically heterogeneous disorder but most studies have not taken a systematic approach to narrowing the phenotype. We followed a logical series of steps to identify more informative phenotypes using a sample of 57 affected sib pairs with autism or another ASD and 45 singletons. Data included measures of autistic symptoms using the ADI-R, measures of level of functioning, IQ on unaffected first degree relatives, and a measure of PDD like traits (the extended autism phenotype) in other family members. In the first step, a factor analysis revealed that the ASD phenotype is composed of two separate dimensions; autistic symptoms and level of functioning (LOF). In the second step, a cluster analysis showed that two more homogeneous subgroups can be identified that essentially differ on LOF; a higher functioning group with autism, Asperger syndrome and PDDNOS and a lower functioning group with just autism. This classification was familial in that proband and affected sibling tended to be in the same cluster (high or low functioning). In the third step, we found that the high functioning cluster appeared to be more familial than the low functioning one since it was associated with a higher risk of the extended autism phenotype. These data suggest that the phenotype to be used in genetic studies should include higher functioning probands and affected siblings. The low functioning cluster may represent an admixture of non-specific mental retardation syndromes. Including a large number of these lower functioning sib pairs in genome scans may make it difficult to then identify susceptibility genes.

Tumor burden and neurological symptoms in neurofibromatosis 2. A. Shenton¹, D.G.R. Evans¹, J.M. Friedman², M.E. Baser³. 1) Department of Medical Genetics, St. Mary's Hospital, Manchester, U.K; 2) Department of Medical Genetics, University of British Columbia, Vancouver, B.C., Canada; 3) Los Angeles, CA, U.S.A.

Neurofibromatosis 2 (NF2) is an autosomal dominant disease that is characterized by nervous system tumors. Vestibular schwannomas (VSS) are the most common type of tumor, but intracranial meningiomas, spinal tumors, non-VS cranial nerve tumors, and peripheral nerve tumors are also very common. We used data from the United Kingdom NF2 registry to examine the association between non-VS nervous system tumors and non-vestibular neurological symptoms in 227 people from 151 families (120 new mutations and 107 inherited cases) who were personally examined by D.G.R.E.; known somatic mosaics were excluded. The prevalence of VSS was 95%. The prevalence of non-vestibular symptoms was mononeuropathy, 11%; headache, 29%; seizures, 20%, paraesthesias, 27%; wasting or weakness, 33%; peripheral neuropathy, 15%; and facial palsy, 47%. Multiple logistic regression was used calculate relative risks (RR). The RR of mononeuropathy decreased 0.86-fold per year increase in age at onset of symptoms (95% confidence interval (CI), 0.80-0.91). The RR of headache was 1.98-fold greater in people with non-VS cranial nerve tumors than in those without, and 1.99-fold greater in people with intracranial meningiomas than in those without (95% CI, 1.06-3.72). The RR of seizures increased 1.26-fold per intracranial meningioma (95% CI, 1.08-1.47). The RR of paraesthesias increased 1.15-fold per peripheral nerve tumor (95% CI, 1.07-1.24) and was 3.22-fold greater in people with intracranial meningiomas than in those without (95% CI, 1.72-5.41). The RR of wasting or weakness increased 1.22-fold per intracranial meningioma (95% CI, 1.05-1.41). The RR of peripheral neuropathy increased 1.09-fold per peripheral nerve tumor (95% CI, 1.02-1.16). The RR of facial palsy was 2.31-fold greater in people with non-VS cranial nerve tumors than in those without (95% CI, 1.29-4.14). In future work, we will examine the relationship between age at onset of symptoms and age at diagnosis of tumors.

EEG abnormalities and epilepsy in Smith-Magenis syndrome [del(17)(p11.2p11.2)]. *L. Potocki*^{1,5,6}, *J.K. Lynch*^{2,3,5}, *D.G. Glaze*^{2,3,4,5,6}, *K. Walz*^{1,5}, *J.L. Noebels*^{2,5}, *J.R. Lupski*^{1,4,5,6}. 1) Department of Molecular and Human Genetics; 2) Peter Kellaway Section of Neurophysiology; 3) Department of Neurology; 4) Department of Pediatrics; 5) Baylor College of Medicine, Houston, TX; 6) Texas Children's Hospital, Houston.

Smith-Magenis syndrome (SMS) is a syndrome of multiple congenital anomalies and mental retardation associated with a deletion of chromosome 17p11.2. The neurobehavioral phenotype in SMS includes sleep disturbance, aggressive and self-injurious behaviors, EEG abnormalities, and seizures. Sixty patients with SMS were evaluated as part of a multidisciplinary clinical protocol at the Texas Childrens Hospital. Prolonged EEGs were obtained during an overnight sleep study. Of the 60 patients, 29 (48.3%) had abnormal EEGs, 27 of these were epileptiform in nature. Focal abnormalities were found in 8/27 (29.6%), and 21/27 (77.8%) showed generalized epileptiform features, including various 2-4 cps spike and slow wave patterns in single waveforms or bursts up to several seconds in duration. Seizures were reported in only 11 (18.3%), and included absence (7/11), generalized tonic-clonic (4/11), and drop attacks (2/11). Half of this group (54.5%) showed abnormal EEGs. Human chromosome 17p11.2 is syntenic to the 32-34 cM region of murine chromosome 11. Interestingly, we found that EEG abnormalities and/or seizures are present in 14-29% of mice (strain-dependent) deleted for the syntenic region of SMS. Epilepsy is a frequent component of SMS. In our study, nearly one-half of patients with SMS have abnormal EEGs, the majority of which are generalized spike and slow wave variants, however, the epileptiform EEG abnormalities do not correlate well with seizure history, which was positive in 11/60. The common SMS interval spans ~3-4Mb. The deletion size does not correlate with the presence of EEG abnormalities or seizures. None of the genes identified within the commonly deleted region have a currently known role in epilepsy. The mouse model will be useful in characterizing the contribution of specific genes to the epilepsy of SMS.

A clinical study of the Troyer syndrome, a recessively inherited form of complicated hereditary spastic paraplegia. *C. Proukakis*^{1,2}, *H. Cross*³, *H. Patel*¹, *M.A. Patton*¹, *A. Valentine*⁴, *A.H. Crosby*¹. 1) Department of Medical Genetics, St George's Medical School, London, England; 2) Department of Clinical Neurosciences, Royal Free and University College Medical School, London, England; 3) Department of Ophthalmology, University of Arizona, Tucson, Arizona; 4) Department of Neuroradiology, Royal Free Hospital, London, England.

The Troyer syndrome is a recessively inherited form of complicated hereditary spastic paraplegia with distal amyotrophy. It was originally described in 1967 in an Old Order Amish population practicing strict endogamy over a number of generations. A few similar cases have been described since around the world. We have performed a detailed clinical study of Troyer syndrome in the Amish population. A total of 21 patients were examined, including 3 from the original study. The cardinal features were spastic paraparesis with upper limb hyperreflexia, dysarthria and distal amyotrophy. Early milestones were delayed, and difficulties at school were reported. Gait and speech were abnormal from the onset. Emotional lability was usually present and the disease was slowly progressive. Mild cerebellar signs were often found, and the most severe cases had choreoathetoid movements. Skeletal abnormalities were also present including pes cavus, short stature and joint hyperextensibility. Blood testing for metabolic disorders was unremarkable. MRI scans in 3 patients revealed white matter hyperintensity in various parts of the brain including periventricular areas (especially temporoparietal), the internal capsules and the cerebellar peduncles. Nerve conduction studies and electromyograms in 2 patients were unremarkable. Parallel gene identification studies of these patients have led to the discovery of a novel gene designated spartin (also presented at this meeting).

Sensory neuropathy with decreased NCV in Fabry patients with preserved renal function. *P. Ribai¹, M. Henri², F. Dehout², D. Roland¹, L. Van Maldergem¹.* 1) Ctr Human Genetics, Inst Pathology and Genetics, Lovreval, Belgium; 2) Dpt of Neurology and Nephrology, ISPPC, Charleroi, Belgium.

The involvement of large myelinated fibers has remained controversial in the pathophysiology of peripheral neuropathy associated with alpha-galactosidase deficiency. If involvement of c-fibers has been clearly demonstrated, alterations in nerve conduction velocities (NCV) and/or amplitude of action potentials of large fibers have been usually attributed to renal insufficiency which is a classical complication in Fabry disease. We have undertaken a systematic motor and sensitive evaluation of a group of eleven Fabry disease's patients, in which three were untreated and eight were under enzyme replacement therapy. Upper and lower limbs NCV were measured by standard methods, at the same skin temperature. Sural, external and internal peroneal nerves were tested in the lower limbs. One untreated patient (a symptomatic female carrier) had a decrease in sural nerve conduction velocity and amplitude of sensory action potential. Her kidney function was normal. Six patients under enzyme replacement therapy had abnormal amplitudes and/or NCV in lower limbs. Interestingly, only three of these six patients had renal insufficiency. These results suggest that a large fibers sensory neuropathy independent from renal insufficiency is present in Fabry patients.

Diprosopus: A unique case and review of the literature. *J. Wu*¹, *A. Shanske*², *D. Staffenberg*¹, *J.B. Mulliken*³. 1) Plastic Surgery, Montefiore Medical Center, Albert Einstein College of Medicine, Bronx, NY; 2) Center for Craniofacial Disorders, Children's Hospital at Montefiore, Albert Einstein College of Medicine, Bronx, NY; 3) Craniofacial Centre, The Children's Hospital, Harvard Medical School, Boston, MA.

Craniofacial duplication, or diprosopus, is considered an unusual variant of conjoined twins. The phenotype comprises a wide spectrum and ranges from partial duplication of a few facial structures to complete dicephalus. These cases are rare and differ sufficiently from one another to make each case unique and worthy of study for their contribution to our understanding of pathogenesis and management. We recently evaluated a male infant with partial duplication. BS was the 2845gm product of a term uneventful pregnancy. The newborn examination revealed low-set pinna, orbital hypertelorism, a widow's peak, and downward obliquity of the palpebral fissures. The forehead had prominent transverse wrinkling. Cupid's bow was wide and the nasal tip was bifid. The maxilla and mandible were duplicated and there were 2 tongues with a common base. The upper labial frenulum was duplicated and the secondary palate was cleft. Imaging revealed bifurcation of the upper cervical spine, absence of the corpus callosum, and abnormal olfactory gyri. The midbrain was dysmorphic, the medulla and clivus were partially split and the pituitary gland and stalk were duplicated. A separate interparietal bone was noted. His postnatal course was complicated by chronic respiratory distress secondary to secretions resulting in a gastrostomy at 3 months. Experimental and embryologic evidence suggests the importance of notochord formation in the development of facial duplication. The notochord process grows between ectoderm and endoderm until it reaches the prochordal plate. It elongates and eventually extends to the oropharyngeal membrane by about 20 days. The temporal-spatial relationships of its development predicts the common involvement of the forebrain, mouth, mandible, maxillae, tongue and thyroid. It is hoped that this case and future cases as well as discoveries in notochordal signalling pathways will result in a clearer understanding of the pathogenesis of this defect.

Autism: Characterization of Sleep Disorders. *P.T. Yu, T.N. Takahashi, J.H. Miles, P.K. Sahota.* Children's Hospital, University of Missouri-Columbia, Columbia, MO.

Autism is a neurobehavioral disorder diagnosed by abnormal social, language and repetitive behaviors. Sleep disruption is an additional symptom that interferes with family functioning and may effect outcome. Because the nature and frequency of sleep problems in autism is poorly understood, we analyzed parental sleep reports for 163 children seen in the Autism Clinic at the University of Missouri from 1996-2002. The prevalence of insomnias (initiating and/or maintaining sleep), parasomnias (night wandering, sleepwalking, enuresis, bruxism, night terrors, etc.) and circadian rhythm disorders was determined and subject comparisons were made. We found a high prevalence (85.3%, 139/163) of any sleep disorder, regardless of age, IQ, seizures, regressive onset, dysmorphology or essential/complex designation. Essential autism (not dysmorphic, normal HC, structurally normal brain) is a more homogeneous, genetic autism subtype. Insomnia occurred in 69.3% (113/163) of subjects, with no difference in problems of sleep initiation alone (14.1%, 23/163) versus sleep maintenance alone (11.7%, 19/163). There was no significant difference in the prevalence of insomnia between the essential and complex groups. Parents reported a higher prevalence of parasomnias (77.3%, 126/163) than insomnias. The most common parasomnias were night wandering (20.9%), bruxism (24.5%), snoring (34.4%), and nocturnal enuresis (31.3%). All of these parasomnias were significantly more common than expected in typical children. Night time wandering occurred 2.4 times more in children with essential autism, suggesting that this may be a problem more specific to autism than complex developmental disorders. Night time enuresis was more frequent in the 5 - 11 year olds with complex autism ($p = .024$). Between the two broad categories of insomnia and parasomnia, subjects were more likely to suffer from parasomnias alone (26.4%, 43/163) than from insomnia alone (6.1%, 10/163), [$p = 7.3 \text{ e-}7$]. There were no significant findings of circadian rhythm disorders in this population. These results indicate that sleep problems, particularly the parasomnias, are common in autism and occur in all autism subgroups.

The neuropathology of Amish lethal microcephaly. *K.A. Strauss¹, R. Pfannl², D.H. Morton¹*. 1) Clinic for Special Children, Strasburg, PA; 2) Harvard Combined Program in Neuropathology.

Introduction: Amish lethal microcephaly (ALM) is a recessive disorder prevalent among Old Order Amish of Lancaster County, PA. The putative mutant protein is an inner mitochondrial membrane transporter which mediates deoxynucleotide diphosphate flux in vitro, and contains a structural motif predicting high-affinity binding to 2-ketoglutarate. Affected children have extreme micrencephaly, massive 2-ketoglutaric aciduria, and early death. We present neuropathology from a deceased 4 month old infant with ALM. Results: The brain weighed 91 grams. Frontal lobes were smooth and rudimentary, with diminutive anterior callosal and corticospinal fibers. Increasing convolution and lamination progressed occipitotemporally. Leptomeninges were focally thickened over the posterior cerebellum and anterolateral brain base; microscopically these were thick neuroglial heterotopias connected by bridge-like extensions to underlying neuropil. There were numerous heterotopic neurons in the intermediate zone within a dense background of reactive astrocytes and vacuolated neuropil. Symmetric, confined, and severe basal ganglia lesions were microscopically characterized by neuronal degeneration, mineral deposits, reactive astrocytosis, and new vessel formation. Conclusions: Enumeration of cells in the neocortical pseudostratified ventricular epithelium (PVE) is linked to histogenetic events that follow. Early cell cycle disruptions along the neuronogenetic gradient affect both spatial order and relative cell composition of the neocortical protomap; the abnormal pattern becomes amplified as histogenesis proceeds. Thus the most hypoplastic brain regions were also histologically most chaotic, remaining radially undifferentiated, with aberrant radial glia, patchy interruptions of the pial migration barrier, mixed heterotopias on the cortical surface, remnant subplate neurons in the intermediate zone, and a numerical dominance of astrocytes. Biochemical vulnerability of the PVE is based on its extraordinary proliferative pace, which demands synchronous nuclear and mitochondrial DNA replication, rapid protein accretion, and a sustained elevation of aerobic energy flux.

Intermediated Phenotype Between Amniotic Bands Sequence and Adams Oliver Syndrome. *F. Suarez, ML. Tamayo, J.C. Prieto.* Instituto de Genetica Humana, Universidad Javeriana, Bogota, Colombia.

Absence defects of limbs, scalp and skull, also know as Adams Oliver syndrome, is characterized by the presence of congenital aplasia cutis, variable terminal transverse defects in upper and lower extremities. The amniotic band sequence is a set of adhesions, mutilations and deformities, attributed to amniotic bands that disrupt fetal parts. Both entities, share clinical findings. In some patients with Adams Oliver syndrome had the initial diagnostic of amniotic band sequence. We report a Masculine patient, 26 months of age, product of first pregnancy, was born by cesarean delivery due to hydrocephaly. The mother was 26 years old, with nonsyndromic neurosensorial deafness of unknown cause, and the father was 25 years old with deafness secondary to meningitis. Physical examination showed turricephaly, shortened front to back diameter of the skull, small forehead, mid-face hypoplasia and linear right nostril defect. Accessory nipple in right hemithorax and a thoracic spine skin dimple. Cutaneous syndactyly, short fingers and terminal transverse defects with constricting rings in hands, short and small toe nails. He has no scalp or skin defects. Magnetic resonance of the brain showed fused thalamus, agenesis of the corpus callosum, obstructive hydrocephalus and skull malformations. Thoracic spine X ray showed bony defect of the posterior thoracic vertebral arches. Chromosomes were normal (46,XY). The physical findings of this patient suggest a secondary sequence to amniotic bands; nevertheless he presents other signs that have been described in the Adams Oliver Syndrome, including the terminal transverse defects in hands, accessory nipples, and short and partially syndactylous fingers and toes. In addition the patient presents with lobar holoprosencephaly, hydrocephaly, severe craniosynostosis and neural tube defect at thoracic level, alterations that are not characteristic of Adams Oliver syndrome, but are not either related of common way to the amniotic bands syndrome. This case shows that these two syndromes are part of a spectrum, which can share a common etiology in a vascular disruption sequence with an unknown genetic basis.

Correlation of genotype with the Autism Diagnostic Interview to stratifying cases of autism spectrum disorder.

*C.J. Stodgell*¹, *S.L. Hyman*², *S.E. Bryson*³. 1) Dept OB/GYN, Univ. of Rochester, Rochester, NY; 2) Dept Pediatrics, Univ. of Rochester; 3) Dalhousie University-IWK Health Centre, Halifax, Nova Scotia.

Autism spectrum disorders (ASDs) are neurodevelopmental disorders characterized by deficits in socialization and communication and, limited interests and preoccupations. Their prevalence is estimated to be 6/1,000 births. This study examined the relationship between the genotypes of candidate genes (e.g., *HOXA1*) and the phenotype of ASDs. We tested the hypothesis that outcome on subscores of the Autism Diagnostic Interview (ADI), a caregiver interview used to diagnose autism, would be predicted by the genotype of specific candidate genes. DNA was extracted from leukocytes isolated from peripheral blood. Each proband was genotyped for the candidate genes. ADI data was examined for probands with differing allelic variants. For example, summary scores evaluating communication indicated that probands with a AG or GG *HOXA1* genotype scored worse than probands with the AA genotype ($p < .001$). Analyses of individual communication items indicated that the G-allele predicted abnormal use of headshaking ($p < .015$) and pointing for communication ($p < .014$). Limited/repetitive interests were significantly more affected for AG probands than AA probands ($p < .001$). AG probands also showed evidence of problems at a significantly earlier age ($p < .002$) and spoke their first words significantly later ($p < .015$) than the AA probands. These data suggest that the G allele is associated with particular aspects of the autism phenotype, for example, nonverbal communication and obsessive interests, but not with deficits in other domains of ASDs such as reciprocal communication and social interaction. (Supported by NICHD RO124969 & PO125466, a Collaborative Program of Excellence in Autism.).

A novel congenital microcephaly phenotype: progressive infantile neuronopathy, cataracts, leukoencephalopathy and autonomic dysfunction. *K.J. Swoboda¹, A.F. Poss², K. Hyland³, J.M. Opitz²*. 1) Dept Neurol, Univ Utah Sch Med, Salt Lake City, UT; 2) Dept Human Genetics, Univ Utah Sch Med, Salt Lake City, UT; 3) Baylor Institute of Metabolic Disease, Dallas, TX.

We describe siblings with a novel neurodegenerative disorder characterized by: 1) congenital microcephaly with poor brain growth and progressive atrophy 2) paucity of central myelin, with a thin corpus callosum and progressive myelin loss 3) progressive neuromuscular weakness evolving in early infancy, most severely affecting the legs and ultimately leading to lower extremity paralysis, intercostal weakness, poor bulbar function, aspiration and tongue fasciculations and 4) autonomic dysregulation including ptosis, bowel dysmotility, gastroesophageal reflux, intermittent color changes, abnormal sweating and temperature regulation and apneic episodes. One sibling had congenital unilateral ptosis and cataracts, and died at one year of age with progressive respiratory failure. The second sibling developed recurrent generalized seizures by 4 months of age; cataracts did not become apparent until after 8 months of age. Parents are nonconsanguineous and have a healthy 5 year old son. Electromyography, muscle and nerve biopsy studies revealed a pattern of abnormalities similar to that seen in 5q SMA, but anterior horn cell drop out on autopsy could not be confirmed. Extensive metabolic evaluation excluded hexosaminidase deficiency, lysosomal disorders, serine deficiency, peroxisomal and mitochondrial disorders; high resolution karyotype and telomere FISH were normal. Cerebrospinal fluid analysis for neurotransmitter metabolites in one sibling revealed evidence of BH4 deficiency and decreased homovanillic acid consistent with a dopamine deficiency state. These abnormalities are almost certainly secondary. She had a partial response to treatment with BH4 and L-dopa/carbidopa with improved ptosis, alertness and circulatory instability, but continued to demonstrate progressive brain involvement and died of an ARDS-like illness at 14 months of age. Identification of similarly affected infants could help to further clarify the genetic and pathophysiologic basis of this disorder.

Congenital visceral and neurocutaneous glomangiomas, an aneurysm of the subhepatic inferior vena cava and diffuse arterial dysplasia. *D.S. Huff¹, P.J. Zhang³, J.A. Golden¹, D.M. McGinn-McDonald², E.H. Zackai².* 1) Dept Pathol, CHOP, Phila, PA; 2) Div of Human Genet and Mol Biol, CHOP, Phila, PA; 3) Pathol and Lab Med, University of Pennsylvania Medical Center, Phila, PA.

Introduction: Glomus bodies are normal intradermal thermal regulating arteriovenous anastomoses containing specialized perivascular smooth muscle cells called glomus cells. Glomus tumors, derived from glomus cells, are typically solitary, solid, perivascular cutaneous tumors of adults. Glomangiomas are a cystic variant of glomus tumors. Multiple glomus tumors or its variants (glomangiomas) are rare and may accompany neurofibromatosis. We present an infant boy with an unusual form of glomangiomas. **History:** The neonate first presented with coagulopathy and cerebral infarcts of intrauterine origin. He subsequently developed pulmonary hypertension, recurrent retinal lesions, a blue subcutaneous epigastric cyst and aneurysm of the subhepatic inferior vena cava with an arterial-vena caval shunt. He died at two months of age with heart failure and Kasabach-Merritt syndrome. **Autopsy:** The 10 x 6 x 5 cm aneurysm of the inferior vena cava filled the right abdomen from diaphragm to pelvis and harbored a 4 x 3 x 2 cm glomangioma in its wall. Multiple glomangiomas were also found in the renal hilum, thyroid, thymus, esophagus, cecum, hepatic hilum, leptomeninges, and skin of breast and epigastrium. Fibromuscular dysplasia involved systemic and pulmonary arteries. Patchy polymicrogyria and focal renal hypoplastic cystic dysplasia suggested midgestational vascular disruption sequences due to the vascular tumors and dysplasia. **Discussion:** Glomangiomas occur in children, may be congenital and is usually benign. Autosomal dominant forms are associated with defects of the Glomulin gene in the VMGLOM locus of 1p21-22. Most involve the skin or subcutaneous tissue of extremities. Rarely they involve venous walls and are associated with varicose veins. Our patient had an unusual form of congenital glomangiomas with extensive visceral involvement including the wall of the inferior vena cava which led to a fatal aortic-caval fistula and caval aneurysm.

High rate of non-penetrance in a six-generation family with long QT syndrome (LQT2) due to a HERG mutation. *C. Ohle¹, M. Qi³, J. Robinson², L. Ning³, Y. Xu³, C.J. Kim¹, A.J. Moss², T.E. Kelly¹.* 1) Division of Medical Genetics, University of Virginia, Charlottesville, VA; 2) Department of Medicine, University of Rochester, Rochester, NY; 3) Department of Pathology and Laboratory Medicine, University of Rochester, Rochester, NY.

The proband, an 18 year old female, was found to have long QT syndrome (LQTS) following successful resuscitation after cardiac arrest. Of the five genes now known to cause LQTS, the proband was found to have mutation in the HERG gene, G1128A/Q376sp. Subsequent study of the family included ECG and mutational analysis. Exon 5 of the HERG gene, the region covering the location of the possible mutation, was sequenced by dye terminator cycle-sequencing on an ABIprism DNA sequencer. This analysis yielded a six-generation kindred with numerous gene-positive, elderly individuals with no history of syncope or arrhythmias and a normal ECG. The proband's obligate heterozygous mother died at 38 years of age of cardiac arrest. A two year old, gene-positive son of the proband had LQTS by ECG. In this large family, the majority of individuals carrying the HERG mutation had no clinical symptoms of LQTS and a normal ECG. Factors which influence the penetrance of the phenotype of this mutation may be epigenetic or environmental, but none have been identified at present.

Management of aortic disease in the Marfan syndrome: a decision analysis. *R.E. Pyeritz, S.Y. Kim, N. Martin, E. Hsia, D.A. Albert.* Divisions of Medical Genetics and Rheumatology, Univ Pennsylvania Sch Med, Philadelphia, PA.

Marfan syndrome (MFS) is a common inherited defect in connective tissue caused by a mutation in the gene coding for fibrillin-1. The major cause of mortality is dissection of the ascending aorta, a complication that can be mitigated somewhat by medical therapy with β -adrenergic blockade and exercise modulation, and largely prevented by replacement of the aortic root with a prosthetic conduit. The standard surgical approach since the mid-1970s has involved a composite graft with a prosthetic aortic valve. Recently, approaches that spare the native aortic valve have gained currency, although the long-term effectiveness of the technique is unclear. We employed classic decision analysis to compare the efficacy of the 2 surgical therapies with each other and medical therapy. Using DATA Professional, we developed a Markov model decision analysis comparing the two surgical options with watchful waiting utilizing medical therapy. In the decision tree, 505 separate elements were assigned probabilities based on published statistics on outcomes and complications as well as on the natural history of aortic disease in Marfan syndrome. We then generated life-expectancy estimates for a hypothetical cohort of 30-year-old patients with Marfan syndrome and aortic dilatation. The results indicate that the composite graft option increases life-expectancy more than medical therapy (life-expectancy of 19.91 yr versus 19.50 yr from the age of 30), and both were preferred to surgery with a valve-sparing procedure (19.06yr). This analysis shows that, as expected, definitive repair of the aortic root with a composite graft leads to improved survival compared to medical therapy. However, in comparing the 2 surgical approaches in this relatively young population, the risk of serious adverse outcomes of anticoagulation, which is part of the management of the composite graft, is not as risky as re-operation, which is increased in the valve-sparing option. Sensitivity analysis will be conducted to examine specific subgroups such as those with a large aorta at presentation, those with a rapid increase in aortic diameter, and those with a family history of dissection.

DiGeorge Anomaly in the Absence of Deletion 22q11.2. *A.F. Rope, E.K. Schorry, R.J. Hopkin, H.M. Saal.* Division of Human Genetics, Cincinnati Children's Hospital Cincinnati, OH.

DiGeorge Anomaly (DGA) is defined as the presence of at least two of the following features: (1) cellular immune deficiency and/or absence of part or all of the thymus; (2) symptomatic hypocalcemia and/or parathyroid deficiency; (3) cardiovascular malformation (CVM). DGA is the most commonly seen as part of velo-cardio-facial syndrome (VCFS), resulting from an interstitial deletion of chromosome 22q11.2 and accounts for >90% of subjects with DGA. Records from individuals who were negative for deletion 22q11.2 studies (n = 308) were reviewed for the presence DGA. Dysmorphic facial features (n = 142), cognitive dysfunction (n = 103), CVMs (n = 96), velopharyngeal insufficiency (n = 66) and cleft palate or Robin sequence (n = 51) were the most common features present in this population. Fourteen cases of DGA in the absence of deletion 22q11.2 were identified. The two most commonly recognized etiologies were diabetic embryopathy and chromosome abnormalities (three cases of each). Also seen were one case each of cocaine embryopathy and CHARGE association. There were six cases of children with multiple anomalies where a specific diagnosis was not identified. In the spectrum of VCFS, the incidence of CVMs, hypocalcemia and immune deficiency is roughly 75%, 60% and <5% respectively. A large number of subjects with VCFS do not meet criteria for DGA and a significant portion of DGA is not accounted for by VCFS. As clinical geneticists it is important to use precise terminology, as it has implications for medical management and genetic counseling. As communicated by Wulfsberg et al in 1996, nomenclature for these entities has proven challenging. We propose that VCFS should be defined by the interstitial microdeletion at 22q11.2. Depending on the criteria outlined above, proper diagnostic terminologies would include DGA in the absence or presence of deletion 22q11.2 and VCFS with and without DGA. These designations continue to afford proper historical recognition to Dr. DiGeorge and refer to the most classic phenotype of deletion 22q11.2.

Searching for PTPN11 mutations in CFC and Costello syndrome patients. A.P. Peiffer¹, M.B. Bamshad¹, J.O. Opitz¹, D.V. Viskochil¹, M.L. Leppert², J.C. Carey¹. 1) Pediatrics, University of Utah, Salt Lake City, UT; 2) Human Genetics, University of Utah, Salt Lake City, UT.

Individuals with Noonan's syndrome have dysmorphic facial features, short stature and cardiac anomalies. A gene for Noonan's syndrome has recently been identified (Tartaglia *et al.* 2001 *Nat Genet* 29:465); PTPN11 encodes a nonreceptor protein tyrosine phosphatase, a component of intracellular signalling transduction pathways. Patients with cardiofaciocutaneous syndrome (CFC; OMIM #115150) or Costello syndrome (OMIM #218040) have clinical features similar to individuals with Noonan's syndrome but with additional facial, cardiac or cutaneous findings. Therefore it is possible that CFC and Costello syndrome are genetic variants of Noonan's syndrome. We collected phenotypic data and DNA samples from 31 patients with CFC or Costello syndrome. We have started searching for PTPN11 mutations in these individuals by direct sequencing. To date, we have screened exons 3, 7 and 8 reported to contain missense mutations in Noonan's syndrome and have found no PTPN11 mutations in our CFC or Costello patients. We are continuing to screen the remaining PTPN11 exons.

Cerebral and abdominal aortic aneurysms in a family with thoracic aortic aneurysms and dissections. *V.T. Tran, D.K. Lemuth, D.M. Milewicz.* Department of Internal Medicine, The University of Texas Medical School, Houston, TX.

Familial thoracic aortic aneurysms and dissections (TAAD) is an autosomal dominantly inherited condition with reduced penetrance and variable expression. Genes predisposing individuals to this condition have been mapped to 5q13-14 and 11q23. Abdominal aortic aneurysms (AAA) can be familial with most studies suggesting an autosomal recessive mode of inheritance. Cerebral aneurysms (CA) can also be inherited within families, although the inheritance pattern is less clearly established. We have identified a family in which 7 affected members spanning 3 generations have had dilatation or rupture of thoracic aortic aneurysms (TAAD), abdominal aortic aneurysms (AAA) or cerebral aneurysms (CA). In this family, two women were affected with cerebral aneurysms diagnosed at ages 52 and 55 years of age. Two women and one man were affected with abdominal aortic aneurysms or rupture at ages 53, 60 and 62 years of age, respectively. Two men were diagnosed with thoracic aortic aneurysms or dissections at ages 67 and 76 years of age. Segregation of the aneurysm phenotype is autosomal dominant with male-to-male transmission. No stigmata of Marfan syndrome or any other connective tissue disorder were present in the affected individuals. Described here are the clinical features of a novel, autosomal dominantly inherited syndrome involving TAAD, AAA and CA, with a variable age of onset and clinical presentation.

Visceral arteriovenous malformations, mucocutaneous telangiectasia and juvenile polyposis in a three-generation family. *G.M. Repetto¹, M. Linares², A. Peña³, F. Garay^{1, 2}, P. Harris¹, I. Concha².* 1) Dept Pediatrics, Hosp Univ Catolica de Chile, Santiago, Chile; 2) Hospital Padre Hurtado, Santiago, Chile; 3) Hospital Sotero del Rio, Santiago, Chile.

We report a family with pulmonary and hepatic arteriovenous malformations (AVM) and mucocutaneous telangiectasia fulfilling clinical criteria for hereditary hemorrhagic telangiectasia (HHT), in association with generalized juvenile polyposis (JP), affecting four individuals in three generations. The grandmother, now 45 years old, developed recurrent epistaxis in late childhood and has mucocutaneous telangiectasis. She was diagnosed with JP at age 15, requiring several polypectomies due to bleeding. The polyps did not show telangiectasis. Two of three offspring are also affected: a 20 year old daughter who has telangiectasis of skin and mucosae and has had several intestinal polypectomies starting at the age of 15 years, and a 10 year old son who has hepatic and pulmonary AVMs, mucocutaneous telangiectasis, JP and hypertrophic osteoarthropathy. A 25 year old daughter is healthy. The affected daughter has a 1 year old son with pulmonary AVMs, one of which required embolization due to hypoxemia. He has no evidence of intestinal polyps. Both boys have required embolization of pulmonary AV malformations due to hypoxemia. Brain MRIs in the adults and CTs in the children were normal, as well as imaging studies of the chest and abdomen in the adult females.

Other cases of a similar association have been published (MIM 175050), the first by Cox et al in 1980, suggesting that this is a distinct clinical entity, rather than coincidence of autosomal dominant JP and HHT. Further studies are necessary to elucidate whether this condition is caused by mutations in genes that cause isolated JP or HHT, has a different single gene etiology or could be explained as a contiguous gene syndrome.

A clinical and genetics study and 23 years follow up on hereditary hyperplasia gingival in a large family in Khorasan, North East of Iran. *K. Ghodsi¹, A. Banihashem², M. Tamizy², M. Golkhandan², R. Akbarzadah¹, M. Gorgi Nejad¹.* 1) Medical Genetics, Mashad University of Med Sch, Khorasan, Khorasan, Iran; 2) Dental School, Mashad University of Med Sch, Khorasan, Khorasan, Iran.

A clinical and genetics study and 23 years follow up on hereditary hyperplasia gingival in a large family in, North East of Iran. Kazem Ghodsi¹, Saeid Ali Banihashem², Mahmood Tamizy², , Reza Akbarzadeh¹, Mohsen Gorgi Nejad¹ and Mahmood Rahimi Golkhandan². Department of Medical Genetics¹, Ghaem Hospital, Faculty of Medicine, Dental school², Mashhad University of Medical Sciences Mashhad Iran. Hereditary hyperplasia gingival is a very rare genetically heterogeneous disorder. It is the most frequently reported to be transmitted as an autosomal dominant trait, but autosomal recessive inheritance has also been reported. The clinical presentation of hyperplasia gingival is variable both in the distribution and in the degree severity of expression. Here we reported a family with 13 affected individual in four generations living in Iran. The proband, the oldest man in family presented with a massive gingival overgrowth, at a regional dental clinic 23 years ago and was treated with extraction of all his teeth and gingival surgery to reduce the overgrowth. Recurrence was not observed. Other members of his family, (8 females, and 4 males) who were also affected have been referred for assessment and treatment. In all cases, the hyperplasia developed after the eruption of teeth and recurrence was observed after surgery in all patients who retained some teeth. Pedigree analysis suggests an autosomal dominant inheritance of hyperplasia gingival in this family. However, autosomal recessive inheritance cannot be ruled out as the family is from a small village in Khorasan, Iran, with possibility of relatedness between families. Additionally, although the proband and his affected children were apparently from a non-consanguineous marriage, other affected individuals are clearly from consanguineous mating. As expected karyotyping revealed no chromosomal abnormality. Further genetic analysis are underway.

Shortening of the bones of the hand in genetically characterized PHP-Ia patients. *L. de Sanctis*¹, *D. Romagnolo*¹, *M.R. Andreo*², *M. Olivero*³, *I. Dianzani*⁴, *C. de Sanctis*². 1) Osp Inf Regina Margherita, Univ Torino, Torino, Italy; 2) Div Pediatr Endocrinology, Osp Inf Regina Margherita, Torino, Italy; 3) IRCC, Candiolo, Univ Torino, Italy; 4) Dept Pediatr and Genet, Univ Piemonte Orientale, Italy.

Pseudohypoparathyroidism type Ia (PHP-Ia), caused by mutations in the *GNAS1* gene, is characterized by resistances to PTH, TSH, FSH/LH and Albright Hereditary Osteodystrophy (AHO), a heterogeneous phenotype described in different disorders. AHO comprises short stature, obesity, subcutaneous calcifications, mental retardation and metacarpophalangeal (MCP) shortness, the most specific sign. Data on MCP shortening in *GNAS1* characterized PHP-Ia patients have not been reported so far. To delineate a typical phenotype marker in PHP-Ia we evaluated the severity of MCP shortness in 11 *GNAS1* characterized patients and we searched for a correlation between MCP shortness and *GNAS1* mutations. Direct sequencing of the whole coding regions and exon/intron boundaries of the *GNAS1* gene allowed to identify the causal mutation in 11 PHP-Ia subjects followed in several Italian pediatric endocrinology units. Hand radiographs were collected from the 11 characterized patients and MCP shortening was evaluated using the method described by Poznanski et al., 1972. MCP shortness and predicted protein structure abnormalities for each identified mutation were considered. In the 11 PHP-Ia patients metacarpals (from 2,8 to 4,5 SD; IV-V above all) and distal phalanges (from -2,7 to 4,2 SD; I above all) were the most shortened bones. Patients with frameshift *GNAS1* mutations that predict for subversion of protein structure were not associated with more severe MCP shortening. One mutation found in various families and another in twins were not associated with similar MCP shortening. In conclusion, a genotype/phenotype correlation cannot be drawn between *GNAS1* mutations and bones shortening as a phenotype marker.

Chorea-acanthocytosis in a large French-Canadian kindred with dominant or pseudo-dominant inheritance and variable expressivity. *E. Andermann*^{1,2}, *A. Badhwar*^{1,2}, *A. Al-Asmi*¹, *C. Shustik*³, *F. Dubeau*¹, *S. Mercho*^{1,2}, *A. Sano*⁴, *F. Andermann*^{1,5}. 1) Dept. of Neurology and Neurosurgery, McGill Univ. Montreal, QC, Canada; 2) Dept. of Human Genetics; 3) Dept. of Internal Medicine, McGill Univ. Montreal, QC, Canada; 4) Dept. of Neuropsychiatry, Ehime Univ., Ehime, Japan; 5) Dept. of Pediatrics, McGill Univ. Montreal, QC, Canada.

We present a large family with neuroacanthocytosis (CHAC; OMIM-200150), familial temporal lobe epilepsy and unusual inheritance. CHAC is an autosomal recessive, rarely dominant, neuro-degenerative disorder with gradual onset of hyperkinetic movements and acanthocytosis. Features include chorea, orofaciolingual dyskinesia, tics, dysarthria, dysphagia, areflexia, seizures and dementia. The gene is located on chromosome 9q21 (Rampoldi et al, 2001). 3 siblings and their maternal first cousin from a consanguineous marriage presented with familial temporal lobe epilepsy and later developed involuntary movements and dysphagia. All 4 patients had evidence for manic-depressive disorder and cognitive deterioration. Carbamazepine and lamotrigine worsened involuntary movements. MRI showed caudate atrophy and increased iron deposition in the globus pallidus bilaterally. EEG and video-telemetry confirmed ictal and interictal temporal abnormalities. DNA testing (Huntington, oculopharyngeal muscular dystrophy) was negative. Blood smears revealed acanthocytosis. The family originates from the Saguenay-Lac St. Jean region of Quebec. Thirty individuals in 4 generations had varying combinations of tics, chorea, epilepsy, psychosis, ptosis and dysphagia. Genetic linkage and mutation studies are underway.

In conclusion patients presented with familial temporal lobe epilepsy, unusual for CHAC. Coexistence of choreiform movements, mood disorder, mental deterioration and acanthocytosis led to the diagnosis. Inheritance appears to be autosomal dominant, but may be pseudo-dominant due to founder effect in this population.

Patients with Multiple/Plexiform Schwannomatosis: Distinct Clinical Entities or NF-Variants? *L.L. Baumbach¹, E. Estrella¹, M. Bauer²*. 1) Univ Miami Sch Medicine, Miami, FL; 2) Miami Children's Hospital, Miami, FL.

The neurofibromatoses (NF) represent a clinically heterogenous collection of disorders that share certain common clinical manifestations, while underlying molecular and pathological mechanism(s) responsible for diverse disease manifestations remain unclear. Appreciation has arisen for variant NF forms. One of the most intriguing is multiple schwannomatosis (MSM), which occurs without any clinical evidence of NF-2. It is still controversial whether MSM represents a third form of NF, or a mosaic form of NF-2. We report our clinical investigations of four unrelated patients who present with either MSM or Plexiform Schwannomas (PSM). The patients have been otherwise healthy, and have had extensive clinical and radiological evaluations that have failed to detect any other features consistent with NF-2. Family history is negative for any clinical features or symptoms consistent with NF for each of the probands. Patient #1, a 19 yr-old Caucasian male, has multiple spinal schwannomas, including a hemorrhagic schwannoma spanning L-4 to S-1, which was surgically removed. Patient #2, a Hispanic 27 year old female, has a long history of peripheral nerve schwannomas. Patient #3, a 20 yr.-old Caucasian male, has a chronic history of a thoracic spinal plexiform neurofibroma/ schwannoma. Patient #4 is a 3 yr.-old girl with multiple schwannomas involving the trigeminal nerves, a large plexiform neurofibroma in the left masticator space, and vagus nerve schwannomas in the left jugular carotid sheath. These patients share in common apparently *de novo* events, childhood onset of symptoms, and confinement of symptoms to benign schwannomas/plexiform neurofibromas involving the CNS or PNS. We are striving to complete *NF2* mutation analysis in peripheral blood and affected tissue specimens from these patients. Continued clinical and molecular investigation of such rare patients will provide important new insights into the etiology of variant presentations of NF-1 and NF-2.

Life threatening events and severe manifestations of Prader Willi syndrome in infancy. *Y.S. Choy¹, S.K. Tan², SK. Tan⁵, M.Z. Norzila³, L.C. Hung⁴.* 1) Genetics Unit, Pediatrics Institute, Kuala Lumpur Hospital, Kuala Lumpur, Malaysia; 2) Cytogenetic Department, Kuala Lumpur Hospital, Kuala Lumpur; 3) Respiratory Unit, Pediatrics Institute, Kuala Lumpur Hospital, Kuala Lumpur; 4) Cardiology Unit, Pediatrics Institute, Kuala Lumpur Hospital, Kuala Lumpur; 5) Division of Molecular Pathology, Institute of Medical Research, Kuala Lumpur, Malaysia.

Infantile failure to thrive and hypotonia with developmental delay and obesity later in life is a typical natural course of many individuals with Prader Willi syndrome described in the literature. With the increase in awareness of the condition, more patients with Prader willi syndrome are now being diagnosed in the neonatal period. 18 patients were confirmed having Prader Willi syndrome over the past two years in the Pediatrics Institute, Kuala Lumpur Hospital by methylation PCR. 12 of the cases (67%) were deletion positive using SNRPN probe. 13 of them were diagnosed in infancy and 9 of them (50%) were diagnosed in neonatal period because of severe central hypotonia associated with respiratory distress and feeding difficulty. 12 of them have more than twice admissions to the hospital for acute life threatening events during infancy. Majority of them were due to pneumonias. Two of the patients required gastrostomy feeding and two needed temporary nasogastric tube feeding. 4 of them had cardiomyopathy and 2 of them had pericardial effusion and cardiac tamponade. Two of the patient with cardiac involvement also had hypothyroidism and the treatment of which resulted in clinical improvement. Two of the patients succumbed to the life threatening events and one suffered severe hypoxic ischemic damage of the brain. Six patients had obstructive sleep apnoea and oxygen desaturation during sleep. Home oxygen therapy and vigorous airway management in these patients resulted in general clinical improvement and prevention of hospitalization.

Central Nervous System Anomalies in Seckel Syndrome: Report of a Case with Central Apnea and Acquired Chiari Malformation. *D.E. Halbert, G.S. Pai, J.K. Cure.* Pediatrics, Medical Univ of South Carolina, Charleston, SC.

Seckel syndrome, also known as Bird-Headed Dwarfism, is a rare syndrome which consists of low birth weight, dwarfism, microcephaly, large eyes, beaklike nose, narrow face, and receding lower jaw. Associated cranial and CNS anomalies have been better elucidated in recent years.

Here we describe a patient with severe microcephaly and an acquired Chiari malformation. The patient was born at 38 weeks gestation to a 20 year old African American Mother. Family history was negative for mental retardation, microcephaly, or consanguinity. Subsequent cytogenetic analysis at 550 band resolution revealed normal XYkaryotype.

The patient suffered from developmental delay and central apnea. MRI study of the brain at 3 months of age demonstrated a Chiari type I malformation with the cerebellar tonsils lying at the lower mid C3 cervical spine level. A prior high resolution MRI using 3 millimeter slices was performed at 1 week of age did not demonstrated the Chiari malformation. The new finding of the malformation was surprising since Chiari malformations generally thought to be congenital anomalies. Subsequent CT scan of the skull with 3 dimensional reconstruction demonstrated bilateral lambdoid and sagittal synostosis.

The patient underwent decompression of the Chiari malformation and cranial reconstruction. Unfortunately, the patient was not able to be extubated due to continued apnea which was felt to be centrally mediated. A tracheostomy was placed but the patient was not able to be weaned from mechanical ventilation. The child died at 4 months of age due to sepsis. An autopsy was not performed.

This case adds to the clinical description of children with Seckel syndrome. It also demonstrates the development of a Chiari malformation postnatally.

Clinical and genetic characterization of familial juvenile hyperuricemic nephropathy. *T.C. Hart^{1,2}, M.M. Gorry¹, H. Zhu¹, M.M. Barmada², A.J. Bleyer³.* 1) Dept Oral Med/Pathology, Univ Pittsburgh, Pittsburgh, PA; 2) Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA; 3) Dept Nephrology, Wake Forest Univ, Winston Salem, NC.

FJHN is an autosomal dominantly transmitted kidney disease that results in precocious gout and kidney failure. Clinical findings vary greatly, and as the disease causing gene is unknown, clinical characterization of FJHN is poor, primarily because genetically affected individuals with mild expression can not be reliably identified. The purpose of this study was use linkage analyses to identify genetically affected individuals and characterize clinical findings in these individuals. Genetic linkage studies performed on 62 individuals from a family segregating FKHN localized the disease gene to a 2 Mb region of chromosome 16p (ZMAX = 12.5 @ D16S3041, theta= 0.01). Haplotype analysis permitted identification of family members who inherited the FJHN disease allele. Linkage and haplotype studies permitted identification of 25 unaffected family members and 37 genetically affected individuals. 83% (31/37) of genetically affected family members suffered from hyperuricemia and either renal failure or a reduced fractional excretion of uric acid. Six females who inherited the FJHN disease haplotype had normal serum uric acid levels despite low fractional excretion of uric acid in four of them. There was considerable overlap between serum uric acid values and fractional excretion of uric acid in genetically affected and unaffected individuals. Only 38 % of genetically affected individuals suffered from gout. Conclusions: using genetic linkage studies we sublocalized the FJHN gene to chromosome 16p13 and to determine which family members were genetic carriers of the FJHN disease gene. While most patients with FJHN suffer from hyperuricemia, reduced fractional excretion of uric acid, and renal failure, not all characteristics are fully penetrant. The variable clinical expression of FJHN is described. These findings suggest that the clinical findings of FJGN vary from severe (lethal without renal transplant) to very mild, and that the definitive diagnosis of disease will likely require genetic testing.

A Novel Ehlers-Danlos-Like Syndrome with Vascular abnormalities and Tortuous Systemic Arteries: Linkage Analysis. *M.F. Ul Haque*¹, *A. Abdul Wahab*², *I.H. Janahi*², *S.H.E. Zaidi*¹, *A.S. Teebi*¹, *L.C. Tsui*¹. 1) Dept Genetics, Hosp Sick Children, Toronto, ON, Canada; 2) Dept Pediatrics, Hamad Medical Corp, Doha, Qatar.

The Ehlers-Danlos syndrome (EDS) is a heterogenous group of heritable connective tissue disorders characterized by skin hyperextensibility, joint hypermobility, and tissue fragility. Thirty two affected individuals from a large consanguineous kindred from Qatar were identified to exhibit similar phenotypic anomalies including skin hyperextensibility of variable degree without bruising and/or echymosis, hypermobility of small and large joints, and dilatation, tortuosity and stenosis of systemic, pulmonary, and coronary arteries. The facial features are peculiar and include epicanthic folds, saggy flat cheeks, an elongated face and micrognathia. Hernia is common and includes inguinal, diaphragmatic and/or hiatus hernia. Skin biopsies from affected individuals show normal collagen fibrils and elastin fibers. Although similar to the EDS phenotype, clinical spectrum of anomalies seen in this family do not fit with any previously described forms of EDS. From our analysis of the kindred, the affected individuals appear to be segregating a recessively inherited mutation. Linkage analysis is being conducted to determine whether the mutant locus in this family corresponded to any of the major loci previously implicated in both recessively or dominantly inherited forms of EDS. Intragenic or closely linked, flanking microsatellite markers are used. Assuming autosomal recessive inheritance there is no evidence for genetic linkage to any of the previously implicated loci for EDS. Further, affected individuals have also been excluded from cutis laxa, Ehlers-Danlos and Marfan syndromes, as well as several other mutations in the genes known to produce vascular abnormalities. We speculate that loss of function in a previously unidentified mutant gene is responsible for conferring this trait. A genome wide screening is currently underway to identify the region harboring this abnormal gene.

Ultrasound analysis of orbicularis oris muscle defects in relatives of individuals with cleft lip with or without cleft palate and their relatives. *S.M. Weinberg¹, K. Neiswanger¹, R.A. Martin², M.P. Mooney¹, R.S. Faix³, B.S. Maher¹, S.S. Petiprin¹, K.M. Bardi¹, R.F. Giles¹, A. Bowen³, M.L. Marazita¹.* 1) Sch Dental Med, Univ Pittsburgh, Pittsburgh, PA; 2) St Louis Children's Hospital, St Louis, MO; 3) Childrens Hospital, Pittsburgh, PA.

Oral-facial clefts affect between 1 in 500 to 1000 births worldwide. Like many other complex phenotypes, the search for susceptibility loci has had limited success. Recently, however, a sub-clinical defect of the orbicularis oris (OO) muscle, was detected through ultrasound in the first-degree relatives of children with CL/P. It has been hypothesized that OO defects may represent an alternative phenotype for gene mapping in families with CL/P. Herein, we present an analysis of OO muscle defects in unaffected relatives of CL/P probands ascertained as part of a large multiplex family study on the cleft phenotype and genotype. Ultrasound images were collected from unaffected relatives (n=69) and scored quantitatively and qualitatively by multiple raters for OO muscle defects. Measures from unaffected relatives were compared to those of 52 previously published controls. OO muscle defects were present in 52.3% of the relatives of CL/P probands versus 13.5% of controls ($\chi^2 = 19.07$, $p < .0001$). These results support the hypothesis that OO muscle defects are a subclinical indicator of increased susceptibility to CL/P. In addition, OO muscle defects may provide an alternative phenotype for mapping genes underlying CL/P. NIH grants DE13076 and RR00084.

Program Nr: 537 from 2002 ASHG Annual Meeting

New Case of Verloes Syndrome. *JC. Prieto^{1,2}, C. Gutierrez¹*. 1) Inst de Genetica Humana, Univ Javeriana, Bogota, Colombia; 2) Hospital la Victoria, Departamento de Genetica, Bogota, Colombia.

We report the first case of Verloes Syndrome in one male in Colombia and the third one worldwide. Verloes et al. in 1990 describe two brothers that shared the following clinical characteristics: postnatal growth deficiency, obesity, coarse facial features with deep-set small eyes, and severe genital anomalies resulting in sexual ambiguity, including persistent müllerian structure. Mental retardation was profound in one; the other sib was only slightly retarded. In this report we describe a slightly mentally retarded post - puberal male. He had 19 years old and he had 46,XY chromosome constitution. Clinical features include moderated gynecoid obesity, coarse face, micropenis, small testis, persistence of Müllerian structures, and low gonadotrophin levels. Those anomalies do fit a previously reported syndrome by Verloes et al, although the general aspect of the propositus clearly resembles Borjeson-Forsman-Lehmann syndrome. In this new case the parents are no consanguineous and no other member of the family was affected, thus in this case we don't have evidence of autosomal or X-linked inheritance.

Syndrome of choanal atresia, ear anomalies, deafness and athelia associated with chronic interstitial lung disease.
D.K. Grange, S.C. Sweet, F.S. Cole. Department of Pediatrics, Washington University School of Medicine and St. Louis Childrens Hospital, St. Louis, MO.

We report a 12 month old girl with bilateral choanal atresia, ear anomalies, sensorineural hearing loss and athelia. She was born at 38 wks gestation to a 24 yr old G1 mother following a normal pregnancy with no teratogen exposures. She has sparse hair, small ears with skin tags on the superior helices, a preauricular pit, small nose with narrow alae nasi and a unilateral branchial cleft sinus tract. There is total absence of the nipples. Heart is normal by echocardiogram. Chromosome analysis was 46,XX. Despite surgical correction of choanal atresia, the patient has required continuous oxygen supplementation. At 6 months, CT scan showed severe diffuse interstitial infiltrates and tiny cysts scattered throughout the lungs. Open lung biopsy revealed chronic interstitial pneumonitis with widening of the alveolar septae by an inflammatory infiltrate. Air spaces were partially obliterated by fibrous connective tissue. She has clubbing of the digits. Postnatal growth has been poor and she is below the 3rd percentile for all parameters. Thyroid function tests were normal. The features in our patient overlap with several previously described conditions, including methimazole embryopathy (choanal atresia, athelia, hypothyroidism), Bamforth syndrome (choanal atresia, cleft palate, abnormal hair, hypothyroidism) and ANOTHER syndrome (athelia, ectodermal dysplasia, hypothyroidism). The association of athelia, choanal atresia and renal tubular dysplasia was reported in 3 brothers by Hisama (AJMG, 1998). Two siblings with anomalies very similar to our patient were reported by Al-Gazali (Clin Dysmorphol, 2002); one had a small thyroid with normal function and interstitial fibrosis of the lungs on CT scan, and the other had hypothyroidism, chronic hypoxemia and died of pneumonia. Bamforth syndrome is caused by mutations in the gene for thyroid transcription factor 2 (TTF-2). TTF-1 is a related protein involved with thyroid specific gene transcription as well as pulmonary production of surfactant, and could therefore be a candidate gene for the disorder in our patient and those of Al-Gazali.

ATYPICAL FAMILIES FOUND WHILE SEARCHING FOR USHER SYNDROME IN COLOMBIA. C.P.

Gonzalez¹, D. Medina², N. Gelvez¹, M. Tamayo¹. 1) Instituto de Genetica Humana, Facultad de Medicina. Universidad Javeriana, Bogota, DC, Colombia; 2) Fundacion Oftalmologica Nacional, Bogota,D.C., Colombia.

Usher Syndrome (USH) is comprised of a group of autosomal recessive disorders characterized by congenital sensorineural hearing loss, vestibular dysfunction, and progressive Retinitis Pigmentosa (RP). This entity is clinically and genetically heterogeneous. The syndrome has been divided into three clinical types, based on the severity of hearing loss, the extent of vestibular involvement, and age at onset and progression of hearing loss. USH is the foremost cause of combined blind/deafness in the world. The prevalence in Colombia is estimated in 3.2/100,000 inhabitants. Our group has been working since 1984 in a screening program for USH, carrying out otological, ophthalmological, genetic studies and also, genetic counselling in affected individuals and their families. In this process, we found out that many patients that were given an initial Usher Syndrome diagnosis by the physician, after considering all the clinical and family traits together, were not the typical Usher Syndrome. We describe the cases and clinical traits of 3 atypical Usher Syndrome families. Family 1, showed RP and sensorineural deafness but in an autosomal dominant pattern in three generations. In Family 2, two of the affected presented autosomal recessive RP with sensorineural profound deafness, but two other affected siblings had only RP. The propositus of these families were diagnosed as Usher Syndrome when considered isolated. Family 3, product of a consanguineous marriage, showed RP in two women but one of them referred hearing loss, with three brothers with deafness and another one with possible RP. Our purpose is to emphasize that researchers and clinicians must be aware of certain cases that seems to be Usher Syndrome families, really are not. There is a high frequency of RP with sensorineural deafness in families without being Usher Syndrome.

Trigonocephaly-associated hypotelorism in an infant with trisomy 9q(p13@qter). *J.R. Corona-Rivera^{1,2}, A. Corona-Rivera¹, J.A. González-Ramírez², S. González-Abarca², T.A. García-Cobian¹, L. Bobadilla-Morales¹, E. Corona-Rivera¹.* 1) Laboratorio de Genética Humana, Centro Universitario de Ciencias de la Salud, Universidad de Guadalajara, Guadalajara, Jalisco, México; 2) División de Pediatría, O.P.D. Hospital Civil de Guadalajara Dr. Juan I. Menchaca.

Trisomy of the distal half of 9q appears to be responsible for the trisomy 9q syndrome phenotype. We describe an infant showing association of trigonocephaly and trisomy 9q. The proposita was born spontaneously to a 37-year-old, G3P2A0 mother after normal gestation and vaginal delivery, complicated with neonatal hypoxia. Aged 1 month showed: height 53 cm (-0.1 SD), weight 2400 g (-4.4 SD), head circumference 32 cm (-3.6 SD), facial asymmetry, wide sagittal suture and fontanel, trigonocephalic head from bulging of the forehead along the metopic suture, prominent eyeballs, hypotelorism, bulbous nose, long filtrum, thin upper lip, short neck, heart murmur, umbilical herniae, pilonidal dimple, clenched hands, and rocker-bottom feet. Apneic episodes and generalized tonic seizures were also observed. Echocardiogram exhibited tetralogy of Fallot. Cranial 3D CT scan confirmed trigonocephaly, hypotelorism and metopic and coronal synostosis. Intracranial structures were normal on CT scan as well as an abdominal ultrasonography. Peripheral blood lymphocytes karyotype showed a 47,XX,+del(9)(p13) in 65 metaphases analyzed after CTG-banding. The proposita died at two months of age. Clinical features in our case were as those observed in 9q trisomy for different segments, as well as complete trisomy 9, including early death. Patients with 9q trisomy were informed with microdolichocephaly and prominent forehead, besides other facial, spine, hand/foot, cardiovascular and urogenital anomalies. To our knowledge, this is the first instance of trigonocephaly-associated hypotelorism in a trisomy 9q therefore suggesting that craniofacial synostotic anomalies might be associated with 9p13@qter trisomy.

The face of Joubert syndrome: a study in dysmorphology and anthropometry. *S.R. Braddock, K.M. Henley, B.L. Maria.* Department of Child Health, University of Missouri, Columbia, MO.

Joubert syndrome is a recessive neurogenetic disorder characterized by hypoplasia of the cerebellar vermis, hypotonia, developmental delay, and abnormal breathing and eye movements. Specific neuroradiologic findings of the “molar tooth” sign aid the diagnosis. Associated phenotypic features described include facial, renal, limb and gastrointestinal malformations. However, a large cohort has not been systematically examined by a dysmorphologist. The purpose of this study is to document the dysmorphology and anthropometry of Joubert syndrome in a large population of affected individuals and to determine whether a specific pattern of malformation exists and is altered significantly with age.

Since its first description in 1969, much attention has been focused on the classic hindbrain malformation. This is characterized by hypogenesis and clefting of the cerebellar vermis with enlargement of the fourth ventricle, deepening of the interpeduncular fossa, and a lack of decussation of the thickened superior cerebellar peduncles, central pontine, and corticospinal tracts. To date there have been few reports and documentation of the physical phenotype of Joubert syndrome other than the neuropathology and behavior, though some 200 cases have been published. In 1999, Maria et al. described clinical features in 19 individuals with the condition. Their findings included a “typical” facies with high rounded eyebrows, broad nasal bridge, epicanthal folds, anteverted nares, a triangular shaped mouth with the tongue almost protruding and low set ears in addition to the vermis hypoplasia, hypotonia, developmental delay, and abnormal eye and breathing patterns. Other conditions sharing multiple features with Joubert syndrome include but are not limited to Ritscher-Schinzel (3C), Oral-Facial-Digital (OFD), Arima, Senior-Löken, Dekaban, and COACH syndromes.

We will present data from dysmorphology evaluations of 22 individuals, ages 14 months to 18 years, with Joubert syndrome. Anthropometric examinations will document whether the facies have distinguishing characteristics or represent the generalized effects of hypotonia.

Karyotype/phenotype correlations in duplication 4q: evidence for a critical region within 4q27-31 for preaxial defects. A. Battaglia¹, L. Hudgins³, S. Morelli², JC. Palumbos², JC. Carey². 1) Inst Child Neurology & Psych, Stella Maris nst/Univ Pisa, Pisa, Italy; 2) Division of Medical Genetics, Dept. of Pediatrics, University of Utah, SLC, UT; 3) Dept. of Pediatrics, Stanford University, CA.

Varying degrees of partial duplication of 4q (dup 4q) have been reported in over 70 patients since 1972. The majority of the cases include partial trisomy with breakpoints at q25 to ter, most due to unbalanced inherited translocations. The different breakpoints, the associated monosomies, and the varying ages of reported patients make it difficult to delineate a recognizable syndrome. However, there are five patients reported with preaxial defects, ranging from thumb hypoplasia to duplication, all having as well renal malformations. From this, Zollino et al. (1995) suggested the presence of genes involved in the development of the acrorenal field on 4q at 22-23. We describe 2 patients with dup 4q27 to ter, one of which is especially helpful in elucidating the critical region for thumb defects in dup4q. The first is a girl with developmental delay, microcephaly, growth delay, absent thumb/hypoplastic thumb and single kidney. Her karyotype is 46,XX, der(11)t(4;11)(q27;q24.2)mat as her mother carries a balanced 4;11 translocation. Thus she has partial dup 4q and deletion of distal 11q. The second patient has multiple anomalies, including double outlet right ventricle, and 46,XY,der(10)t(4;10)(q27;q26.3)pat as his father carries a 4;10 translocation. He has partial dup4q and deletion of distal 10q. He has normal thumbs, demonstrating the variability of this finding in dup4q. Analysis of the dup4q in the previously described patients with thumb defects and our patient indicates that the region of overlap is 4q27-31.3, which is more distal than originally suggested by Zollino et al. (1995). Of note, all 6 patients have renal malformations, consistent with their hypothesis that there are genes important in acrorenal field development in 4q27-31.

Neurocognitive Profile of Adults with 22q11.2 Deletion Syndrome. *E. Chow*^{1,2}, *M. Watson*², *D. Young*³, *R. Weksberg*^{4,5}, *A.S. Bassett*^{1,2}. 1) Department of Psychiatry, University of Toronto, Toronto, ON, Canada; 2) Clinical Genetics Research Program, CAMH, Toronto, ON, Canada; 3) Schizophrenia & Continuing Care, CAMH, Toronto, ON, Canada; 4) Department of Paediatrics, University of Toronto, Toronto, ON, Canada; 5) Clinical and Metabolic Genetics, HSC, Toronto, ON, Canada.

Background: 22q11.2 Deletion Syndrome (22qDS) has been associated with neurocognitive weaknesses in children. The neurocognitive profile of 22qDS adults is less well understood. **Objective:** To determine the neurocognitive profile of adults with 22qDS. **Method:** 45 adults with 22qDS were assessed using a comprehensive battery of neurocognitive tests. The 25 subjects with schizophrenia (22qDS-SZ) were compared with 20 subjects with no psychosis (22qDS-NP). **Results:** The 22qDS-SZ and 22qDS-NP groups had similar mean overall IQ (71.5 SD 7.7 vs. 73.3 SD 9.0, respectively), mean verbal IQ (71.9 SD 4.8 vs. 74.1 SD 8.5), and mean performance IQ (71.2 SD 5.1 vs 74.2 SD 10.2). The groups also had similar academic achievement in reading (Grade 6-7 level), spelling (Grade 6-7), and arithmetic (Grade 4), and mild to moderate impairment in attention, visual-spatial skills, motor and executive functioning. Compared to the 22qDS-NP subjects, 22qDS-SZ subjects had poorer performance in verbal learning (Rey Auditory Verbal Learning Test, $p=0.006$), delayed verbal recall (Wechsler Memory Scale-Revised, Logical Memory II, $p=0.01$) and executive functioning (Trail B, $p=0.004$). **Conclusion:** These findings in 22qDS adults are mostly similar to those reported in 22qDS children. There are significant differences in neurocognitive domains between psychotic and non-psychotic 22qDS subjects, consistent with the profile for other forms of schizophrenia.

Congenital Onychodysplasia and Juvenile Hypertrophy of Breast: A new syndrome. *T.C. Falik-Zaccai¹, M. Khayat¹, J. Govrin-Yehudain², L. Kogan², S. Linn³.* 1) Div Medical Genetics, Western Galilee Hosp, Nahariya, Israel; 2) Plastic surgery unit, Western Galilee Hosp, Nahariya; 3) Epidemiology unit, Rambam Medical Cent. Bruce Rappaport Faculty of Medicine, Technion, Haifa, Israel.

Familial Juvenile hypertrophy of the breast (JHB) is a very rare condition described only once in the literature. The pathology is limited to the breast, leading to gigantomastia in peripubertal females with otherwise normal growth and development. Familial Onychodysplasia and dysplasia of distal phalanges (ODP) is a mild bone dysplasia with normal height and no functional limitation. This is a very rare congenital syndrome that was also described only once before in the literature. We report here for the first time on a familial pattern of JHB accompanied by ODP. These two traits segregated in a four-generation family in an autosomal dominant (AD) fashion with complete penetrance among females (JHB and ODP) and partial penetrance among males (ODP only). There were no affected individuals in generations II and I, six affected individuals out of fourteen in generation III and six affected individuals out of ten in generation IV. One obligate carrier in generation II was asymptomatic. Five affected females had breast reduction surgeries and suffered curtailment of their social activity and cessation of schooling. The mothers of these five patients had normal breasts and nails while their fathers had ODP but no JHB. Eight affected males exhibit ODP with no JHB. Females that did not present with JHB had normal hands and feet. Thus, suggesting male to male transmission of the ODP and male to female transmission of ODP combined with JHB. Statistical analysis supported a possible cryptic chromosomal aberration or a common gene mutation responsible for the two traits. A germline new mutation or chromosomal aberration has possibly occurred in generation II leading to multiple affected in generation III; alternatively, a silent mutation exhibiting the anticipation phenomenon is the cause for the unusual phenotype. The genetic basis for this new syndrome is yet to be determined. The large kindred provides the basis for mapping and cloning of the possible gene responsible for this new syndrome.

Interstitial deletion del(9)(q22.32q33.2) associated with additional familial translocation t(9;17)(q34.11;p11.2) in a patient with Gorlin-Goltz syndrome and features of nail-patella syndrome. A.T. Midro¹, B. Panasiuk¹, Z. Tumer⁶, P. Stankiewicz⁷, J.R. Lupski^{7,8}, Z. Zemanova⁹, J. Brezinova⁹, B. Stasiewicz-Jarocka¹, E. Hubert², E. Tarasow³, W. Famulski⁴, E. Wasilewska⁵, K. Michalova⁹, N. Tommerup⁶. 1) Department of Clinical Genetics; 2) Clinic of Maxilla-Facial Surgery; 3) Department of Radiology; 4) Department of Clinical Pathology; 5) Clinic of Hematology, Medical Academy of Bialystok, Bialystok, Poland; 6) Institute of Medical Biochemistry and Genetics, Department of Medical Genetics, The Panum Institute, University of Copenhagen, Denmark; 7) Department of Molecular & Human Genetics; 8) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 9) 3rd Medical Clinic, ILF UK, Praha, Czech Republic.

The phenotype of Gorlin-Goltz syndrome (NBCSS, 109400 OMIM), a Mendelian entity due to changes in the *PTCH*, has been reported in association with interstitial chromosomal 9q deletion. We present an 11-year-old girl with clinical features consistent with NBCSS including: bridging of the sella turcica, frontal and biparietal bossing, downward slanting palpebral fissures, mandibular prognathism, pectus excavatum, thumb abnormalities, spina bifida occulta at L5-S4, and basal cell nevi. Cytogenetic analysis using high-resolution banding techniques and fluorescence *in situ* hybridization (FISH) revealed interstitial chromosomal deletion del(9)(q22.32q33.2) involving the *PTCH* as a secondary breakage event to chromosome translocation t(9;17)(q34.1;p11.2)mat. Further FISH studies showed the localization of the translocation breakpoint on 9q34.11, between the BAC clone RP11-88G17 and *LMX1B*. The latter gene encodes a transcription factor, in which loss of function mutations are responsible for the nail-patella syndrome (NPS). Interestingly, some features in our proband (e.g. bilateral dysplasia of patella and abnormal shape of clavicle) and in her healthy sister, carrier of the same translocation, are also found in the patients with NPS. The chromosome 17p11.2 breakpoint was identified to map in the Smith-Magenis syndrome common deletion region, within two overlapping BAC clones CTD-2354J3 and RP11-311F12.

Immunodeficiency in Kabuki syndrome. *J.E. Ming, K.L. Russell, D.M. McDonald-McGinn, E.H. Zackai.* Division of Human Genetics, Department of Pediatrics, The Children's Hospital of Philadelphia and the University of Pennsylvania School of Medicine, Philadelphia, PA.

Immunodeficiency is associated with a number of genetic syndromes. Frequent infections, especially sinopulmonary infections, often occur in patients with Kabuki syndrome. For most patients, the possibility of an underlying immune deficit has not been investigated. A small number of individuals with Kabuki syndrome have been described with immune defects or autoimmune disease. We describe five patients with Kabuki syndrome evaluated at The Childrens Hospital of Philadelphia who have an immunologic abnormality and/or presented with an autoimmune condition. Patient #1 had a history of frequent episodes of otitis media. At 13 years of age, he presented with thrombocytopenia and hemolytic anemia. He was later hospitalized with Pneumococcal pneumonia. He had undetectable IgG levels, and decreased IgM and IgA levels. Patient #2 had recurrent otitis media requiring three sets of ear tubes and a hospitalization for an RSV infection. She subsequently presented with thrombocytopenia. She had low IgG and IgA levels and a low normal IgM level. Patient #3 had pneumonia in infancy and chronic otitis media. He had a decreased IgA level with low normal IgG and IgM levels. Patient #4 had three episodes of pneumonia and recurrent otitis media. He was noted to have low IgA and IgG3 levels with low normal levels of IgM and other IgG subclasses. Patient #5 presented with thrombocytopenia and anemia. He has a history of recurrent otitis media and *C. difficile* infection. His IgA level was borderline normal and his IgG level was in the low normal range. The relatively high frequency of antibody deficiency suggests that immunologic abnormalities are a manifestation of Kabuki syndrome. The immune defect resembles common variable immune deficiency. The autoimmune disease is likely to be a reflection of the underlying dysfunction of the humoral immune system. We recommend that immunologic testing focusing on the humoral immune system be performed at regular intervals.

A novel Treacher Collins-like syndrome in an Alaskan Inupiat community with autosomal recessive inheritance.

A.V. Hing¹, C. LeBlond², D.W. Shaw¹, M.A. Parisi¹. 1) Univ Washington, Seattle, WA; 2) Division of Public Health, Anchorage, AK.

Classic mandibulofacial dysostosis or Treacher Collins syndrome is characterized by malar and mandibular hypoplasia, down-slanting palpebral fissures, lower eyelid coloboma, auricular malformations with/without aural atresia, and conductive hearing loss. Although cleft palate and choanal atresia have been reported, cleft lip has not. Inheritance is autosomal dominant and is associated with mutations in the *TCOF1* gene on chromosome 5q32 in most individuals.

We present a 21-year-old Inupiat female with malar and mandibular hypoplasia, bilateral lower lid colobomas, preauricular ear tag, small cup-shaped ears, profound mixed hearing loss, choanal atresia, and normal intelligence. Her hands and feet appear normal. Three-dimensional facial CT images show bilateral infra-orbital defects, retrognathia, and hypertrophy of the zygomatic arch with an accessory bony projection of the lateral orbital walls. Immediate family history is notable for six healthy siblings, three miscarriages, and two infant deaths; a female with bladder exstrophy and a male infant with imperforate anus, multiple ear tags, orofacial cleft, and absent left eyelid. Review of extended family pedigree reveals additional male and female relatives with Treacher Collins-like syndrome. These include a first cousin-once-removed, a second cousin, and a newborn second cousin-once-removed; all with mandibulofacial dysostosis and bilateral cleft lip/palate anomalies. Two of the cousins presented in the newborn period with choanal atresia and one child also has a multicystic dysplastic kidney and imperforate anus. All four individuals are Inupiat Eskimo and live in remote neighboring fishing villages in Seward peninsula of Alaska.

We describe a novel form of mandibulofacial dysostosis with presumed autosomal recessive inheritance, normal intelligence, additional clinical features of primary palatal clefting and anal atresia, and a unique radiographic facial structure.

Cleidocranial dysplasia, parietal foramina, cutaneous lesions and anal atresia: A new genetic disorder. *R. Mendoza-Londono, D. Napierala, S. Carter, W. McCormack, Y. Chen, E. Munivez, K. Wakui, L. Shaffer, B. Lee.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Cleidocranial dysplasia (CCD, MIM # 119600) is an autosomal dominant disorder characterized by hypoplastic or absent clavicles and delayed closure of fontanel. CCD is caused by mutations in the Runt domain transcriptional factor RUNX2, which is required for both osteoblast differentiation and chondrocyte maturation. We present a patient referred for evaluation in the newborn period because of dysmorphic features and imperforate anus. Examination revealed mid-face hypoplasia, frontal bossing with large anterior and posterior fontanel, open metopic suture extending down to the nasal bridge, imperforate anus, hypoplastic clavicles, and rocker bottom feet. The skin showed papules over the brow and posterior hairline. Chromosome analysis revealed normal female karyotype, 46,XX. Skeletal survey showed poor ossification of the parietal bones, hypoplasia of the sphenoid bone and of the mid facial bones and absence of the medial aspects of the clavicles. Head CT confirmed wide metopic suture and bi-parietal foramina as well as bicoronal synostosis. Spinal, renal and bladder US, and MRI of the brain were normal. Echocardiogram showed PFO and mild right ventricular hypertrophy. The skin lesions progressed and at four months of age were found on the face and extremities as papules and ruptured vesicles with an erythematous indurated border, in a psoriasis-like distribution. They did not respond to treatment with topical steroids. Skin biopsy of one of the lesions showed lichenoid dermatitis with eosinophils. Mutation analysis of the RUNX2 gene and other candidate genes failed to identify a mutation in this patient. FISH studies excluded deletions of the same genes. To this date, two families with affected sibs with a similar spectrum of findings have been described in the literature. We contend that our patient has a similar phenotype and together they constitute a CCD-related condition that is inherited in autosomal recessive fashion. We hypothesize that this condition may be caused by mutations in a novel protein that regulates the well-known context dependent function of RUNX2.

Survival with Schimke immuno-osseous dysplasia. *S. Lou*¹, *P. Lamfers*², *N. McGuire*², *C. Boerkoel*¹. 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Mercy Pediatrics and Adolescent Clinic, Clear Lake, IA.

Schimke immuno-osseous dysplasia (SIOD, MIM 242900) is an autosomal recessive pleiotropic disorder caused by mutations in *SMARCAL1*. Classically SIOD has been divided into an infantile or severe early-onset form and a juvenile or milder later-onset form, but based on data we have collected from 33 families, we suggest the disease severity and onset follows continuum such that patients with early onset and severe symptoms usually die early in life whereas those with later onset and mild symptoms survive into adulthood if treated with renal dialysis or transplantation. Severity and age of onset of symptoms do not, however, invariably predict survival because we also report a patient who has survived to 20 years despite having a homozygous *SMARCAL1* nonsense mutation and relatively severe early-onset disease. These observations provide not only an overview of the longevity of SIOD patients but also show that some severely affected patients can survive to adulthood.

New Phenotypes and Diagnostic Criteria for Alström Syndrome Based on Evaluation of 134 Cases. J.D.

Marshall¹, R.T. Bronson¹, R.B. Paisey², C. Carey², S. MacDermott², G.B. Collin¹, A.D. Nordstrom³, P. Maffei⁴, S. Beck⁵, J. Davis⁶, G.B. Pozzan⁴, S.E. Shea⁷, G. Shatirishvili⁸, C. Fiscuci⁹, L. McEwan², P.M. Nishina¹. 1) Jackson Laboratory, Bar Harbor, ME; 2) Torbay Hospital, Devon UK; 3) University New Hampshire, Durham, NH; 4) University School Medicine, Padua, Italy; 5) Centro Genetica Clin, Lisbon, Portugal; 6) Valley Children's Hospital, Madera, CA; 7) IWK-Grace Medical Center, Halifax, NS; 8) Program Rare Diseases, Tbilisi, Georgia; 9) County Hospital, Constanta, Romania.

Alström Syndrome is characterized by retinopathy and blindness, neural deafness, obesity, insulin resistance, type 2 diabetes, hypertriglyceridemia, normal intelligence, and no polydactyly. Multiple organ failure (including cardiac, hepatic, and renal) occurs as patients age. Diagnosis can be confounded by the delay in appearance, progressive nature and variable clinical expression of this rare syndrome. Awareness of the complete phenotype is necessary for an earlier, more accurate diagnosis. Here we describe additional features including pulmonary, urological, neurological, developmental, and gastrointestinal dysfunction in 134 cases (69 female; 65 male, 2w-42y). Pathological work-ups on five patients are presented. We obtained clinical data through review of all available medical records, physician interviews, and standardized questionnaires administered to parents. Cardiomyopathy in 63% of patients fell into two distinct groups: a) infant onset, and b) adolescent/adult onset. Minor to severe urological dysfunction occurred in 65 patients (55%). Persistent pulmonary symptoms (bronchitis, asthma, chronic obstructive pulmonary disease, acute respiratory distress syndrome) occurred in 68 patients (58%). Twenty-seven patients had gastrointestinal reflux (23%). Neurological symptoms in 39% included absence seizures, Asperger's-like behaviors, clonic tics, or motor/language delays. Pathological findings include fibrotic infiltration in multiple organ systems: kidney, liver, lung, and heart. Further study of the clinical diversity will contribute to a better understanding of this complex disorder and aid physicians in making an early and accurate diagnosis for Alström Syndrome patients.

Novel X-linked Iron-Storage Disorder with Apparent Neurodegeneration and Skin Involvement. *J.M. Opitz¹, J.C. Carey¹, M.J. Bamshad¹, K. Swoboda², H. Zhou³, E. Gilbert-Barness⁴.* 1) Dept Ped, Div Medical Genetics, Univ Utah, Salt Lake City, UT; 2) Dept Ped, Div Pediatric Neurology, Univ Utah, Salt Lake City, UT; 3) Dept Ped, Div Pathology, Univ Utah, Salt Lake City, UT; 4) University of South Florida Department of Pathology, Tampa General Hospital, Tampa, FL.

We report on a unique family segregating for a previously unreported X-linked condition involving CNS and skin, and affecting 2 younger brothers in a sibship of 7 and their nephew, born to their older sister. Carriers are apparently completely normal; however, the mother of the original sibship died of metastatic breast cancer within a day of her older affected son. Affected boys are born normally without intrauterine growth retardation and undergo apparently normal psychomotor development for 6 months; a premonitory sign is a dolls eye/head bobbling phenomenon shortly before the onset of seizures at 7 months with subsequent relentless downhill course, loss of all psychomotor maturation and vision, with only an occasional smile in response to touch and voice. MRI of CNS and results of all neuro-metabolic tests are normal; however, one of the brothers developed microcephaly. By the time of death, an initially ichthyosis-like skin rash on trunk and axillae had become a histologically psoriasis-like disorder. Studies of fatty alcohol NAD activity is normal, ruling out Sjgren-Larsson syndrome. The affected nephew has a large head; not (as yet) developed skin involvement. Death is due to pneumonia. On autopsy of the younger brother a massive degree of iron deposition was found in all viscera, most strikingly in liver; in his brain there was a scattered loss of neurons. No linkage to the sideroachrestic anemia/MR locus was found.

BRITTLE CORNEA SYNDROME AND ITS DELINEATION FROM THE KYPHOSCOLIOTIC TYPE OF EHLERS-DANLOS SYNDROME: REPORT ON 23 PATIENTS AND REVIEW OF THE LITERATURE. B.

Steinmann¹, H. Al-Hussain², S. Zeisberger¹, P.R. Huber³, C. Giunta¹. 1) Division of Metabolism & Molecular Pediatrics, University Children's Hospital, CH-8032 Zurich, Switzerland; 2) King Khaled Eye Specialist Hospital, Riyadh, Saudi Arabia; 3) University Hospital, Dept. Clinical Chemistry, CH-4031 Basel, Switzerland.

The Brittle Cornea Syndrome (BCS) is a rare, generalized connective tissue disorder characterized by ruptures of the cornea without adequate trauma, keratoconus or keratoglobus, blue sclerae, hyperelasticity of the skin without fragility, and hypermobility of the joints. It is inherited as an autosomal recessive trait but its genetic defect remains elusive. We present 23 (11 male) patients from 13 nuclear families followed at the King Khaled Eye Specialist Hospital, Riyadh, Saudi Arabia. They were aged 3 to 28 years at last follow-up. A total of 28 events of ruptures were noted in 15 patients (8 male); 9 among them had bilateral ruptures, 8 unilateral ruptures (4 of the right cornea), and 2 re-ruptures 2 and 4 years after surgery; 6 patients (aged 3-21 years) had no ruptures. We describe the natural history of our cases and discuss them with those reported in the literature. Because of similarities of the BCS with the kyphoscoliotic type of the Ehlers-Danlos syndrome (EDS VI) both disorders have been confounded. Here, we show biochemically that all patients with BCS had biochemical findings reflecting normal lysyl hydroxylase activity such as normal urinary total pyridinoline ratios (lysyl pyridinoline / hydroxylysyl pyridinoline; mean 0.23, range 0.16-0.38, n=18; controls: 0.20 ± 0.10 , range 0.10-0.38; EDS VI: 5.97 ± 0.99 , range 4.3-8.1, n=17) and/or normal electrophoretic migration of the α -chains of various collagens produced by the fibroblasts. We conclude that the BCS is an entity distinct from that of the kyphoscoliotic type of Ehlers-Danlos syndrome which is caused by a deficiency of the enzyme collagen lysyl hydroxylase and has a much poorer prognosis (Steinmann et al.: The Ehlers-Danlos syndrome. In: *Connective Tissue and Its Heritable Disorders* (P. M. Royce and B. Steinmann, eds), 2nd ed., pp. 431-523, Wiley-Liss, New York, 2002).

Interstitial del 20p (Alagille syndrome) associated with imperforate anus and hypopituitarism. *R.A. Pinter¹, W.A. Hogge¹, U. Surti^{1, 3}, E. McPherson^{1, 2}.* 1) Dept Genetics, Magee-Womens Hosp Pittsburgh, PA; 2) Dept Pediatrics, Childrens Hosp Pittsburgh, PA; 3) Dept Pathology, University of Pittsburgh, PA.

A 2950-gram male was born at 38 weeks to a 29 year-old G6P5 woman by induced vaginal delivery due to prenatal diagnosis of right multicystic dysplastic kidney, left hydronephrosis, and inability to identify sex on ultrasound. Upon newborn examination he was found to be a male with a small non-rugated, non-pigmented scrotum, micropenis, and testes in the inguinal canals, and with an imperforate anus. He had a broad forehead, but otherwise did not have the facial appearance of Alagille syndrome. His anterior fontanel was large and full. His nipples were wide set, and he had excess nuchal skin, clubfoot, long fingers with hyperconvex nails and hypoplastic toenails, and decreased central tone. Eye examination was normal. Hypoglycemia was noted at birth, and low cortisol and hypothyroidism with low TSH were subsequently found. He developed direct hyperbilirubinemia over the next few days. X-rays showed butterfly vertebrae and sacral malformation. Abdominal ultrasound confirmed the prenatal findings, and showed no hepatic anomaly. A brain MRI showed severe maldevelopment of the pituitary gland, and an echocardiogram was remarkable for two small ventricular septal defects. Blood karyotype was 46,XY,del(20)(p11.23-p13). His parents' karyotypes were normal.

The proband exhibits many features of Alagille syndrome, known to be associated with the deletion of *JAG1* at 20p12. This is the first case reported with imperforate anus and hypopituitarism in association with deletion in this area.

Novel CNS syndrome and ectodermal dysplasia. *R. Zannolli¹, C. Miracco², M.M. de Santi², F. Macucci¹, R. Di Bartolo¹, L. Serracca¹, F. Giannini³, A. Malandrini⁴, P. Galluzzi⁵, S. de Robertis⁶, S. Cavani⁹, T. Hadjistilianou⁶, R. Perotti⁷, T. Doldo⁸, M. Fimiani⁷, R. Giorgetti⁸, M. Pierluigi⁹.* 1) Dept. of Pediatrics, Obstetrics and Reproductive Medicine, Section of Pediatrics, Policlinico Le Scotte, University of Siena, Siena, Italy; 2) Dept. of Pathological Anatomy and Histology, Policlinico Le Scotte, University of Siena, Siena, Italy; 3) Dept. of Neuroscience, Section of Neurology, Policlinico Le Scotte, University of Siena, Siena, Italy; 4) Dept. of Neurological Sciences, Policlinico Le Scotte, University of Siena, Siena, Italy; 5) Neuroradiology Unit, Azienda Ospedaliera Senese, Policlinico Le Scotte, Siena, Italy; 6) Dept. of Ophthalmology and Neurosurgery, Policlinico Le Scotte, University of Siena, Siena, Italy; 7) Dept. of Dermatology, Policlinico Le Scotte, University of Siena, Siena, Italy; 8) Dept. of Orthodontics, School of Dentistry, University of Siena, Policlinico Le Scotte, Siena, Italy; 9) Human Genetics Laboratory, Galliera Hospital, Genoa, Italy.

We report a novel CNS syndrome in a 5-year-old male, with a tower-like skull, cerebral hemisphere asymmetry, retinal dystrophy, joint laxity, temporal triangular alopecia, and defective skin, hair and mammalian gland development. Interestingly, a skin biopsy showed a reduced number of hair follicles, hypoplasia of sebaceous glands, abnormal position of eccrine sweat glands, areas lacking filaggrin, hair follicle hyperkeratinization, signs of degeneration, aberrant melanosomes, and collagen fiber disorganization. Before the skin biopsy, diagnosis of this complex syndrome was delayed for several years. For some aspects, this syndrome was similar to Gomez-Lopez-Hernandez syndrome [MIM 601853] for including the same skull shape, a patch of alopecia, and clynodactyly; however it was quite different for the absence of ataxia, trigeminal anesthesia, cerebellar anomaly, corneal opacities. We believe it is important to report this case, as it shows that CNS syndromes are frequent associated with ED traits, often unrecognized. They sometimes present in very intriguing forms, not always matching classifications and previous descriptions.

Overlap of clinical features of Kabuki Syndrome and Branchio-Oto-Renal Syndrome: Contiguous gene syndrome, locus heterogeneity or coincidence? *M.S. Williams*. Dept Pediatrics, Gundersen Lutheran Medical Ctr, La Crosse, WI.

An 8-year-old boy was diagnosed with Kabuki syndrome on the basis of characteristic clinical features. Additionally, he was found to have bilateral preauricular pits, unilateral high frequency sensorineural hearing and unilateral renal agenesis. A review of Kabuki syndrome indicates that preauricular pits are seen in 39% of patients and clinically significant hearing loss is seen in 32% of patients. Some patients show a high frequency sensorineural hearing loss associated with Mondini dysplasia, while conductive and mixed losses are also seen. The correlation between the presence of preauricular pits and hearing loss has not been studied in Kabuki syndrome. Renal anomalies, including horseshoe kidney and renal dysplasia have been reported in Kabuki syndrome, but no cases of unilateral renal agenesis have been previously described. Branchial clefts or cysts also have not been reported. Several cases of Kabuki syndrome have been associated with chromosomal anomalies, but none of these involve chromosome 8. Autosomal dominant inheritance has been reported in several families. Branchio-oto-renal (BOR) syndrome is a well-characterized autosomal dominant syndrome consisting of the association of branchial arch anomalies, hearing loss (sensorineural, conductive or mixed) and renal anomalies. Mondini dysplasia and ossicular chain anomalies have been reported in BOR syndrome. Mutations in the EYA1 gene located at chromosome 8q13.3 are found in 30-70% of classic BOR patients. The phenotypic overlap of Kabuki and BOR syndromes is intriguing, and suggests that the EYA1 locus should be evaluated for microdeletions in the subset of Kabuki patients with preauricular pits and hearing loss, despite the fact that the few patients with such a deletion have not exhibited typical features of Kabuki syndrome. Exclusion of 8q13.3 in some families with autosomal dominant Branchio-otic syndrome has been observed, but none of these families has shown renal involvement. Correlations between preauricular pits, hearing loss, middle and inner ear structural malformations and renal abnormalities in Kabuki syndrome patients should be sought.

A dominantly inherited syndrome with frontonasal malformation : variant of Teebi hypertelorism syndrome or new entity ? A. Verloes^{1,2}, C. Baumann¹. 1) Clinical Genetics Unit, Hosp Robert Debre, Paris, France; 2) INSERM E9935.

We report a 3 generational family with 4 affected patients, showing dominant transmission of hypertelorism and other anomalies of the periorbital area, normal stature, brachydactyly, and variable anomalies : low birthweight (3/4), preauricular anomalies (tags 1/4 and pits 3/4), clefting (2/4), herniae (inguinal 2/4, diaphragmatic :1/4). Low normal mental development was present in 3 patients, whereas moderate mental retardation with autistic behaviour was present in the proband. Facial anomalies resemble craniofrontonasal dysplasia, but absence of craniosynostosis and presence of anomalies in other systems allow easy distinction. Teebi hypertelorism syndrome (hypertelorism, broad nose with broad basis and bridge, abnormal palpebral slit, wide set, arched eyebrows) appears the most suitable diagnosis for this family, although presence of several extra features could justify the delineation of a new entity within the frontonasal community of syndromes.

Syngnathia, vertebral segmentation defect and mental retardation : a new case of Dobrow syndrome. *M. Raoul¹, D. Geneviève¹, Y. Sznajer¹, C. Baumann¹, J. Lombet², V. Rigo², JP. Misson², A. Wilmont³, A. Verloes¹.* 1) Service de Génétique et INSERM E9935, Hopital Robert Debré, Paris, France; 2) Département de Pédiatrie, Hopital La Citadelle, Liège, Belgique; 3) Service de Chirurgie Maxillo - faciale, Hopital La Citadelle, Liège, Belgique.

Congenital bony fusion of the maxilla and mandible is a rare condition. Dawson et al (1997) proposed to subdivide syngnathia in type 1 (isolated syngnathia) and type 2 (syndromal syngnathia), among which type 2a is associated with aglossia and type 2b with agenesis or hypoplasia of the proximal mandible. Most of the reported cases (about 20 to date) are consistent with either Hanhart (aglossia - adactylia) or Goldenhar (facioauriculovertebral) syndromes.

We report a case of multiple defects associated with bilateral syngnathia in a female newborn. Bony fusion of the left mandible and maxilla was associated with severe dysplasia of the left temporomandibular joint and hypoplasia of the mandible and maxilla. This was confirmed by 3D reconstruction of facial CT scan. She had microcephaly, up-slanted palpebral fissures, unilateral coloboma of the iris, small dysplastic ears, cleft palate, severe retrognathism, and skeletal anomalies, namely hemivertebrae and costal fusions. Neurological examination revealed persistent hypotonia, nystagmus and neurosensitive impairment with normal cerebral CT scan. Follow up at 18 months showed developmental delay and seizures. Blood chromosomes were normal and there was no toxic exposure during pregnancy.

This patient is almost similar to the patient described by Dobrow (Syndrome identification case report 96, *J Clin Dismorphol.* 1983;1(2):5-7). This allows to delineate a new MCA/MR syndrome with syngnathia distinct from the types defined by Dawson.

Methylation pattern of human GRB10 (growth factor receptor binding protein) gene in patients with Silver-Russell syndrome or intrauterine growth retardation. *H-W. Yoo^{1,2}, S-S. Kim², G-H. Kim²*. 1) Dept Pediatrics, Asan Medical Ctr, University of Ulsan College of Medicine, Seoul, Korea; 2) Medical Genetics Clinic & Laboratory, Asan Medical Center, Seoul, Korea.

Silver-Russell syndrome(SRS) is characterized by intrauterine growth retardation, postnatal growth failure, and typical dysmorphic features including a small triangular facies, fifth-finger clinodactyly, and asymmetry of head and limbs with a relatively large, prominent forehead. The GRB10 gene, mapped on chromosome 7p11.2-p12, has been suggested as one of the strong candidate genes for SRS. GRB10 gene, which is known to be imprinted in both mouse and human in a paradoxical way, codes for growth factor receptor binding proteins. Overexpression of GRB10 leads to growth suppression by inhibiting tyrosine kinase activity. In this study, efforts was focused on the clarification of methylation pattern in genomic DNA of patients with SRS or intrauterine growth retardation(IUGR) without postnatal catch-up growth. Genomic DNA was isolated from peripheral lymphocytes of 15 patients with SRS and 23 patients with IUGR. After modification of genomic DNA with bisulfite treatment, methylation specific nested PCR was carried out using two sets of primers, one set specific for the bisulfite modified 5' UTR region of GRB10, the other for nested PCR with modified primers to create MboI restriction site for an imprinted allele derived from paternal origin. After nested PCR of bisulfite modified genomic DNA, the PCR product was subsequently digested with MboI restriction enzyme so that allelic pattern could be differentiated. Among 38 patients(15 SRS and 23 IUGR) screened, only 3 patients(1 SRS and 2 IUGR) showed mono-allelic methylation pattern. One out of 15 patients with SRS revealed a paternal mono-allelic pattern. Two out of 23 patients with IUGR showed a paternal and maternal mono-allelic pattern respectively. In these patients, DNA sequencing at methylation specific region using bisulfite-modified PCR product and STR genotyping using D7S481, D7S691, D7S2428, D7S2445, and D7S636 were undertaken. In conclusion, loss of maternal or paternal allele of GRB10 is associated with SRS and IUGR.

A new autosomal dominant skeletal dysplasia caused by a mutation of the *COMP* gene. *H.M. Saal¹, J.A. Johnson¹, J.W. Longshore², R.S. Lachman³.* 1) Div Human Genetics, Cincinnati Hosp Med Center, Cincinnati, OH; 2) DNA Diagnostic Laboratory, Carolinas Medical Center, Charlotte, NC; 3) Medical Genetics-Birth Defects Center, Cedars-Sinai Medical Center, Los Angeles, CA.

Mutations of the gene encoding the cartilage oligomeric matrix protein (COMP) have been associated with pseudoachondroplasia and multiple epiphyseal dysplasia (MED). We have seen 3 members of a multiplex family with disproportionate short stature in 13 individuals. X ray survey performed in childhood on one adult member showed multiple epiphyseal dysplasia. The proband, a 13 month old boy presented with short stature. He was 48.3 cm at birth. At 4 months his length was less than 5th centile (58 cm) and at 13 months his length was 67.5 cm (50th centile for 6 months). The patient's mother and aunt both had disproportionate short stature with micromelia and brachydactyly. Heights of affected males ranged from 153-157 cm, and affected females 144-147 cm. There was no history of significant joint pain or limitation of ambulation, except for mild osteoarthritis. No individual required any orthopedic interventions. X rays of the proband showed multiple changes, including brachydactyly, abnormal carpals and metacarpals with premature fusion of the epiphyses of the phalanges and metacarpals. The vertebrae were flattened with posterior wedging and interpedicular narrowing in the lumbar region. Analysis for a *COMP* gene mutation by direct DNA sequencing demonstrated a missense mutation within exon 11 at position 1181 with an A to C substitution predicting an amino acid change of N386H (asparagine to histidine). Pseudoachondroplasia is an autosomal dominant condition that usually presents in the second year of life with deceleration of linear growth and progressive degenerative changes in the hips and knees. Severe osteoarthritis is common, as is scoliosis. Adult height ranges from 82-130 cm. The MEDs are more variable. The two most commonly described are the Fairbank type and the milder Ribbing type. However in the MEDs, body proportions tend to be normal except for the presence of brachydactyly. Our family clearly does not fit well within either phenotypic group, sharing features of both.

True thymic hyperplasia in an infant with Beckwith-Wiedemann Syndrome. *I. Scala¹, R. Della Casa¹, V. Fiorito¹, A. Riccio², G. Sebastio¹, G. Andria¹.* 1) Department of Pediatrics, Federico II University, Naples, Naples, Italy; 2) Second University of Naples, Naples, Italy.

Beckwith-Wiedemann syndrome (BWS) is a variable disorder whose major features include omphalocele, macroglossia, and macrosomia. Overgrowth may be generalized or segmental and may involve selected organs such as kidneys, pancreas, adrenal glands, liver. True thymic hyperplasia is a rare childhood disorder consisting of increased organ volume by excessive growth of normal thymic structures. Thymic dysplasia has been reported in association with BWS, but, in these cases, the thymus was hypoplastic and immunodeficiency was associated. Up to now, the association of true thymic hyperplasia with BWS has been reported only in one case. A new case of true thymic hyperplasia in an infant with BWS is here reported. Case report. A five months old girl came to our attention for crossed segmental hemi-hyperplasia, overgrowth, umbilical hernia, tongue hemi-hypertrophy, enlarged kidneys. The clinical diagnosis of BWS was confirmed by molecular analysis of the BWS chromosomal region 11p15.5, which showed hypomethylation of the KvDMR1 locus and hypermethylation of the H19 locus. An occasional chest x-ray revealed a mediastinic mass occupying the superior-posterior mediastinum. An ultrasonic examination of the mediastinum did not support thymic neoplasia or cysts. MRI showed an expansive homogeneous mass with a signal identical to a normal thymic tissue. The mass had caused hypoplasia of the pulmonal apex, dislocated the superior vena cava and reached the right paravertebral region. The child did not present symptoms related to the thymic mass. Conclusions. Here we describe a new case of BWS associated with true thymic hyperplasia. Although macroglossia, omphalocele and gigantism are the most frequent manifestations of BWS, the syndrome is often variable. Patients were described who lacked any of the three major manifestations but showed visceral histological lesions. The finding of thymic hyperplasia in this BWS case suggests that it might not be a rare finding in this syndrome. Hence, true thymic hyperplasia might be looked for in those infants with uncertain clinical diagnosis of BWS.

A Study of the Neuropsychological Manifestations in Children with 22q11 Deletion Syndrome. *V. Shashi¹, M.N. Berry¹, T.R. Kwapil².* 1) Pediatrics, Wake Forest Univ Sch Med, Winston-Salem, NC; 2) Psychology, University of North Carolina at Greensboro, NC.

Schizophrenia is increasingly viewed as a neurodevelopmental disorder, but prospective studies of the etiology and premorbid manifestations are hampered by the lack of a homogeneous study population. Chromosome 22q11 deletion syndrome (22q11DS) is an autosomal dominant microdeletion syndrome, associated with congenital abnormalities, cognitive impairment and a markedly increased incidence (40%) of schizophrenia and other major psychoses in late adolescence/adulthood. Due to the relatively recent discovery of the relationship between 22q11DS and psychoses, there is a paucity of knowledge regarding the pathogenesis, neurobiology and the clinical course of psychoses in these individuals. We carried out a pilot study to gather cross-sectional data on 10 children with 22q11DS and 10 age, gender and socioeconomically matched healthy control subjects. This cross-sectional study assessed neurodevelopmental history (including pre- and perinatal complications), pedigree data, medical status, intellectual ability, psychometric/biobehavioral/neurocognitive measures of risk for schizophrenia and structural brain abnormalities by morphometric analyses. Our preliminary data indicate that children with 22q11DS exhibit higher rates of anxiety disorders and AD/HD, in addition to cognitive deficits. On preliminary qualitative brain MRI analysis, structural abnormalities are common, such as a small cerebellar vermis, white matter hyperdensities and midline deviations such as cavum septum pellucidum/vergae (4/7 patients). Our findings are suggestive of increased rates of neuropsychological and neuroanatomical abnormalities in children and adolescents with 22q11DS. Further characterization of these abnormalities in the proposed cross-sectional study will form the basis of a future longitudinal study of risk for schizophrenia and other psychoses in these children. The future longitudinal study would increase the understanding of the causative mechanisms, specify the clinical phenotypes and identify biopsychosocial factors that may increase or decrease the likelihood of developing psychosis.

Postaxial acrofacial dysostosis in two brothers: Miller syndrome or a new entity? *G. Viot¹, S. Fert², A. Munnich¹, V. Cormier¹*. 1) Department of Genetics, Necker-Enfants malades , Paris, France; 2) Service de cytogenetique, Centre Hospitalier de Chambéry, France.

The acrofacial dysostosis syndromes are a heterogeneous group of disorders combining defects of craniofacial and limb development. Usually, the difference between these syndromes lies in the preaxial (namely Nager syndrome) or postaxial (namely Miller syndrome) site of the defect. But the delineation of these different entities is sometimes difficult because of a great clinical variability. Therefore, we report the cases of two brothers with ulnar ray deficiency, camptodactyly, shortened forearms, absence of toes from the lateral border of the feet and bifid first toes. Facial dysmorphism consisted of mild malar hypoplasia responsible for antimongoloid slant of the palpebral fissures, cup-shaped ears, lower lid ectropion, broad nose with unilateral choanal atresia, cleft palate and square chin . They also presented hypoplastic pectoral girdle, cryptorchidism, hearing problems and feeding difficulties. The first boy died shortly after birth because of pneumopathy. The second is 18 years-old and has normal intelligence. Limb defects presented by these two brothers are consistent with the Miller syndrome but the facial dysmorphism and the absence of other skeletal abnormalities suggest that this familial form of postaxial acrofacial dysostosis could be a new entity with an autosomal recessive or an X-linked inheritance.

Defining the clinical spectrum of Alveolar Capillary Dysplasia (ACD). *P. Sen*¹, *C. Langston*^{1,2}, *B.A. Bejjani*³. 1) Pediatrics, Baylor College of Medicine, Houston, TX; 2) Pathology, Baylor College of Medicine, Houston, TX; 3) Mol/Hum Genetics, Baylor College of Medicine, Houston, TX.

Alveolar Capillary Dysplasia (ACD) is a rare and lethal developmental anomaly of the pulmonary vasculature. It is described as the failure of formation of the normal air-blood diffusion barrier in the newborn lung. ACD is usually associated with misalignment or displacement of the pulmonary veins. The disease presents very early in infancy, usually after a few hours of normal breathing. Infants become critically ill very rapidly in the first days of life with severe hypoxemia and pulmonary hypertension. The disease is uniformly lethal. Standard therapies include mechanical ventilation, high concentrations of inspired oxygen, inhaled nitric oxide and ECMO support. These therapies may prolong life by days to weeks, but have led to no long-term survival. We have established a close working relationship with the ACD Association, the only parent support organization and have already collected 29 families, each with one or more infant with ACD in preparation for positional mapping and eventually cloning the ACD gene(s). Clinical records and pathological samples from affected individuals, and DNA from affected and unaffected individuals were obtained. Our review of the pre and postmortem records of affected individuals allows us to define better both the natural history of this condition and the associated anomalies with the ACD phenotype. Our collection of families corroborates the possible recessive nature of this condition and provides additional data for genetic and prenatal counseling. Analysis of the various associated anomalies allows us to formulate a hypothesis regarding possible candidate genes and/or signaling pathways. The material collected here represents the largest cohort of ACD patients ever assembled. It also allows for positional mapping of the putative ACD gene as a first step towards understanding this condition. Understanding the clinical spectrum of ACD and cloning an ACD gene have implications for counseling, for prenatal testing, and for understanding the molecular pathophysiology of ACD and other organ malformation that are associated with this condition.

Chromosome 22q11 deletion syndrome and sclerocornea in an infant boy. *M.L. Raff¹, A.L. Mitchell², W. Robinson³, K.A. Leppig⁴, A.H. Weiss⁵.* 1) Div. of Genetics and Development, Children's Hospital and Regional Medical Center and the Dept. of Pediatrics, University of Washington, Seattle, WA; 2) Div. of Medical Genetics, Dept. of Medicine, University of Washington, Seattle, WA; 3) Dept. of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 4) Group Health Cooperative, Seattle, WA; 5) Dept. of Ophthalmology, University of Washington, Seattle, WA.

Anterior segment dysgenesis of the eye has not previously been reported in an individual with a 22q11.2 deletion. We report a male child with congenital sclerocornea with mild microphthalmia and a FISH-positive 22q11.2. A moderately-sized ventricular septal defect was documented at 3 months of age. At 5 months, he was admitted to hospital for growth failure, at which time his length was at the 50th centile for a 2 month old, his weight was at the 50th centile for a 1-1/2 month old, and his OFC was at the 5th centile. Karyotype performed at that time was normal, but FISH analysis was positive for the 22q11 deletion. The child later manifested global developmental delays, severe gastroesophageal reflux necessitating a Nissen fundoplication, and small bowel obstruction requiring. Corneal opacification precluded visualizing the posterior segment of the eye. However, B-scan ultrasound revealed a clear vitreous and attached retina. ERG showed a normal photopic and scotopic response. Head CT scan at 5 month of age confirmed mild microphthalmia with a globe axial length of 16mm bilaterally. Visual acuity evaluations found no consistent response to the low vision Teller cards, implying a visual acuity of less than 20/2000. Molecular analysis demonstrated heterozygosity of flanking microsatellite markers D22S427 and D22S425, suggesting that this child's deletion could not be significantly larger than the usual deletion associated with 22q11 deletion syndrome. While this represents a relatively severe case of the syndrome, all of the features described here other than the sclerocornea are previously described associations with a 22q11.2 deletion. Thus, we propose that anterior segment dysgenesis be added to the list of associated findings in 22q11 deletion syndrome.

Subtle 2p24-p25 deletion in a boy with Pierre Robin sequence and developmental delay. *P. Gosset¹, C. Ozilou¹, G. Baujat², V. Abadie², M. Picq¹, M. Vekemans¹, S. Lyonnet¹, MC. de Blois¹.* 1) Dept Genetics, Hopital Necker-Enfants Malades, Paris, France; 2) Dept Pediatrics, Hopital Necker-Enfants Malades, Paris, France.

Cryptic rearrangements of subtelomeric chromosome regions are found in about 7% of children with unexplained mental retardation. Here we report the presence of a subtelomeric deletion of the short arm of chromosome 2 in a patient with severe Pierre Robin sequence and developmental delay.

The proband is the first child of young and healthy parents. During pregnancy, amniocentesis was performed because of the discovery of IUGR and Pierre Robin sequence. The karyotype was interpreted as normal. Pregnancy was continued. At birth weight was 1670g and length 40cm. Severe Pierre Robin sequence was noted. Proband was seen at 18 months of age because of developmental delay and dysmorphic features including large forehead, hypertelorism, narrow palpebral fissures, epicanthal folds, small nose and microstomia. Microretrognathism was severe and the ears were low set. The new High resolution R and G banding, was normal. A subtelomeric screen using Multiprobe-T System (Cytocell, UK) was performed. It revealed a deletion of the distal end of a chromosome 2p. This deletion was confirmed using appropriate FISH probes.

The present study illustrates the importance of subtelomeric screen in cases of unexplained mental retardation and dysmorphic features.

Two Filipino Cases With Rare Autosomal Trisomies. *B.C.V. Cavan*¹, *A. Milagrosa*², *E.M.C. Cutiongco*^{1,3}, *C.D. Padilla*^{1,3}. 1) Department of Pediatrics, University of the Philippines College of Medicine-Philippine General Hospital, Manila, Philippines; 2) Department of Pediatrics, Ilocos Training and Medical Regional Center, San Fernando City, La Union, Philippines; 3) Institute of Human Genetics, National Institutes of Health, University of the Philippines, Manila, Philippines.

Trisomies for autosomes other than chromosomes 21, 18 and 13 are noted to have severe consequences and inevitably result to fetal death in utero. There are rare instances wherein these other autosomal trisomies survive the neonatal period. We report two such cases. The first is a case of a 1-month old male born premature to a non-consanguineous Filipino couple. This case presented with intrauterine growth retardation, microcephaly, hypertelorism, epicanthic folds, midface hypoplasia, low set ears, multiple ventricular septal defects and a hypoplastic 5th distal phalanx. The diagnosis of trisomy 22 was confirmed in all cells examined by chromosomal analysis (G-banding). The second case is a 3-month old female born term to non-consanguineous Filipino parents. She presented with a high arched palate, low set ears, bifrontal hair whorls, unequal palpebral fissures, hypertelorism, limited movement of the left eye, overlapping fingers on the right hand (5th digit over the 4th digit, 2nd digit over the 3rd digit), large flat nipples with a hypopigmented central area of the areola, a sacral dimple, and a wide gap between the first and second toes. Chest radiographs showed eleven pairs of ribs. Chromosomal analysis by G-banding confirmed the diagnosis of Trisomy 11. To our knowledge, there are no other case reports of trisomy 11 in literature. Mosaicism is not discounted as a possible cause for the prolonged survival of our patient. These cases add to the world literature on autosomal trisomies in liveborns.

CPO1: A Cleft Palate Gene on 2q32.3. *D.R. FitzPatrick¹, J.A. Fantes¹, L. McLaren², N. McGill¹, H. Firth⁴, K. Williamson¹, J.P. Leek³, I.M. Carr³, S. Hassan³, P.J. Wightman¹, A.F. Markham³, D.T. Bonthron³.* 1) Cell & Molecular Genetics, MRC Human Genetics Unit, Edinburgh, UK; 2) Molecular Medicine Centre, University of Edinburgh, Western General Hospital, Edinburgh EH4 2XU, UK; 3) Molecular Medicine Unit, University of Leeds, Clinical Sciences Building, St James's University Hospital, Leeds LS9 7TF, UK; 4) Department of Clinical Genetics, Addenbrooke's Hospital, Cambridge CB2 2QQ, UK.

We previously reported two unrelated children with very similar clinical phenotype and de novo apparently balanced chromosomal translocations involving 2q32.2 associated with isolated cleft palate - *Am J Hum Genet* 1999, 65:387-96. High resolution FISH mapping of these breakpoints demonstrated that one interrupts the transcription unit of the gene, KIAA1034 which we have renamed CPO1. The second breakpoint is 70 kb 3' of the polyadenylation signal in a region of non-coding DNA. This gene has telomeric-centromeric orientation and resides in a gene poor region of 2q32.3. The nearest confirmed neighbouring gene is 1.26 MB centromeric to the CPO1 polyadenylation signal. CPO1 has 12 exons which span 191kB of genomic DNA. It encodes a protein of 733 amino acids that has two CUT domains and a homeodomain and shows an extraordinary degree of evolutionary conservation with only 3/733 amino acid residues differing between the mouse and human peptides. Significant homology was also found to the chromatin binding protein SATB1 and the drosophila protein DVE1. Whole mount in situ hybridisation to mouse embryos using antisense riboprobes derived from two different regions of mouse CPO1 showed site- and stage-specific expression only in the developing palate. Haploinsufficiency for this gene appears to be responsible for the phenotype in at least one of these children and it is likely that the disruption of long-range gene regulation is involved in the second breakpoint. However, mutation analysis of 150 unrelated patients with isolated CPO did not reveal any potentially pathogenic changes or polymorphisms in the coding region suggesting that this gene is not a major contributor to the etiology of isolated cleft palate.

Identification of deletion of 4q34.2-qter in three generations of a family. *J.M. Cowan^{1, 2}, P.G. Wheeler²*. 1) Cytogenetics Laboratory, Tufts-New England Medical Ctr, Boston, MA; 2) Division of Genetics, Department of Pediatrics, Tufts University School of Medicine, Boston, MA.

The majority of microscopically visible deletions are characterized by dysmorphic features and often congenital abnormalities. Deletions of terminal 4q have been associated previously with facioscapulohumeral muscular dystrophy (FHD).

We have identified a family in which a deletion of 4q34.2-qter was present in three generations. The family was ascertained through identification of a terminal deletion of 4q in an amniotic fluid sample drawn for advanced maternal age. A level 2 ultrasound scan of the fetus did not reveal any abnormalities. A study of parental karyotypes revealed the same deletion in the mother of the fetus, while the father's karyotype was normal. The deletion was confirmed by telomere FISH. An expanded study of the mother's family identified the deletion in the proband's mother and brother. The phenotype of the affected individuals is characterized by difficulty in school, and though all are described as "slow" they are functioning adults, able to hold jobs.

Deletion of the distal part of 4q has not resulted in dysmorphic features in this family, though the affected individuals are intellectually slower than unaffected members of the family. In addition, the affected members have a history of miscarriage - the proband's mother had 5, and the proband's brother has had 2 losses. It is unclear at present whether this is directly related to the loss of distal 4q.

Four new patients with 2q terminal deletion syndrome: hemidiaphragmatic hernia as a novel finding and patterns of malformation among 47 reported cases. *K.A. Casas¹, H.J. Lin², C.N. Mikail¹, R.E. Falk¹.* 1) Medical Genetics/Birth Defects Ctr, Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) Division of Medical Genetics, Harbor-UCLA Medical Ctr, Torrance, CA.

At least 43 individuals carrying an isolated, terminal deletion of chromosome 2q, with the breakpoint at or distal to region 3 band 5, have been described since 1983. We report four new subjects and examine phenotypes associated with breakpoints. Subject 1 (6 day-old male; breakpoint at 2q37.1) had multiple anomalies, including hemidiaphragmatic hernia, atrial septal defect, horseshoe kidney, and microtia. Subjects 2 and 3 (1 year-old male and 2 year-old male, respectively; breakpoint at 2q37.1) had global developmental delay, hypotonia, and unusual facies. Subject 4 (6 year-old female; breakpoint at 2q37.3) had developmental delay, autistic behavior, and unusual dentition. Whereas subtelomeric deletion polymorphisms within 2q are estimated to occur in five percent of the population, the frequency of larger, significant deletions is unknown. Such 2q deletions may be underdiagnosed. Among known subjects, developmental delay occurred in 95 percent of those surviving the newborn period. Other common manifestations were: hypotonia (51 percent); major malformation (32 percent); and autistic behavior (26 percent). Positions of breakpoints may be roughly associated with certain abnormalities. For example, a subject with a subtelomeric breakpoint displayed only autistic behavior and developmental delay. Facial features (e.g., frontal bossing, dysmorphic ears, short nose, flat nasal bridge) and short hands and feet were frequent in subjects with breakpoints at or proximal to 2q37.3. Reports of structural brain anomalies, horseshoe kidney, and Wilms tumor were limited to cases with the breakpoint within or proximal to 2q37.1. Cleft palate was reported only in subjects with proximal breakpoints (2q36 or 2q35). Hiatal hernia occurred in a subject who had a breakpoint at 2q37 (no sub-band identified), but no other diaphragmatic defect had been observed prior to Subject 1 above. Such information on breakpoints and phenotypes may be useful in counseling, if confirmed by further reporting.

Detection by PCR and FISH analyses of Y-chromosome specific sequences in genomic- and gonadal-DNA in patients with Ullrich-Turner syndrome. *F.J. Alvarez Nava, M.L. SOTO QUINTANA, L. BORJAS, A. ROJAS ATENCIO, M.A. SANCHEZ, E. FERNANDEZ, A. MORALES MACHIN.* Unidad de Genetica Medica, Univ del Zulia, Maracaibo Zulia, ZULIA, Venezuela.

Ullrich-Turner syndrome (UTS) is associated in 40-60% with 45,X karyotype, whereas the remaining cytogenetics findings have numerical or structural anomalies in second sexual chromosome (X or Y) in form pure or with mosaicism. It has been proposed that all females with UTS and 45,X karyotypes carry a cell line containing two sex chromosome at low level of mosaicism. This mosaicism is undetectable by standard cytogenetics analysis. Theoretically, this hidden mosaicism may has a Y chromosome. Gonadal dysgenesis seen in UTS patients is associated with gonadoblastoma when Y-chromosome is present in their genome. So it is crucial to carry out molecular analysis in these subjects to rule out Y-chromosome sequences. The present study was performed to examine the presence of Y-chromosome material in lymphocytes- and gonadal-DNA in UTS patients. Fifty-two Venezuelan patients were screened by polymerase chain reaction (PCR) to detect Y-chromosome fragments using ten Y-chromosome specific primer pairs. These primers are spanned all seven intervals of the Y-chromosome. Patients with virilization and/or with positive Y-chromosome sequences by PCR underwent gonadectomy. Fluorescence in situ hybridization (FISH) was used to confirm that chromosomes were Y-derived. For patients (two with 45,X/46,XY, one with 45,X/46,X,+mar, and one with 45,X karyotypes) were positive in lymphocytes-DNA to Y-sequences specific. All patients had Y chromosome material on gonadal-DNA. FISH confirmed their Y-chromosome origin. Only one of them (45,X) presented bilateral gonadoblastoma and she did not exhibit virilization. Our results suggest that the molecular analysis must be applied for detection of Y-chromosome in all UTS patients and do not to limit to UTS patients with cytogenetically identifiable Y-chromosome and/or virilization.

Sex chromosome aneuploidy diagnosed in younger children. *J. Bodurtha, U.T. Sundaram, C. Jackson-Cook.* VCU, Richmond, VA.

Early diagnosis of genetic conditions can help families plan for the future and address the worry associated with not having a diagnosis. Sex chromosome conditions in males are common, and include the classic Klinefelter syndrome, (46,XXY) as well as the rarer conditions with multiple X-chromosomes. Klinefelter syndrome is considered in the differential diagnosis in an adolescent with gynecomastia, and inadequate testosterone production, or in adult men being evaluated for infertility. Although developmental delay, such as mild delay in motor and language milestones, and learning difficulty are reported in sex chromosome aneuploidy conditions in males, they may not be strongly considered in children presenting with these symptoms leading to the under diagnosis in children. We report two male patients, who were diagnosed at 21 months and 15 months with sex chromosome aneuploidy. The first patient had developmental delay (especially speech), short stature, radio-ulnar synostosis, round face, and micropenis. He had been evaluated for metabolic disorders at two other institutions, and had received testosterone for micropenis with good response. We evaluated him after this intervention and ordered chromosome studies that revealed a 49, XXXXY complement. Some authors consider this condition to be a Klinefelter variant while others believe it is a distinct entity. The literature indicates a positive correlation between the number of X-chromosomes, and the severity of developmental delay and /or mental retardation. The second patient is an adopted child who we evaluated due to developmental delay (especially speech). He had a round face, hypertelorism, and shawl scrotum. Chromosome analysis revealed a 47, XXY complement. Sex chromosome aneuploidy, especially classic Klinefelter syndrome, may be frequently diagnosed prenatally but less so in infancy. These cases underscore the need to perform chromosome testing in male children who have delayed development, in particular speech impairment, and minimal distinctive findings, including small testes, micropenis and round face in infancy. An early diagnosis can benefit the patient through referral for early infant intervention as well as doing long term health and educational planning.

A study of congenital malformation associated with consanguinity in Khorasan Province, North East of Iran. *R. Akbarzadah¹, K. Ghodsi¹, G. Mamoori², A. Mohammadzadah², A. Shahfarhat², M. Akbarzadah¹, M. Gorgi Nejad¹, N. Khadem³, L. Hafizi³, S. Kadkhodaian³, N. Saghafi³, N. Lotfi², R. Akbarzadah¹, J. Parizadah².* 1) medical genetics, Ghaem hospital, Mashhad, Khorasan, Iran; 2) Pediatric, Ghaem hospital, Mashhad, Khorasan, Iran; 3) Gynecology, Ghaem hospital, Mashhad, Khorasan, Iran.

A study of congenital malformation associated with consanguinity in Khorasan province, North East of Iran. Reza Akbarzadeh¹, Kazem Ghodsi¹, Gholam Ali Mamoori², Ashraf Mohammadzadeh², Ahmad Shahfarhat², Marjaneh Akbarzadah¹, Mohsen Gorgi Nejad¹, Naierah Khadem³, Laili Hafizi³, Sima Kadkhodaian³, Nafisah Saghafi³, Nosrat Lotfi², Rehanah Akbarzadah¹, and Javad Parizadeh². Department of Medical Genetics¹, Department of Pediatric² and Department of Gynecology³, Ghaem and Emam Reza Hospitals, Faculty of Medicine, Mashhad University of Medical Sciences Mashhad Iran. First cousin marriage is common in Khorasan which is the biggest province in Iran. It is consisted of various people and cultures. We randomly studied 3624 marriage in 25 cities of this province, to investigate the role of first cousin marriage and genetic disorders. In this group consanguinity was present in 25.9%. Analyzing by gender demonstrated that 44.2% of patients were girls and 57.8% boys. Pedigrees were analyzed and showed that 33.2% of congenital abnormalities were born to consanguinity families. It also showed that death under one year old 10.3%, recurrent abortion 32.7% and other anomalies 57% including disorders of bone and connective tissues 30.3%, gastrointestinal tract 20.7%, central nervous system disorders 18.5%, kidney diseases 12.2%, congenital heart disease 6.7%, deafness 3.3%, blindness 2.5%, and skin disorders 3.8% were presented in patients. Etiological study showed that multifactorial inheritance was 42%, autosomal dominant 21.3%, autosomal recessive 4.3%, X-linked 2.6% unknown causes 15.8% and chromosomal abnormalities containing trisomy 21, 13 and 21/21 translocation 14%.

Gender ambiguity and fragile X: a new syndrome. *K.J. Griffin¹, T. Bei¹, J. Meck², L.-J. Wong², C. Bondy¹, C.A. Stratakis¹.* 1) UGEN/DEB, NICHD, NIH, Bethesda, MD; 2) Institute for Molecular & Human Genetics, Georgetown University, Washington DC.

We recently encountered a family with a novel condition: the concurrent presence of ambiguous genitalia and FXS in a 16-year-old male with severe mental retardation (MR) and a 29-year-old female with mild MR. Both were children of a 55-year-old woman with no MR but mild stigmata of FXS and paucity of axillary and pubic hair. The female child was born with ambiguous genitalia; cryptorchid testes were removed at birth. A third sibling, a 19-year-old female, was phenotypically normal and had normal hair. The mother and the 3rd sibling had a 46,XX chromosomal constitution; the father and the two affected siblings had 46,XY. Molecular analysis revealed normal androgen receptor (AR) by FISH and identical X in all 3 siblings by microsatellite markers; FMR-1 analysis showed that the mother was a carrier for a premutation; the affected children had a heterogeneous expansion up to 270 repeats in the male and 600 repeats in the female. The 46, XY female also had the premutation; she was an apparent mosaic, as was her mother. These findings were confirmed by EcoRI/EagI digests. AR sequencing of the 46,XY female showed no known disease-causing mutations; cDNA of the receptor (from peripheral lymphocytes) was also normal. However, the AR exon 1 glycine repeat track length was only 10 repeats, which has been associated with decreased AR function under certain conditions. This change was also present in the unaffected 3rd sibling, a normal 46,XX female. The present report identifies a family with sexual ambiguity and FXS. Apparent mosaicism for a mutation and premutation status of FMR-1 may explain the phenotypic differences between the 2 affected siblings. Mosaicism for FMR-1 gene mutation and/or other genetic defects may affect the expression or function of the AR gene carrying certain polymorphisms, or alter FXS phenotype to include sexual ambiguity.

ECTRODACTYLY IN THE GENETICS CLINIC. *B.G. Kousseff.* Pediatrics & Genetics, USF Regional Genetics Prog, Tampa, FL.

Ectrodactyly is encountered in mendelian traits as well as in rare chromosomal anomalies and as sporadic. The anomaly occurs during organogenesis and recently its pathogenesis is better understood (Wolpert, *Pediatr Res* 46:247-254, 1999). Retrospective analysis of the 51 probands with confirmed or suspected ectrodactyly evaluated at the USF genetics/dysmorphology and prenatal clinics between 1/2/82 and 12/31/00 is presented. The probands were part of the 38,706 probands/families evaluated during the period. They were retrieved using patient database. Ectrodactyly/split hand was one of the 3 primary diagnoses. Four of the 51 were no shows in the clinic and were excluded. There were 29 males and 18 females. Twenty-eight of 47 were Caucasian, 10 Hispanic, and 9 African-American mismatching the racial ratio of the population of West Central Florida. Typical lobster claw anomaly type I was present in 19 and atypical in 28. Two had chromosome anomaly, t(13q14q) paternal with maternal class A 1 diabetes mellitus in one and another with complex chromosome rearrangement with 6 breaks on chromosomes 2,3,5,11, and 13 resulting in interstitial deletion 13q. (Kousseff et al. *Clin Genet* 42:135-142 1992). Three probands had mothers with diabetes mellitus but no other anomalies to diagnose diabetic embryopathy. Twelve of the 47 had positive family history indicative of autosomal dominant trait with reduced penetrance. Eighteen of the 47 had associated anomalies implying syndromes. Among them were 3 probands with ectrodactyly-ectodermal dysplasia-cleft palate. This study showed that ectrodactyly has 1. varied phenotypes difficult to classify and 2. is genetically heterogeneous. As to a candidate gene only the probands with chromosomal abnormalities implied chromosome 13.

Severe psychomotor retardation associated with mosaic Down syndrome and mosaic Turner syndrome involving trisomy 21, monosomy X and ring X cell lines. *M.T. Jodah¹, L.L. Estabrooks², K. Clark², B.G. Kousseff¹*. 1) Dept. of Pediatrics, USF Regional Genetics Program, Tampa, FL; 2) Genzyme Genetics, Tampa, FL.

CASE REPORT: A three-year old, Mexican female (IV) was referred to the genetic clinic with a diagnosis of Down syndrome, diagnosed prenatally via amniocentesis for advanced maternal age; the cytogenetic report was unavailable. The phenotype of IV consisted of intermittent nystagmus, synophrys, patent ductus arteriosus, minimal upslant to the palpebral fissures, epicanthal folds, Brushfield spots, large ears with a pit on the right, short neck with redundant skin, bilateral simian creases, and fifth finger clinodactyly. She was wheelchair bound, had cortical blindness, bilateral profound hearing loss, severe speech delay and myoclonic seizures. Repeat chromosome analysis on peripheral lymphocytes showed 46,X,+mar[14]/47,XX,+21[12]/45,X[4]. FISH analysis revealed the marker was a ring X and lacked the X inactivation locus (XIST). At least three possible mechanisms could result in the observed cell lines. The first is that the original cell line was 47,XX,+21 with loss of the 21 giving a 46,XX cell line; a subsequent break in the X chromosome results in the 46,X,r(X) cell line. As ring chromosomes are unstable, they may be lost creating the 45,X cell line. A 46,XX cell line was not seen in this analysis, but its presence cannot be completely ruled out; it may be confined to a specific tissue. The second mechanism is a possible re-absorbed twin, one with a 47,XX,+21 karyotype and the other with a 46,X,r(X) and subsequent loss of the ring X. The third possibility is that this is a true chimera. The phenotype in cases with a ring X depends on the presence of the XIST locus and euchromatic material. If gene-coding material is present, in the absence of the XIST locus, it will be expressed, along with genes on the normal X chromosome. It results in a lack of dosage compensation for the X-linked genes and leads to an abnormal phenotype that may include mental and growth retardation and multiple congenital anomalies. The phenotype suggests the predominant cell line in this child is 46,X,r(X). The amount of euchromatic material that might be present on the ring X could not be determined.

Mild phenotype associated with tandem duplication of chromosome 16q. *L. Mehta*¹, *M.J. Macera*², *S. Sastry*¹, *S. Kleyman*², *A. Babu*². 1) Div. Medical Genetics, Schneider Children's Hosp./ North Shore Univ. Hosp., Manhasset, NY; 2) Div. Mol. Medicine & Genetics, Wyckoff Heights Medical Center, Brooklyn, NY.

A 15 year old Korean male was evaluated for mild mental retardation and behavioral abnormalities. As an infant he had a small cardiac septal defect that closed spontaneously and inguinal hernia repair. Growth was normal. Dysmorphic features were mild and included peaked anterior hairline, flat occiput, wide and flat nasal bridge, small ears with overfolded helices, short fifth fingers and widely separated toes. IQ was measured as 70. He had adequate verbal skills. Attention span was poor with hyperactivity and an immature affect. Plasma amino acids, urine organic acids and fragile X DNA studies were normal. Chromosome analysis of peripheral blood lymphocytes revealed an abnormal chromosome 16 with additional material in the long arm. Other chromosomes were normal. Parental karyotypes were normal indicating a de novo origin of the abnormal chromosome 16. FISH studies using whole chromosome paint 16 indicated that the additional material was derived from 16. Comparing band on band homology, bands 16q21-q22 were considered to be duplicated making the patient trisomic for 16q21-22. The karyotype was designated 46,XY,add(16)(q21).ish der(16)dup(16)(q21q22)(wcp16+). Direct interstitial duplications of chromosome 16 are rare but have been reported for 16p and proximal 16q segments. This is the first case report of direct duplication of 16q21-22. Only 5 reports of direct 16q duplications were ascertained; three were dup16q11-q13, one was dup16q13-q21 and one was dup16q11-q22. All 5 patients had moderate to severe mental retardation with inconsistent dysmorphic features. Our patient represents the smallest 16q duplication to date and has a significantly milder phenotype with only minor dysmorphisms and a clinically insignificant cardiac defect. Behavioral abnormalities are however reported in at least three of the other patients and were noted in our patient. Phenotypic correlations for partial trisomy 16 are difficult given the almost invariable association with other chromosome imbalance. Direct duplications such as this may yield more specific information in the future.

Analysis of dicentric Y chromosome in patient with Turner syndrome: clinical, cytogenetic, and molecular studies. *J.W. Kim¹, J.M. Kim¹, Y.M. Kim¹, I.O. Song², H.M. Ryu^{1,2}, Y.H. Cho³, S.Y. Park¹.* 1) Genetic Research Laboratory, Samsung Cheil Hosp, Seoul, Korea; 2) Department of Obstetrics and Gynecology, Samsung Cheil Hosp. Seoul, Korea; 3) Department of Medical Genetics, College of Medicine, Hyanyang University, Seoul, Korea.

We describe the results of clinical, cytogenetic and molecular studies of dicentric mosaic marker derived from chromosome Y. The patient referred for genetic study because of Turner syndrome with primary amenorrhea and has detected an abnormal karyotype of $mos\ 45,X[106]/46,X,+mar[27]$. We used special cytogenetic techniques, fluorescence in situ hybridization (FISH) and polymerase chain reaction (PCR) to characterize the structure and origin of the marker chromosome. The marker chromosome was confirmed negative NOR and faintly positive with C-, DA-DAPI banding. FISH using a LSI SRY/CEP X dual color probe analyzed the duplication copies of SRY gene and one copy of centromeric region in X chromosome as control. CEP Y(a)/CEP Y(satIII) dual color probe was indicated the duplication copies of centromeric region on Y chromosome. PCR analysis was shown to the presence between SRY and sY134 loci without sY156, sY254, sY255 and heterochromatin regions. PCR and FISH analysis confirmed to present two copies of the SRY gene and centromeric region in all analyzed cells. These are attractive tool for the character of the mosaic marker chromosome origin. Our results support the hypothesis that the coexisting 45,X cell line is more influential on the determination of the sex phenotype in patients with 45,X/46,X,dic(Y) mosaicism.

Down syndrome cerebellar phenotypes in Ts65Dn and Ts1Cje segmentally trisomic mice: Implications for the mechanism of gene action. *L.E. Olson¹, L.L. Baxter¹, E.J. Carlson², C.J. Epstein², R.H. Reeves¹*. 1) Johns Hopkins University School of Medicine, Baltimore, MD; 2) University of California at San Francisco.

In rare individuals with chromosomal translocations, Down syndrome (DS) is caused by partial trisomy of chromosome (Chr) 21. Correlation of the smallest regions of overlap in such individuals also displaying the same characteristics of DS has led to the hypothesis that many aspects of the phenotype arise from dosage imbalance of one or a few genes. An alternative hypothesis asserts that DS phenotypes result from small effects of hundreds of genes at dosage imbalance. Segmentally trisomic mice, which produce dosage imbalance for different numbers of Chr 21 gene orthologs, provide sensitive models in which to test this hypothesis.

By comparing mouse Chr 16 and human Chr 21, we know that Ts1Cje and Ts65Dn mice are respectively trisomic for 85 and 124 of the 225 catalogued Chr 21 genes. Ts65Dn mice, like individuals with DS, have reduced volume and cellular density in the cerebellum (Baxter et al., 2000); thus, trisomy for roughly half of the genes on Chr 21 is sufficient to produce this DS phenotype. The cerebellum of the Ts1Cje mouse is affected more mildly than that of the Ts65Dn mouse. Although cerebellar volume is reduced to the same extent as Ts65Dn mice (88% of euploid), granule cell density is substantially less affected in Ts1Cje (90% of euploid) as compared to Ts65Dn (76%). The Ts1Cje mice did not show the reduced Purkinje cell density found in Ts65Dn. This graded severity of the cerebellar phenotype with decreasing amounts of trisomy supports the hypothesis that multiple genes contribute to this phenotype of DS.

Baxter, L. L., T. H. Moran, J. T. Richtsmeier, J. Troncoso, and R. H. Reeves. 2000. Discovery and genetic localization of Down syndrome cerebellar phenotypes using the Ts65Dn mouse. *Hum Mol Genet* 9: 195-202.

Further clinical delineation and microsatellite profile in 1p36 deletion patients. *F.R. Vargas^{1,2,4}, J.C. Llerena Jr³, M.C. Ramos⁴, J.G. Barbosa-Neto⁴, K.R.L. Souza^{1,2}, H. Ramos³, R.R. Santos⁵, J.C. Cabral de Almeida³.* 1) Genetics, Instituto Nacional do Cancer, Rio de Janeiro, RJ, Brazil; 2) Universidade do Rio de Janeiro (UNI-RIO), Rio de Janeiro, Brazil; 3) Instituto Fernandes Figueira, FIOCRUZ, Rio de Janeiro, Brazil; 4) Gen Genetica Medica & Citogenetica Ltda, Rio de Janeiro, Brazil; 5) Instituto Estadual de Diabetes e Endocrinologia, Rio de Janeiro, Brazil.

The 1p36 deletion has been recently recognized as an apparently new chromosomal syndrome. We studied six unrelated cases of de novo 1p36 deletions. All of them showed only one signal with the fluorescence in situ hybridization (FISH) probe located at 1p36. In one of the patients the deletion was not visible in 550-800 GTG banded preparations. All six patients showed very similar clinical findings, allowing for the clinical recognition of this recently identified chromosomal syndrome. Approximately 30-40 cases of de novo 1p36 deletion have been identified to date (Am J Hum Genet 61:642-650, 1997; J Med Genet 36:657-663, 1999). The deleted chromosome appears to be of maternal origin in of cases, with at least three preferential breakpoint regions within 1p36. However, genotype-phenotype correlation does not seem to be straightforward. In regard to growth pattern, there seems to be two different phenotypes. While most affected children show postnatal growth retardation, some patients develop hyperphagia and obesity resembling Prader-Willi syndrome (PWS). Two of our patients fell in this category. Besides, two of our patients presented with dental anomalies that were not previously observed, which should probably be added to the clinical spectrum. Studies with a set of four microsatellites located at 1p36 (D1S243, D1S244, D1S450, D1S468) showed that the deleted chromosome was of paternal origin in at least two cases. Further investigation with a larger set of microsatellite markers spanning the 1p36 region is currently underway.

Thyroid Dysfunction, In children and adolescents with Down'Syndrome In Kuwait. *A.A. Sadika¹, R.L. Al-Naggar¹, N.M Al-Awadi², M.M. Abu-Henedi¹, L.A Bastaki¹.* 1) Obstetric, Kuwait Medical Genetic Center, Kuwait, Kuwait(KMGC); 2) West Salmiya health Clinic, Ministry of Health, Kuwait.

Objectives: The association of thyroid dysfunction with Down's syndrome(DS) has become well recognized, and abnormal thyroid function has been reported at all ages. The aim of this study is to evaluate the thyroid function in individuals with DS who are receiving health care in KMGC and related clinics. Methods: 61 patients and 40 normal controls were selected to be age and sex matched. Karyotyping was carried out to confirm diagnosis of DS and examined for evidence of hormonal and autoimmune thyroid dysfunction at the time of their referral for routine health care. Thyroxine(T₄), thyrotropine(TSH) and thyroid autoantibodies were measured by radioimmunoassay and hemagglutination tests respectively. Results: 15% of DS patients had hypothyroidism, 1.6% hyperthyroidism, 39% subclinical thyroid dysfunction and 44.4% of DS patients had euthyroidism. All hypothyroid patients had raised antithyroglobulin(ATG) and antiperoxidase(AP) antibodies. Elevated ATG antibody titre has been found in 25% of subclinical hypothyroid subjects. Thyroid dysfunction and autoantibodies have been found more at the ages of 10 to 20 years and the dysfunction is equally distributed by sex. Conclusion: The frequency of hypothyroidism in DS patients was in keeping with the other studies, while the frequency of subclinical hypothyroidism exceeded that reported in certain series. On the other hand the frequency of hyperthyroidism in DS patients was similar to that reported in the normal population. The positive thyroid autoantibodies in DS patients could be a possible cause of thyroid dysfunction despite of the insignificant association with age in our work. We recommend regular thyroid function assessment annually and every 6 months in case of positive thyroid autoantibodies. Down syndrome patients with any thyroid dysfunction should receive the proper management.

Paternally derived inv dup(15) chromosome associated with Prader-Willi syndrome. *D.J. Waggoner¹, R. Brown¹, S. Pihl¹, J. Kobori², S. Christian¹, D. Ledbetter¹.* 1) University of Chicago, Chicago, IL; 2) Permanente Medical Group, California.

Supernumerary marker chromosomes occur relatively frequently in the population with an incidence of 0.7-1.5/1000 live births. Inv dup(15) is the most common and accounts for approximately 50% of all supernumerary markers. Generally, inv dup(15) chromosomes can be classified into two groups, those containing the Prader-Willi (PWS)/Angelman syndrome (AS) critical region (large markers) and those not containing the PWS/AS critical region (small markers). Small inv dup(15) are commonly inherited and are not associated with a specific phenotype, although there is an increased incidence of uniparental disomy (UPD), which is usually maternal UPD and associated with PWS. Large inv dup(15) are almost always maternally derived and associated with a severe phenotype of seizures, mental retardation, dysmorphic features, and autistic behaviors. We describe four patients with paternal inheritance of a large inv dup(15) chromosome and maternal UPD, which represents a novel mechanism leading to PWS. Methylation studies show biparental methylation patterns, and microsatellite data confirms the paternal origin of these cases. The clinical phenotype of these patients is reviewed and reveals that despite the presence of one or two paternal copies of the PWS/AS critical region and normal methylation studies, there is no difference in the phenotype expected with PWS. The literature was reviewed and revealed on other case of paternally inherited large inv dup(15), with maternal UPD, Prader-Willi phenotype, and normal methylation studies. Mechanisms to explain these observations and a suggested approach for the evaluation of an inv dup(15) chromosome are explored.

Somatic Mosaicism in Sturge Weber Syndrome. *F.J. Serajee, M. Mally, D.C. Chugani, AHMM. Huq.* Departments of Pediatrics and Neurology, Wayne State University, Detroit, MI.

We have tested the hypothesis that lesions in the Sturge-Weber syndrome (SWS) result from somatic mutations in affected areas. Possible categories of such mutations include chromosomal anomalies and point mutations, deletions or duplications in a single gene. We collected samples from affected and unaffected tissues in six subjects with SWS and established short-term cultures. The cultured cells were then examined for chromosomal rearrangements. Cells cultured from unaffected areas revealed a normal chromosome pattern with expected random loss of chromosomes in all cell lines. However, short-term culture established from tissues from affected areas of two subjects revealed a significant proportion of cells with chromosomal abnormalities. In one subject, paracentric inversion of chromosome 4q (q22>q28) was present in 40% of cells cultured from leptomeningeal angiomas. The inversion was not present in cells cultured from blood of the same subject. Cells cultured from a port-wine stain of a second subject revealed trisomy of chromosome 10 in 50% of the cells. These abnormalities were not present in the blood or normal skin. Our study demonstrates that tissues from affected areas were genetically mosaic in selected patients with SWS, suggesting that mutant cells form a large subset of all cells in affected tissue. The lesions in SWS may result from somatic cell mosaicism for a disease causing chromosomal change or mutation. The chromosomal changes may also indicate chromosomal or genomic instability in affected areas in SWS. Alternatively, SWS lesions may simply be a marker of chromosomal mosaicism as in hypomelanosis of Ito.

Oral Motor, Speech and Voice Functions in Smith Magenis Syndrome Children: A Research Update. B.I.

Solomon¹, L. McCullagh², D. Krasnewich³, A.C.M. Smith³ and The SMS Research Unit. 1) Rehabilitation Medicine Dept., W.G. Magnuson Clinical Center, National Institutes of Health, Bethesda, MD; 2) W. G. Magnuson Clinical Center, National Institutes of Health, Bethesda, MD; 3) Medical Genetics, Branch, National Human Genome Research Institute, National Institutes of Health.

Smith Magenis Syndrome (SMS) is a known multiple congenital anomaly and mental retardation disorder associated with del of 17p11.2. The distinct clinical phenotype of developmental delays in speech/language, fine motor and gross motor skills as well physical and neurobehavioral features have been reported. Since our initial report (Sonies et. al, AJHG 61(4):A5), we have accrued 13 additional SMS children for study of oral motor and voice functions in the SMS population. We now report the findings of 27 SMS children (17F; 10M) ranging from 4 months-16 years. The presence of oral sensory motor deficits was seen in all of the children and included: oral tactile defensiveness, labial weakness, drooling, exaggerated lingual papillae, and open mouth posturing. Deficits in tongue range of motion and strength were seen in 26/27 of the children. Structural and physiologic anomalies of the larynx and hard/soft palates were seen in 21/25. Speech, at the time of evaluations, demonstrated various vehicles for expression including vocalizations, babbling and use of gestures and signs. Of the speaking children, velopharyngeal insufficiency and a perceived nasal speech quality was evident in 8/13 and voice impairments in 16/19. The impairments were characterized as hoarse, wet and harsh vocal qualities. Our findings are consistent with previously reported otolaryngologic reports in SMS children (Greenberg et. al, AJMG 62:247-254 and Sonies et. al, AJHG 61(4):A5) and do offer physiological explanations for the functional impairments seen in swallowing, speech and voice production. The clinical significance of the findings and its implications for speech and swallowing development and use of total communication as a treatment will be discussed.

Clinical delineation of chromosome 3q27>ter deletion: Rare aberration, variable phenotype. *H. Shapira¹, E. Shachar², A. Ramadan³, C. Halabi⁴, N. Kfir¹, H. Barel⁵, H. Dar⁵, T.C. Falik-Zaccai¹.* 1) Div. of Human Genetics, Hosp. for Western Galilee, Naharia, Israel; 2) Div. of Ped. Neurology, Rambam Med. Cent., Haifa; 3) Kupat Cholim Leumit, Nazereth; 4) Sherutei Briut Clalit, Haifa; 5) Cytogenetic Laboratory, Bnai Zion Med. Cent., Haifa, Israel.

A distal deletion of chromosome 3q is a rare aberration with only five previous reports in the literature. We report 2 new cases and summarize the clinical characteristics of this deletion. The first 2 years old girl presented with failure to thrive (FTT), microcephaly, down slanted eyes, absent tearing, hypertrophy of gingiva, short neck, hyperpigmentation of skin, excessive sweating, hypertonicity of four limbs and mild developmental delay. The second 4 years old boy presented with microcephaly, deep set eyes, epicanthal folds, strabismus, prominent nasal bridge and nose, high arched palate with velopharyngeal incompetence, small ears, short neck, mild ataxia, bilateral inguinal hernia and mild development and speech delay. Both children had an abnormal karyotype 46,XX and 46,XY respectively with del 3q27>ter. Three females and 2 males were previously described with this deletion. In the first case mild dysmorphic features and closed parietal meningocele were found along with inability to walk at the age of 20 months, and increased tone in the lower limbs. Dilatation of sweat glands and a mild skin rash were determined as well. Another 8 years old boy is described with short stature, FTT, small ears and high arched palate, hypotonia and mild developmental and speech delay. In 3 other cases bilateral anophthalmia/ micro-ophthalmia, congenital heart defects, abnormal genitalia, micrognathia, small ears, short nose, short neck and microcephaly were described. Deletion of 3q27>ter presents with variable phenotypes. Each additional report is of significance for its clinical delineation. Developmental delay, abnormalities of muscular tone, small ears, short neck, broad nose, FTT, and microcephaly appear to be the rule. Severe congenital anomalies in different organs are common. Differences in the molecular boundaries and parental origin of the deletion might be possible explanations for the variable phenotypes.

Unusual phenotype and cytogenetic features in a case of trisomy 18 due to isochromosome 18q: clinical, cytogenetic and molecular characterization. *T. Sahoo*¹, *R. Naeem*¹, *K. Pham*¹, *S. Chheng*¹, *S. Noblin*², *C. Bacino*¹, *M.J. Gambello*³. 1) Dept Human & Molec Gen, Baylor Col Medicine, Houston, TX; 2) Ob & Gyn and Genetics, LBJ General Hospital, Houston, TX; 3) Pediatrics and Medical Genetics, UTHSC Houston, Medical School, Houston, TX.

Trisomy 18 is a recognizable syndrome with distinctive clinical features. Unlike full trisomy 18, trisomy due to isochromosome 18 [i(18)(q10) or, i(18)(p10)] has been recognized to present with diverse phenotypic features. We report the characterization and genetic studies in a patient with an unusual presentation of trisomy 18 syndrome due to an isochromosome of 18q with partial monosomy for 18p. The proband was a male child born at 33 weeks gestation to a 24 year old mother with poor antenatal care and a complicated neonatal course. The infant presented with features of trisomy 18, including: intrauterine growth retardation, simple low-set ears, micropenis, cardiovascular defects and bilateral absence of radii and thumbs. Additional clinical features included: brachycephaly, median cleft lip and palate, hypotelorism, mid-facial hypoplasia and transient thrombocytopenia early in the neonatal period. Differential diagnoses at initial examination included chromosomal abnormalities, thrombocytopenia-absent radii syndrome (TAR), Roberts syndrome and Fanconi anemia. G-banded cytogenetic analysis revealed replacement of one chromosome 18 by an isochromosome for the long arm of chromosome 18 [46,XY,i(18)(q10)] in all cells. Additionally, 70% of the cells showed a derivative chromosome 10 that was shown by FISH analysis to arise from an unbalanced translocation between 18pter and 10qter. Interestingly, the derivative chromosome 10 retained its q-arm telomere in addition to the translocated 18qtel. The isochromosome 18q was monocentric as seen by C-banding and FISH for chromosome 18 centromere. Parental karyotypes were normal. The unusual phenotype in this infant was, therefore, due to trisomy for 18q and partial monosomy for 18p. Additional cytogenetic and molecular studies to elucidate the mechanism of formation of isochromosome 18q and retention of dual telomeres at 10qter in this case will be important.

A case of severe developmental delay with pharyngeal anomaly due to a *de novo* translocation [46, XY, t(6;12)(q16;p12)]. K. Yamada¹, T. Ono¹, T. Ohki², Y. Yamada¹, N. Ishihara^{1,3}, K. Miura², T. Kumagai², S. Sonta¹, N. Wakamatsu¹. 1) Dept Genet, Inst Developmental Res; 2) Pediatric Neurology, Central Hosp, Aichi Human Serv Ctr, Aichi; 3) Dept Pediatr, Nagoya Univ Sch Med, Nagoya, Japan.

We report a case of a four-year-old boy with a *de novo* translocation t(6;12)(q16-21;p12), severe developmental delay and a pharyngeal anomaly. He suffered profound mental retardation and severe delayed motor development with repeated bouts of aspiration pneumonia. Fluorescent *in situ* hybridization (FISH) experiments were performed to determine the break points of each chromosome using RP11-BAC clones. The results showed that in chromosome 6q16-21 to be located within a single BAC clone of 98I9 and that of chromosome 12p12 between 684O24 and 841C19. We performed Southern analysis using *MGC23817*, *COQ3* and *DKFZp564B0769* cDNAs of 6q16-21 and a *PEPP2* cDNA of 12p12 as probes. Although all these genes are included in the above BAC clones, none demonstrated any breakpoint. More detailed studies including analysis of the promoter regions of each gene are necessary to determine the molecular mechanisms underlying this disease.

Diminished plasma levels of zinc and alterations in lymphocyte subpopulations in Down syndrome patients. *M.L. SOTO QUINTANA¹, F.A. ALVAREZ NAVA¹, A. ROJAS ATENCIO¹, V. GRANADILLO¹, D. FERNANDEZ¹, A. OCANDO¹, E. LOPEZ¹, W. FULCADO².* 1) UNIDAD DE GENETICA MEDICA, UNIVERSIDAD DEL ZULIA, MARACAIBO, ZULIA, VENEZUELA; 2) HOSPITAL CLNICO DE MARACAIBO.

Alterations of plasma levels of zinc and immune system in Down syndrome (DS) had been reported. These alterations had been associated with high infectious illness rate, which represents the main cause of mortality in this disease. The objectives of this study are to determine plasma levels of zinc and to evaluate the immune system in DS patients. Peripheral blood samples from 43 DS patients were extracted. These patients were examined at Unidad de Genetica Mdica, Universidad del Zulia and their mean DS of age were 2,3 2,0 years. As control group 40 healthy children were studied (mean DS 2,3 2,0 years). Karyotypes by standard technique, determination of plasma levels zinc by absorption atomic spectrofotometry and evaluation of immune system by flow cytometry were carried out in study group. All DS patients were free trisomy 21. Significant diminished plasma levels zinc, helper T lymphocyte (CD4) percentage, helper/cytotoxic (CD4/CD8) ratio and B- cells (CD19) were found in DS patients by matching with control group. No significative difference between DS patients with diminished plasma levels zinc and DS patients with normal zinc were found. These findings suggest that zinc deficiency is not sole etiology involved in disorders of immune system seen in DS patients. Other factors, such as thymic alterations, molecular abnormalities due to gene overexpression of loci located on chromosome 21 could be involved. To supply according to needed dosage in DS patients with zinc deficiency is recommended to adjust the disturbance that this deficiency might provoke in these patients. Thus, morbidity-mortality indexes could be diminished in this disease.

Deletion for chromosome 21 with abnormal brain morphogenesis. *G. Yao¹, X-N. Chen¹, R.P. Morse², J.R. Korenberg¹.* 1) Med Gen, Cedars-Sinai Med Ctr, UCLA, Los Angeles, CA; 2) Dartmouth-Hitchcock Med Ctr, Lebanon, NH.

Monosomy 21 is usually lethal prenatally. Therefore to identify the genes responsible, we have previously defined the molecular structure and clinical features of a panel of 14 patients with independent partial deletions of chromosome 21. Here we report a new deletion 21 (HH) and its molecular analysis to further explore the correlations between brain phenotype and genotype. The subject, HH, is a 2 year old boy with global developmental delay and intractable, epileptic seizures. There is facial asymmetry with left ocular buphthalmia and right microphthalmia accompanied by bilateral lenticular fibrosis. He also has microcephaly, a broad nasal bridge, micrognathia, unilateral hearing loss, moderate pes planus and forefoot abduction, bilateral inguinal hernia, and micropenis. MRI of the brain revealed a paucity of cerebral white matter, most marked in the left parietal lobe, diffuse ventriculomegaly and widening of the sulci, hypoplastic cerebellar vermis and corpus callosum, symmetrically dysplastic hippocampus, and decreased subcortical white matter in the frontal and temporal lobes and insula, consistent with delayed myelination. The pathologic report for globe shows proliferating fibroblasts which extend through the pupil and surround the iris. Small atrial septal defect (ASD) was noted and abnormally thick sternum detected on X-ray, and the sternum and pelvic bones appears sclerotic for newborns. Cytogenetic analysis revealed 46, XY,del(21)(q22.1). Molecular analysis employed Fluorescence in situ Hybridization (FISH) using BACs and Cosmids spanning the region from D21S232 (21q11.1) to D21S403 (21q22.3 distal), representing twenty chromosome 21 markers. We determined that the deletion encompassed genes/markers from ETS2 through D21S403 (LA 161) and included the genes for ETS2, DSCAM(D21S348 D21S349), PFKL, ITGB2 and COL 6A1. Our current case provides evidence that the genes in the region of 21q22.3 are involved with the morphogenesis of the brain and may help to unravel the genetic origin of the cognitive defects of Down syndrome.

Contiguous gene deletion syndrome involving the TWIST locus and the HOXA cluster. *R. Kosaki¹, Y. Yoshida², H. Ohashi¹, T. Takahashi², K. Kosaki².* 1) Div Medical Genetics, Saitama Children's Medical Ctr, Saitama, Japan; 2) Dept Pediatrics, Keio Univ Sch Med, Tokyo, Japan.

Haploinsufficiency of the TWIST gene at 7p21 is associated with the Saethre-Chotzen syndrome characterized by craniosynostosis, maxillary hypoplasia, prominent ear crus, anal atresia, and short fifth fingers. Haploinsufficiency of the HOXA13 gene at 7p15 leads to the hand-foot-genital syndrome characterized by postaxial limb defect and anogenital defects. The phenotype of the deletion of the entire HOXA gene resembles that of mutations in HOXA13, most likely due to functional redundancy of the remaining HOX genes. We present a patient with 46,XY,del(7)(p15.3p21) who had combined features of Saethre-Chotzen syndrome and hand-foot-genital syndrome. The patient was a Japanese newborn male. Characteristic features were flat supra-orbital ridges, proptotic eyes, prominent ear crus, short fifth fingers, anal atresia with rectal dermal fistula. FISH analysis revealed deletion of TWIST and the entire HOXA cluster. We thus conclude that the combination of Saethre-Chotzen syndrome phenotype, postaxial limb defects, and the anal defect in this patient resulted from combined haploinsufficiency of TWIST and the HOXA cluster. Hence, the phenotype may define a new contiguous gene syndrome on 7p.

PMX2B, a new candidate gene for Hirschsprung disease. *H. Karmous, B. Laudier, JM. Lapierre, D. Sanlaville, S. Lyonnet, T. Attie, M. Vekemans, MC. de Blois, J. Amiel, S.P. Romana.* Departement de Genetique, Hopital Necker-Enfants Malades, Paris, France.

Hirschsprung disease (HSCR) is a congenital intestinal malformation of the enteric nervous system. It is a multigenic malformation and until now, 8 genes have been involved in the etiology of this disease: genes encoding proteins of the RET signaling pathway (RET, GDNF and NTN), genes participating in the endothelin (EDN) type B receptor pathway (EDNRB, EDN3 and ECE), the SOX10 gene and, the SIP1 gene that is mutated in syndromic forms of HSCR. However alterations of these genes are found in not more than 50-60% of affected individuals. We report here the results of a molecular cytogenetic study that identifies the PMX2B gene as a new candidate gene for HSCR disease. The patient is a 2-year-old girl who presents a short segment HSCR, facial dysmorphism and developmental delay. High resolution karyotype detected a t(4;8)(p13;p22) translocation with a 4p13 deletion confirmed by CGH. A molecular characterization of this rearrangement was undertaken using a series of specific 4p and 8p probes. The 8p22 breakpoint maps between BAC 279L11 and BAC 143D15, which are 3Mb apart. No compelling HSCR candidate gene for HSCR was localized in this region. The 4p13 deletion maps between BAC 1102H24 and 1147H2, a region of 5Mb in length. Interestingly, in this region lies the Paired Mesoderm Paired-type Homeobox Gene (PMX2B) (MIM 603851), a gene involved in the RET signaling pathway. We confirmed PMX2B gene deletion in our patient using FISH with BAC 227F19 encompassing the PMX2B locus. PMX2B is essential for the development of autonomic neural crest derivatives. It has been demonstrated that the defect in the enteric nervous system of *Pmx2b*^{-/-} mice at E10.5 is similar to the one observed in *Ret*^{-/-} mutants. Moreover, *Ret* expression is absent in the sympathetic and enteric ganglia of *Pmx2b*^{-/-} mice. Finally, we analyzed the expression pattern of PMX2B during human embryonic development that shows an intense PMX2B expression in the gut. So far, the PMX2B gene has not been implicated in HSCR. The present observation suggests however that PMX2B haploinsufficiency might predispose to HSCR.

Hemizyosity of d-Catenin (CTNND2) and Semaphorin F genes is not always associated with severe mental retardation in Cri-du-chat syndrome. A. Salin, C. Ozilou, O. Raoul, MC. de Blois, M. Prieur, A. Munnich, M. Vekemans, C. Turleau, S.P. Romana. Departement de Genetique, Hopital Necker-Enfants Malades, Paris , France.

It has been proposed that the critical region for mental retardation of the Cri-du-chat syndrome (CdCCR) was lying in 5p15.2 band. However, a controversy still exists about the precise location of the CdCCR in the 5p15.2 band. A first region have been proposed with the Semaphorin F as a candidate gene and a second region, more proximal, with the d-Catenin as a candidate gene. We report here the molecular cytogenetic characterisation of 3 patients (two with interstitial deletion) with del(5p) detected by high resolution banding and without severe mental retardation. Because of the atypical features of these patients, we decided to map their deletion using FISH with YACs encompassing 5p14-p15 bands. We found that patient 1 had a terminal deletion with a proximal bin between YAC 938G6 (deleted) and YAC 747B11 (present) attesting a terminal del(5)(p15.2) encompassing the two proposed CdCCR. The second and the third patients have both an interstitial deletion mapped between YAC938G (present) and YAC 933G1, split for patient 2 and present for patient 3. These data attested for these two patients an interstitial del(5)(p15.1p15.1) encompassing only the most proximal CdCCR proposed region. Because the Semaphorin F and the d-Catenin are candidate genes for the severe mental retardation of the Cri-du-chat syndrome, we searched for haploinsufficiency of these two genes using FISH with BAC/PAC clones 502L6, 162O17, 248B21 encompassing the d-Catenin gene and BAC 5H13 clone encompassing the Semaphorin F gene. We found that the Semaphorin F was deleted in patient 1 (terminal deletion) and present for the two other patients. The d-Catenin gene was deleted in patient 1, split in patient 2 and present in patient 3. Altogether, these data indicate haploinsufficiency of the Semaphorin F and d-Catenin are not always linked to the severe mental retardation of the Cri-du-chat syndrome.

"Phylloid" pattern skin mosaicism in a 15 month old girl with multiple congenital malformations and mosaicism for partial monosomy13 [46XX/46XX,-13,+r(13)]. *F.A. Collins¹, K. Maclean¹, Z.H. Wu², P. Malafiej², A.*

Darmanian², A. Daniel², G. Peters². 1) Dept Clinical Genetics, Children's Hosp at Westmead, Sydney, Australia; 2) Dept Cytogenetics, Children's Hospital at Westmead, Sydney Australia.

A 15 monthold girl was referred for evaluation of a rapidly progressive scoliosis. She presented with severe retardation and multiple congenital anomalies. Her skin showed streaky hypo- and hyperpigmentation following along the lines of Blaschko over all her limbs and thorax. In addition there were irregular, variable sized oval patches of hyperpigmentation over trunk and limbs.

Blood karyotype was 46XX, in all cells analysed, Skin biopsies were taken from two separate sites - one apparently hyperpigmented and one hypopigmented. Karyotype analysis showed predominantly abnormal karyotype: 46XX,-13,+r(13), in 95% of cells. FISH studies confirmed that the fragment was a small ring 13, retaining only the pericentric component of 13q.

Mosaic skin pigmentary disorders following the lines of Blaschko have been reported with X chromosome abnormalities as well as other autosomal chromosomal mosaicism. This patients's skin is suggestive of a "phylloid" pattern as described by Happle. The phylloid pattern has predominantly been reported in cases with trisomy 13 mosaicism. This patient is of interest because of the resulting partial monosomy 13.

X inactivation studies are presented from blood and skin and show non random X-inactivation in the fibroblast cell line suggesting the abnormal cell line originated in a somatic cell, subsequent to X inactivation.

The association of chromosome 13 trisomy and/or deletion with phylloid pigmentary mosaicism may be a chance event. However there are a few potential genes on chromosome 13 which may explain its involvement. The potential role of Endothelin type B receptor (EDNRB) located at 13q22 and Dopachrome tautomerase (DCT) are discussed.

Ring chromosome 9: clinical and cytogenetics characterization. *D. Concolino¹, M.T Moricca¹, M.A. Iembo¹, R. Apa¹, D. Caloiero², E. Saullo², P. Strisciuglio¹.* 1) Dept.of Pediatrics, University Magna Graecia Catanzaro, Catanzaro Italy; 2) Div.of Pediatrics Soveria Mannelli Hospital, Italy.

The syndrome associated to ring chromosome 9 is not commonly observed and phenotypic manifestations may be extremely mild, particularly in the neonatal period. We report a female infant with ring 9 mosaicism detected by routine cytogenetic analysis and characterized by FISH studies with specific sub-telomeric probes of chromosome 9 as del 9p (pter-p24). The proband was the second child of healthy and unrelated parents. The family history, the pregnancy and the delivery were unremarkable. Physical examination at the age of 1 month showed normal weight, length and head circumference, mild dysmorphic features, cleft soft palate. The echocardiography showed a mild ventricular septal defect. The neuropsychiatric examination at the age of 19 months showed moderate psychomotor retardation. Chromosome analysis was performed on QFQ banded metaphases from synchronized peripheral lymphocyte cultures using standard procedures. Proband's karyotype was interpreted as 46,XX(35%)/46,XX, r(9)(65%). The ring 9 was investigated by FISH with sub-telomeric probes for 9p and 9q. The 9q sub-telomeric region was intact but there was no 9p ter fluorescent signal on the ring chromosome 9 and in the chromosome 9 of normal lines. The FISH analysis with chromoprobe multiprobe-T system (Cytocell) in both parents resulted normal. These results suggest that in our patient is present a de novo del 9p syndrome with mild phenotype. Further molecular studies are necessary to determine the extent of the deletion in the 9 pter region in order to compare the phenotype of this patient with the size of telomeric deletions.

Partial trisomy 1q: A phenocopy of neonatal Marfan syndrome. *K.L. David¹, C.S. Cressman¹, P.A. Ankola², M.A. Perle³.* 1) Genetics/Dept. of Pediatrics, Metropolitan Hospital Center, NY, NY; 2) Neonatology/Dept. of Pediatrics, Metropolitan Hospital Center, NY, NY; 3) Dept. of Pathology, NYU School of Medicine, NY, NY.

Neonatal Marfan syndrome is a well-documented disorder presenting with arachnodactyly, flexion contractures, joint laxity, loose redundant skin, and severe cardiac valve insufficiency and dilation of the aorta. Mutations in the fibrillin 1 gene on chromosome 15 have been detected in this syndrome. We report a chromosomally abnormal infant whose peripheral blood G-banded karyotype revealed a de novo $46,X,del(X)(q22.3)/46,X,der(X)t(X;1)(q22.3;q21)$. This infant was initially suspected to have neonatal Marfan syndrome. The infant's features at birth included severe arachnodactyly of fingers and toes, loose skin, pectus carinatum, aplasia cutis congenita of the scalp, hyperextensible joints, and septal hypertrophy and ASD on echocardiography. While many features were suggestive of neonatal Marfan syndrome, aplasia cutis congenita has not been reported in that condition. On the neonatal exam, no features could be clearly ascribed to the $46,X,del(X)(q22.3)$ cell line. Review of the literature on partial trisomy 1q reveals a significant phenotypic overlap with neonatal Marfan syndrome. In addition, patches of skin aplasia have been noted in some cases of partial trisomy 1q. This cytogenetic entity should be considered in the differential diagnosis of neonatal Marfan syndrome. X chromosome inactivation studies are planned.

***De novo* interstitial deletion of chromosome 14q that helps further localize a putative gene for eye and CNS embryonic development.** *G.S. Kupchik¹, S.K. Barrett¹, M. Velinov^{1,2}, M. Macera³, A. Babu³, M. Genovese², S. Brooks², M. Strominger¹, E.C. Jenkins².* 1) Dept Pediatrics, Maimonides Medical Ctr, Brooklyn, NY; 2) Dept Cytogenetics, New York State Institute of Basic Research, Staten Island, NY; 3) Wyckoff Heights Medical Center, Brooklyn, NY.

A newborn male presented with IUGR and significant facial dysmorphic features. Chromosome analysis showed 46,XY, del(14)(q22.3q24.1), a *de novo* deletion of 14q. He had a VSD and duplex collecting system of the right kidney with absent left kidney. Brain MRI was significant for vermis hypoplasia, but the pituitary gland was present and normal. On physical exam, he had an unusual umbilicus, hypoplastic nails and the sandal sign. He twice failed ABR-based hearing evaluation. Ophthalmology exam showed a normally formed anterior segment. On dilated funduscopy, there were large central optic nerve pits. The neuroretinal rim was normal with mild peripapillary pigment hyperplasia. There was no evidence of iris, retinal or choroidal coloboma. The child is currently 18 months of age and has significant growth and developmental delay.

Two other cases with interstitial deletion involving band 14q22 were reported to date: deletion(14)(q22.1q22.3)(Elliot J et al., J. Med. Genet 20:251, 1993) and deletion(14)(q22q23)(Bennet CP et al, J. Med. Genet 28(4):280; 1991). In these two cases, the phenotype included anophthalmia and absent pituitary gland. Our patient does not have anophthalmia and the pituitary is present. Since the breakpoints in the present case are more distal than those reported in the previously published cases with anophthalmia and absent pituitary, it is likely this is due to deletion of chromosome material from the proximal 14q22 region. This region, therefore, could be a likely location for a gene(s) with an important role in eye and CNS development on chromosome 14.

Autosomal dominant inheritance of infantile myofibromatosis. *D.J. Zand¹, S. Saitta¹, K. Russell¹, D. Huff², E. Zackai¹.* 1) Division of Human and Molecular Genetics, Department of Pediatrics; 2) Department of Pathology, CHOP, Philadelphia, Pa.

We present two families with infantile myofibromatosis (IM) in multiple generations, and suggest that despite previous classification in OMIM (#228550) as autosomal recessive (AR), it is inherited in an autosomal dominant (AD) manner. In Family I, individuals were diagnosed by both clinical and pathological examination: a father (multiple progressive lesions since birth inclusive of meningeal, soft tissue, vocal cords, and kidney), his daughter (soft tissue and bone lesions present at birth), and his maternal nephew (multiple lesions since birth inclusive of bone soft tissue, polyposis of the GI tract). By history, the father's sister and their mother all had single nodules removed. In Family II, clinical examination and/or pathological review have been completed for 5 family members: a father and two male children, his maternal nephew and his nephew's male child, presenting with soft tissue and/or bone lesions at birth or within the first two years of age. By history, the father's sister and their father also had nodules removed. Review of the literature revealed an affected father and daughter (*Am J Surg Path* 8:529-538,1984), an affected grandfather, daughter and four grandchildren (*Schweiz Med Wschr* 101:1381-1385,1971), and two maternal half siblings (*Klinische Wochenschrift* 88:92-94,1976). Our families together with these support autosomal dominant inheritance. We suggest that pedigrees with only siblings affected may represent AD with non-penetrance or spontaneous regression of nodules in the "unaffected parent".

Features of Kabuki syndrome in a child with deletion 7p21ter. *P.D. Turnpenny¹, C. Hayes², R.P. Martin³, R.T. Howell⁴.* 1) Clinical Genetics, Royal Devon & Exeter Hosp, Exeter, UK; 2) Child Health, Royal Devon & Exeter Hospital, Exeter, UK; 3) Paediatric Cardiology, Royal Hospital for Sick Children, Bristol, UK; 4) Cytogenetics, Southmead Hospital, Bristol, UK.

More than 300 cases of Kabuki syndrome (MIM 147920) (KS) have been reported worldwide but the cause of the condition remains to be elucidated. The large majority of cases are sporadic with no increased incidence of parental consanguinity. There have been isolated cases reported in association with various chromosome aberrations on 1p, 4p, 6q, 12q, 13q, 15q, 17q and Xp. We describe a male patient with many features of KS, the first child of non-consanguineous Sudanese parents, with a de novo cytogenetically visible terminal deletion of chromosome 7p21, confirmed by sub-telomeric FISH probing. He was symmetrically growth retarded at full term after a normal pregnancy, birth weight 1.8 kg. He was diagnosed with Tetralogy of Fallot at 6 weeks and exhibited severe failure to thrive with feeding difficulties, gastro-oesophageal reflux and mid-gut malrotation. His dysmorphic features comprise unusual facies with interrupted eyebrows, marked epicanthic folds extending well below the lower eyelid, upslanting, long palpebral fissures, large ears, down-turned mouth, high palate, mild fetal finger pads, coronal hypospadias, and a sacral dimple. Cranial MRI scan showed some hypoplasia of the deep white matter and renal ultrasound was normal. Postnatal growth failure was persistent and severe and, although manifesting developmental delay, some neurodevelopmental progress has taken place. He has some features in common with other reported cases of 7p deletion but his striking peri-orbital 'Kabuki' features are not generally seen in these reports. KS may be a phenotype with significant genetic heterogeneity.

No association between dermatoglyphics and atopic asthma in children. *E. Corona-Rivera¹, J.R. Corona-Rivera^{1,2}, A. Santana-González², J.J. Pérez-Molina², A. Corona-Rivera¹, E. Nuñez-Nuñez².* 1) Laboratorio de Genética Humana, Centro Universitario de Ciencias de la Salud, Universidad de Guadalajara, Guadalajara, México; 2) División de Pediatría, O.P.D. Hospital Civil de Guadalajara Dr. Juan I. Menchaca.

Four previous reports inform the presence of dermatoglyphic anomalies in children with atopic asthma (AA), however, we were not able to identify common consistent patterns in such reports. We evaluated dermatoglyphic prints from 100 children with AA (45 girls/55 boys; mean age 9.9 SD 3.3ys), and their controls (39 girls/61 boys; mean age 10.1 SD 3.3ys). AA diagnosis was made according to the NHLBI criteria. Atopy was determined by prick skin test in 95 cases and by EAST test in five cases. Allergic rhinosinusitis and atopic dermatitis were present in 44% and 12% of the AA cases, respectively. Control group was integrated by 100 children without atopic problems. Previous parents consent, absence of atopy was confirmed by negative prick skin test. Ten quantitative dermatoglyphic variants were considered in both hands of each group (number of archs, whorls, ulnar loops, radial loops, a-b ridge count, total finger ridge count (TFRC), d-t ridge count, atd angle, tda angle and main-line index), as well as 30 additional qualitative patterns in which odds ratios and 95% CI were considered. Children with AA showed decreased average a-b ridge counts at each hand (right hand: 41.5 SD 5.4 vs. 43.3 SD 4.8, $P=0.01$; left hand: 42.2 SD 6.7 vs. 44.1 SD 5.5, $P=0.05$), and both hands (83.8 SD 11.1 vs. 87.4 SD 9.5, $P=0.02$). No other statistical differences were observed in the remaining quantitative and qualitative dermatoglyphic patterns. Distally displaced axial triradius, larger TFRC, increased whorls, decreased archs and low d-t ridge count, previously informed in children with AA, were not confirmed in this group. The lower a-b ridge count found was within normal reference studies range, and had limited clinical significance in reported entities with low a-b ridge count. We conclude that considered dermatoglyphic traits were not genetic indicators to the occurrence of AA in children.

A Puerto Rican boy with dislocated hips and radial heads and carpal coalition: a new case of a syndrome described only in Puerto Rican children. *E.S. Moran¹, S. Vepa², J.G. Pappas³.* 1) Orthopedic Inst, Hosp Joint Diseases, New York, NY; 2) Dept Pediatrics, New York Univ, Sch of Med, New York, NY; 3) Human Genetics Program, Dept Pediatrics, New York Univ, Sch of Med, New York, NY.

We describe a 12 year old boy who presented with multiple joint dislocations, limited range of motion of hips, knees and elbows and mild developmental delay. Clinical examination revealed height at the 10th percentile, upper to lower segment ratio equal to one, elongated face with malar hypoplasia, myopia, high arched palate, prognathism, bilateral dislocated elbows and patellae with limited range of motion of wrists, hips and knees. X-rays revealed dislocation of the radial heads, fusion between the lunate and triquetrum, markedly shallow acetabulum bilaterally, right greater than left, subluxed left femoral head and superior-lateral dislocation of the right femoral head. Shortened femoral necks and bilateral sclerotic lateral femoral condyles with small ossific fragments were present. Multiple vertebral anomalies of the cervical spine with concomitant atlantoaxial instability were present. He was status post surgical stabilization of C1-C2. By report, the proband's mother had congenital bilateral external rotation of feet and early onset myopia. Our case had a full sibling and a maternal half sibling; both female and unaffected. The features of our case are characteristic of a syndrome described in one publication of 23 Puerto Rican children (HH Steel et al, J Bone Joint Surg A 1993;75:259-264). Common features of our case and the published cases include dislocation of the hips, dislocated radial heads, short stature, fusion of the lunate and triquetrum and atlanto-axial subluxation. Our case had childhood onset myopia, elongated face, malar hypoplasia, high arched palate and mild developmental delay. The features of our case may expand the phenotype of the syndrome. In addition, there may be incomplete expression of the same syndrome in his mother which suggests autosomal dominant inheritance.

Clinical differences in subjects with Prader-Willi syndrome having type I or type II deletions. *N. Kibiryeve¹, D. Bittel¹, Z. Talebizadeh¹, T. Thompson², M.G. Butler¹.* 1) Childrens Mercy Hospitals and Clinics and University of Missouri-Kansas City School of Medicine, Kansas City, MO; 2) University of Kansas Medical Center, Kansas City, KS.

Prader-Willi syndrome (PWS) is due to the absence of paternal genes from the 15q11-q13 chromosome region. The major features of PWS include infantile hypotonia with feeding problems, mental deficiency and behavior problems, small hands and feet, hypogonadism and hyperphagia leading to marked obesity. The majority of subjects have an interstitial deletion of the 15q11-q13 region. Two proximal breakpoints (BP1 and BP2) have been reported centromeric to locus ZNF127. The second proximal breakpoint (BP2) lies between loci D15S541/S542 and D15S543 while breakpoint BP1 is proximal to D15S541/S542. Type I deletion is larger and involves BP1 while the type II deletion involves BP2 located about 500 kb distal to BP1. We analyzed clinical, anthropometric and behavioral data in 13 PWS subjects (6 males, 7 females; mean age 25.0 + 8.6y) with type I deletion and 12 PWS subjects (4 males, 8 females; mean age 18.8 + 5.9y) with type II deletion. We found significant differences between these two groups in multiple psychological tests. For example, PWS deletion type I subjects showed significantly worse self injurious behavior [e.g., externalized maladaptive index score (-14.1 + 14.6 for type I vs. -2.2 + 7.2 for type II: t-test; p=0.018)] compared with type II deletion subjects. Adaptive behavioral scores [e.g., motor skills (27.2 + 6.6 for type I vs. 42.4 + 13.6 for type II: t-test; p=0.002)] were significantly worse in PWS subjects with deletion type I. In addition, obsessive compulsive behavior [e.g., YBOCS control compulsion (3.2 + 1.5 for type I vs. 1.9 + 1.3 for type II: t-test; p=0.045)] was more evident in PWS subjects with deletion type I. PWS deletion type I subjects also had more difficulties with reading and mathematics and visual-motor integration. The results of this study indicate that the loss of genetic material between breakpoints BP1 and BP2 in the 15q11-q13 region significantly increases the severity of behavioral and psychological problems associated with Prader-Willi syndrome.

Kabuki syndrome with profound motor and intellectual disabilities. *H. Kawame*¹, *N. Fueki*², *Y. Fukushima*³. 1) Div. Medical Genetics; 2) Div. Neurology, Nagano Children's Hospital, Nagano, Japan; 3) Div. Clinical and Molecular Genetics, Shinshu Univ. Sch. Med., Nagano, Japan.

Kabuki syndrome (Niikawa-Kuroki syndrome) is a disorder of unknown cause with characteristic facies, postnatal growth retardation, mental retardation, and other anomalies. The phenotypic spectrum is very broad and a wide range of associated anomalies has been described. The range of motor and cognitive abilities is also broad, but most of patients in the literature were reported to have moderate or mild retardation. We present a 4-year-old female with profound motor and intellectual delay. She was born at 40 weeks gestation. Her birth weight was 2865 g, length, 50 cm. At birth, she was found to have coarctation of the aorta, VSD, and PFO. She also had imperforate anus with anovestibular fistula, and sacral dimple. Heart surgery was performed on 10 day life. After the surgery, she developed chronic lung disease due to recurrent airway infections and had tracheostomy at age 6 months. She had GERD, bilateral severe sensorineural hearing loss, and frequent otitis. Her MRI at age 24 months revealed delayed myelination and thinning of corpus callosum. On examination at age 4 years, her length was 85 cm (-4.0SD), weight; 10.8 Kg (-2.6SD), and OFC; 44.8 cm (-2.9SD). She continued to receive gavage feeding and tracheostomy. She rolled over, but lacked complete head control. She watched face and vocalized but had no meaningful words. She recognized her parent. She had characteristic facies and persistent finger pads. Along with common and more characteristic anomalies for Kabuki syndrome, such as coarctation of the aorta, and anovestibular fistula, she was diagnosed to having Kabuki syndrome. Her chromosome was normal, 46,XX. In the literature, only a few severely retarded and nonambulatory patients with Kabuki syndrome have been reported. We confirm that Kabuki syndrome should be considered as a differential diagnosis for patients with multiple congenital anomalies and severe motor and intellectual disabilities.

Cervical spine instability in patients with the 22q11.2 deletion. *E.H. Zackai, K. Russell, L. States, J. Tamai, M. Tonnesen, E. Simon, J. Catanzaro, P. Schiffman, D. Drummond, D.M. McDonald-McGinn.* The Children's Hospital of Philadelphia, University of Pennsylvania School of Medicine, Philadelphia, PA.

A patient with a 22q11.2 deletion was found incidentally to have congenital cervical spine abnormalities (fusion posterior elements of C2-C3) during an evaluation to determine the presence of a laryngeal web. Following this, we retrospectively reviewed dental lateral cephalometric radiographs in 11 patients with 22q11.2 deletion and 6 (55%) had congenital cervical spine abnormalities: congenital fusion of C2-C3, an abnormally shaped dens, anomalous C1. Prompted by these findings, we prospectively obtained flexion-extension cervical spine radiographs in 39 consecutive patients with the 22q11.2 deletion 3 years of age and older, including the index patient. We noted abnormalities including an abnormally shaped dens in 77%, upswept C2 in 76%, hypoplastic/anomalous C1 in 59%, posterior element fusion with block vertebrae in 23% and without block vertebrae in 21%, and occipitalization of the atlas in 8%. Ten of the thirty-nine patients (26%) had associated cervical spine instability. Since cervical instability, together with narrowing of the spinal canal, can be associated with increased susceptibility to spinal cord injury following minor trauma, as well as myelopathy, MRI was recommended. Of the three patients who have had MRIs thus far, two had anterior and posterior narrowing of the spinal canal. CT imaging of both showed C1 abnormalities with lack of fusion of the anterior arch, lack of fusion of the posterior arch, changing the configuration of the ring, resulting in a narrow canal. Surgical intervention was recommended for these two patients.

Cervical spine x-rays including flexion-extension images are recommended in all patients with the 22q11.2 deletion, 3 years of age and older, in order to promptly identify and manage those with an increased risk for complications. Cervical spine abnormalities in these patients may be due to developmental genes in the deleted region whose role is important in signaling for segmentation and resegmentation of the cervical vertebrae.

Comparison of fatness patterning between obese and Prader-Willi syndrome subjects: Deletion versus UPD. Z. Talebizadeh, D. Bittel, N. Kibiryeve, M.G. Butler. Children's Mercy Hospitals and Clinics and University of Missouri-Kansas City School of Medicine, Kansas City, MO.

Prader-Willi syndrome (PWS), the most common cause of severe obesity in humans, is usually due to a deletion of chromosome 15q11-q13 or maternal disomy 15 (UPD). Obesity is due to energy imbalance but few studies have examined the regulation of fat metabolism or patterning in PWS subjects with deletion or UPD. We examined for differences in fatness patterning and correlation with lipid and endocrine data in three groups of subjects (obese controls, PWS-UPD and PWS-deletion). Fasting blood samples and cross-sectional MRI scans at the level of the umbilicus were obtained in 56 subjects: 21 PWS-deletion (9 males, 12 females; average age of 22y), 17 PWS-UPD (9 males, 8 females; average age of 21y) and 18 obese controls (8 males, 10 females; average age of 28y). Areas of subcutaneous fat (SFA), intra-abdominal visceral fat (VFA) and their ratio (SFA: VFA) were calculated. No significant differences were observed for SFA, VFA and their ratio among the three groups. Fasting plasma lipid, glucose and insulin levels were not significantly different in the three groups; however, triglyceride levels were lower in the PWS-deletion group compared with controls ($p=0.04$). Both SFA and VFA were positively correlated with insulin in the PWS-UPD ($r=0.99$; $p=0.10$ and $r=0.98$; $p=0.12$, respectively) and the PWS-deletion ($r=0.38$; $p=0.22$ and $r=0.37$; $p=0.24$, respectively) groups. In contrast, in the control group a negative trend and a flat association were seen, respectively, between SFA and insulin ($r=-0.23$; $p=0.40$) or VFA and insulin ($r=0.02$; $p=0.95$). VFA was significantly positively correlated with total cholesterol in the PWS-deletion group ($r=0.55$; $p=0.01$). This significant association was not observed in the UPD ($r=0.11$; $p=0.71$) or obese control ($r=0.17$; $p=0.52$) groups. In addition, growth hormone (GH) levels were significantly negatively correlated with VFA in PWS ($r=-0.56$; $p<0.01$) and in the obese control ($r=-0.72$; $p<0.05$) groups. GH deficiency is common in PWS and may contribute to abnormal fat patterning and reduced fat oxidation.

Development of original computer software "GenDis English version" useful in the diagnosis of congenital anomalies. *K. Naritomi¹, T. Kaname¹, Y. Chinen², T. Tohma²*. 1) Dept Medical Genetics, Univ Ryukyus Sch Medicine, Okinawa, Japan; 2) Dept Pediatr, Univ Ryukyus Sch Medicine, Okinawa, Japan.

At 51st Annual Meeting of ASHG, last year, we introduced our original computer software "GenDis" for diagnosis of congenital anomalies. Following an input of all clinical findings of the patient, the GenDis automatically selects candidate syndromes in order of increasing matched number of findings. Applying GenDis in out- and inpatient with congenital anomalies produced a good result, i.e. an appropriate diagnosis was suggested in 64% of each 393 patients tested. Since the GenDis is programmed using Japanese OS-driven Macintosh computer, this software could not use in English OS-driven Macintosh as well as Windows OS computers. Thus, we reprogrammed it for English version, both for Macintosh and Windows computers. The reference data included were quoted from our original database, UR-DBMS version 9, which has a data through April 1, 2002. These data have been updating everyday mainly through O-MIM in the web. The GenDis includes clinical findings, comments and reference data more than 7,000 diseases. It adopted two reference systems, one is referring from all findings without requisite findings and the other with requisite findings (maximum 5). The answer will be returned within about 10 seconds. Application of the GenDis will be a useful diagnostic tool in clinical genetics for quick diagnosis and further examinations to confirm the diagnosis.

Osteopathia Striata with Cranial Sclerosis: A brief clinical report on a Bedouin girl. *R.L. Alnaggar¹, S. Al-Awadi¹, M. Abu-Henedi¹, S. Gouda¹, H. Fathi², L. Bastaki¹.* 1) Obstetric, Kuwait Medical Genetic Center, Kuwait, Kuwait; 2) Pediatric Department Aljahra Hospital.

Objective: This report describes a case of Osteopathia striata with cranial sclerosis (OS-CS) in a Bedouin girl. Our case could be the first to be reported from Kuwait Genetic Center. **Methods:** Clinical examination, skeletal survey, echocardiography, ultrasonography and chromosomal analysis were carried out. **Results:** The patient had overgrowth of the craniofacial bones, developmental delay, hearing impairment, VSD and repeated attacks of seizures. **Radiographic findings** included marked ossification and sclerosis of the base of the skull and metaphyseal widening of the long bones with linear striations. **Conclusion:** Our case represents the typical form of the syndrome with dominant inheritance and could be added to the countable cases all over the world.

POLYSYNDACTYLY, COMPLEXE CARDIOPATHY AND HEPATIC DUCTAL PLATE ANOMALIES : AN AUTOSOMAL RECESSIVE SYNDROME. *B. GASSER, C. STOLL.* Medical Genetics, Hpital de Hautepierre, STRASBOURG, France.

A distinct syndrome was ascertained in a 3 year-old girl and her brother. The proband was the first child of first cousin parents. She was born after an uneventful pregnancy. At birth multiple congenital anomalies were noted : ptosis of the left eyelid, hypertelorism, anteverted nares, large fontanel, long philtrum, ungueal hypoplasia, polysyndactyly, simian crease, complex cardiopathy and hepatic cysts. During another pregnancy of the mother, fetal ultrasonographic examination showed an hypertrophy of the right ventricle and atria, a dextroposition of the aorta, a bilateral pyelic dilatation and a club foot. After termination of the pregnancy, necropsy showed a facial dysmorphia, a small penis, a polysyndactyly, a ventricular septum defect and a malformation of the ductal plate. Bonneau et al. (1983) described a family in which 3 sibs had a complex cardiac malformation, hexadactyly of the first toe, and syndactyly of the third and fourth fingers. Rejab (1997) described two sibs with similar features in an Omani family. The sibs described in this report had anomalies of the ductal plate which were not reported in the two other families. These new findings are in favour of autosomal inheritance of this condition which is amenable to antenatal diagnosis.

An unusual type of XY sex reversal associated with the presence of female gonads. *J.C. Ferreira¹, M. Nicolau², B. Marques², P. Borralho¹, P. Rendeiro³, C. Nunes¹, F. Torres³, R. Lemos³, J. Gonçalves².* 1) Obstetrics and Gynecology, Garcia de Orta Hospital, Almada, Portugal; 2) Centro de Genética Humana, INS Dr. Ricardo Jorge, Lisboa, Portugal; 3) Centro de Genética Clínica, Porto, Portugal.

Molecular studies performed in patients with gonadal dysgenesis or with sex reversal have been providing some hints on the complex molecular mechanisms of human sex determination pathway. A few genes have been identified (ex. SRY, SOX9, SF1, WT1, WNT4, DMRT1,2) and mutations in these genes in XY individuals usually cause complete gonadal dysgenesis or partial gonadal dysgenesis associated with completely female phenotype or with ambiguous phenotype, respectively.

We report a fetus with a unique combination of anomalies, which also had an unusual XY sex reversal.

Case report

A 22 week fetus was found with severe oligohydramnios, polycystic kidneys and hypoplastic left heart. A karyotype from cultured fibroblast cells showed a 46,XY karyotype. Postnatal evaluation confirmed the prenatal findings. Facial dysmorphism and normal female internal and external genitalia was found. Gonad histology, revealed two ovaries with primary oocytes. No signs of dysgenesis and testis tissue were found. The skeletal X-ray survey was normal. Tissue interphase FISH demonstrated the presence of Y chromosome material in all ovarian cells analyzed. Molecular studies of DNA extracted from fetal ovaries and liver evidenced the presence of the SRY gene. DNA sequencing of the SRY HMG domain was normal.

This unusual XY sex reversal may be caused by a mutation in a unknown gene involved in the morphogenesis of several organs and in male gonad development. Other explanation could be a continuous gene deletion syndrome that would include a new sex determination gene. It seems that lack of function of an unknown gene, involved in primary sex determination, apparently suppressed the SRY testis determining action and allowed the development of female gonads.

Abnormal trajectory of the internal carotid within the middle ear in a patient with Smith-Magenis syndrome. V.

Drouin-Garraud¹, V. Brossard², M.F. Obstoy³, J-P. Marie³, M. Monroc⁴, T. Frebourg¹. 1) Department of Genetics, CHU de Rouen; 2) Department of Neonatology, CHU de Rouen; 3) Department of Otorhinolaryngology, CHU de Rouen; 4) Department of Pediatric Radiology, CHU de Rouen, 76031 Rouen, France.

The Smith-Magenis syndrome results from an interstitial deletion within the 17p11.2 chromosomal region. Clinical features include mental retardation, particular facial features (flat mid-face, prominent jaw), behavior problems with hyperactivity and self injuries, severe sleep disturbance, and heart defect. Hearing impairment, resulting from conductive and/or sensory neural hearing loss, is frequently observed. We report the case of a patient who was born at 36 weeks after an uneventful pregnancy. Neonatal course was marked by respiratory distress secondary to laryngomalacia, and auricular septal defect. Dysmorphic facial features were obvious with mid-face hypoplasia and macroglossia. High resolution chromosomal examination showed a 17p11 deletion. At 18 months of age, she had developmental delay. Audiometric testing was performed showing mixed hearing loss. Otoscopy showed bilateral retro-tympanic mass and CT scan revealed an aberrant course of the internal carotid within the middle ear. Only about fifty cases of this vascular mal-positioning have been reported so far. It is the first reported case associated with the Smith-Magenis syndrome. This report suggests that careful otorhinolaryngological examination should be recommended in Smith-Magenis patients to prevent the risk of major haemorrhage and potential neurological complications.

LETHAL SYNDROME WITH ABLEPHARON: A VARIANT OF THE ABLEPHARON MACROSTOMIA SYNDROME OR AN INTERMEDIATE FORM BETWEEN THIS ONE AND THE FRASER SYNDROME?

D.P. Cavalcanti¹, D.V. Luquetti¹, R.J.M. Natalino², M.F. Mello². 1) Dept Med Genet FCM, UNICAMP, Campinas, SP, Brazil, MD; 2) Dept Anat Patol FCM, UNICAMP, Campinas, SP, Brazil, MD.

The eyelids are structures developed from two small folds of ectoderm with mesenchymal core in the sixth week of embryonic development. The absence of eyelids, also designated as ablepharon, is a rare abnormality described in few syndromes. In this report a male stillbirth presenting multiple anomalies including absence of eyelids is described. This male stillbirth with 22 weeks of gestation was the product of the first gestation of young and nonconsanguineous parents. There was no significant family history. Pregnancy was complicated by severe gestational hypertension. Ultrasound examination had shown oligohydramnios and fetal hydrops. Postmortem examination showed alopecia, redundant and ichthyosiform skin, specially in abdominal region and distal limbs, absent eyelids, telecanthus, hypoplastic alae nasi, flat malar region and philtrum, macrostomia, very low insertion of the umbilical cord, hypoplastic scrotum, abducted hips, skin syndactyly of fingers and toes (2nd, 3rd, 4th /5th) and contracture of the left elbow. Osteopenia and increased metaphyseal density in femur was observed in skeletal X-ray. The necropsy showed laryngeal and epiglottal agenesis, tracheomalacia, esophageal stenosis, lung hyperplasia, malrotation of small intestine, bilateral renal agenesis and hypoplastic bladder. Microscopic examination showed disorganization of the ossification centers of the long bones and thickening of the stratum corneum of the epidermis. The placenta was senescent and had a microcorangyoma. The karyotype, performed from peripheral blood lymphocytes, was normal (46,XY). The phenotype of this case is not compatible with the syndromes associated with ablepharon. However, the dysmorphologic analysis suggests that it is a lethal variant of the Ablepharon Macrostomia syndrome or an intermediate form between this one and the Fraser syndrome. (Grants : FAPESP, # 98/16006-6).

Phenotypic overlap with central polydactyly in Bardet-Biedl and McKusick-Kaufman syndromes. *M. Gerard*¹, *C. Barrey*², *C. Deffert*³, *F. Niel*³, *E. Girodon*³, *C. Romana*⁴, *S. Amselem*³, *M. Le Merrer*⁵. 1) Medical genetics, Neonatology, CHIC, Creteil, France; 2) Pediatrics, Hopital Sainte Camille, Bry sur Marne, France; 3) Molecular genetics, Hopital Henri Mondor, Creteil, France; 4) Pediatric surgery, Hopital Trousseau, Paris, France; 5) Medical genetics department, Hopital Necker-Enfants Malades, Paris, France.

The fifth child of a consanguineous marriage has mild mental retardation, situs inversus, feet postaxial polydactyly, and central polydactyly by Y duplication of the third metacarpal. The eldest brother had the same malformative pattern, acquired blindness, and died at 22 years of renal failure. The other siblings are healthy. Clinical examination shows hypogenitalism with micropenis and atrophic testes, obesity (plus 4 SD), normal stature and OFC (M). Mild facial dysmorphism is noted, with downturned corners of mouth, short nose with anteverted nostrils and midface hypoplasia. Dyschromatopsia is present, and ERG is extinguished. The diagnosis of Bardet-Biedl syndrome (BBS) was first raised, given the association of mental retardation, polydactyly, hypogenitalism, obesity, with secondary apparition of renal failure and blindness. However, situs inversus has been documented in only 3 cases of BBS (Lorda-Sanchez et al., 2000). Central polydactyly is not a feature of BBS, but is frequent in the McKusick-Kaufman syndrome (MKKS), which associates hydrometrocolpos in females, cardiopathy and polydactyly. Intermediate forms between BBS and MKKS had been described (David et al., 1999; Slavotinek and Biesecker, 2000). At least, seven locus (*BBS1-7*) are involved in BBS, while one (*BBS6/MKKS*, 20p12) is involved in MKKS (Slavotinek et al., 2000). Triallelic inheritance for BBS has been recently proved, patients being homozygotes or compound heterozygotes at one BBS locus, and heterozygotes at another BBS locus (Katsanis et al., 2001). In the present case, microsatellite analysis at the *BBS6/MKKS* locus showed heterozygosity. Investigations of the other known loci are in process. This familial observation, with situs inversus and central polydactyly, will further document the molecular bases of the Bardet-Biedl/McKusick-Kaufman syndrome.

Gonadal Mosaicism in Pallister-Hall Syndrome. *D. Ng, J.J. Johnston, J.T. Turner, L.G. Biesecker.* GDRB/NHGRI, National Institutes of Health, Bethesda, MD.

Pallister-Hall syndrome [PHS, MIM #146510] is characterized by central polydactyly, postaxial polydactyly, hypothalamic hamartoma [HH], asymptomatic bifid epiglottis, imperforate anus, renal abnormalities, and pulmonary segmentation anomalies. It is inherited in an autosomal dominant pattern. Here we describe a family with two affected children manifesting HH, bifid epiglottis, brachydactyly, and imperforate anus. Atypical features include severe mental retardation, behavioral problems, and difficult to control generalized seizures. Both parents are healthy, with normal intelligence, and have no identifiable malformations on physical, laryngoscopic, and cranial MRI exam. The atypical presentation of these children coupled with the absence of parental manifestations suggest an autosomal recessive mode of inheritance or gonadal mosaicism. Sequencing of the *GLI3* gene revealed a 2 nucleotide deletion in exon 15 [c.3385_3386delTT] resulting in a frameshift and premature stop codon at aa 1129 [p.F1129X] in the children while both parents have wild type alleles. Genotyping with *GLI3* intragenic STRPs revealed that both children inherited the abnormal allele from their mother thus supporting gonadal mosaicism as the underlying mechanism of inheritance and paternity was confirmed. This is the first reported case of gonadal mosaicism in Pallister-Hall syndrome. The severe CNS manifestations of these children are reminiscent of individuals with non-syndromic or isolated HH who oftentimes develop progressive mental retardation with behavioral problems and have seizures that are refractory to medical management. We conclude that the phenotype of PHS can include severe CNS manifestations of intractable seizures and that recurrence risks for PHS must include a proviso for gonadal mosaicism, though the risk cannot be calculated from a single case report.

A Japanese boy with Noonan syndrome with abnormally high urinary VMA and HVA levels. *T. Kondoh¹, E. Ishii², Y. Aoki³, T. Shimizu¹, T. Matsumoto⁴, Y. Matsubara³, H. Moriuchi¹.* 1) Dept Pediatrics, Nagasaki Univ Sch Medicine, Nagasaki, Japan; 2) Dept Pediatrics, Saga Med Sch, Saga, Japan; 3) Dept Med Genet, Tohoku Univ Sch Medicine, Sendai, Japan; 4) Dept Nursing, Nagasaki Univ Sch Medicine, Nagasaki, Japan.

Noonan syndrome (NS) is a malformation disorder characterized by dysmorphic facial features, webbed neck, cubitus valgus, short stature and heart disease. Recently PTPN11 was identified as the causative gene, encoding the nonreceptor protein tyrosine phosphatase SHP-2. NS has also been associated with malignant diseases including a number of cases of lymphoblastic leukemia, and a few cases of neuroblastoma. We here report a Japanese boy with NS with high urinary catecholamine levels. He has a novel de novo missense mutation (Ser502Thr) in PTPN11 gene, never found in 77 normal controls. His urinary VMA and HVA at the age of six months in nation-wide mass screening test were 27.7 and 29.1 ug/mgCre, respectively. MRI showed an 8-mm-diameter mass in his left adrenal gland, which was compatible with neuroblastoma. His tumor spontaneously disappeared radiographically during the next 6 months. Despite regression of the mass, his VMA and HVA levels have been increasing gradually. Our case might indicate that SHP-2 is involved in catecholamine metabolism or proliferation of catecholamine-producing cells, and that certain mutations of PTPN11 gene may result in neuroblastoma formation or overproduction of catecholamines.

Unusual cardiac presentation of an infant with tuberous sclerosis. *J. Lindsey, E. Pivnick, L. Winkeler, J. Ring, D. Nelson.* Department of Pediatrics, University of Tennessee, Memphis, TN.

Tuberous sclerosis complex (TSC) is a systemic disorder characterized by widespread hamartomas. Cardiac rhabdomyomas (CR) are known to be associated with TSC. These tumors tend to regress in the first year of life. The in-utero growth pattern and self-limiting proliferation of CR is not well understood. We report an infant with TSC who presented with an unusual form of tachycardia, chaotic atrial rhythm (CAR), and widespread intra-myocardial lesions. The male infant was born at 37 weeks gestation to a 26 year old mother. The mother's HIV status was discovered at 33 weeks. She received zidovudine (ZVD) for the remainder of the pregnancy. The neonatal course was complicated by pulmonary hypertension requiring mechanical ventilation. The infant was discharged home at 16 days to complete 6 weeks of ZDV for HIV prophylaxis. At age 7 weeks the infant presented with bronchiolitis. He had tachycardia at 210/min and a few hypo-pigmented skin maculae. Soon after admission he developed CAR. Holter monitoring showed >100 episodes of described rhythm. Infant was begun on propranolol therapy. Echocardiogram revealed multiple echodense lesions consistent with very small intra-myocardial CR of the left ventricle. Because of the suspicion of TSC, an MRI of the head was obtained and revealed many subcortical tubers. Fundoscopy illustrated an astrocytoma of the right retina. At 6 months of age the CAR has resolved and the myocardial lesions have disappeared. It has been demonstrated that ZDV preferentially incorporates in telomeric sequences of immortalized cell cultures derived from certain tumors and makes those cells more susceptible to apoptosis. It has been proposed that CR is due to delay or failure of apoptosis that occurs as part of the normal remodeling process in the heart. It has been shown, however, that the regression of CR is due to an increased rate of cell death. It is intriguing to speculate that the antiretroviral therapy this infant received may have accelerated this process. Conversely, the intra-myocardial changes may be just one end of the spectrum of CR in TSC. This is the first report of CAR associated with TSC.

A new case of intractable infant diarrhoea associated with phenotypic abnormalities and immunologic disorders.

F. Mochel¹, C. Talbotec¹, S. Lyonnet², O. Goulet¹. 1) Pediatric Gastroenterology, Necker-Enfants malades ,Paris; 2) Department of genetics, Necker,Paris.

The syndrome of Intractable Diarrhoea of Infancy (IDI) is an entity that includes Microvillous inclusion disease, Epithelial dysplasia, Syndromatic diarrhoea and Autoimmune enteropathy. We report the case of a one-year-old girl highly suspected of syndromatic diarrhoea (J Pediatr 125:36-42,1994) in front of the association of intrauterine growth retardation, IDI, facial dysmorphism, hair abnormalities and immunological disorders. The girl, from Kurd origins and issued from a consanguineous marriage, was born on 35 weeks of gestation, with a birth weight of 1050 g (<<-5c). Her first weeks of life were characterized by the onset of a severe, watery, bloodless diarrhoea, persisting despite bowel rest and requiring total parenteral nutrition. Clinically, she presented the classical phenotype with prominent forehead and cheeks, hypertelorism and a broad nose associated with woolly, poorly pigmented and undressable hair. However, microscopic analysis of the hair observed an aspect of pili torti and not the trichorrhexis nodosum usually found. Repeated intestinal biopsies showed a partial villous atrophy but without the typical features seen in the other IDI. Immunologic analyses revealed a complete lack of sub-class of immunoglobulins G and a weak antibody response to antigens. Standard karyotype, skeletal X-Rays and metabolic screening were then normal. Finally, among the other features non usually associated with the syndromatic diarrhoea, the child presented a spina bifida occulta, bilateral ovary herniae, transitory hypothyroidism- without any manifestation of autoimmunity- and a persistent arterial canal requiring surgery. The girl is now stabilised, starting back growing with home parenteral nutrition supporting minor oral feeding. Therefore, after excluding the other types of IDI but also primary or acquired immunodeficiencies, we concluded on a new case of syndromatic diarrhoea. It is to be noted that, on nine cases reported, here is the third case occurring in a consanguineous family so that genetic counselling should be quite careful.

Bilateral asymmetry in a Chinese sample with nonsyndromic cleft lip with or without cleft palate. K.

Neiswanger¹, M.E. Cooper¹, W.S. Holmes¹, Y.-E. Liu², M. Melnick³, M.L. Marazita¹. 1) Center for Craniofacial and Dental Genetics, University of Pittsburgh School of Dental Medicine, Pittsburgh, PA; 2) Zhabei Genetic Research Institute, Shanghai, China; 3) Laboratory for Developmental Genetics, University of Southern California, Los Angeles, CA.

Increased bilateral asymmetry may be seen in individuals with diverse congenital anomalies. We employed a case - control study design in order to determine if Chinese individuals with nonsyndromic cleft lip with or without cleft palate (CL/P) displayed more bilateral asymmetry than their unaffected relatives. Left and right mid-finger length, palm length, palpebral fissure width, and ear length were collected from 313 CL/P probands and 201 unaffected relatives in Shanghai, China. Asymmetry scores between right and left sides were defined for each of the four anthropometric measures by calculating the quotient of the right measurement divided by the left. Asymmetry quotients were compared between probands and their unaffected relatives using standard t tests, paired t tests and multivariate repeated measures analysis (ANOVA).

For all four measures, the probands' asymmetry scores did not differ significantly from the scores of unaffected relatives utilizing standard t tests. Paired t tests on a subset of 187 pairs of probands matched to their unaffected relatives also showed no significant differences for any of the measures. Subdivision of the sample according to gender, cleft type, and laterality did not change the results. However, when gender-matched proband/relative pairs (n = 74 male-male or female-female pairs) were analyzed by ANOVA, there were significant differences in the asymmetry scores for palpebral fissure width (p = 0.007), that depended both on cleft type (p = 0.004; CL alone vs CL/P) and laterality (p = 0.0001; unilateral vs bilateral). These differences were not seen in the non-gender matched sample (n = 113 male-female and female-male pairs). Supported by NIH grant# DE-09886.

A study of congenital cataract in 5000 newborns in Mashhad Hospitals, North East of Iran. *G.Ali. Mamoori¹, K. Ghodsi², A. Derakhshan³, F. Behmanesh¹, R. Akbarzadah², S. Mosavian¹, P. Sasan Nejad¹.* 1) Pediatric, Mashhad University of Medical , Mashhad, Khorasan, Iran; 2) Medical genetics, Mashhad University of Medical , Mashhad, Khorasan, Iran; 3) Ophthalmology, Mashhad University of Medical , Mashhad, Khorasan, Iran.

A study of congenital cataract in 5000 newborns in Mashhad Hospitals, North East of Iran. Gholam Ali Mamoori¹ Kazem Ghodsi², Akbar Derakhshan³, Fatemah Behmanesh¹, Reza Akbarzadeh², Saied Javad Mosavi Baigy¹ and Payam Sasan Nejad¹. Department of Pediatric¹, Department of Medical Genetics², and Department of Ophthalmology³, Ghaem and Emam Reza Hospitals, Faculty of Medicine, Mashhad University of Medical Sciences Mashhad Iran. Here we presented a study of congenital cataract in 5000 newborns in three major Mashhad Hospitals, 2000 to 2001 year. Twelve infants have been diagnosed with congenital cataract. Clinical studies showed that 45% of patients affected with bilateral eyes, three with right eyes and two patients had left eyes affected. Five infants had other abnormalities including cleft palate, cleft lips, microcephaly, polydactyly, bilateral cryptorchidism, VSD, hydrocephaly, hepatosplenomegaly, low seat ear, high arch palate, microstomy, calcification in around brain ventricular in CT scan. Patients study by gender showed that 55.5% were female and 44.5% male. Consanguinity study showed one patient with first cousin marriage parents and clinical findings in this patient were one eye affected, VSD, cleft palate, 1700 grams weight, lower limb hyperplasic trisomy 13. Age of pregnancy was in 55% were less than 37 weeks and 66% of infants had less than 2500 grams weight. To study chromosomal abnormalities peripheral blood samples from patients were taken and cells were harvested, GTG banding was carried out. Cytogenetic results showed two patients with trisomy 13 and the rest did not reveal any abnormal chromosome. DNA samples from patients and families were stored for future molecular study. This project is one of our current projects.

LIMB REDUCTION DEFICIENCIES IN THE SECOND GENERATION AND DEAFNESS IN THE THIRD GENERATION OF INTRAUTERINE EXPOSED FETUSES TO DIETHYLSTILBESTROL. C. STOLL, Y. ALEMBIK, B. DOTT. Medical Genetics, Hpital de Hautepierre, STRASBOURG, France.

Diethylstilbestrol (DES) was widely prescribed to pregnant women between 1938 and 1975 for treatment of imminent and habitual abortions. It is well known since the early 1970s that maternal treatment with diethylstilbestrol during pregnancy can produce vaginal adenocarcinoma and other abnormalities of the vagina in her daughters when they reach adolescence or adulthood. Concerning malformations in newborn whose mothers were treated with DES, clitoromegaly and malformations of the uterus were reported in female and genital lesions as well as pathological changes in spermatozoa in male. However the frequencies of major congenital anomalies were not greater than expected. We report 3 cases (2 males and 1 female) with limb reduction deficiencies (LRD) in the second generation of children whose mothers were treated with DES during pregnancy, and two children (1 male, 1 female) with deafness in the third generation after intrauterine exposure to DES. The LRD were not associated with other congenital anomalies and were of the terminal transverse type. LRD were not familial. The malformed children were born between 1965 and 1973. The two children with deafness, had sensorineural congenital deafness. Deafness was sporadic nonsyndromic. No genetic causes responsible for the hearing impairment were detected, i.e. mutation of CX26 or GJB2. These children were born in 1989 and 1994, respectively. They were not exposed to DES in utero. However their mothers, born in 1965 and 1963, respectively were exposed to DES in utero. This is the second example of transgenerational effect of DES in human beings, the first one being 4 children born with hypospadias, the sons of women exposed in utero to DES (Lancet, 2002;359:1102-7). Genetic or epigenetic changes in germ or (less likely) somatic cells of the exposed women are suggested as the biological explanation of this transgenerational effect of DES. Although DES is no longer used weaker estrogens are present in oral contraceptives, phyto-estrogens in the diet, and certain solvents or pesticides.

Anophthalmia/Microphthalmia(A/M) Registry: Results of first 2 years of gene screening. Is A/M biallelic? A.

Schneider¹, P. Mathers², V. Voronina², C. O'Kernick², C. Ramsburg², J. Murray³, E. Semina³, T. Glaser⁴, S. Tarle⁴, E. Oliver⁴, S. Banfi⁵, C. Vitiello⁵, E. Silva⁶, O. Sundin⁶, M. Dwyer¹. 1) Dept Genetics, Albert Einstein Medical Ctr, Philadelphia, PA; 2) Sensory Neuroscience Research Center, West Virginia University School of Medicine, Morgantown, WV; 3) Department of Pediatrics, University of Iowa, Iowa City, IA; 4) Departments of Internal Medicine and Human Genetics, University of Michigan, Ann Arbor, MI; 5) Telethon Institute of Genetics and Medicine, Naples, Italy; 6) Wilmer Eye Institute, Baltimore, MD.

The A/M registry at Albert Einstein Medical Center (AEMC) was established in 1994 and has been offering gene screening to registry participants since 1999. Testing involves mutational screening of 17 eye development genes with 8 participating labs. The DNA is collected from the affected individuals and family members with buccal brushes and/or blood which is sent in the mail from the central clearing house at AEMC to each lab. Samples are sent to all labs with minimal pre-selection. Results from 5 of the participating labs are as follows: No mutations have been noted in the PITX2, PITX3, PAX6 genes and ATHO7. A few silent polymorphisms in VAX1 have been identified. Two heterozygotes with a de novo Q147X mutation in the RX gene have been documented. In the SIX6 gene one heterozygous intronic change, IVS1-66t/c, has been found. The finding of heterozygous mutations in affected individuals is unexpected as these are known to be autosomal recessive genes. This raises the question as to whether a mutation in another gene is present in each of these individuals and therefore the possibility of biallelic inheritance.

Congenital absence, abnormal shape and reduced size tooth as manifestation of same genetic defect. *D. Saavedra*¹, *E. Barberia*¹, *M. Orera*². 1) Odontopediatrics, UCM, Madrid, Spain; 2) Genetics, H. Gregorio Maranon.

INTRODUCTION. Tooth development is a complex process including several stages through which the primordial cell passes: initiation, proliferation, histodifferentiation, morphodifferentiation, apposition, calcification and eruption. These abnormalities may result from genetic or environmental factors or a combination of both, producing excessive or deficient development at those stages. Until now it's not clear the extent to which heredity influences the final size, form and number of teeth or the number of loci contributing to various dental normal and abnormal traits.

MATERIAL AND METHODS. A 11 years old male child was studied because his dental anomalies. He presented oligodontia since the primary dentition with lack of both superior lateral incisors and canines. These teeth were also missing in the permanent dentition. He also presented a delayed eruption of permanent teeth but the main feature was the abnormal shape of the two present superior incisors and the four lower incisors which showed a conic shape since the primary dentition. No facial or other malformations were present nor skin, hair or nails abnormalities. When the parents were examined a significant small size in all mother's teeth was noted. The familial pedigree showed an autosomal dominant transmission of this trait in the mother's side as well as a history of oligodontia, also dominantly inherited.

DISCUSSION There are several pedigrees showing an autosomal dominant inheritance of hypodontia as an isolated trait affecting third molars or lateral incisors of permanent dentition, but it is so rarely involving canines at the primary dentition as our patient had. There are also some pedigrees that related small size with hypodontia suggesting a dominant inheritance with incomplete penetrance and variable expression of the same gene defect, but there are no many instances where also an abnormal tooth shape were present at the same family. The present pedigree confirms these three abnormalities, as produced by the same autosomal dominant mutant gene with reduced penetrance and clinical variable expression from small dental size to conical shape or missing tooth.

Urorectal septum malformation sequence: a case suggesting a separate entity from caudal regression sequence and a developmental field defect etiology. *M.C. Wilson¹, R. Wilcox², G. Murdoch², M. Grompe¹*. 1) Molecular & Med Genetics/L103, Oregon Health & Sci Univ, Portland, OR; 2) Dept of Pathology/L113, Oregon Health & Sci Univ, Portland, OR.

The urorectal septum malformation sequence is a term originally proposed in 1987 by Escobar et. al. for a category of anomalies that include absence of the perineal and anal openings, ambiguous genitalia, and associated anomalies. An absence of mesodermal cell migration into the caudal region of the embryo has been proposed as the basic cause of the malformation. We present a case where the lack of perineal and anal openings and ambiguous genitalia are clearly seen, yet there is normal development of the sacrum and a lack of other associated anomalies. Despite a 46 X,X karyotype by amniocentesis, the genitalia consisted of a primitive small phallic structure without urethral structures, absence of labial or scrotal structures, and no vagina. Further we can see the persistence of the plane of tissue containing the bladder wall, uterus, and sigmoid colon where there is no development of the urorectal septum, apparently leading to lack of development of the perineal structures. This case is more consistent with the original proposal by Escobar of an abnormality in the induction of the formation of perineal structures and genitalia secondary to the lack of development of the urorectal septum. Further it suggests a separate entity from the caudal regression sequence with possibly separate etiological factors.

Inherited capillary malformation is associated with a high flow vascular malformation. *L. Boon*^{1,2}, *J.B. Mulliken*³, *A.Ch. Bataille*², *G. Vittu*⁴, *R. Vanwijck*², *M. Vikkula*¹. 1) Center for Vascular Anomalies, Université catholique de Louvain, Brussels, Belgium; 2) Laboratory of Human Molecular Genetics, Christian de Duve Institute and Université catholique de Louvain, Brussels, Belgium; 3) Division of Plastic Surgery, Center for Vascular Anomalies, Children's Hospital, Boston, MA, USA; 4) Division of Neonatology, Hôpital Pédiatrique Saint-Antoine, Université catholique de Lille, France.

Capillary malformation (CM, portwine stain) is a common cutaneous vascular anomaly occurring in 0,3% of neonates. Except for rare reports of familial nuchal CM (stork bite), CM is considered sporadic. Clinical diagnosis is usually straightforward, however, CM can masquerade a high-flow vascular lesion, i.e., stage one AVM (arterio-venous malformation) or AVF (arterio-venous fistula). We identified several families with inherited CM. We clinically examined each family member, noted all vascular anomalies and collected informed consents and blood samples. Inter- and intrafamilial variation was observed, from nuchal CM persisting throughout life and extending below the hairline, to solitary or multiple CM disseminated all over the body. Seven of our families with inherited CM had at least one member affected with a high-flow vascular malformation. Three of them had either AVM (n=2) or AVF (n=1). Four families had two members with AVM (n=8) including Parkes Weber syndrome (n=3), AVM with multiple CM (n= 3), or intraosseus AVM with cutaneous blush (n=1) or extensive CM (n=1). These data confirmed autosomal inheritance of CM. In addition, the high incidence of high-flow vascular malformations observed within families with inherited CM suggests genetic predisposition for AVM and/or AVF in these families. (vikkula@bchm.ucl.ac.be) (<http://www.icp.ucl.ac.be/vikkula>).

Mosaicism for deletion of 15q11.2q13 in a patient with atypical Angelman Syndrome phenotype: A second case.
L.K. Berkheim, S.O. Lewin, B. Issa, E. Drozd-Borydiuk, A. Meloni-Ehrig, R. Mao, A.R. Brothman, J.C. Carey. Division of Medical Genetics, University of Utah, Salt Lake City, UT.

We report a young girl with mosaicism for a deletion 15q11.2q13 involving the PWS/AS critical region. Our patient has global developmental delay with language more severely impaired than motor skills, normal growth with head circumference at the 95th centile, unusual gait and sleep disturbance. Her facial features include a long philtrum with a thin upper lip, prominent forehead and wide mouth. A seizure disorder was recognized at 3 years of age with an EEG pattern consistent with Angelman syndrome (AS). Chromosome analysis on peripheral blood lymphocytes indicated mosaicism with a visible deletion at 15q11.2q13 at the 550 band level in 35% of cells. FISH studies showed mosaicism for a deletion in the AS critical region (SNRPN/D15S10) in 50% of scored cells. PCR based methylation studies indicated a normal biparental methylation pattern, although the sample showed slightly reduced amplification of the maternal signal, supporting that the deletion is maternally derived. Tekin et al. (*Am J Med Genet* 95:145-149, 2000) reported a similar case with normal methylation pattern and mosaic deletion of the AS critical region detected by FISH. Our patient closely resembles the reported case in facial features and developmental profile. Both cases appear to have a milder presentation compared to typical AS patients. In summary, methylation studies are commonly used as an initial screening for AS because most cases show only paternal methylation regardless of the molecular explanation for the condition. However, these two cases demonstrate that methylation studies alone are not sufficient to rule out AS. High resolution chromosome analysis with FISH should also be performed in patients with clinical features of AS despite a normal methylation pattern.

Role of a COL5A1 polymorphic variant(G530S) in the classical Ehlers-Danlos phenotype. *A.L. Mitchell, P.H. Byers.* Medical Genetics, University of Washington, Seattle, WA.

Classical Ehlers-Danlos syndrome (EDS type I/II) is characterized by soft, hyperextensible skin, hypermobile joints, and abnormal scar formation. Most affected individuals have mutations in the type V collagen genes (COL5A1 and COL5A2). In the COL5A1 gene these mutations result in substitutions for glycines in the triple helical domain, exon skipping, or haploinsufficiency mutations, while in the COL5A2 gene, most mutations alter triple helical glycine residues. One mutation in the COL5A1 gene leads to skipping of two exons (exons 5 and 6) in the region that encodes the amino-terminal propeptide of the pro α 1(V) chain. A second amino-terminal sequence variation (substitution of serine for the glycine at position 530, G530S) has recently been proposed to influence the expression of a mutation on the other allele and, in the homozygous state, to produce the classical EDS phenotype itself. To better understand the role of this variant sequence, we determined its frequency in individuals with inherited connective tissue disorders and in other groups without these disorders. Among 72 individuals with classical EDS there were 6 530S alleles (4.2%); 8/188 (4.2%) alleles in people with EDS type IV, and 9/164 (5.5%) alleles in people with osteogenesis imperfecta. Study of DNA samples from individuals without connective tissue disorders identified 16/300 (5.3%) of the COL5A1 alleles as the 530S variant. One of the anonymous DNA samples was homozygous for the variant. The incidence of homozygosity of 1/398 individuals is consistent with the allele frequency in the population studied. In an individual with classical EDS and a COL5A1 haploinsufficiency mutation, the 530S variant was on the unstable allele. A COL5A1 or COL5A2 mutation has not been identified in the other 5 classical EDS patients, but the presence of the 530S variant did not appear to modify the phenotype. These studies suggest that, contrary to published data, the COL5A1 530S allele has little role in modifying the classical EDS phenotype.

Redefining the MFS2 Locus at 3p24.2-25 as a Second Locus for Familial Thoracic Aortic Aneurysms and Dissections (TAAD2). *S.N. Hasham¹, A. Muilenberg², R. He¹, V. Tran¹, M. Willing², S. Shete³, D.M. Milewicz¹.* 1) Internal Medicine, Univ TX Med Sch Houston, Houston, TX; 2) Dept of Pediatrics, Univ of Iowa, Iowa; 3) Dept of Epidemiology, MD Anderson Cancer Centre, Houston, TX.

Marfan syndrome (MFS) is an autosomal dominant disorder that affects the ocular, skeletal and cardiovascular systems. MFS results from mutations in *FBN1* on 15q21. A second locus for a MFS-like syndrome was mapped to 3p24-25 using a large French family (MFS2 locus), raising the possibility of genetic heterogeneity for MFS. The data concerning the clinical characterization and molecular studies of the French family was controversial, raising doubts about the validity of the mapping of the locus and questions about the associated clinical phenotype. We studied a family of 4 generations with 81 members with autosomal dominant inheritance of thoracic aortic aneurysms and dissections (TAAD), in which the phenotype was not linked to any of the identified loci for TAAD. None of the affected members meet the diagnostic criteria for MFS. Affected and unaffected status was based solely on the cardiovascular features, i.e., aortic aneurysm or dissection or aortic root dilatation. A genome wide screen, using 400 highly polymorphic markers spaced approximately 10 cM throughout the human autosomes, was completed and LOD scores were obtained using the MLink program under the assumption of an autosomal dominant model with age related penetrance. Loci demonstrating a LOD score >0.6 were investigated further using markers spaced 1-3 cM apart. TAAD in this family was linked to a 30 cM region at 3p24-25, directly overlapping the MFS2 locus. Linkage analysis demonstrated eleven markers in the region with a positive LOD score above 3.0 and a maximum multipoint LOD score of 3.68 was obtained with marker D3S2336. The data confirms the existence of a locus on 3p for familial TAAD with reduced penetrance of the cardiovascular manifestations. In addition, the clinical phenotype associated with the locus in our family is not MFS, but rather TAAD.

Characterization of DPH Syndrome: a new autosomal dominant constellation of dermatoglyph hypoplasia and palpebral hypertrichosis. *J.P. Doucet¹, A.K. Lirette¹, S.M. Robichaux¹, A. Duke¹, R. Self II¹, Y. Lacassie^{2,3}.* 1) Biological Sciences, Nicholls State University, Thibodaux, LA; 2) Pediatrics, LSU Health Sciences Center, New Orleans, LA; 3) Children's Hospital, New Orleans, LA.

We report a large family expressing a unique constellation of dermal abnormalities. The cardinal features of the syndrome include dermal ridges hypoplasia of both the palmar and plantar surfaces, distichiasis and hypertrichotic growth across the eyelids as the brows thicken and descend toward the lateral canthi, raised and pyramidal fingerpads and toepads, underkeratinized and sweaty palmar and plantar surfaces, dorsal hyperpigmentation of the phalangeal surfaces, excessive tearing of the eyes, and coarse body hair. The syndrome affects at least four generations of an extended southern Louisiana family of Acadian descent. This unique unreported constellation of abnormalities, inherited in an autosomal dominant pattern, suggests the presence of a new syndrome.

KID syndrome (Keratosis, Ichthyosis and Deafness). *P. Lenane*¹, *S. Cammisuli*¹, *B. Krafchik*¹, *A. Pai*², *D. Chitayat*².
1) Dept. of Pediatrics, Division of Dermatology, Hospital of Sick Children, Toronto, Ontario, Canada; 2) Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital.

KID syndrome is a rare, congenital ectodermal disorder, consisting of the triad of a vascularising keratitis, ichthyosis and deafness. The condition is most probably autosomal dominant with full penetrance and most cases were the result of a new dominant mutation. We report an additional case of this rare condition detected prenatally with Dandy-Walker malformation. The patient was born to a non-consanguineous couple of Portuguese descent and the pregnancy was complicated with fetal ultrasound finding of Dandy-Walker malformation. Delivery was spontaneous and vaginal at term. After delivery the female newborn was found to have dystrophy of her finger and toe nails, erythematous scaly papules on her palms and soles and papillomatous hyperkeratosis covering her scalp, trunk and limbs. She had multiple milia extending from the bridge of her nose across both cheeks, onto her pinnae and filling both external ear canals. Peribuccal grooves, sparse hair growth on the scalp and alopecia of the eyebrows and eyelashes were also noted. The diagnosis of a Dandy Walker malformation was confirmed but no other fetal abnormalities were detected. The cutaneous findings evolved over 3 months with resolution of the milia and the generalized papillomatous hyperkeratosis. Normal nail growth has been noted on 2 fingernails but she has developed spiny processes on the palms of the hands and soles of her feet. Thickened areas of hyperkeratosis have developed at the angles of her mouth and across her eyebrows. She has recurrent episodes of conjunctivitis and bacterial and candidal skin infections. Auditory evoked responses have confirmed the presence of profound sensorineural deafness.

Misoprostol embryopathy: clinical evaluations of 13 patients with congenital hydrocephaly. *C.H. Gonzalez^{1,2}, M.J. Marques-Dias², C.A. Kim², J.A. Paz², S.M.M. Sugayama², M. Valente².* 1) Dept. Biology. Instituto de Biocincias - USP -Brazil; 2) Dept.of Pediatrics - Instituto da Criana. University of So Paulo - So Paulo -Brazil.

Misoprostol, a synthetic analog of prostaglandin E1 has been misused as abortifacient in Brazil, where abortion is not a legal procedure. The drug is used, in the vast majority of the cases, in not medically controlled conditions, with a great percentage of failure. We have been studying and have already published(a,b) the clinical findings of children with birth defects exposed in utero to misoprostol. In a consecutive series of 67 patients evaluated between June, 1992 and April, 2002, congenital hydrocephaly was diagnosed in 13 cases (19,4%). Among them, 11 also presented equinovarus feet. Nine had cranial nerve deficiencies, most involving the fifth to seventh nerves (Mbius anomaly); 5 had arthrogriposis. One patient presented syndactylies of the fingers and another of the toes. Ten of these children's mothers took 400-800 mcg of misoprostol (Cytotec) orally or vaginally at 4-12 weeks of pregnancy. One mother took 8000 mcg orally and 8000 vaginally. In 9 patients the imaging study showed a non-communicating hydrocephaly with signs of aqueduct stenosis. Other cerebral abnormalities were also seen . Cranial nerve deficiencies (Mbius anomaly), terminal transverse limb defects, constriction bands, arthrogriposis, equinovarus, amyoplasia and hydrocephaly are characteristics of misoprostol embryopathy, a complex phenotype not yet fully described. These deformities can be attributed to a mechanism of vascular disruption provoked by the uterine contractions induced by misoprostol. A question to be answered is: can a vascular disruption phenomenon, explain all these findings? Another question, an estimate of the potential teratogenicity of misoprostol is still to be determined. aGonzalez et al. *Am J Med Genet*, 1993; 47: 59-64, bGonzalez et al. *Lancet* 1998; 351: 1624-1627.

Dysmorphological diagnosis of fetal alcohol syndrome (FAS) in two ethnic groups: African-Americans and Caucasians. *R.D. Blackston, J.A. Kable, C.D. Coles, M.E. Meeks.* Div Med Gen, Dept Pediatrics, Emory Univ Sch Medicine, Atlanta, GA.

Initial descriptions of dysmorphia in FAS were based on Caucasian samples (Jones and Smith, 1973). However, this disorder has been identified more frequently among minority groups, particularly Native Americans and African-Americans. It has long been a concern that facial features characteristic of African-Americans may contribute an overdiagnosis. These features include lower nasal bridge, anteverted nares, wide mouth and dermal patterns. In this study, we report preliminary data from a large metropolitan comprehensive fetal alcohol clinic where clientele is almost equally African-Americans and Caucasians. All patients are evaluated for FAS using a standard dysmorphology checklist which yields a weighted score (PedScore) of alcohol-related dysmorphology. To ascertain whether specific features contribute to an overdiagnosis of FAS in African-Americans, both summary data and individual items were evaluated in 254 consecutive cases, of whom 99 met our criteria for FAS. Among all children applying for services, Caucasians had a mean PedScore of 11.38 while African-Americans had a mean of 15.029, ($F=10.91$, $p<.001$) indicating a significant difference between these groups. Items that discriminated the groups included, light for gestational age (GA), small head for GA, ptosis, low nasal bridge, anteverted nares, thin upper lip, small mandible, large mouth, unusual palmar creases and hypoplastic nails. Because these findings could be biased by a higher incidence of FAS among African-Americans, we also analyzed the subgroup ($n=99$) who were diagnosed with FAS (PedScore >15). Among this group, there was no ethnic difference in mean scores (Caucasians: 20.897; African-Americans: 21.457; $F=2.93$, $p=0.59$). These findings may be accounted for in two ways. First, the teratogenic effects of alcohol itself could well influence the morphology, and secondly the results may be influenced by using the full body PedScore checklist. These data suggest that: 1) There are ethnic differences in craniofacial features that may contribute to overdiagnosis of FAS among African-Americans; 2) Physical examination for FAS should not be limited to craniofacial features.

An Unusual Presentation of Cenani-Lenz Syndactyly in a Patient with Kabuki Syndrome. *A.M. Elliott¹, M.H. Reed^{2,4}, J.A. Evans^{1,3,4}, A.E. Chudley^{1,3,4}.* 1) Department of Biochemistry & Medical Genetics, University of Manitoba; 2) Department of Radiology; 3) Department of Pediatrics and Child Health; 4) Children's Hospital, Winnipeg, Manitoba, Canada.

Cenani-Lenz syndactyly (CLS) a proposed AR entity, is classically characterized by total digit syndactyly, metacarpal and carpal fusions, and in some cases, radio-ulnar synostosis. The feet may only show 2-3 cutaneous syndactyly. We report a 6-year-old male with an unusual presentation of CLS who was the only child born to his French Canadian mother and Swedish/Scottish father. Evaluation at 5 months revealed 3 malformed digits on each hand. Radiographically, there was hypoplasia of the phalanges of the thumbs. Metacarpals 1 and 2 were normal. The index fingers were abnormal, with a widened proximal phalanx (PP) and a medially placed delta phalanx. Distally, there were 2 irregular ossicles side by side. The right 3rd and 4th metacarpals were closely proximated and an abnormal digit articulated with their heads. The PP of this digit was wide with 2 "kissing delta phalanges." The middle phalanx of this digit was wide, and the distal phalanx was reasonably normal. The 4th metacarpal was abnormally shaped. On the right, there was another relatively normal medial digit. On the left, in addition to the 5th digit, there was a crossbone that articulated with the medial aspect of the 4th metacarpal. Subsequent analysis revealed carpal coalition and posterior subluxation of the radial heads. The feet showed 2-3 cutaneous syndactyly. Renal ultrasound was normal. Examination at 6 years revealed normal growth, the digital anomalies, oligodontia, and features suggestive of Kabuki syndrome including: large prominent ears, sparse medially flared and arched eyebrows, wide palpebral fissures, long eyelashes and persistent fingertip pads. He has had recurrent episodes of otitis media and pneumonia. Development has been normal, according to his mother. Although he does not show the typical spoon hand configuration, he resembles other reported CLS patients. CLS should be considered in patients presenting with an unusual syndactyly/oligodactyly. The findings of CLS and Kabuki Syndrome in this child may be coincidental.

Siblings with Extreme Short Stature: The Differential Diagnosis of Primordial Dwarfism. *C. Flora¹, J. Neidich^{1,2}.*
1) Section of Genetics, St. Joseph's Children's Hosp, Paterson, NJ; 2) Global TeleGenetics, Palo Alto, CA.

Primordial dwarfisms are a group of syndromes characterized by extreme short stature with microcephaly. Patients with osteodysplastic types of primordial dwarfism have a variety of skeletal and other anomalies. Some individuals in published reports were diagnosed with Seckel syndrome, but may have other types of primordial dwarfism. The delineation of these syndromes has been difficult due to heterogeneity and syndrome rarity.

The patients are two siblings with extreme short stature who are the offspring of first cousins. The elder, a female, was 32 months old at exam. Height was 50-centile for 8 1/2 months, weight for 4 1/2 months and OFC for 4 months. Bone age was significantly delayed. Developmental milestones were within normal limits. Her similarly affected brother was 12 months at exam. His growth parameters were height for 1 1/2 months, weight for 5 weeks, and OFC for 1 month. Both were growth retarded premature infants without other health problems or internal anomalies. They both had high-pitched voices, and were bilingual in English and Arabic.

The literature on primordial dwarfs and Seckel syndrome predominantly consists of case reports. Geneticists have suggested three types of osteodysplastic primordial dwarfism, in addition to Seckel syndrome and Silver-Russell syndrome. Most reports from the old literature do not establish that the individuals did not have a form of pituitary dwarfism. We review the literature, and present the likely diagnosis for these siblings.

Mosaic Monosomy 14- Clinical features and recognisable facies. *V.P.M. McConnell, D. McManus, P.J. Morrison.*
Department of Genetics, Belfast City Hospital Trust, Belfast, Co Antrim, Northern Ireland.

Monosomy 14 has not been described previously. Only 2 case reports of mosaic monosomy 14, in an Arab child with a low level (10%) of mosaicism and a Japanese child where the level of mosaicism was not indicated, have been described. We report a 1 year old child with severe mosaic monosomy 14 with up to 30% mosaicism. Prenatally ultrasound revealed ascites with cerebral ventricular dilatation and a left ovarian cyst with resolution of the ascites occurring post oophorectomy. Amniotic fluid analysis demonstrated complete monosomy of chromosome 14 in 31% of cells with the remaining 69% cells having a ring 14 chromosome. This result was confirmed on blood lymphocyte analysis post delivery. Clinical examination revealed facial dysmorphism including microcephaly and dolichocephaly, bilateral lower segment iris colobomas and retinal pigmentation, severe eczema and curly blond hair. Hypotonia with severe mental retardation and severe seizures were also present. This case demonstrates several of the abnormalities found in r14 and interstitial 14q deletions. In addition, several of the features are accounted for by loss of distal 14q, and the severe mental retardation has been attributed to the monosomy. This combination of 31% mosaic monosomy 14 / ring 14 appears to be the most severe phenotype described in a living case to date. Chromosome 14 appears to be important for craniofacial and skin development. The mental deterioration is severe and is compounded by the uncontrollable seizures.

Lethal bone dysplasia in spontaneous abortion fetus. A new non-described entity. *V. Moran¹, C. Ortiz-Hidalgo^{1,2}, I. Garcia-Pelaez^{1,3,4}, L. Cornejo⁴, E. Monterrubio¹, O. Aguirre⁴, H. Perez-Pineda^{1,4}, M. Arteaga^{1,3,4}.* 1) School of Medicine, Universidad Panamericana; 2) ABC Hospital; 3) Faculty of Medicine, National Autonomous University of Mexico; 4) Hospital Infantil de Mexico Federico Gomez, Mexico City, Mexico.

Introduction. Bone dysplasias are a complex group of disorders of difficult classification, with phenotypes that many times overlap, the difficulty is increased in affected fetuses, that may just resemble the phenotype in postnatal stages or even be lethal. **Case report.** A 18 wks gestation female fetus was obtained from a spontaneous abortion. The parents were non-consanguineous and there was no exposition to teratogens. The fetus presented generalized edema, head and body disproportion, increased cephalic perimeter, low-set ears, depressed nasal bridge, anteverted nostrils, elonged philtrum, arched mouth, very thick lips, microretrognathia, short neck, narrow torax, generalized shortening of limbs mainly rhizomelic and very thick skin. Karyotype analysis could not be performed. The necropsy showed an anomalous pulmonary venous connection, probably infradiaphragmatic. Histopathologic analysis showed thickening of the skin at expense of both edema and increased deposit of mucopolysaccharides; the femur had an abnormal growth plate with irregular proliferative zone; in other bones increased osteoclast activity was observed. **Discussion.** This case sheared representative characteristics of several diagnosis but did not full-filled a specific one. We considered Chondrodysplasia punctata because the rhizomelic shortening and the growth plate abnormalities as seen in this case, however our case lacked typical data in the radiological analysis. Another considered diagnosis was Geleophysic dysplasia because the similarity of the skin mucopolysaccharides deposits in facial area however, in our case the deposit was generalized, neither had the typical phenotype. **Conclusions.** We consider this case as a bone dysplasia of the Geleophysic or Chondrodysplasia punctata varieties, with more severe afectation, because of the lethal consequences, with the unusual characteristics described above, that probably had not been described before.

Marfanoid habitus with abnormal situs: A new syndrome? *K. Kosaki*¹, *L. Bird*², *R. Kosaki*³, *J. Maeda*¹, *M. Jones*², *M. Matsumoto*⁴. 1) Dept Pediatrics, Keio Univ, Tokyo, Japan; 2) Dept Dysmorphology, San Diego Children's Hosp, San Diego, CA; 3) Div Med Genet, Saitama Children's Hosp, Itwatsuki, Japan; 4) Dept Orthopedics, Keio Univ, Tokyo, Japan.

Marfanoid habitus suggests abnormal microfibril formation, whereas a situs ambiguus or situs inversus phenotype points to defective left-right axis determination. The concurrence of these two abnormalities had not been known until recently, when Gokce et al. reported a 22-year-old female with Marfan syndrome-like body habitus and situs inversus. We report two cases of a similar combination in unrelated patients. Case 1: A Japanese male was diagnosed as having valvular pulmonary stenosis, dextrocardia, azygous connection, and polysplenia during newborn period. At 14 years of age, he had decreased upper-lower segment ratio, large ears, pectus carinatum, scoliosis, hyperextensible fingers, arachnodactyly, and a positive wrist sign. Ophthalmologic examination revealed myopia, but there was no subluxation of the lenses. A skeletal survey revealed mild osteoporosis. The chromosomes were normal. Case 2: A Caucasian female was diagnosed as having situs inversus. At 11 years of age, the patient had decreased upper-lower segmentation ratio, large ears, scoliosis, hyperextensible fingers, arachnodactyly, and a positive wrist sign. Echocardiography showed dilatation of the aortic root. A skeletal survey revealed mild osteoporosis. Documentation of this specific combination of marfanoid habitus and abnormal situs in two additional patients gives further credence to the concept that the combination may represent a previously unrecognized syndrome.

Arterial aneurysms in two unrelated individuals with Sotos syndrome. *T. Jewett, L. Terry.* Dept. of Pediatrics, Div. of Medical Genetics, Wake Forest Univ. Health Sciences, Winston-Salem, NC.

Sotos syndrome, sometimes referred to as "cerebral gigantism," is an overgrowth syndrome characterized by birth weight and length greater than the 90th percentile, excessive linear growth in the first years of life, advanced bone age, and an unusual facies. Dysmorphic features include macrodolichocephaly, downslanting palpebral fissures, and a prominent, pointed chin. Most cases are sporadic, although autosomal dominant inheritance is suggested in some families. Affected children typically manifest speech and motor delays in early life, but intelligence is usually normal. There is an increased risk for neoplasia in Sotos syndrome of ~4%; otherwise, affected children are generally healthy. We report two, unrelated individuals with Sotos syndrome and arterial aneurysms of unknown cause, an association not previously described.

K.I. is a 9 y.o. boy who was diagnosed with Sotos syndrome at one year of age by a medical geneticist. Aside from Horner syndrome involving the left eye from early childhood, no neurologic deficits were noted. Intelligence is normal. At age 7, he presented with a one day history of progressive weakness and incoordination. Head imaging studies showed right cerebellar and bilateral brain stem infarcts, and angiography showed abnormal tortuosity and ectasia of the internal carotid arteries and multiple cerebral vessels, with dissection and thrombi in some arteries. He is being treated with anticoagulation.

R.B. is a 22 y.o. man who was diagnosed with Sotos syndrome by a medical geneticist at 8 years of age. He is mildly mentally retarded. At age 21, he presented to the emergency department complaining of exertional chest pain for one month. Cardiac catheterization showed a reduced ejection fraction, enlargement of the left ventricle, and decreased heart motion with aneurysms of the proximal left anterior descending, left circumflex, and right coronary arteries with thrombus formation. The possibility of past Kawasaki disease was questioned, but there is no history to support this. He has undergone coronary artery bypass and graft.

Mutation analysis of TBX1, HOXA3, HOXB3, and HOXD3 in patients with CHARGE association. *N. Yahagi¹, R. Kosaki², T. Suzuki¹, S. Lalani³, T. Takahashi¹, J. Belmont³, K. Kosaki¹.* 1) Pediatrics, Keio Univ, Tokyo, Japan; 2) Dept of Med Genetics, Saitama Children's Med Ctr, Iwatsuki, Japan; 3) Dept of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

The CHARGE association represents a nonrandom clustering of ocular coloboma, heart malformation, choanal atresia, retarded growth and development, central nervous system malformations, genital hypoplasia, ear abnormalities, or deafness. Based on anatomical distribution of major defects in CHARGE association, abnormal development of tissues derived from neural crest is implicated. Although pathogenesis of the CHARGE association is unknown, recurrence in several families points to contribution of genetic factors. Several patients with chromosomal abnormalities have been reported including deletion of 22q11. Because mice with loss-of-function mutation in *Tbx1* exhibit phenotype similar to CHARGE association and human *TBX1* resides within the interval commonly deleted in the 22q deletion syndrome, *TBX1* was considered as a promising candidate. In addition, because mice with loss-of-function mutation in *Hoxa3* leads to neural crestopathy, *HOXA3* was analyzed together with paralogous *HOX* genes *HOXB3* and *HOXD3* which presumably play complementary roles with *HOXA3*. Nineteen classic cases of CHARGE association were screened for mutations in using direct sequencing of PCR products amplified from genomic DNA. No pathogenic mutations were found in any of the genes. A novel Threonine to Proline amino acid change, which was found in both patients and normal controls, was considered as polymorphism. We conclude that mutation of the *HOXA3*, *B3*, *D3* and *TBX1* are not a common cause of the CHARGE association.

Three cases of Leber congenital amaurosis with an Ehlers-Danlos-like syndrome. *C. Yasutsugu¹, K. Naritomi², S. Takaesu³, T. Ohta¹.* 1) Dept Pediatrics, Univ Ryukyus Sch Medicine, Okinawa, Japan; 2) Dept Medical Genetics, Univ Ryukyus Sch Medicine, Okinawa, Japan; 3) Dept Ophthalmology, Univ Ryukyus Sch Medicine, Okinawa, Japan.

Leber congenital amaurosis (LCA) is the earliest and the most severe form of all inherited retinal dystrophies. Autosomal recessive inheritance is suspected in most LCA families. LCA is clinically and genetically heterogeneous and often associated with systemic anomalies. We report on three patients in two nonconsanguineous families, who had weak or no visual acuity, pigmentary retinal degeneration, nonrecordable electroretinograms on ophthalmological examinations in all cases, mental retardation, inability to walk with ataxia, characterized facies with bitemporal hollowing, high nasal bridge, thin upper lip, prominent chin, skeletal anomalies such as hyperextensible joints, cigarette-paper scar in one, odontoid instability in one, cerebellar vermis hypoplasia in one, growth hormone deficiency in one. The serum amino acid and blood gas analyses and the pyruvate and lactate levels in blood were all normal. This is the second report on Leber congenital amaurosis with an Ehlers-Danlos-like syndrome.

Development of skull dysmorphology in Ts65Dn segmentally trisomic mice. *J.T. Richtsmeier^{1,2,4}, J. Leszl^{1,2}, C.A. Hill¹, V. Aquino³, R.H. Reeves³*. 1) Department of Anthropology, The Pennsylvania State University, University Park, PA; 2) Program in Genetics, The Pennsylvania State University, University Park, PA; 3) Department of Physiology, The Johns Hopkins University, School of Medicine, Baltimore, MD; 4) Center for Craniofacial Development and Disorders, The Johns Hopkins University, School of Medicine, Baltimore, MD.

Down syndrome (DS) is the most frequent live-born aneuploidy and is caused by trisomy for human Chromosome (Chr) 21. DS results in a characteristic spectrum of developmental anomalies including effects on craniofacial tissues. The facial appearance in DS is highly characteristic, however, quantitative analysis demonstrates a marked variability in phenotypic expression among DS individuals. The increased variability noted in the DS population is argued to be a result of developmental instability, a process by which dosage imbalance for large numbers of genes disrupts multiple genetic pathways, resulting in developmental anomalies. The Ts65Dn mouse has segmental trisomy for mouse Chr 16 and is at dosage imbalance for many of the same genes triplicated in DS. We have previously quantified specific, completely penetrant skull phenotypes in adult Ts65Dn mice that parallel those defined for humans with DS. These skull phenotypes are caused by trisomy of the same genes triplicated in DS. We examine developmental instability of the Ts65Dn mouse by analyzing fluctuating asymmetry of skull features, and present the results of a morphometric analysis of the skulls of P0 Ts65Dn trisomic mice and their euploid littermates. Our analysis of fluctuating asymmetry reveals that developmental instability contributes to the documented skull dysmorphology in adult Ts65Dn mice. Our morphometric analysis demonstrates that the skull dysmorphology is already established at birth. The disruption of development that causes the skull phenotypes occurs prenatally, affects the size of all skull elements, and produces localized changes in shape of specific skull regions.

A complex autosomal dominant syndactyly type-I in a very large Indian family. *U.C. Rao¹, M. Raveendrababu¹, M.R. Memon², J.V. Solanki³, U. Ratnamala¹, U. Radhakrishna¹.* 1) GeneHealth, Green Cross Blood Bank & Genetics Centre, Ahmedabad; 2) Department of Zoology, School of Sciences, Gujarat University Ahmedabad; 3) Department of Animal Genetics & Breeding, College of Veterinary Science & Animal Husbandry, Gujarat Agricultural University, Anand-388001, India.

Syndactyly is the most common malformation of the hand with a frequency of 1:2000 to 1:3000 live births. It was classified into five different types. Syndactyly type-I (SDTY1) (OMIM 185900) involves complete or partial bilateral syndactyly between third and fifth fingers which is occasionally associated with fusion of the distal phalanges. Feet are rarely affected. It may be an isolated condition. The genes responsible for SDTY1 and SDTY2 have been mapped to chromosome 2q34-q36 (Am J Hum Genet 67:492-97, 2000; Am J Med Genet 104:147-151, 2001 and 2q31 (Hum Molec Genet 4:1453-1458,1995), respectively. We have studied a large six generation Indian pedigree with an autosomal dominant SDTY1. The pedigree consists of 645 individuals including 290 affecteds (127 males/163 females). The anomaly was present in both extremities and the phenotype appeared to be 100% penetrant. The expression of the phenotype was quite variable and ranged from bilaterally affected with typical features of SDTY1 affecting the 3rd and 4th fingers to unilateral, bilateral hand syndactyly and unilateral partial syndactyly of 2nd and 3rd toes, unilateral elongation of 2nd and 3rd toes with complete soft tissue syndactyly of all fingers, complete ectrodactyly involving toes, reduction in finger size, nail syndactyly, duplication of nails. Unilateral Polydactyly of 3rd finger with duplication of 5th toe was observed in two patients. The degree of severity was very high when both parents were affected with SDTY1. These include ectrodactyly of hand, soft tissue syndyctyly of all fingers and toes, hypoplastic nails, absent nails, club shaped hand and foot. Distortion of dermatoglyphic patterns was also observed. Linkage studies with markers closely linked to SDTY1 will both confirm allelism to this locus and may reduce the genetic interval encompassing the SDTY1 gene or provide evidence for genetic heterogeneity. u_c_rao@hotmail.com.

A TDT and Candidate Gene Analysis demonstrates a role for genes of folate metabolism (RFC1, MTHFR) in clefting. *D.M. Caprau¹, J.C. Murray¹, P.A. Romitti², R. Grady¹.* 1) Dept of Pediatrics, Univ of Iowa, Iowa City, IA; 2) Dept of Epidemiology, Univ of Iowa, Iowa City, Iowa.

Cleft lip and cleft palate are among the most common birth defects. Each has a complex etiology involving genetic and environmental factors. Candidate gene analysis has previously suggested both MSX1 and TGFB3 are risk factors for clefting in Caucasian populations. This study looked at triads (mother, father and affected proband). The objective of this study is to evaluate the role of selected candidate genes in the etiology of CL/P from a predominantly Caucasian population born in Iowa. The genes selected are: MTHFR, GCP II, RFC1 (folate metabolism), MSX1 (transcription) and TGFB3, TGFA, PVRL2 (signaling molecules). These genes were selected based on their expression in the developing palate, phenotype in knockout mice or from their role in gene-nutrient interactions. Patients were evaluated by pediatricians and clinical geneticists for phenotype classification. DNA was extracted from whole blood or buccal swabs. All samples were genotyped for at least one polymorphism in each gene using conventional or kinetic PCR. A TDT was used to look for evidence of transmission distortion. 261 triads were genotyped for all markers. Significant p-values on the TDT test were found for over transmission of the A allele for RFC1 G80A marker ($p=0.0001$). The C allele for MTHFR C677T was also over transmitted with CL/P ($p=0.02$). This study carried out an extensive search for evidence of transmission distortion in 7 candidate genes of high priority for the study of cleft lip and palate. Significant p-values found for RFC1 and MTHFR suggests a strong role for folate metabolism contributing to clefting. Other studies of human birth defects, especially NTDs, have also supported a role for folate deficiency in etiology. The role of RFC1 and MTHFR suggests that a subpopulation of individuals may have a genetically increased risk for clefts. Such groups may benefit from more targeted and/or higher doses of folate for prevention of recurrences or occurrences.

Toward a Genetic Etiology of CHARGE Syndrome. *S.R. Lalani¹, D.W. Stockton¹, C. Bacino¹, L.M. Molinari¹, N.L. Glass^{2,3}, S.D. Fernbach¹, J.A. Towbin^{1,3,4}, W.J. Craigen¹, J.M. Graham, Jr.⁶, M.A. Hefner⁷, A.E. Lin⁸, K.L. McBride¹, S.L. Davenport⁵, D.M. Martin⁹*. 1) Dept of Molecular and Human Genetics; 2) Dept of Anesthesiology; 3) Dept of Pediatrics; 4) Dept of Pediatric Cardiology, Baylor College of Medicine, Houston, TX; 5) Sensory Genetics/ Neuro-Development; 6) Cedars Sinai Medical Center, UCLA Medical School, Los Angeles, CA; 7) Dept of Pediatrics, St. Louis University, MO; 8) Genetics and Teratology Unit, MA; 9) Depts of Pediatrics and Human Genetics, University of Michigan, MI.

CHARGE syndrome is characterized by ocular coloboma, cranial nerve abnormalities, distinctive heart defects, choanal atresia, retardation of growth and development, genital hypoplasia, ear abnormalities and/or hearing loss. While clinical delineation of this syndrome has progressed, the molecular basis for the disorder remains unknown. We hypothesized that CHARGE is caused by genomic microdeletion(s) and performed genotyping in ten case/parent trios to detect potential loss of heterozygosity. Using 811 microsatellite markers of 5 cM average spacing from the ABI Prism Linkage Mapping set-HD5 v.2, eight markers showed a persistent non-Mendelian pattern of inheritance in 1/10 to 3/10 families. BAC and PAC clones containing the sequence of these markers, *DIS2833*, *D5S417*, *D6S434*, *D7S2560*, *D9S271*, *D12S1646*, *D19S420* and *D20S178* were used to perform fluorescence *in situ* hybridization, but no deletion was observed at these loci. Interestingly, *D12S1646* maps within the *TBX5* gene. Southern blot was performed using a cDNA probe, which excluded a deletion of the *TBX5* gene in the proband. Using this experimental design, approximately 40% of the genome has been ruled out for a 2 Mb deletion in 10 patients with CHARGE syndrome. Efforts are also underway to identify chromosomal breakpoints in a patient with CHARGE syndrome described by Martin et al. (AJMG 99:115-9) with an apparently balanced translocation t(2;7)(p14;q21.11). This patient offers a unique opportunity to identify genes that may be involved in critical developmental pathways in CHARGE syndrome.

Diencephalic tumour-emaciation syndrome X Lipoatrophies: differential diagnosis. *C.A. Kim, L.M. Pinto, A.C. Paula, L.M.J. Albano, A.L.F. Tupinamba, M.G. Vallada, H.S. Marques, E. Vidolin, Y.K.L. Koda, D.R. Bertola.* Dept Pediatrics, Inst da Crianca, Sao Paulo, Brazil.

The diencephalic tumour-emaciation syndrome of infancy, first described by Russell (1950), is caused by a slowly growing glioma in the anterior hypothalamus, usually an astrocytoma. It is characterized by a progressive emaciation in spite of good food intake, undiminished alertness, pallor without anemia, occasional vomiting and nystagmus. No neurological symptoms and signs could be detected for a long time, causing delay in its diagnosis. Usually, its onset is precocious, varying from early infancy to the end of the second year of life. We report on a 1y7mo girl with this syndrome in order to emphasize its differential diagnosis with lipodystrophy. She was the first child from a healthy and nonconsanguineous couple. Her birth weight was 3,800 g and length, 49 cm. She was normal until 6 months of age, when she presented severe and progressive failure to thrive in spite of a good food intake and sporadic diarrheas. Physical exam at 1y7mo showed an active and alert girl, with a weight of 6,300g ($p < 2,5$); height of 76 cm ($p < 2,5$); and OFC of 46cm ($p = 50$); normal hair, generalized absence of adipose tissue, without muscular hypertrophy or hepatomegaly. Laboratorial findings showed normal values of glucose tolerance test, lipaemia, absorption tests. Abdominal ultrasonography was also normal. Ophthalmologic funduscopy revealed a pallor and partial atrophy of optic nerves. CT scan and MRI images showed a hypophalamic tumour lesion with ventricles enlargement. She was submitted to a partial resection (40%) of the tumor and currently, under chemotherapy. We recommend the investigation of diencephalic tumors in other syndromes that share the emaciation signs, such as leprechaunism, lipodystrophies, Cockayne and other progeroids syndromes, once a prompt diagnosis of this tumor can improve its clinical course and survival.

A twin study of ADHD. *M.B. Strassberg*¹, *L. Murrelle*^{2, 3}, *L. Corey*^{2, 3}, *M.L. Marazita*^{4, 5, 6}, *B.S. Maher*^{4, 5}, *M.M. Vanyukov*^{4, 7}. 1) University of Texas, Houston Health Science Center, Houston, TX; 2) Mid-Atlantic Twin Registry, Virginia Commonwealth University, Richmond, VA; 3) Virginia Institute for Psychiatric and Behavioral Genetics, Virginia, Commonwealth University, Richmond, VA; 4) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 5) Cleft Palate-Craniofacial Center, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 6) Department of Oral and Maxillofacial Surgery, University of Pittsburgh, Pittsburgh, PA; 7) Center for Education and Drug Abuse Research (CEDAR), Department of Pharmaceutical Sciences, University of Pittsburgh, Pittsburgh, PA.

Attention Deficit/ Hyperactivity Disorder (ADHD) is a significant public health problem. The main purpose of the present study was to evaluate the heritability of liability to ADHD and its dimensions in preschool aged children. This study used model-fitting to estimate genetic and environmental contributions to the variation in the core behavioral dimensions associated with ADHD in two sets of young twins, aged 1 -5 years. Data from the CBCL 1 -5 years was obtained for 21 pairs of monozygotic (MZ) twins and 21 pairs of dizygotic (DZ) twins enrolled in the Pittsburgh Registry of Twin Multiplets (PRIM). Data from the Young Twins Survey was obtained for 101 pairs of MZ twins and 147 pairs of DZ twins enrolled in the Mid-Atlantic Twin Registry (MATR). Univariate analyses supported a substantial contribution of genetic factors in the expression of inattention, impulsivity/hyperactivity and ADHD problems in males, and a lesser contribution of genetic factors involved in the expression of these traits in females. Bivariate analyses indicated that the correlation between attention and hyperactivity/impulsivity is genetically mediated.

Conclusion: Genetic factors are important in variation in the expression of the separate dimensions of ADHD and in the covariation between them in young children. The extent of genetic effect differs between males and females.

Exclusion of candidate loci and autozygosity mapping of Jeune asphyxiating thoracic dystrophy. *N.V. Morgan¹, C. Bacchelli², M. Silengo³, J.H. Tuerlings⁴, L.C. Wilson⁵, L.A. Brueton⁶, E.R. Maher¹, R.C. Trembath⁷, P.J. Scambler², F.R. Goodman², C.A. Johnson¹.* 1) Medical and Molecular Genetics, University of Birmingham, Birmingham, W. Midlands, UK; 2) Molecular Medicine Unit, Institute of Child Health, London, UK; 3) Dipartimento di Scienze Pediatriche e dell'Adolescenza, Università degli Studi di Torino, Torino, Italy; 4) Department of Human Genetics, University Hospital Nijmegen, Nijmegen, The Netherlands; 5) Department of Clinical & Molecular Genetics, Institute of Child Health, London, UK; 6) Clinical Genetics Unit, Birmingham Womens Hospital, Birmingham, UK; 7) Division of Medical Genetics, University of Leicester, Leicester, UK.

Jeune asphyxiating thoracic dystrophy (JATD; MIM No 208500) is a rare recessively-inherited malformation syndrome characterised by both skeletal and extra-skeletal involvement. Skeletal abnormalities include a small narrow thorax, shortening of the ribs and long bones, metaphyseal irregularities and occasional postaxial polydactyly. Renal, hepatic, pancreatic and retinal abnormalities may also occur. Severely affected infants often die in the neonatal period from respiratory insufficiency, and chronic renal failure is common in those patients who survive. The molecular basis of JATD is at present unknown. A similar phenotype occurs in Ellis-van Creveld syndrome, and has been reported in one case with a de novo deletion of 12p11-p12. JATD may therefore result from mutations in the EVC gene, or in a gene located on chromosome 12p. A possible mouse model of JATD, the shorty (srt) mutant, has also recently been identified through an ENU mutagenesis screen. We have ascertained 6 consanguineous JATD families (3 from Pakistan, 2 from Italy and 1 from Holland) for linkage studies. 2 families have 2 affected children. In all 6 families, haplotype analysis has excluded linkage to the EVC gene, to chromosome 12p, and to the chromosomal regions that are syntenic to the 7 cM interval on mouse chromosome 17 to which srt has been mapped. To identify loci linked to JATD, we have therefore adopted an autozygosity mapping approach and are currently carrying out a genome-wide linkage screen of the 8 affected children.

A novel locus for Meckel-Gruber syndrome, MKS3, maps to chromosome 8q24. *C.A. Johnson¹, N.V. Morgan¹, P. Gissen^{1,2}, S. Malik Sharif³, L. Baumber⁴, J. Sutherland⁴, D.A Kelly², K. Aminu⁴, C.P. Bennett⁵, C.G. Woods³, R.F. Mueller^{3,5}, R.C. Trembath⁴, E.R. Maher¹.* 1) Medical & Molecular Genetics, University of Birmingham, Birmingham, W. Midlands, UK; 2) Children's Liver Unit, Princess of Wales Children's Hospital, Steelhouse Lane, Birmingham, UK; 3) Department of Clinical Genetics, Yorkshire Regional Genetics Service, St. James's University Hospital, Beckett Street, Leeds, UK; 4) Division of Medical Genetics, Departments of Medicine and Genetics, University of Leicester, Leicester, UK; 5) Molecular Medicine Unit, University of Leeds, St. James's University Hospital, Leeds, UK.

Meckel-Gruber syndrome (MKS), the most common monogenic cause of neural tube defects, is an autosomal recessive disorder characterized by a combination of renal cysts and variably associated features, including developmental anomalies of the central nervous system (typically encephalcoele), hepatic ductal dysplasia and cysts, and polydactyly. Locus heterogeneity has been demonstrated by the mapping of the MKS1 locus to 17q21-24 in Finnish kindreds, and of MKS2 to 11q13 in North African-Middle Eastern cohorts. In the present study, we have investigated the genetic basis of MKS in eight consanguineous kindreds, originating from the Indian subcontinent, that do not show linkage to either MKS1 or MKS2. We report the localization of a third MKS locus (MKS3) to chromosome 8q24 in this cohort by a genome-wide linkage search using autozygosity mapping. We identified a 26 cM region of autozygosity between D8S586 and D8S1108 with a maximum two-point LOD score at D8S1179. A heterogeneity test provided evidence of one unlinked family. Exclusion of this family from multipoint analysis maximized the multipoint LOD score at locus D8S1128 ($Z_{\max} = 5.65$). Furthermore, a heterozygous SNP in DDEF1, a putative candidate gene, suggested that MKS3 mapped within a 15 cM interval. Comparison of the clinical features of MKS3-linked cases with reports of MKS1- and MKS2-linked kindreds suggests that polydactyly (and possibly encephalocele) appear less common in MKS3-linked families.

Familial Venous-occlusive disease of the liver with immunodeficiency: homozygosity mapping and call for patients.

T. Roscioli¹, M.F. Buckley¹, E. Kirk², D. Isaacs³, M. Wong³, J. Ziegler⁴, R. Lindeman¹. 1) Centre for Thrombosis and Vascular Biology, University of NSW, Sydney, Australia; 2) Department of Medical Genetics, Sydney Childrens Hospital, Randwick, Sydney, Australia; 3) Department of Immunology and Infectious disease, The Childrens Hospital, Westmead, Australia; 4) Department of Immunology and Infectious disease, Sydney Childrens Hospital, Randwick, Sydney, Australia.

We present three families of Middle Eastern origin (Mellis et al, 1976, Wong et al., in review) with an apparently heritable form of venous-occlusive disease of the liver with immunodeficiency (VODI) requiring treatment with intravenous immunoglobulin. Multiple consanguinity in two families with common ethnic origins suggests the presence of a causative autosomal recessive gene. Familial forms of this condition have not appeared in the literature subsequent to the initial reports. These families therefore represent a unique resource to aid in the genetic mapping of VODI. Venous-occlusive disease of the liver (VODL) consists of fibrous concentric narrowing/obliteration of zone 3 terminal hepatic venules with subsequent damage to centrilobular hepatocytes (Shulman et al., 1980, Valla et al., 1991). This histological appearance was first described in VODL secondary to ingestion of beverages containing pyrrolizidine alkaloids (Selzer et al., 1951). VODL has subsequently been reported with the ingestion of alcohol, toxins, the oral contraceptive, antineoplastic medications and hepatic irradiation. VODL is now most often seen within twenty days of a post bone marrow transplant. This cohort of consanguineous families with a common ethnic origin allows the opportunity to identify regions of homozygosity in affected individuals via homozygosity mapping. Identification of such regions may allow a candidate gene approach to identify a genetic aetiology for VODI. Identification of the genetic basis for VODI could lead to therapies for a life threatening complication of bone marrow transplantation. A genome wide scan is currently in progress.

***SMADIP1* is not a major gene in isolated agenesis of the corpus callosum.** *Y. Espinosa-Parrilla, F. Encha-Razavi, T. Atti-Bitach, P. Gosset, A. Munnich, M. Vekemans, S. Lyonnet, J. Amiel.* Department of Genetics, INSERM U-393. Hpital Necker-Enfants Malades, Paris, France.

Mutations of the smad binding protein 1 gene (*SMADIP1*, MIM 605802) result in a polytopic embryonic defect (Lurie-Mowat syndrome, MIM 235730), including facial dysmorphism, mental retardation, epilepsy and postnatal microcephaly as consistent features. However, frequent additional abnormalities include enteric nervous system malformation (Hirschsprung disease), agenesis of the corpus callosum (ACC), cardiac defects, renal abnormalities, and hypospadias. Among this broad spectrum of malformations ascribed to *SMADIP1* haploinsufficiency, ACC is the only feature that can be detected antenatally. In order to investigate whether the *SMADIP1* gene may be a major gene in ACC, we searched for *SMADIP1* deletions or mutations in a total of 8 fetuses collected from legally terminated pregnancies (16-36 weeks of gestation) after diagnosis of ACC by antenatal echography survey and normal chromosomal analyses (RTBG, 400 bands resolution). In addition, a significant proportion of cases presented cardiac defects (3/8) and/or urogenital anomalies (2/8). Screening for *SMADIP1* deletions was performed both by poly (CA) microsatellite markers flanking *SMADIP1* and by real-time semiquantitative PCR. Point mutation detection was performed by SSCP of the whole gene coding sequence. Neither deletions encompassing the *SMADIP1* gene, nor mutations could be detected. These results exclude the *SMADIP1* gene as a major gene in ACC.

Further molecular characterization of a boy with Sotos syndrome and partial trisomy of the long arm of chromosome 7. B.A. Fernandez¹, L. Penney¹, C. Prasad², S. Moore¹, I. Teshima³, K. Nakabayashi³, S.W. Scherer³. 1) Discipline of Genetics, Faculty of Medicine, Memorial University of Newfoundland, St John's, NF, Canada; 2) Dept of Child Health and Pediatrics, Childrens Hospital, Winnipeg, MB, Canada; 3) Dept of Genetics, The Hospital for Sick Children, Toronto, ON, Canada.

Sotos syndrome (OMIM # 117550) is characterized by overgrowth, advanced bone age, developmental delay and particular facial features. Most cases are sporadic, although autosomal dominant pedigrees have been reported. Recently *NSDI* was isolated from the 5q35 breakpoint of an individual with Sotos syndrome. Haploinsufficiency of *NSDI* appears to be a major cause of the syndrome, but genetic heterogeneity is believed to exist. A limited number of affected individuals with other cytogenetic abnormalities have been described; none of these has involved chromosome 7.

We report a 16 year-old boy with Sotos syndrome and an unbalanced karyotype. Bilateral cryptorchidism was noted at birth, and he was large for gestational age. He now has macrocephaly, with height at the 95th percentile and weight at the 75th percentile. He has global developmental delay, and functions at an 8-year level. His features include frontoparietal balding, a prominent chin, and disproportionately large hands. Brain MRI showed mild cerebral ventriculomegaly. DNA testing for Fragile X syndrome was negative, as was his family history.

Routine and spectral karyotyping revealed a *de novo* unbalanced karyotype with partial trisomy of 7q [46,XYder(14)t(7;14)(q32~34;p12~13)]. FISH studies delineated a trisomic segment extending from 7q35-qter. BACs from 7q35 (NH413B12 and CIT2572A14), as well as a BAC containing *D7S427* from 7q36, all showed trisomic signals. STR analysis to determine the parent-of-origin of the trisomic segment are in progress, and the *NSDI* locus will be examined to determine whether or not it is intact. The association of Sotos syndrome with partial trisomy of 7q suggests that this syndrome may sometimes be due to a dosage effect of one or more genes from this region.

Exclusion of the transcriptional repressor *SALL1* as a candidate gene in Branchio-oculo-facial syndrome. W.

*Just*¹, *D. Müller*², *T. Trautmann*¹, *A. Baumstark*¹. 1) Dept Human Genetics, Universitätsklinikum Ulm, Ulm, Germany; 2) Klinikum Chemnitz, Säuglingsklinik, Chemnitz, Germany.

Branchio-oculo-facial syndrome (BOF; MIM 113620); is a rare autosomal dominant disorder. The symptoms of this disorder include bilateral postauricular cervical branchial sinus defects with hemangiomatous, scarred skin, cleft lip with or without cleft palate, pseudocleft of the upper lip, nasolacrimal duct obstruction, low set ears with posterior rotation, a malformed, asymmetric nose with broad bridge and flattened tip, and -occasionally- prematurely gray hair. Previous attempts to associate the phenotype with a candidate gene excluded the members 1-4 of the *EYA* (eyes abSENT) gene family. It was also shown that the similar branchio-otic and branchio-oto-renal syndromes are not allelic with BOFS. Recent findings about the expression of *SALL1* in the developing brain and the limbs suggested that this transcriptional repressor might be a candidate gene for BOF syndrome. *SALL1* is the gene mutated in Townes-Brocks syndrome (MIM: 107480), another syndrome with sensorineural hearing loss, urogenital anomalies, and preauricular protuberances. The overlapping symptoms prompted a study of *SALL1* as a candidate gene for BOF syndrome. We studied the cosegregation of *SALL1* alleles with the phenotype in a three generation family with five affected members. This is the largest pedigree with BOF syndrome reported until now. For that purpose we analyzed highly polymorphic dinucleotide repeat markers in an interval of 26 Mbp on chromosome 16. In an interval of 7.2 Mbp, where *SALL1* maps, we excluded cosegregation of alleles with the phenotype and thus present evidence that *SALL1* is not a candidate gene for BOF syndrome.

PHENOTYPICAL ANALYSIS OF AN AFFECTED POPULATION WITH WAARDENBURG SYNDROME IN COLOMBIA. *M. Rodriguez, N. Gelvez, M.C. Lattig, M. Tamayo.* Instituto de Genetica Humana, Facultad de Medicina, Universidad Javeiana, Bogota, Colombia.

Waardenburg Syndrome (WS) is characterized by hypopigmentation (hair, eyes and skin), deafness, broad nasal root and dystopia canthorum. The lateral displacement of the inner canthi of the eyes, classify this syndrome in WS type 1 (presence of the dystopia) and WS type 2 (absent of the dystopia). It is an autosomal dominant disorder with remarkable clinical and genetic heterogeneity. The purpose of this study was to expand the clinical knowledge on Waardenburg Syndrome (WS). We evaluated 138 individuals with Waardenburg Syndrome (93 propositus and 45 affected relatives) and carry out ophthalmological, audiological and genetic evaluation, to establish the phenotypic variability in our Colombian affected population. The most frequent phenotypic feature among affected individuals, was sensorineural deafness (80.5%), followed by broad nasal root (60.1%), white forelock (31.8%), synophrys (28.2%), heterochromia irides (25.3%), skin hypopigmentation (23.1%), blue intense iris (13.7%), parpebral ptosis (12.3%), and premature gray (8.7%). Curiously, we found a very low frequency of refractive errors. With regards to the kind of deafness we defined a profound and bilateral sensorineural deafness in the 63.7%, unilateral sensorineural in the 5.9% and, asymmetrical sensorineural in the 10.9%. The remaining 19.5% had normal hearing. Neurological development was normal in the 86.8% and abnormal in the 13.2%. We emphasize that not all of the affected individuals showed a complete set of clinical findings for Waardenburg Syndrome. In our study, the propositus were found to have 2 or 3 typical characteristics, while their relatives of them presented only one. This fact, makes the diagnosis more difficult and remarks the necessity to improve a complete familial study in each affected individual. Our information about phenotypic characteristics of the syndrome, confirm intra and inter familial clinical variability, and the researcher must be aware of this fact in order to make a correct clinical diagnosis and give to patients an adequate genetic counseling.

Analysis of genes deleted in Williams syndrome based on measurement of gene copy number by real-time PCR.

M.J. Park¹, E.J. Seo^{1,2}, S.M. Park¹, Y.O. Yoo¹, Y.H. Kim^{1,3}, J.K. Ko^{1,3}, H.W. Yoo^{1,3}, I.S. Park^{1,3}. 1) Genome Research Center, Asan Medical Center, Seoul, Korea; 2) Dept. of Clinical Pathology, University of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea; 3) Dept. of Pediatrics, University of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea.

Williams syndrome (WS) is a contiguous gene syndrome with variable phenotypic expression caused by a submicroscopic deletion at 7q11.23 that involve several genes, including elastin(ELN), LIMK1, syntaxin 1A(STX1A), and FZD. Haploinsufficiency for these genes in the deletion causes the WS phenotype and variability in the phenotype could be due to the heterogeneity of size and location of the deletion breakpoints. We have investigated the size of the deletions and defined the deleted map of the critical region from 27 patients with classical WS. Conventional methods to detect the haploinsufficiency include southern blots, pulsed-field gel electrophoresis, fluorescence in situ hybridization and analysis of polymorphic markers. However these methodologies are time-consuming and labor-intensive. In this study, we used a real-time quantitative PCR assay to assess gene copy number for detection of haploinsufficiency on WS regions. Six genes which are CNDL4, FZD4, STX1A, ELN, LIMK1, and WBSCR23 were analyzed by using TaqMan probes specific to each genes and the comparative CT method. Twenty-four patients had a deletion beginning from CNDL4.

Molecular analysis of EEC and related syndromes: Rapp-Hodgkin syndrome is due to mutations in P63. I.

*Dianzani*¹, *E. Garelli*², *V. Cavallo*², *A. Carando*², *B. Gustafsson*³, *P. Gustavsson*⁴, *N. Dahl*⁴, *G. Annerén*⁴. 1) Dept Medical Sciences, Univ. Piemonte Orientale, Novara, Italy; 2) Dpt. Pediatric Sciences, Univ. Torino, Italy; 3) Karolinska Institute, Stockholm, Sweden; 4) Dept. Genetics and Pathology, Uppsala University, Sweden.

Mutations in P63 have been identified in several malformative syndromes, most of which are characterized by ectodermal dysplasia. An apparent conclusive genotype-phenotype correlation has been observed. EEC (ectodermal dysplasia, ectrodactily, lip/palate cleft: MIM 604292) and split-hand/foot malformation (SHFM: MIM 183600) are caused by mutations affecting the DNA binding domain of the p63 protein, whereas ankyloblefaron-ectodermal dysplasia-cleft (AEC: MIM 106260) is caused by mutations affecting the SAM domain and limb-mammary syndrome (LM: MIM 603543) is caused by frameshift mutations in exon 13-14. The aim of our study has been to characterise three multiplex families: two had EEC, one had Rapp-Hodgkin syndrome (RH, cleft lip/palate and ectodermal dysplasia: MIM 129400). Segregation of 3q highly polymorphic markers (D3S3530 and D3S1294) showed concordant segregation with the disease in all the families. Causal mutations were found in the three families. Mutations showed concordant segregation with the disease in the three families. EEC families carried mutations in the DNA binding domain of p63 (R279C, R304Q). These mutations are recurrent mutations since they have been found in several unrelated families, so far. Our data show that RH syndrome is due by a defect in P63. The mutation, which is new, is located in exon 14 and is a frameshift mutation (1860DelA). All the frameshift mutations identified so far in this region were present in patients with limb-mammary syndrome. The patients in our family have normal nipples and the affected mother has breast-fed her children. The hypothesis of a conclusive genotype-phenotype correlation as previously reported has not been completely supported by our data.

Type II methemoglobinemia: a novel mutation in NADH-cytochrome b5 reductase. *M. Galdzicka¹, P.E. Newburger², L.A. Demmer², S. Patnala¹, J.F. Cai¹, M.G. Hirshman¹, E.I. Ginns¹.* 1) Brudnick Neuropsychiatric Research Institute, Dept. of Psychiatry, Univ. of Massachusetts Medical School, Worcester, MA; 2) Dept. of Pediatrics, Univ. of Massachusetts Medical School, Worcester, MA.

Autosomal recessive methemoglobinemia is characterized by a decreased activity of either NADH-Cytochrome b5 reductase (b5R; DIA1) or of cytochrome b5. In type I the enzyme deficiency is limited to red cells, while in type II it is present in all tissues and involves both the soluble and microsomal forms of the enzyme. Individuals with type I methemoglobinemia have clinical manifestations limited to their hematopoietic system, while those with type II methemoglobinemia have a severe course with profound mental retardation and progressive neurological manifestations. In this report, we describe the clinical and molecular findings in a girl with type II methemoglobinemia.

Baby girl HL presented with severe neonatal methemoglobinemia, with up to 25% methemoglobin in the first week of life. NADH-Cytochrome b5 reductase (b5R) activity was 1 IU/gram hemoglobin (normal range 6-12 IU/gram) in her peripheral blood erythrocytes at age 27days. At her present age of 11 months, she has chronic mild methemoglobinemia (9%). On examination she is severely developmentally delayed with microcephaly and hypotonia.

The gene for DIA1 is located on chromosome 22 and is 31kb in size. It contains 9 exons (1922bp) and 8 introns, encoding a protein of 301 amino acids. The 5'UTR of 58bp is in exon 1 and the 3'UTR of 958bp is in exon 9. Sequence analysis of all 9 exons and exon/intron junctions of gene in the patient and her mother revealed a novel mutation, deletion of a G in exon 5, that was homozygous and heterozygous in the child and mother, respectively. This deletion of G in exon 5 results in a stop codon in exon 6, truncating the enzyme at 177 amino acids. The mutation identified in our patient supports the previous suggestion that methemoglobinemia type II is more often associated with full stops or deletions in the gene, while in type I disease, missense mutations are more frequently observed.

Genotype Governs the Clinical Spectrum of Neuroserpinopathy. *F.L. Lacbawan*^{1,2}, *R.L. Davis*³, *G.H. Collins*³, *P. Kent*⁵, *P.D. Holohan*⁴, *A.E Shrimpton*³, *M. Muenke*², *D. Krasnewich*². 1) Medical Genetics, Children's Natl Med Ctr, GWU, Washington DC; 2) Medical Genetics Br, NHGRI, NIH Bethesda MD; 3) Pathology; 4) Pharmacology; 5) Neurology, SUNY Upstate Medical University, Syracuse NY.

Neuroserpin is a brain-associated inhibitor of tissue plasminogen activator involved in modulating cell migration, axon outgrowth and synaptic plasticity. After our report of the first mutations S49P and S52R in Familial Encephalopathy with Neuroserpin Inclusion Bodies (FENIB) (Davis et al., 1999a, 1999b), S52R (Takao, et al., 2000), G392E and H338R (Davis, et al., 2002) were reported. These mutations in the shutter region cause misfolding and accumulation of mutant neuroserpin (Collins bodies) in the neurons of the cortex and subcortical structures because of loop-sheet polymerization similar to the α -1-antitrypsin variants. The loss of inhibitory function of S49P mutant has been clearly demonstrated (Belorgey, et al., 2002). However, we have presented strong evidence that the inclusion-body formation is a sufficient cause of neurodegeneration as supported by the direct correlation of the rate and magnitude of protein aggregation and the onset and severity of the disorder (Davis, et al., 2002). As a consequence of the severe degree of molecular instability, G392E>H338R>S52R> S49P, the G392E patient died at 19 years of age. Multiple grape-like Collins bodies are noted and progressive myoclonic epilepsy (PME) presented as cognitive delay and generalized seizures initially at age 13 years. In contrast, review of medical records of the seven affected members of the original family with S49P revealed onset at the fifth decade of life with course of about 16 years. Collins bodies are rarely in clusters with dementia as the predominant manifestation with variable extrapyramidal and frontal lobe symptoms and seldom seizures. PME is more common in children and young adults as opposed to dementia in older adults. Despite some clinical heterogeneity that exists within the same genotype, the genotype still dictates the onset and severity of this conformational disease. Hence, it must be an essential differential diagnosis for patients of any age presenting with cognitive delay, seizures, myoclonus, and/or early-onset dementia.

Program Nr: 654 from 2002 ASHG Annual Meeting

Friedreich's Ataxia mimicking Hereditary Motor and Sensory Neuropathy. *M. Panas, N. Kalfakis, G. Karadima, P. Davaki, D. Vassilopoulos.* Dept Neurology, Athens National University, Athens, Greece.

Four patients from three unrelated families, with clinical and electrophysiological findings compatible with the diagnosis of hereditary motor and sensory neuropathy, are presented. The molecular analysis showed that the affected individuals were homozygous for the mutation in the X25 gene, characteristic of Friedreich's ataxia. These patients seem to represent a form of Friedreich's ataxia mimicking Charcot-Marie-Tooth disease.

Sensitivity and Specificity of the clinical diagnosis of spinocerebellar ataxias compared to molecular diagnosis.

*A.O. Rasmussen*¹, *M. Fragoso-Benitez*². 1) Dept Neurogenetics, Inst Nacl Neurologia y Neuroci, Mexico City, Mexico; 2) Mexican Faculty of Medicine, Universidad La Salle, Mexico City, Mexico.

The spinocerebellar ataxias are a clinically and genetically heterogeneous group of diseases, with 16 assigned loci. The diagnosis of an individual with ataxia is based on molecular testing, available for 9 SCAs: 1, 2, 3, 6, 7, 8, 10, 12 and 17. One of the difficulties encountered in a clinical setting is that the phenotypic overlap of the different SCAs often makes it necessary to perform the complete ataxia testing panel, implying an elevated cost that may be unaffordable for low-income populations, e.g. in Developing Countries. A more rational approach would be focused-testing based on a presumptive clinical diagnosis. We analyzed a cohort of 94 Mexican SCA patients: a presumptive clinical diagnosis was made by a blind observer and was later compared to the results of the molecular test. Clinical suspicion was helpful in the identification of SCA7, SCA10 and probably SCA17, but we were unsuccessful in the classification of SCA1, 2, 3, 6, 8 and 12. We suggest that a rational approach to molecular testing would be to test for SCA7, SCA10 or SCA17 when a strong clinical suspicion exists, and then to test according to the prevalence of each SCA in a given population.

Financed by CONACYT M30790.

Phenotypic diversity in human malformation syndromes are modifier genes important? *A.M. Slavotinek*. Bldg 49, Rm 4B75, NHGRI/NIH, Bethesda, MD.

It has proven difficult to establish phenotype-genotype correlations for human malformation syndromes. The role of modifier genes in phenotypic variation has most clearly been established for metabolic diseases such as cystic fibrosis and phenylketonuria. Recently, complex inheritance patterns including modifier genes have been described for syndromes and malformations, including triallelic inheritance in Bardet-Biedl syndrome and oligogenic inheritance in Hirschsprung disease. It can therefore be hypothesized that modifier genes are underestimated as determinants of phenotypic variability in human malformation syndromes. Published case reports of two autosomal recessive syndromes were examined, one syndrome with a relatively specific phenotype (Robinow syndrome [RS]; 71 cases) and one showing greater phenotypic variation with heterozygote manifestations and overlap with other syndromes (Ellis-van Creveld syndrome [EVC]; 66 cases). The data include an incidence of consanguinity of 43.2% in RS and 45.3% in EVC. In RS, five out of eight sib pairs were discordant for at least one of the four cardinal phenotypic features of short stature (SS), fetal facies, mesomelic shortening and genital hypoplasia (GH). Two of these four sib pairs were also discordant for SS. In EVC, four out of fifteen sib pairs were discordant for congenital heart disease but concordant for the remaining diagnostic features of chondrodystrophy, ectodermal dysplasia and postaxial polydactyly. Assuming that the sib pairs have inherited the same disease causing mutation(s), the phenotypic discordance can be explained by the effect of modifier genes on specific clinical features in these syndromes, with the implication that recurrence risks may be variable for physical traits within malformation syndromes.

Delineation of a novel 5q35.3 microdeletion syndrome. *A.M. Rauch¹, M. Beese², H.G. Doerr², E. Mayatepek³, D. Wenzel², U. Trautmann¹.* 1) Institute of Human Genetics, Friedrich-Alexander University, Erlangen, Germany; 2) Department of Pediatrics, Friedrich-Alexander University, Erlangen, Germany; 3) Department of Pediatrics, University Heidelberg, Germany.

Recently 2.2 Mbp-microdeletions within chromosomal band 5q35 were identified as major cause of Sotos syndrome, an overgrowth syndrome with characteristic facial appearance, hypotonia and developmental delay (Kurotaki et al. 2002, Nat Genet 30:365-366). However, a patient with subtle cytogenetically visible deletion 5q35.3 in addition to overgrowth, hypotonia and mild developmental delay showed a short neck with nuchal edema, bell-shaped chest, and a very flat nasal bridge with epicanthus and large, retroverted ears (Stratton et al. 1994, Am J Med Genet 51:150-152). We observed a further patient with a very similar phenotype including short neck with nuchal edema, bell-shaped chest, a very flat nasal bridge with epicanthus and large, retroverted ears, but instead of overgrowth and advanced bone age presenting with shortness of stature and delayed ossification with huge anterior fontanel. Despite pronounced hypotonia and delayed motor development, speech development was within normal limits. While karyotyping after GTG banding showed normal results on a 850 bands level, subtelomeric analysis revealed a cryptic terminal 5q35.3 deletion. Further delineation of the deletion size with additional BAC clones showed a 3 Mbp-microdeletion distally adjacent to the Sotos syndrome deletion site. The phenotype of the patient described by Stratton et al. can now be explained as a compound phenotype of Sotos and the novel distal 5q35.3 microdeletion syndrome. As the Sotos syndrome microdeletion commonly occurs within the same boundaries, flanking low copy repeat regions are likely. Because the breakpoint of our patient is at the site of the assumed distally located low copy repeat, this novel microdeletion syndrome may occur more commonly. This syndrome will be of major impact also for prenatal diagnostics, as the nuchal edema in our patient was recognized in early pregnancy by increased fetal nuchal translucency.

Hoyeraal-Hreidarsson (HH) syndrome in three children. *Y. Sznajer¹, Cl. Baumann¹, F. Mechinaud³, A. David³, H. Journel⁴, D. Genevive¹, M. Raoul¹, M. Dumont², J-F. Segura², J-P. Cezard², T. Vulliamy⁵, I. Dokal⁵, A. Verloes¹.* 1) Clinical Genetics, Hôpital Robert Debré, Paris, France; 2) Department of Gastroenterology Hôpital Robert Debré, Paris, France; 3) Department of Clinical Genetics, Hôpital Mère Enfant, Nantes France; 4) Department of Clinical Genetics, Vannes, France; 5) Department of Haematology, Imperial College of Sciences, Technology and Medicine, Hammersmith Hospital, London, England.

Hoyeraal-Hreidarsson syndrome - a severe variant of X-linked dyskeratosis congenita - is characterized by Intra Uterine Growth Retardation (IUGR), cerebellar hypoplasia, microcephaly, immunodeficiency and aplastic anemia. We report on three patients with HH syndrome. Two brothers from unrelated parents presented IUGR. There was no family history. They developed failure to thrive with chronic diarrhea during the first year of life. Skin depigmentation, hair loss, mouth and tongue ulcerations and nail dystrophy were noted. They developed thrombopenia and pancytopenia. Patient 3, fourth child from a healthy mother, had severe IUGR. At the age of 7 months, he developed a first episode of mastoiditis and diarrhea. Aplastic anemia, thrombopenia and then pancytopenia were noted. In the first two patients, on bowel biopsies, epithelium was unusually dystrophic and atrophic; exsudative phenomena and microkystic glandular changes were found in all three. Brain Magnetic Resonance Imaging showed cerebellar atrophy in all three cases. They all died before the age of five. PCR Amplification followed by restriction enzyme digestion indicated a mutation (hemizygous) of DKC 1 gene (146 - C to T) in patient one and two as for their mother. In patient three, the analysis did not show any mutation. Our three patients developed HH syndrome. This was confirmed by mutation analysis in the first two cases and facilitated the genetic counselling. Not all cases of HH syndrome are identified by mutation analysis and this may account for possible genetic transmission heterogeneity.

Endocrine studies in subjects with Prader-Willi syndrome and simple obesity. *M.G. Butler¹, K. Kibiryeveva¹, D. Bittel¹, Z. Talebizadeh¹, T. Thompson².* 1) Childrens Mercy Hospital and University of Missouri Kansas City School of Medicine, Kansas City, MO; 2) University of Kansas Medical Center, Kansas City, KS.

Prader-Willi syndrome (PWS) is usually due to a 15q1-q13 deletion or maternal disomy 15 (UPD). Features in this syndrome can overlap with hypothyroidism or growth hormone deficiency. We analyzed thyroid and endocrine data in 48 PWS subjects (27 females, 21 males; 27 deletion, 21 UPD; mean age + SD = 22.9 + 8.5y) and 29 obese comparison subjects (20 females, 9 males; mean age + SD = 27.1 + 12.9y). No difference was seen in thyroid stimulating hormone levels between PWS or obese groups (2.2 + 1.3 vs 2.2 + 1.6 mcu/ml, respectively) or between PWS-deletion or PWS-UPD (2.4 + 1.5 vs 2.0 + 0.9 mcu/ml, respectively); however, significantly lower T3 levels were observed in the PWS group compared with obese (136 + 37 vs 158 + 32 ng/dl; $p = 0.02$, respectively). Free thyroxine levels were significantly lower in PWS compared with obese (1.12 + 0.21 vs 1.32 + 0.57 ng/dl; $p=0.04$, respectively) while total thyroxine levels were significantly lower but only in PWS females compared with obese females (7.86 + 2.14 vs 9.97 + 2.63ng/dl; $p=0.01$, respectively). Testosterone levels were lower in PWS males compared with obese males (1.27 + 1.02 vs 2.79 + 1.66ng/ml; $p = 0.01$, respectively) but no difference was found in the PWS-deletion or UPD. Estrogen levels were lower in PWS females than obese females (28.5 + 16.1 vs 74.1 + 55.9pg/ml; $p = 0.001$, respectively). Follicle stimulating hormone levels were similar in the PWS or obese groups but leutinizing hormone was lower in PWS compared with obese (1.9 + 1.8 vs 4.0 + 4.7miu/ml; $p = 0.01$, respectively) and a significant difference found in PWS females compared with obese females (1.5 + 1.3 vs 4.7 + 5.9miu/ml; $p = 0.01$, respectively). Growth hormone (GH) levels were low in both groups (PWS 0.74 + 0.16 vs obese 0.64 + 0.14ng/ml). Plasma IGF-I levels were significantly lower in PWS compared with obese (122 + 15 vs 174 + 21ng/ml; $p<0.05$, respectively) indicating GH deficiency [78% of PWS subjects had IGF-I levels < 10%ile for age compared with 43% of obese controls ($p<0.05$)]. GH is an important mediator for adipose tissue lipolysis and fat oxidation.

Multiple Sclerosis in an Individual with Maternal Uniparental Isodisomy for Chromosome 14. *V.R. Sutton¹, J.M. Greally², L.G. Shaffer¹*. 1) Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Departments of Medicine and Molecular Genetics, Albert Einstein College of Medicine, Bronx, NY.

Our 32 year old, previously-reported patient with maternal uniparental disomy for chromosome 14 (UPD 14) is the oldest known individual with this disorder. She recently has been diagnosed with multiple sclerosis (MS) based on MRI white matter changes and presence of oligoclonal bands in the cerebrospinal fluid. Both the T-cell receptor (TCR) alpha chain and TCR delta chain (nested within the alpha chain) are encoded by genes located on 14q11.2. Expression of TCRs occurs in a very specific order and determines which T-cells express alpha/beta TCRs and which express delta/gamma TCRs. We hypothesize that this region containing the alpha and delta TCRs may be subject to parent of origin effects and that maternal UPD 14 could alter the normal sequence of TCR rearrangement and expression. A scan of the DNA content across the region shows a trough of SINE content and locally high L1 content. This combination can indicate a paternally-expressed imprinted region. We hypothesize that over-expression of some relevant TCRs may have occurred at some critical time point, perhaps in the thymus, and this could then have resulted in abnormalities of tolerance mechanisms eventually leading to an autoimmune disease. We present clinical information, data on the SINE content of the region and a detailed analysis of the possible mechanisms whereby maternal UPD 14 could result in autoimmunity.

Pilot study to assess diabetic nephropathy in the HBDI collection of diabetic sib pairs. *J. Sowinski¹, K. Gogolin Ewens², C.A. Henry¹, R.S. Spielman².* 1) NDRI/HBDI, Philadelphia PA; 2) Dept of Genetics, Univ of Pennsylvania School of Medicine, Philadelphia, PA.

We have carried out a pilot study to re-contact diabetic offspring in 45 families that are part of the HBDI collection of multiplex families identified on questionnaires as having diabetic nephropathy (DN). This collection is especially valuable since DNA has already been collected and banked for all parents and diabetic siblings. In addition, the long duration of diabetes (mean=24.6 years) makes most offspring informative for DN or absence of DN despite long-term diabetes. Updated medical information, including the presence of end stage renal disease (ESRD) and information on relevant medications (ACE inhibitors and AGTR1 blockers), was obtained from 93 (82%) of 113 diabetic offspring in the 45 families. DN status was determined by measuring the albumin/creatinine ratio (ACR) in two or three spot urine samples collected at least 6 weeks apart. Phenotypes were assigned as DN (ESRD or overt proteinuria with ACR >300 mg/mg), or unaffected for DN (normoalbuminuria with ACR <30 mg/mg, duration of diabetes >15 years and not taking any relevant medications). Diabetic individuals with duration <15 years, ACR 30-300ug/mg or ACR <30 mg/mg but taking relevant medications could not be classified into either group.

Of the 93 individuals studied, 34 (37%) were affected with DN and 18 (19%) unaffected with DN; 27 (29%) could not be classified into either group. Fourteen individuals (15%) are still of unknown status. Thus we are currently able to assign a nephropathy phenotype (affected or unaffected) to 56% of the individuals in this study, and expect that number to reach 65-70% when the project is completed. Based on the results of this pilot study, we are now beginning to re-contact 390 families in the HBDI collection for whom contact information is available. We expect that we will be able to assign informative nephropathy phenotypes to at least 200-250 diabetic families, which will significantly increase the number of trios and multiplex families available for studies of the genetics of diabetic kidney complications.

HENNEKAM SYNDROME PRESENTING AS NONIMMUNE HYDROPS FETALIS, CONGENITAL CHYLOTHORAX, AND CONGENITAL PULMONARY LYMPHANGIECTASIA. *C. Bellini, M. Mazzella, C. Arioni, G. Serra.* Servizio Patologia Neonatale, Universita Genova, Istituto Gaslini, Genova, Italia.

Case Report. During pregnancy polyhydramnios had become evident at 30 weeks of gestation. At birth (33 weeks) respiratory problems due to hydrops fetalis urged immediate intubation, artificial ventilation, and surgical draining; a chylothorax was diagnosed. Physical examination showed a flat face, epicanthal folds, a broad, depressed nasal bridge, a bulbous nasal tip. Generalized lymphedema was evident. Laboratory examinations showed hypoproteinemia and hypogammaglobulinemia. Repeated examinations of faecal excretion of alpha-1-antitrypsin showed elevated values (550 to 650/gr wet), suggesting intestinal lymphangiectasia. Chromosome studies (46, XX), TORCH titer, plasmatic 7-dehydrocholesterol level, renal and cardiac ultrasonography, gave normal results. High Resolution Computed Tomography at 45 days of age confirmed pulmonary lymphangiectasia. At the age of 55 days radionuclide lymphoscintigraphy of hands and feet showed abnormal drainage of the lower limb and the thoracic duct. Initial dermal back-flow was evident in the distal hand and foot. Back-flow within the thoracic duct was evident. In 1989, Hennekam and co-workers reported a new autosomal recessive entity (OMIM 235510) characterized by lymphedema of limbs, genitalia and face, secondary facial dysmorphic features, intestinal lymphangiectasia, and varying degrees of mental retardation. Since the first report 24 patients have been described. Here we report on a newborn girl with this entity who presented with nonimmune hydrops fetalis, and was found to have a congenital chylothorax and pulmonary lymphangiectasia. Generalized maldevelopment of the lymphatic system is the main characteristic of the syndrome, preferentially affecting intestines, limbs, genitalia, but it can also affect the pleura, pericardium, thyroid gland, kidneys. Pleural lymph vessel anomalies have been reported in 7/21 cases. An important point of this work is the original demonstration obtained by lymphoscintigraphic study of the direct involvement of the thoracic duct in the pathogenesis of nonimmune hydrops fetalis, chylothorax, and pulmonary lymphangiectasia.

Altered lung function in Fabry's Disease (FD). *S. Magage, A. Linhart, J.C. Lubanda, Z. Susa, J. Bultas, D. Karetova, M. Elleder, J. Zeman.* Cardiology, Charles University, Prague, Czech Republic.

Background: Fabry disease is an X-linked hereditary metabolic disorder caused by deficient levels of the lysosomal enzyme α -galactosidase A leading to intracellular accumulation of neutral glycosphingolipids within many organ systems. Bronchopulmonary involvement has been reported but pulmonary function findings were never compared to a control population.

Objectives: To compare spirometric values obtained in patients with confirmed Fabry disease with healthy volunteers.

Materials and methods: Spirometry was performed in 50 Fabry disease patients (23 males and 27 females), and in 50 gender, age, allergic reactions and smoking habit matched healthy volunteers. A set of spirometric variables (FVC, FEV₁, and FEF₂₅₋₇₅) was obtained. FEV₁ >80% and FEF₂₅₋₇₅ <70% defined small airway obstruction, FEV₁ of 60-79% = mild obstruction, FEV₁ 50-59% = moderate obstruction, and FEV₁ <50% = severe bronchial obstruction.

Results: All mean spirometric variables (% predicted) were lower in affected males than in females. FVC (% predicted) was reduced 15.4% ($97.7 \pm 18.7\%$ in Fabry patients vs $110.3 \pm 13.6\%$ in normal controls; $p < 0.001$). FEV₁ (% predicted) was reduced 20.6% ($81.5 \pm 19.8\%$ in Fabry patients vs $102.6 \pm 11.6\%$ in normal controls, $p < 0.0001$). FEF₂₅₋₇₅ (% predicted) was reduced 43.1% ($48.4 \pm 19.7\%$ in Fabry patients vs $85.1 \pm 18.7\%$ in normal controls; $p < 0.0001$). Evidence of bronchial obstruction was present in 40 Fabry patients (80%) of whom 25% demonstrated small airway disease; 5 had mild, 3 moderate and 2 severe obstruction. Small airway obstruction alone was detected in 12 control individuals ($p < 0.0001$).

Conclusions: Fabry patients demonstrate significantly lower spirometric parameters than normal controls, suggesting a reduction in ventilatory capacity and the presence of bronchial obstruction. Hemizygous males are significantly more severely affected than heterozygous females.

Phenotype description of Van der Woude Syndrome (VWS) unlinked to chromosome 1 containing IRF6. H. Okur¹, I. Vargel², S. Kondo³, B.C. Schutte³, F. Ozgur², S. Balci⁴, S. Ozusta⁵, I. Cekirge⁶, B. Girgin¹, Y. Erk², J.C Murray³, A.N Akarsu¹. 1) Gene Mapping Laboratory, Ped.Res.Cent. Hacettepe Univ; 2) Dept. of Plastic and Reconstructive Surgery, Hacettepe Univ; 3) Dept. of Pediatrics, University of IOWA, IA, USA; 4) Departments of Clinical Genetics; 5) Child Psychiatry; 6) Radiology, Hacettepe University, Sıhhiye, 06100, Ankara, Turkey.

VWS is a malformation manifesting cleft lip(CL)and/or palate (CP),lower lip pits (P) and hypodontia. Significant abnormalities in brain structure and function were also described. Associations such as poplyteal pterygium, ankyleblepharon filiforme and syngnathia were commonly reported. First VWS locus has been mapped to chromosome 1q32-q41 with remarkable genetic homogeneity in all populations. A second locus was reported to 1p34 using a large Finnish pedigree. The Finnish pedigree linked to 1p34 closely resembled non-syndromic forms of CL/P and suggested that sub-phenotypes may exist in VWS. We have previously presented two distinct Turkish families with “typical” as well as “complicated” forms of VWS and reported no linkage to chromosome 1q32-q41 in the complicated one (*AJHG*; 2001;69: 289 Abstract 617). CP(80%);P(60%) and CL(46%)were the clinical findings of typical VWS family linked to 1q32 region. Major striking observation in the complicated family is that affected members segregate with CL(100%) and P(30%) without CP in at least five generation. Additionally, ankyleblepharon filiforme and syngnathia was observed in one affected case. Normal intelligence and brain structure were detected in affected members. Genetic linkage analysis excluded both VWS loci using 16 DNA markers. Recently, mutations in Interferon Regulatory Factor 6 (IRF6) gene were identified as a cause of Van der Woude and Popliteal Pterygium syndromes. No mutation has been detected in the coding region of IRF6 gene for “complicated” family whereas a missense mutation in exon 4 including the DNA binding domain(nt:A332G; aa:Y111C) was detected in the family with typical findings. Thus, the family presenting CL (without CP), pit, ankyleblepharon filiforme, normal brain structure and function could be another example of sub-phenotype of VWS. *nakarsu@hacettepe.edu.tr*.

Small terminal deletion of chromosome 9q34: a novel recognizable phenotype? V. Cormier-Daire, F. Molinari, M. Rio, M.C. de Blois, S. Romana, M. Vekemans, A. Munnich, L. Colleaux. INSERM U393 and Department of Genetics, Hopital Necker, Paris, France.

Cryptic subtelomeric chromosome anomalies have been recognized as a significant cause of idiopathic mental retardation. Some microscopic deletions such as 4p-, 5p-, 9p- or 13q- are associated with distinctive clinical features and can, therefore, be ascertained through specific phenotypes. However, the phenotype of the various subtelomeric deletions is largely unknown.

Here we report the clinical and molecular findings in two unrelated mentally retarded boys with a small *de novo* submicroscopic deletion of chromosome 9q34 region. Both patients shared a clinical pattern of severe mental retardation, abnormal genitalia (hypospadias and cryptorchidism) and dysmorphic features characterized by flat face, high forehead, synophrism, anteverted nostrils, long philtrum, thin upper lip, protruding tongue and short extremities. They also developed progressive obesity with food seeking behaviour (with weight $> +6$ SD in the oldest one at 9 years of age), hyperactivity, sleep disturbance and absence of speech. The size of the telomeric deletion is about 3 Mb. These findings are discussed in light of the detailed molecular analysis of the rearrangement. Although several of these clinical manifestations can be observed in other chromosomal disorders, their combination could be a distinctive feature suggesting that this association defines a novel clinical entity.

Cerebro-Oculo-Facio-Lymphatic syndrome (COFL): A new MR/MCA syndrome with proposed cardinal diagnostic features. *J.M. Milunsky¹, D.M. Capin²*. 1) Ctr Human Genetics and Dept. Pediatrics, Boston Univ Sch Medicine, Boston, MA; 2) Pediatric Neurology, Cambridge Hospital, Cambridge, MA.

Fryns and Aftimos [2000] described a new MR/MCA syndrome with distinct facial appearance and general habitus, broad and webbed neck, hypoplastic inverted nipples, epilepsy, and pachygyria especially of the frontal lobes. We evaluated a 12 year old male with profound mental retardation, seizures, and MCA including lissencephaly, facial dysmorphism, and lymphatic abnormalities, who had clinical features remarkably similar to the initial two cases reported. Our Brazilian proband was born at 28 weeks gestation to a non-consanguineous couple with a noncontributory family history. Tonic and myoclonic seizures were first noted at 8 months and seizures have continued daily despite multiple anti-epileptic medications. He has never walked and has single words only. At 12 years, his weight was 10th centile, length 5th centile and OFC less than 3rd centile. General habitus included wasted muscle mass, knee and elbow contractures, and bilateral equinovarus deformity. Craniofacies is notable for bitemporal narrowing, trigonocephaly, thick hair, facial edema, bilateral ptosis, hypertelorism, epicanthal folds, broad nasal bridge, bulbous nasal tip, protuberant posteriorly rotated ears, a thin upper vermilion border, everted lower lip, long flat philtrum, macrostomia with prominent upper central incisors, and micrognathia. He has a high arched palate, a broad, short, webbed neck with a low posterior hairline, pectus excavatum, kyphosis and wide inverted hypoplastic nipples. Loose skin on his hands, which appeared short and broad along with tapered fingers are noted. He has a shallow scrotum and small testes. Hypertonia, spastic paraparesis, rotary nystagmus, and strabismus are present. Head MRI demonstrated lissencephalic cortical dysplasia with anterior pachygyria. High-resolution chromosomes, subtelomeric FISH, Miller-Dieker FISH, and metabolic testing including cholesterol and 7-dehydrocholesterol did not reveal an underlying diagnosis. We propose a name (COFL syndrome) for this disorder, suggest cardinal diagnostic features, and discuss several possible overlapping syndromic diagnoses.

Mutation Analysis and Phenotypic Description of Three Severely affected Smith-Lemli-Opitz Syndrome Patients.
D. Cozma, L.S. Correa-Cerro, P.A. Krakowiak, F.D. Porter. Heritable Disorder Branch, National Institute of Health, Bethesda, MD.

Smith-Lemli-Opitz Syndrome (SLOS) is an autosomal recessive malformation syndrome caused by mutations in the gene encoding the sterol delta-7 reductase. This protein catalyzes the reduction of 7-dehydrocholesterol to cholesterol in the last step of cholesterol biosynthesis. To date over 70 different mutations have been reported. Failure to ascertain severe cases, due to prenatal and perinatal death, is thought to skew reported allele frequencies. Here, we report the clinical and molecular data of three severely affected SLOS patients. The first patient was a 46,XY infant who died at 2 months of age. This infant had alobar holoprosencephaly, cleft lip, cleft palate, polydactyly, syndactyly and ambiguous genitalia. The ratio of 7-dehydrocholesterol/cholesterol was 73%. Both parents were heterozygous for the IVS8-1G>C mutation. The second patient was a 46,XY infant with ambiguous genitalia, who died at 12 hours of age. Congenital heart malformation consisted of hypoplastic left ventricle, dysplastic mitral valve, and patent foramen ovale. The biochemical studies revealed markedly increased 7-dehydrocholesterol level of 39 ug/ml and reduced level of cholesterol of 8.1 mg/dl. The DHCR7 genotype in this case was IVS8-1G>C/T319A. The third patient was a 46,XY infant with micrognathia, cleft palate, cataracts, postaxial polydactyly and ectrodactyly. 7-DHC was elevated at 80 ug/ml and cholesterol was 6mg/dl. Genotype was W151X/T154R. Genotypes identified in these three severely affected SLOS infants were W151X/T154R, IVS8-1G>C/T319A and IVS8-1G>C/IVS8-1G>C. PCR/RFLP assays were developed to confirm the T154R and T319A mutations. Genotyping of severely affected infants is important to avoid skewing of allele frequencies determined from less severely affected, SLOS populations.

Normal cognition and behavior in a Smith-Lemli-Opitz syndrome patient who presented with Hirschsprung's. C. Mueller¹, S. Patel², M. Irons³, K. Antshel³, G.S. Tint⁴, C. Bay⁵. 1) Magee Women's Hospital, Pittsburgh, PA; 2) Medical University of South Carolina, Charleston, SC; 3) Children's Hospital, Boston, MA; 4) VA Medical Center, East Orange, NJ; 5) Children's Hospital, Pittsburgh, PA.

Smith-Lemli-Opitz syndrome (SLOS) is an autosomal recessive disorder of cholesterol metabolism. It is caused by mutations in the gene for 7-dehydrocholesterol-D7-reductase (DHCR7), which catalyzes the final step in cholesterol biosynthesis, and results in cholesterol deficiency. We present the case of a 3.5 year old female child with normal cognition and behavior in whom molecular studies have identified two missense mutations in DHCR7: V326L and F248L. She was born at term following an uncomplicated pregnancy and delivery, and presented 12 days of age with poor feeding, abdominal distention, and jaundice. Colonic biopsy was consistent with Hirschsprung disease. On physical examination she had mild ptosis, 2,3 syndactyly borderline on one foot and 1mm above significance on the other, micrognathia, and a short, upturned nose. Her 7-dehydrocholesterol level was markedly elevated at 87mg/ml (normal 0.10+/-0.05) and her cholesterol level was normal at 61 mg/dl (normal 50-80mg/dl). Karyotype was 46,XX. Breast milk feeding was initiated and continued for 18 months. Cholesterol supplementation was implemented at 100mg/kg/day at 3 months, which has resulted in increased cholesterol levels and much lower dehydrocholesterol levels. Neuropsychological testing shows her functioning in the low average range, between the 14-18th centile when compared to same-age peers. This is markedly higher than most children with SLOS. She has no behavioral problems. MRI and MRS testing of the brain revealed no structural abnormalities. This is in contrast to a recently reported case by Prasad (AJMG 2002) with a mild phenotype, behavioral problems, and abnormal MRI, who is compound heterozygote for both a null and missense mutation. A higher residual enzyme activity could be the explanation for the milder clinical phenotype and normal cognition and behavior of our patient. Feeding abnormalities may be the most consistent feature of SLOS. Hirschsprung disease could be an indication for testing.

Carrier Frequency of the Smith-Lemli-Opitz IVS8-1G>C mutation of the DHCR7 gene in African Americans.

*B.S. Wright*¹, *N.A. Nwokoro*¹, *J.S. Waye*², *C.W. Wassif*¹, *M.J. Nowaczyk*², *F.D. Porter*¹. 1) Heritable Disorders Branch, NICHD/NIH, Bethesda, MD; 2) Department of Pathology and Molecular Medicine, McMaster University, Ontario, Canada.

Smith-Lemli-Opitz syndrome (SLOS) is an autosomal recessive multiple congenital anomaly/mental retardation syndrome due to a deficiency of 3 β -hydroxysterol D⁷-reductase (DHCR7) activity. DHCR7 catalyzes the reduction of 7-dehydrocholesterol (7DHC) to form cholesterol via the Kandutsch-Russell pathway. SLOS is thought to be most prevalent in individuals of northern and central European descent with the incidence estimated to be between 1/10,000 and 1/60,000. The most common SLOS mutation is IVS8-1G>C, which accounts for approximately one third of reported SLOS alleles. The carrier frequency of the IVS8-1G>C mutation has been reported to be on the order of 1% in North America. SLOS is thought to be rare in individuals of African descent, and the description of only one African American patient has been reported. To define the carrier frequency of the IVS8-1G>C SLOS mutation in the African American population, 1378 anonymous African American newborn whole blood spot samples were screened for the mutant allele using an amplification refractory mutation system (ARMS) assay. Ten of the 1378 samples contained the IVS8-1G>C allele, and all ten positives were determined to be heterozygous for the mutation. This indicates a carrier frequency of 0.73% with a 95% confidence interval of 0.35-1.33%. This would predict an SLOS incidence of 1/75,000 in African Americans. Consistent with previous work showing that the IVS8-1G>C mutation exists on haplotype A, at least eight of the IVS8-1G>C carriers were found to be haplotype A on one or more alleles. Haplotype analysis was ambiguous in two samples, but haplotype A was indicated as a possibility in both cases. These results suggest that SLOS may more prevalent in African Americans than previously thought.

Novel IGHMBP2 mutations in Spinal Muscular Atrophy with Respiratory Distress (SMARD1). *L. Viollet, M. Zarhrate, P. Burlet, S. Lefebvre, A. Munnich.* INSERM U393 and Department of Genetics, Hopital NECKER, Paris, France.

Spinal Muscular Atrophy with Respiratory Distress -also known as diaphragmatic spinal muscular atrophy or Distal Hereditary Motor Neuronopathy type VI- is a rare autosomal recessive neuromuscular disorder characterized by progressive anterior horn cell degeneration, leading to neurogenic muscular atrophy with early lifethreatening respiratory insufficiency. In contrast to classical autosomal recessive spinal muscular atrophy (SMA), distal muscles are severely affected in SMARD and diaphragmatic paralysis is the most prominent presenting symptom. Clinical and genetic heterogeneity of SMARD has been previously shown and one form, characterized by the onset of respiratory distress during the first weeks of life (SMARD1), has been ascribed to chromosome 11q13-q21 (Grohmann et al, 1999). Recently, seven mutations have been reported in the immunoglobulin m-binding protein 2 gene (IGHMBP2), in six unrelated SMARD1 families (Grohmann et al, 2001). This gene, also mapped to 11q13, is homologous to the mouse IGHMBP2 gene, which accounts for spinal muscular atrophy in the neuromuscular degeneration mouse (nmd). The cellular function of IGHMBP2 is still unknown. We report here on compound heterozygosity for IGHMBP2 mutations in a Caucasian male patient, presenting a typical SMARD1 phenotype with onset at the age of 4 weeks. These mutations were detected by DHPLC analysis of the IGHMBP2 sequence and confirmed by direct double strand DNA sequencing. One mutation was a T752C substitution which changed a leucine into a proline (L251P) in a conserved residue of the protein. This substitution resulted in the creation of an HpaII cleavage site. The other mutation is a T1730C substitution, changing a leucine into a proline (L577P) in one of the putative helicase domains of IGHMBP2. For this second mutation, SSCP analysis of the mutated DNA fragment revealed a specific band shift. These two variants were not identified by restriction digestion with HpaII and SSCP analysis in 200 chromosomes of unrelated healthy subjects. The identification of novel IGHMBP2 variants will help to diagnosing SMARD1 and may contribute to the functional characterization of IGHMBP2 gene product.

The Natural History of Bardet-Biedl Syndrome (BBS) by Genotype: Incident Events in a Longitudinal Study. S.

Moore¹, J. Green¹, E. Dicks¹, Y. Fan², A. Bhogal², W. Davidson², B. Fernandez³, D. Macgregor³, L. Penney¹, P. Parfrey¹. 1) Memorial University of Newfoundland, St John's, NF, Canada; 2) Simon Fraser University, Vancouver, BC, Canada; 3) Newfoundland and Labrador Medical Genetics Program, St John's, NF, Canada.

BBS (OMIM:209900) is a genetically and clinically heterogeneous disorder characterised by retinal dystrophy, obesity, renal abnormalities, dystrophic extremities and hypogenitalism. Forty-six patients with Bardet-Biedl syndrome (BBS) from 26 families in Newfoundland were entered into a longitudinal study (started in 1985). Medical charts were reviewed for all cases, and 25/46 were examined in 2001. Patients from 5 families were linked to the BBS1 locus on 11q13, one to 16q21 (BBS2), 5 patients from 1 pedigree linked to 3p12 (BBS3), and 5 patients from another family linked to 2q31 (BBS5). In a further 12 patients from 6 families, a mutation was identified in the *MKKS* gene associated with BBS6. The genotype was unknown in the other 17/46 (37%) patients from 12 families (2 patients from 1 family were excluded from all loci). The Kaplan-Meier method was used to analyse age of onset of clinical endpoints, including blindness, chronic renal failure, hypertension, diabetes mellitus and death. The visual loss was severe and early onset for all genotypes, with a median age of 18 years to register blind. Early-onset hypertension was common, occurring in 69% (median age of onset 34 years). Forty-five percent of patients had diabetes mellitus (median age of onset 45 years). Chronic renal failure occurred in 37%, with a median age of onset of 60 years; 4 developed end stage renal disease. These outcomes were similar for all genotypes. Twelve patients died, the median age of death was 62 years. These data suggest that the natural history of BBS does not differ by genotype, and the BBS genes are involved in a common embryogenic pathway.

Puberty and adolescence in Cornelia de Lange syndrome: a survey of 67 patients. *A.D. Kline¹, L. Audette²*. 1) Harvey Inst Human Gen, Greater Baltimore Medical Ctr, Baltimore, MD; 2) Cornelia de Lange Syndrome Foundation, Avon, CT.

Few publications address adolescent and young adulthood issues in genetic syndromes. CdLS patients originally evaluated as infants or young children are now entering adulthood. To further understand pubertal changes, 67 puberty questionnaires distributed to member families of the CdLS Foundation have been evaluated to date. Two additional surveys have been received on female children with precocious puberty. The average age of puberty onset was 13 years in females and 14 years in males. Among 43 females with CdLS, the following data regarding pubertal changes were reported: 37% growth spurt in height, 53% growth spurt in weight, 93% pubic hair, 88% breast development, 19% axillary hair, 70% menses, and 7% lack of menarche. Two individuals were found to have a bicornuate uterus with a duplicated cervical os. Premenstrual syndrome is common and menstrual irregularity is noted. Control of menses include hormone replacement therapy, hysterectomy and gynecologic procedures. 24 responses regarding pubertal changes on males with CdLS indicated: 50% growth spurt in height, 33% growth spurt in weight, 92% pubic hair, 29% axillary hair, 67% facial hair and 29% increased size of genitalia. 43% of all patients reported worsening gastroesophageal reflux during puberty. Other medical problems include scoliosis, nasal polyps, seizures and psychiatric disorders. 64% reported problems with circulation, including cold, painful extremities with changes in color. Behavioral issues are extremely common and worsen with the onset of puberty, including aggression, self-injury, obsessive-compulsive tendencies, oppositional behaviors and moodiness. Sleep patterns change, and masturbation is mentioned. Management of behavioral issues provides the most difficult challenge to the caregivers. Only by following patients with syndromes through adolescence and into adulthood, will geneticists be able to address peripubertal and adult issues and advise both the families and the primary care providers about implications for health care, changes in family dynamics, and prognosis. In addition, this type of information will be helpful for genotype-phenotype correlations.

The phenotype of normal tension glaucoma patients with and without OPA1 polymorphisms. *T. Aung*^{1,2,3}, *K. Okada*^{3,4}, *D. Poinosawmy*³, *L. Membrey*³, *G. Brice*^{3,5}, *A. Child*^{3,5}, *S. Bhattacharya*¹, *O. Lehmann*^{1,3}, *D. Garway-Heath*³, *R. Hitchings*³. 1) Molecular Genetics, Institute of Ophthalmology, London, London, United Kingdom; 2) Singapore National Eye Centre, Singapore; 3) Moorfields Eye Hospital, London, UK; 4) Department of Ophthalmology, Hiroshima University Faculty of Medicine, Hiroshima, Japan; 5) St Georges Hospital Med School, London, UK.

Purpose. Polymorphisms in *OPA1*, the gene responsible for autosomal dominant optic atrophy, were recently found to be strongly associated with normal tension glaucoma (NTG). The aim of this study was to determine whether *OPA1* polymorphisms affect the phenotype of NTG patients. **Methods.** A retrospective analysis was performed of 108 well-characterized NTG patients who had been genotyped for *OPA1* variations, and had previously undergone automated perimetry and Heidelberg retina tomography (HRT). Twenty-five NTG patients had the at-risk *OPA1* genotype (IVS 8 +4 C/T; +32 T/C) and 83 NTG patients did not. Differences between groups were sought in a wide range of structural, psychophysical and demographic factors. For a subgroup of patients with at least 5 years of follow-up and 10 visual field tests, pointwise linear regression analysis (PROGRESSOR for Windows software) was applied to the visual field series. **Results.** There was no significant difference in the 2 groups with respect to sex, age at diagnosis, family history of glaucoma, history of ischaemic risk factors and vasospasm or laterality of glaucoma. The comparison of IOP, CD ratio and visual field global indices, MD and CPSD in the 2 groups showed no significant difference. There were no differences in the mean values for any of the HRT parameters analyzed. For the subgroup of patients with at least 5 years of follow-up, there was also no significant difference in the number of patients with progressing locations, the mean number of progressing locations per subject, the mean slope of the progressing locations or the mean slope for whole visual field. **Conclusions.** The absence of phenotypic differences in NTG patients with and without the *OPA1* polymorphisms IVS 8 +4 C/T; +32 T/C suggest that these *OPA1* polymorphisms do not underlie any major phenotypic diversity in these patients.

Severe Myoclonus-Dystonia syndrome associated with a novel epsilon-sarcoglycan gene truncating mutation. *L.*

Marechal^{1, 2}, G. Raux², C. Dumanchin², G. Lefebvre¹, E. Deslandre¹, C. Girard¹, D. Champion², D. Parain³, T. Frebourg², D. Hannequin^{1,2}. 1) Department of Neurology, CHU de Rouen; 2) INSERM EMI 9906, Faculty of Medicine, 22 bd Gambetta, 76183 Rouen; 3) Laboratory of Neurophysiology, CHU de Rouen, France.

Myoclonic-dystonia (MDS) is an autosomal dominant disorder characterized by myoclonic and dystonic muscle contractions, associated to psychiatric manifestations. MDS is usually considered as a benign disease. In most of the families, MDS is linked to chromosome 7q21 and mutations within the epsilon-sarcoglycan (*SGCE*) gene have been recently described. We report the detailed phenotype, including neurological, neuropsychological and psychiatric assessment, of a large French MDS family. The phenotype in this family was severe and heterogeneous, including myoclonus with important functional impact and several psychiatric features, characterized by depression, obsessive-compulsive disorders and anxiety. This phenotype was shown to be associated to a novel truncating mutation located within exon 4 of *SGCE*. Asymptomatic mutation carriers carried the mutation on their maternal chromosome in agreement with previous segregation analysis of MDS families linked to the *SGCE* locus, which suggested that the penetrance of the mutation is highly dependent on the parental origin of the disease allele. This report demonstrates that *SGCE* mutation can result into a severe phenotype not compatible with normal life.

DYSMORPHOLOGY ASSOCIATED WITH IN-UTERO COCAINE EXPOSURE. *N.H. Robin*^{1,2}, *A.A. Alt*², *B. Salbert*³, *L. Ellison*², *S. Minnes*², *L. Singer*². 1) Center for Human Genetics, Dept. Genetics; 2) Dept. Pediatrics, Univ Hosp Cleveland, CWRU Sch Med, Clev, OH; 3) Clinical Genetics, MetroHealth Med Ctr., Cleveland, OH.

The effects of prenatal cocaine exposure (CE) have been debated for some time. While some studies have not shown any adverse effects, others have demonstrated a variety of neurodevelopmental sequelae. Similarly, the question of CE causing physical anomalies is also unresolved. The possibility that it causes a distinctive phenotype was suggested, but a blinded study of cocaine exposed newborns failed to confirm the existence of a cocaine syndrome. Methods: To further explore the relationship between CE and dysmorphology, we have evaluated 208 6-year-old children, 114 CE, and 94 age matched controls non CE. While the groups were divided by CE, exposure to nicotine, alcohol, and marijuana was also identified and used for phenotype correlations. Each child underwent a complete dysmorphology examination, with 10%; having a repeat exam to maximize reliability. The exam included a series of anthropomorphic measurements (e.g. head circumference, eye spacing, arm span), and a dysmorphologic examination to assess the presence or absence of 130 findings. Data was analyzed by SAS. Results: In preliminary analysis, few findings correlated with CE, alcohol, marijuana, or nicotine. CE correlated with palpebral fissure (PF) abnormalities: 11%; (13/114) CE vs. 3%; (3/94) NCE, $p=0.027$. However, there was no consistency among the PF anomaly - both long and short were noted. Alcohol exposure correlated with a higher rate of brachydactyly: 32%; (44/136) alcohol exposed vs. 18%; (13/72) non-exposed, $p=0.028$. Philtrum score negatively correlated with both nicotine and marijuana exposure, $p=0.0029$. Conclusions: We were unable to document a higher rate of dysmorphic findings among CE children in this cohort. While some abnormalities were noted, they did not occur in a consistent or recognizable pattern. This suggests that prenatal CE does not cause a distinct dysmorphic syndrome, nor a higher rate of minor anomalies. We agree with Little et al. [Teratol 54:145, 1999] that, if a congenital cocaine syndrome exists, it occurs at a low rate among CE children.

Oxycontin exposed fetuses and possible recurring facial phenotype. *B.D. Hall.* Dept Pediatrics/Genetics, Univ Kentucky Col Med, Lexington, KY.

Oxycontin is an opioid analgesic, which has a pregnancy classification as a Category B drug, with no fetal malformations in rats or rabbits of po exposed mothers. No human studies exist and no literature reports, anecdotal or otherwise, have dealt with the human experience. Kentucky was one of the first states to experience an epidemic of Oxycontin abuse with its increased rate of addiction and death. Most abuse results from breaking up the tablets and snorting, swallowing, or injecting the powder.

Four consecutive children ages 7 weeks to 10 months, whose mothers abused Oxycontin for all (N3) or part (N1) of their pregnancies, were referred for evaluation of dysmorphic features. Three of the children had normal pre-/postnatal growth and all 4 were within normal limits for psychomotor development. Three infants had neonatal withdrawal symptoms with one still showing hypertonia and tremors at 4 months. All 4 children had micrognathia and a small mouth while 2 had upslanted eyes; and each one had either a cleft palate, blunt upturned nose, simple philtrum, high forehead or overlapping toes.

The facial phenotype in these 4 Oxycontin exposed children is similar. If Oxycontin has teratogenic effects the resulting phenotype may be an important diagnostic clue. Experience with previous opioids such as morphine does not indicate an increased teratogenic risk. Nevertheless, further analysis of the offspring of mothers abusing Oxycontin is indicated.

Valproate embryopathy: Clinical and cognitive profile in 5 siblings. *E.K. Schorry, S.G. Oppenheimer, H.M. Saal.*
Div. Human Genetics, Pav 3-52, Children's Hosp Medical Ctr, Cincinnati, OH.

Valproate embryopathy is a well recognized syndrome caused by prenatal exposure to the anticonvulsant valproic acid (Depakote). We report 5 half-siblings with the same mother (4 different fathers) who all have valproate embryopathy. Valproic acid was the sole anticonvulsant in all 5 pregnancies, with doses ranging from 500 mg-2000 mg per day. All children were examined by a clinical geneticist and had extensive developmental testing. Mean birth weight at term was 2950 gms (range 2400-3400 gms). Common features in the 5 children included: flat, broad nasal bridge (5/5), hypoplastic midface (4/5), apparent hypertelorism/telocanthus (3/5), smooth philtrum with thin upper lip (5/5), long thin tapering fingers (4/5), hypoplastic 5th toenails (2/5), and irregularly placed toes (2/5). Less frequent features were cleft palate (1/5), duplication cyst of small intestine (1/5), and hemangioma (1/5). None had neural tube defect. Cognitive testing of the 3 children above 4 years of age showed cognitive ability in the low normal or borderline range (mean IQ=83; range 75-86), with significantly lower scores in adaptive behavior and motor skills. Study of this family offers insight into the high risk of valproate embryopathy in exposed pregnancies, and affords a unique opportunity to study the variability of expression and cognitive profile of the syndrome within one family.

Endostatin measurement as preliminary screening test for the diagnosis of Knobloch syndrome. *O.T. Suzuki*¹, *F. Kok*², *V.M. Der Kaloustian*³, *B. Olsen*⁴, *M.R. Passos-Bueno*¹. 1) CEGH-USP, São Paulo, SP, Brazil; 2) FMUSP, São Paulo, SP, Brazil; 3) McGill University, Canada; 4) Harvard University, USA.

Knobloch syndrome (KS) is a rare autosomal recessive disorder characterized by high myopia, vitreoretinal degeneration with retinal detachment, macular abnormalities and occipital encephalocele. It is caused by mutations in the *COL18A1* gene, which encodes the extracellular matrix protein collagen XVIII (Sertié *et al.*, 2000, HMG, 9:2051). This gene includes 43 exons and its two distinct promoters regulate the transcription of 3 mRNA variants. Endostatin is a 20 kDa fragment produced by proteolytic cleavage of collagen XVIII and is common to all variants. This fragment originally characterized as a potent inhibitor of angiogenesis, also plays a role in apoptosis and endothelial cell proliferation. We measured endostatin plasma levels through an ELISA assay in 19 individuals (9 KS patients and 10 healthy relatives) from 5 unrelated families. Six patients bear mutations that affect only the short collagen XVIII variant (IVS1-2A®T), one patient bears mutations that affect all known variants (c2105delC / c3514-3515delCT) and 2 other patients did not reveal any mutations after screening the entire coding region of the gene. All the mutations found result in a truncated protein. Patients and healthy carriers for the mutation IVS1-2A®T present levels (from 17.9 to 32.7 ng/ml) comparable to the average value found in control individuals (20.3 ± 11.5 ng/ml). These findings support the hypothesis that circulating endostatin levels are most likely derived from the medium and long isoforms as these patients have deficiency of only the short form. Normal endostatin levels were also found in patients without detectable mutations, suggesting genetic heterogeneity or non-detectable mutations affecting only one variant. Low level (8.5ng/ml) was observed only in the patient with null alleles that affect all variants. This was unexpected, as lack of endostatin was observed in mice with *Coll18a1* null alleles (Fukai *et al.*, 2002, EMBO J, 21:1535). These results demonstrate that endostatin measurement may be used to help the KS diagnostic and the mutation screening. FAPESP, PRONEX, CNPq, HHMI.

The fragile X premutation and autistic spectrum disorders. *R.J. Hagerman¹, B.L. Goodlin-Jones¹, S. Spence², L. Albrecht¹, S. Bacalman¹, F. Tassone³, L.W. Gane¹, S.W. Harris¹, P.J. Hagerman³.* 1) M.I.N.D. Institute, UC Davis Medical Center, Sacramento, CA; 2) Autism Genetic Research Exchange and Department of Pediatrics, UCLA, Los Angeles, CA; 3) Department of Biological Chemistry, University of California, Davis, CA.

This paper reports on eight subjects, ages 3 years to 33 years, with the fragile X premutation and a diagnosis of Autistic Spectrum Disorder. In these 8 subjects the CGG repeats ranged from 56 to 180 while the FMRP levels were in the normal or mildly deficient range. All subjects exhibited features of fragile X syndrome, including cognitive and language problems, avoidance of eye contact, and some hand stereotypies. All subjects were assessed with standardized measures for autism (e.g. ADOS, ADI-R) as part of the clinical protocol. Five subjects made criterion for autism both clinically and with the standardized measures while three made criterion for autistic spectrum disorder (including Asperger and PDD-NOS). The subjects had autistic features including impairment in social reciprocity, repetitive behaviors, and impoverished social overtures which were observed in addition to the features of fragile X syndrome. Information will be presented about a range of mRNA elevations in these patients. One hypothesis may be that this association of autism and the fragile X premutation is related to the FMRP gene dysfunction, specifically a translation defect that begins in the premutation range. In addition, a second gene affect may be additive to the premutation to predispose patients to an autism spectrum disorder.

Fragile X and autism diagnosis by two standard methodologies. *S.W. Harris, B.L. Goodlin-Jones, S. Bacalman, T. Jardini, S. Rao, R.J. Hagerman.* M.I.N.D. Institute, UC Davis Medical Center, Sacramento, CA.

Autism is often associated with fragile X syndrome (FXS) and previous reports have shown that 15% to 33% of males with FXS have autism. The prevalence rates have varied depending on the measures used to document autism. Only one published study has utilized the ADOS and ADI-R that are considered the gold standards for the diagnosis of autism. That study reported that 33% of preschool children with FXS had autism. We will address the assessment of autism in a consecutive sample of 40 children with fragile X syndrome seen for comprehensive neurodevelopmental assessments. The mean age was 7 years and there were 38 males. Children completed the ADOS-Module 1, 2 or 3 and their parent completed the ADI-R with trained examiners. The ADOS assesses current behaviors while the ADI-R reviews developmental history by parental report and its algorithm emphasizes the age 4 to 5 years old. Of the 40 children, 35% made criteria for Autistic Spectrum Disorder on the ADOS algorithm and were also judged to be autistic clinically. Interestingly, 42% of the 40 children did make criteria on the ADI-R for autism. This percentage is higher than the 35% because the criteria for autism is related to behavior at age 4 to 5 years and several of the children with FXS improved by middle childhood and did not meet criteria when they were evaluated in the clinic. Those cases that appeared to improve dramatically from an earlier age will be described in terms of cognitive, language abilities, interventions received and molecular variables.

Phenotypic consequences in a child with a de novo X;1 translocation. *S. Yatsenko, T. Sahoo, M. Santini, J. Wu, F. Scaglia, R. Naeem.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

X chromosome inactivation is a process occurring in somatic cells of mammalian females that leads to the silencing of the majority of genes on one X chromosome and serves as a mechanism of X-linked gene dosage compensation between the sexes. It is a random event occurring early in embryogenesis and the molecular mechanism remains unclear. Individuals harboring structural abnormalities of the X chromosome, including X;autosome translocations, provide a valuable resource to characterize genotype-phenotype correlates in the context of X chromosome gene content and inactivation. In cases of unbalanced X;autosome translocation the derivative X is usually inactivated and the X inactivation spreads variably into an attached autosomal segment. Replication behavior of translocated autosomal segments indicates a delay in replication that may also be discontinuous, and is probably the reason for an attenuated phenotype in many cases. We report a case of X;1 translocation in a 9-month-old girl with mild dysmorphic features and developmental delay. High-resolution chromosome analysis showed a de novo unbalanced translocation between the chromosomes X and 1 [46,X,der(X),t(X;1)(q27;q31.2)]. Fluorescence in situ hybridization (FISH) using chromosomes X and 1 telomere-specific probes confirmed the finding. The genotype in the patient results in monosomy for Xq27-qter and trisomy for 1q31-qter. Patients with trisomy for the distal segment of 1q present a more severe phenotype compared to that seen in our patient and include facial dysmorphisms, urogenital and cardiac anomalies. The absence of manifestations typical of trisomy 1q suggests that the inactivation of the derivative X chromosome significantly attenuates the phenotype in our patient, which can be explained by the possible lack of inactivation of some segments of chromosome 1 on the derivative X. Interestingly, the deletion breakpoint on the X chromosome occurs within the fragile site at Xq27. Further studies to determine the role of X inactivation on the resulting phenotype, as well as association of X chromosome fragile site in X;1 translocation, will be important to characterize genotype-phenotype correlation.

Distal 10q deletion in a boy with developmental delay and heart defect using subtelomeric FISH probe. A.
Asamoah, A. Wiktor, J. Roberson, D.L. Van Dyke. Department of Medical Genetics, Henry Ford Hospital, Detroit, MI.

New cytogenetic telomeric probe sets have identified small chromosomal rearrangements involving the terminal bands (subtelomeric sequences) in approximately 4-7% of cases of previously unexplained mental retardation. We report a 16-month old boy with 10q26.3 deletion that was found using a subtelomeric probe kit (Vysis, Inc). His mother's karyotype was normal. Initial karyotype and FISH for 22q deletion at 6 months of age were normal (46,XY). The pregnancy history was significant for maternal ingestion of 2 cups of vodka per week prior to learning she was pregnant, and marijuana use. These were discontinued after her first missed menstruation. The parents are not consanguineous. He had a maternal half-sibling and three paternal half-siblings who were reported to be healthy. He was born at term by spontaneous vaginal delivery to a 21-year old mother and a 22-year old father. Birth weight was 2438 grams, birth length was 46 cm and head circumference was 32.5 cm. He had hypotonia, global developmental delay, poor growth, microcephaly, hypertelorism, long and flat philtrum, thin upper lip, small chin, low-set ears, left torticollis, left plagiocephaly, and fisted hands. He was s/p repair of total anomalous pulmonary venous return and atrial septal defect, grade 5 vesico-ureteral reflux with hydronephrosis, reactive airway disease, left esotropia, myopia, and mild gastro-esophageal reflux. Metabolic work-up was unremarkable. At 11 months, his weight, length and head circumference were below the third percentile. He was not sitting, he was not reaching purposefully for objects, and he did not have any speech. Telomeric probe set use will reveal new cytogenetic syndromes such as the present case.

Cytogenetic Approaches to Finding Auditory Genes. *R.E. Williamson¹, C.C. Morton^{1,2}*. 1) Harvard Medical School, Boston, MA; 2) Brigham and Women's Hospital, Boston, MA.

Hearing loss is a common sensory disorder with an estimated incidence of 1 in 1000 human births. Approximately half of cases are attributed to environmental factors, while at least 50% are due to genetic causes. Genes with a role in the auditory system have been identified through both genetic linkage studies of families with heritable deafness and positional candidate gene approaches. Another method for gene discovery is to ascertain deaf individuals that carry balanced translocations and identify disrupted or dysregulated genes at the site of chromosomal rearrangement. Here, FISH experiments were done to map the breakpoint regions on each of four derivative chromosomes in two deaf individuals. One case, designated DGAP090, has a translocation between chromosomes 8 and 9 [t(8;9)(q13;p22)]. These breakpoints were determined by karyotype and probes were chosen based on proximity to the affected region. Successive FISH experiments were then performed to identify a split BAC that hybridized to the normal chromosome as well as to both of the derivative chromosomes. Further refinement of the breakpoint was done using PCR products. The chromosome 8 breakpoint disrupts a hypothetical gene and, on chromosome 9, a known gene is located in the breakpoint region. The other case, DGAP056, carries a translocation between chromosome 2 and chromosome 13 [t(2;13)(p24;q21)]. Hypothetical genes appear to be disrupted by the breaks on both chromosomes 2 and 13. Confirmation of the disruption of these sequences at the breakpoints is currently underway using a variety of approaches including FISH with cDNAs where available and Southern blot analysis.

Mendelian cytogenetics: Fine physical mapping of a gene for autosomal recessive syndromic neuronal migration defect using homozygosity for a balanced reciprocal translocation. *L. Baala^{1, 2}, S. Briault³, F. Laumonnier³, J. Amiel¹, H. Natiq², A. Assermouh⁴, M. Vekemans¹, A. Munnich¹, A. Sefiani², C. Moraine³, S. Lyonnet¹.* 1) Genetique INSERM U393, Hopital Necker, Paris, France; 2) Institut National d Hygiene, Rabat, Maroc; 3) Service de genetique, INSERM U316, CHRU Bretonneau, Tours, France; 4) Hopital Enfants Avicenne, Rabat, Maroc.

We report on syndromic neuronal migration defect (NMD) in four patients belonging to a large inbred Moroccan family. Associated features included craniosynostosis, adducted thumbs, and severe psychomotor retardation. Three children died at 15, 18 and 36 months respectively. To our knowledge, this combination of features has not been reported before. Interestingly, this family segregates a balanced reciprocal translocation $t(3;10)(p24-q23)$, and the three affected family members originating from three family branches were found homozygous for the translocation while their parents were heterozygous. Inbreeding and absence of symptoms in the parents suggested an autosomal recessive mode of inheritance. When assuming a fully penetrant autosomal recessive disorder, linkage analysis between the disease phenotype and translocation breakpoints used as polymorphic markers yielded a maximum lodscore of $Z = 3.45$ at 3p24 or 10q23, when including three affected individuals only. Indeed, using homozygosity mapping, we identified a region homozygous by descent for each of the two chromosomes. These data prompted us to hypothesize that: i) the mutated locus for this novel syndromic NMD maps to either chromosome 3p or 10q, and ii) the translocation breakpoint disrupts a recessive disease-causing gene. Bacterial artificial chromosome (BAC) contigs encompassing the 3p and 10q breakpoints were constructed, and BACs crossing the breakpoints were identified for both chromosomes, defining minimal candidate regions of 200 kb and 52 kb in length respectively. Characterization of full-length cDNAs and ESTs in BACs clones overlapping on chromosomes 3p and 10q is underway, as well as a long-range PCR approach in order to determine whether a gene(s) sequence(s) is (are) altered by this familial reciprocal translocation.

Severe brain malformation associated to ring chromosome 22. *R. Linares¹, M. Orera², M.A. Palomar¹, C. Alonso³, J. Delcan¹, C. Lostau², E. Garcia Poblete¹, M.D. Lillo², S. G.Gomez de las Heras¹.* 1) Embriology, U. Rey Juan Carlos, Alcorcon, Madrid, Spain; 2) Genetics, H. Gregorio Maranon; 3) Clinical Analysis. H. de la Princesa.

INTRODUCTION: Ring chromosome 22 is a fairly uncommon cytogenetic abnormality, with some 50 cases published so far. The clinical features more frequently described include craneofacial anomalies, global developmental delay, hypotonia, unsteady gait and severe speech retardation, suggesting an alteration in neurological development. **MATERIAL AND METHODS:** We performed an amniocentesis in a 34 years old patient on her 16th gestational week because of maternal anxiety. The fetal karyotype was 46 XX, r22 in a non mosaic form. We also performed FISH analysis with WCP 22 (VYSIS) and a mix of probes for bands 22q11.2 and 22q13.3 . The results confirmed the presence of a ring chromosome 22 with no deletions of the above mentioned bands. The parental karyotypes were normal. The macroscopic external appearance of the fetus was normal. The thoracic and abdominal organs did not showed any apparent anomaly. The morphologic study of the encephalon showed total agenesis of the corpus callosum, septum pellucidum and fornix. The longitudinal cerebral fissure was covered in all its extension by glial epithelial cells. This cells have a ciliated border and therefore are identified as ependymal cells, of the type that usually cover the ventricular cavities and the ependymal conduct. We explain the presence of these cells covering the entire longitudinal cerebral fissure, because of the total absence of telencephalic comissures. **DISCUSSION:** We describe severe SNC malformations associated with non mosaic ring 22 chromosome complement. The total absence of telencephalic comissures hinders communication between both cerebral hemispheres. This circumstance could be interconnected with the etiopathogenic pathway of the neurological aspects of the syndrome. The development of telencephalic comissures is been connected with FGF8, EMX1 and GLI3. None of these genes is located in 22q13.3-ter, therefore we hypothesize the presence of a novel gene in this area involved in development of the telencephalon.

Deletion of the CNS Calcium binding protein CALN1 in WMS with high function. *G. Mohapatra¹, X.N. Chen¹, H. Wijesuriya¹, U. Bellugi², J.R. Korenberg¹.* 1) Med Genet, Cedars-Sinai Medical Center, UCLA, Los Angeles, CA; 2) The Salk Institute, San Diego, CA.

Williams syndrome (WMS) is a complex neurodevelopmental disorder due to the deletion of at least 17 genes on 7q11.23. Majority of the WMS patients have a similar de novo deletion suggesting that the deletion breakpoints fall within a defined physical region. Therefore, WMS subjects with partial deletions are now providing clues to explore the genes responsible for subsets of the neurocognitive phenotype. The Calneuron 1 (CALN1) gene maps to 7q11, about 1Mb upstream of the common WS deletion breakpoint and encodes a calcium-binding protein of the calmodulin superfamily, specific to the adult brain. Here, we report the deletion of the CALN1 gene in an atypical WMS subject, 5623, with high cognitive function. This was determined by using FISH, PCR of hybrid cell lines, Southern blot and familial genotyping. To determine the possible contribution of CALN1 deletion to typical WMS, we examined the deletion structure of a cohort of 41 WMS subjects, using a panel of BACs (815K3 CALN1, 1008H17 FZD9, 592D8 ELN and 1184P14 GTF2I), hybridized in groups of 3 to evaluate order and spacing. Of the 41 cases, only subject 5623 showed a deletion of BAC815K3 which contains the 5'UTR and 1st exon of CALN1 gene. We subsequently confirmed the CALN1 deletion by using PCR of DNA markers from the clones spanning the CALN1 gene in 5623 hybrid cell lines and localized the breakpoint between markers WI-21143 and D7S1776 located between exon 3 and exon 4 of the CALN1 gene. Genotyping of the 5623 family using 11 polymorphic markers from the typical WMS deletion and flanking regions revealed the deletion to be paternal in origin and confirmed the loss of D7S653 in 5623. Further analysis of the father's chromosome using BACs 815K3, 208H19, 1184P14 and 1129E22 by 4-color FISH, showed the father to be a carrier of an inversion polymorphism. The lack of CALN1 deletion in our WMS cohort suggests that the CALN1 deletion is not a major contributor to the WMS phenotype. However, the deletion of CALN1 in 5623 provides an unexpected opportunity to define the role of brain specific Ca²⁺ signaling in human cognition.

A locus for brain development maps to chromosome 6q26-qter. *N. Qin¹, B. White¹, E. Woolley², L. Duckworth¹, A. Anguiano¹, R.E. Schnur².* 1) Quest Diagnostics Nichols Institute, San Juan Capistrano, CA; 2) Childrens Regional Hospital at Cooper Hospital/Robert Wood Johnson Medical School, Camden, New Jersey.

A male infant was born with massive hydrocephalus and macrocephaly. Other growth parameters were normal. He had relatively minor dysmorphic features. These included small palpebral fissures, low set but normally formed ears, wide spaced nipples, sacral anomaly, and adducted thumbs. He had generalized hypotonia, a weak cry, and abnormal EEG. He also had optic atrophy. MRI showed massive hydrocephalus with a normal 4th ventricle, consistent with aqueductal stenosis. The cortical rim was very thin in the occipital, parietal and posterior frontal lobes. There was evidence of semilobar holoprosencephaly, with a monoventricle, fused thalami and absent septum pellucidum. Partial agenesis of the corpus callosum was also noted. Cytogenetic analysis revealed a subtle terminal deletion of the long arm of one homologue of chromosome 6 [karyotype: 46,XY,del(6)(q26)]. FISH using a 6q subtelomeric probe confirmed the suspected deletion. Parental chromosomes and FISH studies were normal. Therefore, the proband's deletion is apparently de novo, barring parental mosaicism. Occult trisomy for another chromosomal segment has not yet been fully excluded. Deletions of chromosome 6q with breakpoints distal to 6q25 are distinctly uncommon. Non-specific brain malformations and hydrocephalus, sometimes with aqueductal stenosis are associated with these deletions, as they are with ring (6) chromosomes. Our case with a variant of holoprosencephaly and aqueductal stenosis lends additional support to the localization of a gene critical to brain development that lies within the terminal 6q region.

Familial premature centromere division report: cell cycle studies and review of the literature. A. Corona-Rivera^{1,3}, T.A. Garca-Cobian¹, F. Salamanca-Gomez⁴, C. Palomino-Cueva¹, L. Bobadilla-Morales¹, J.R. Corona-Rivera^{1,2}, E. Corona-Rivera¹. 1) Laboratorio de Genetica Humana, Univ. de Guadalajara, CUCS, Guadalajara, Jalisco, Mexico; 2) OPD, Hospital Civil Juan I Menchaca, Guadalajara, Jal., Mexico; 3) OPD, Hospital Civil de Belen, Guadalajara, Jal., Mexico; 4) Unit of Investigation in Human Genetics, National Medical Center, IMMS, DF, Mexico.

Anaphasic figures, with all or almost all chromosomes with separated primary constrictions and splayed chromatids are rarely observed in lymphocyte cultures. High rates of anaphases (more than 5%), have been observed in at least ten previous family reports, referred as premature centromere division (PCD). We report a family in which four members of the paternal lineage, including the propositus with a MCA/MR syndrome, showed increased anaphases (8-36%) with no aneuploidies. Active centromeres were detected in the propositus and his parents by NORs stain. Statistical cell cycle time reduction (21.8h;SD0.4 in PCD individuals vs. 31.8h;SD3.9 in controls), and increased cell proliferation kinetic were observed in anaphasic cells of PCD individuals by differential sister chromatid analysis. FISH studies revealed the presence of alpha satellite DNA and CENP-B box sequences. Such findings emerges as distinctive features supporting cell cycle involvement in PCD trait. Autosomal dominant inheritance of PCD is confirmed. 38 out 47 PCD individuals previously reported have been phenotypically normal or with coincidental findings, however, abortion or infertility has been observed in 6 out 10 families. Two paternal aunts showed infertility in this family. We propose that increased spontaneous abortion and infertility is involved more than could be supposed when PCD is present.

Del 5p15.3 in a Family with Cat-like Cry and Developmental Delay. *D. LaGrave*¹, *P.L. Bader*², *J.K. Bader*², *X. Yang*¹, *B. White*¹. 1) Quest Diagnostics' Nichols Institute, San Juan Capistrano, CA; 2) Northeast Indiana Genetic Counselling Center, Ft. Wayne, In.

We describe a family consisting of a mother and her two children (two year-old female and newborn male), who all three share a terminal deletion at 5p15.3. They share features such as a cat-like cry in infancy, learning disabilities, hypotonia, small size at birth, and failure to thrive. They share mildly dysmorphic features as well, including a triangular face, malar hypoplasia, micrognathia, partial 2-3 syndactyly and curvature of the 5th finger and the 4th and 5th toes. Cytogenetic analysis on the mothers peripheral blood lymphocytes revealed a terminal deletion of the short arm of one chromosome 5, consistent with cri-du-chat syndrome. However, FISH analysis using a probe specific for the cri-du-chat critical region demonstrated a normal hybridization pattern, indicating the chromosome breakpoint was distal to the usual segment deleted in persons with cri-du-chat syndrome. Due to developmental delay in the proband's daughter and poor feeding in her son, cytogenetic testing (karyotype and FISH for cri-du-chat) was performed and revealed that both children had inherited the deletion from their mother. FISH for all subtelomeres was performed (probe grid, Cytocell, Ltd.) and confirmed a terminal deletion of 5p in both children. The signal for the SubTel 5p probe was not observed elsewhere in the children's karyotypes, ruling out the presence of a subtle rearrangement. The mother's SubTel 5p study confirmed that she also carried a true deletion. Karyotypes of peripheral blood lymphocytes done on the proband's parents were normal, indicating the proband's deletion of 5p was *de novo*. In summary, we describe a family with an unusual terminal deletion of 5p in that they demonstrate many of the symptoms of cri-du-chat syndrome, including the characteristic cat-like cry, but are not missing the critical region for cri-du-chat. Mental outcome appears to be much better than in patients with the typical cri-du-chat deletion with only mild to moderate developmental delay and eventual learning disabilities.

Partial deletion of the common 1,5 Mb critical region in an infant with classical Williams-Beuren syndrome. A. Winterpacht¹, A. Rauch¹, S. Endele¹, B. Schroeder², C. Steglich², S. Luetzgen², R. Heller². 1) Institute of Human Genetics, University of Erlangen-Nuremberg, Erlangen, Germany; 2) Institute of Human Genetics, University of Hamburg, Hamburg, Germany.

Williams-Beuren syndrome (WBS; OMIM 194050) is a contiguous gene deletion disorder with a variable clinical phenotype that is caused in most cases by a heterozygous microdeletion in 7q11.23. Due to two highly homologous flanking ~300 kb duplicons, the microdeletion is usually of similar size in almost all cases and encompasses a common ~1,5 Mb interval that contains at least 17 genes mostly of uncertain pathogenetic relevance. Phenotype-genotype correlation studies for WBS are hampered by the uniform size of the microdeletion. Here we report the case of a 1-year-old boy with a full WBS-phenotype that is caused by a partial deletion of the common ~1.5 Mb interval. Initial analysis with two sets of commercially available FISH-probes (Appligene/Oncor and Vysis) yielded conflicting results. We therefore carried out deletion mapping with microsatellite markers and an array of targeted FISH probes. We mapped the proximal and distal breakpoint of the deletion on two BAC clones. The deletion spans a region between the elastin gene (*ELN*) and the distal duplicon and therefore excludes *STX1A* and *FZD9* from the WBS minimal critical region of deletion. Fine mapping and sequencing of the breakpoints is in progress. Evidence from two similar cases in the literature also suggests that the centromeric portion of the 1,5 Mb interval is not always deleted in patients with full WBS-phenotype, defining a WBS critical region estimated to be less than 1 Mb. The conclusions from our work concern diagnosis and molecular etiology of WBS: 1. Quantitative differences in signal intensity after FISH analysis with commercial probes for a WBS microdeletion should be followed up carefully if partial deletions are not to be missed. 2. Even in patients with full WBS-phenotype the underlying molecular defect may be more variable than previously thought.

Chromosome instability induced in vitro with mitomycin C in five Seckel syndrome patients. *L. Bobadilla-Morales¹, A. Corona-Rivera^{1,2,3}, J.R. Corona-Rivera^{1,2,3}, T.A. Garcia-Cobian¹, D. Garcia-Cruz^{2,4}, E. Corona-Rivera¹.*
1) Laboratorio de Genetica Humana, Universidad de Guadalajara, CUCS, Guadalajara, Jalisco, Mexico; 2) Doctorado en Genetica Humana, CUCS, U. de G; 3) OPD, Hospitales Civiles de Guadalajara; 4) Centro de Investigacion Biomedica de Occidente, CMNO, IMSS.

The Seckel syndrome (SS) is an autosomal recessive entity with short stature and prenatal onset microcephaly, bird-headed profile, and severe mental delay. Hematological anomalies have been observed in around 25 % of the patients. Chromosome instability induced by mitomycin C (MMC), has been observed in previous reports. The purpose of this work is to report cytogenetic features in five patients with SS whose lymphocyte cultures were induced with MMC. The patients had low birth weight (mean 1870g), mental retardation, dwarfism (DS,-7.9), short stature (DS,-6.36), microcephaly (OFC;DS,-8.1), bird-like face and multiple articular dislocations. None of them had anemia at the time of examination. In all cases their parents were healthy and non-consanguineous. Lymphocytes of SS patients and a control group (n=9) matched by age and sex, were cultured with and without MMC, added 24 hs after the setup and harvested at 72 and 96 hs. Chromosome aberrations (chromatid and chromosomal gaps and breaks, deletions, fragments, and exchanges), were scored in 100 metaphases per culture. Sister chromatid exchanges method was also performed with no differences between both groups. Statistical increase of chromosome aberrations was observed in 96 hs MMC cultures in the five patients (40.2 vs 2.8 %), meanwhile in 72hs MMC cultures, such difference was observed in one patient (24 vs 4 %). The fact that patients with SS present chromosome instability induced with MMC, strongly support the existence of subgroups with pancytopenia as previously proposed and those without hematological disorders as our cases, since genetic heterogeneity has been suggested. The presence of triradial and tetradials in two patients suggest SS and Fanconi pancytopenia relation. Induced MMC chromosome instability in SS patients is a feature that must be ascertained in future studies.

Twin brothers with MIDAS syndrome and XX-male karyotype. *A. Anguiano¹, X. Yang¹, J.K. Felix², J.J. Hoo³.* 1) Cytogenetics Dept, Quest Diag, Nichols Inst, San Juan Capist, CA; 2) Pediatrix Medical Group, Inc., Arnot Ogden Medical Center, Elmira, NY; 3) Department of Pediatrics, SUNY Upstate Medical University, Syracuse, NY.

Twin brothers with microphthalmia, facial dermal hypoplasia, sclerocornea, and supraventricular tachycardia, are reported. Their clinical features are compatible with MIDAS syndrome, a known X-linked and hemizygous male lethal condition. Their karyotypes showed an XX sex chromosome modality with a subtle Xp/Yp translocation proven by the presence of SRY gene. The pregnancy was complicated with fetal supraventricular tachycardia, which was treated with digoxin prenatally. Postnatally, both twins required treatment with adenosine, digoxin and propranolol to remain in normal sinus rhythm. The possible involvement of the heart, only in the form of cardiomyopathy with arrhythmia is emphasized. Peripheral blood samples from each twin were submitted for a conventional GTG cytogenetic study. Both revealed an apparently normal 46,XX karyotype. Since these twins have a male phenotype with the suspected MIDAS condition, subsequent FISH assays revealed a positive signal for the SRY probe, and lack of hybridization in one X chromosome of the probes in the Kallmann and in the Steroid Sulfatase Probe (STS) loci at the terminal region of Xp. Replication studies with R banding, imaging storage and subsequent FISH assays in which SRY and STS probes were used on the same slides, demonstrated that the X chromosome bearing the SRY region also had a deletion of the STS probe. The chromosome X with the rearrangement at Xp22.3 was documented as invariably late replicating (X inactivated) in all 20 metaphases that were examined for each patient. In this rearranged X chromosome, the Xp terminal region consistently showed a dark contrast in the R banding study, indicating that this region escaped X inactivation, as normally happens in the pseudoautosomal region of the X chromosome. To our knowledge, this is the first report of twin brothers having MIDAS syndrome and XX-male karyotype.

Molecular cytogenetic characterization of mosaic and partial microduplication 21qter associated with non-specific mental retardation. *J.J. Lespinasse¹, C. Ucla², T. Billette de Villemeur³, M.J. Brunel¹, S. Fert-Ferrer¹, C. Paravy¹, M.O. Rethoré⁴, S. Deutsch², S. Dahoun², A. Reymond¹.* 1) Lab Cytogenetics, General Hospital, Chambéry Cedex, France; 2) Division of Medical Genetics, University of Geneva Medical School, Geneva, Switzerland; 3) Service de Neuropédiatrie, Hôpital Armand Trousseau, 75571 Paris, France; 4) Centre Médical Jérôme Lejeune, 75116 Paris, France.

We report a patient with autistic disorder and partial microduplication of chromosome 21qter without features of Down Syndrome. The patient, a 20-year-old female, was reported to have severe mental retardation and discrete clinical features including blue sclerae, Brushfield spots, thin upper lip, webbed neck. High-resolution chromosome analysis (GBTG, RTBG) from peripheral blood lymphocytes revealed a 46,XX constitution. Fluorescence in situ hybridization (FISH) with subtelomeric commercially available probes (Vysis and Oncor) suggested a mosaic with a distal 21q22.3qter duplication. Her karyotype was 46,XX,ish dup(21)(q22.3qter)(Tel21qx2, D21S1219x2, D21S1220x2)[50]/21(q22.3qter)(Tel21qx2, D21S1219x2, D21S1220x2)[50], while her parents were karyotypically normal. The patient karyotype was confirmed by quantitative SNPs analysis using the Pyrosequencing technology (Pyrosequencing). This type of chromosome anomaly is never reported in the literature to our knowledge. Further studies are required to confirm a causal relationship of 21qter microduplication and psychotic disorder.

Familial Partial Duplication (1)(p33p22.3). *R.L. Young¹, T.F. Thurmon¹, H. Chen¹, M. Nordberg², J.A. Bocchini, Jr¹.*
1) Pediatrics, LSUHSC, Shreveport, LA; 2) Pathology, LSUHSC, Shreveport, LA.

At birth, the proband's head circumference was 35 cm (58th percentile), length 51 cm (63rd percentile), and weight 3562 gm (58th percentile). He had redundant neck skin, low-set ears with simple architecture, close-set eyes, broad nose with upturned tip, retrognathia, midline posterior cleft palate, and small hands and feet. A bridging crease joined his two palmar creases. Echocardiography showed a small muscular ventricular septal defect, patent foramen ovale, small ductus arteriosus, and mild insufficiency of the mitral and tricuspid valves. Spine x-ray showed poorly developed cervical vertebrae. Renal ultrasound showed crossed fused ectopia of the kidneys (horseshoe kidney). Postnatal swallowing dysfunction required a feeding gastrostomy. BMI has remained over 50th percentile, but growth and development parameters were below 3rd percentile at 1 year of age. Chromosome analysis with GTG banding at 500 band level from a commercial laboratory was interpreted as 46,XY,duplication(10)(q11.21q22.1). We noticed that the mother's 42-year-old half-sister was visibly similar, had poor mental function and was small: Head circumference 50 cm (less than 1st percentile), height 153 cm (2nd percentile), and weight 47.27 kg (3rd percentile). Our GTG banded karyotype showed a chromosome 10 that appeared identical to the proband's, but chromosome-specific FISH indicated that the duplication was from another chromosome. Karyotypes of the mother, maternal uncle and maternal grandmother showed a balanced rearrangement in which bands p33p22.3 of chromosome 1p had been inserted into chromosome 10q. The proband and his maternal aunt had only the 1p insertion into 10p. In the duplicated segment, McKusick's morbid anatomy of the genome lists 26 disease-related genes that might be expected to show dosage effects. To date, neither of the affected patients has displayed evidence of any of them. Two other reports provided data to suggest familial transmission of a balanced insertion of part of 1p but our case is the first clearly documented one. In those reports, the segment was inserted into different chromosomes, possibly reflecting areas of duplication of 1p.

Mapping the Wolf-Hirschhorn syndrome phenotype outside the currently defined Wolf-Hirschhorn syndrome

critical region. *M. ZOLLINO¹, R. Lecce¹, R. Fischetto², A. Selicorni³, F. Faravelli⁷, M. Murdolo¹, C. Butt⁴, G. Capovilla⁶, L. Memo⁵, G. Neri¹.* 1) Institute of Medical Genetics, Universit Catt. Sacro Cuore, Rome, Rome, Italy; 2) Divisione di Malattie Metaboliche e Genetiche. A.O. di Venere-Giovanni XXIII, Bari; 3) Clinica Pediatrica Universit di Milano; 4) IRCCS E. Medea Associazione La Nostra Famiglia, Bosisio Parini, Lecco; 5) U.O. Patologia Neonatale Ospedale Ca' Foncello, Treviso; 6) Neuropsichiatria Infantile A.O. Carlo Poma, Mantova; 7) Ospedali Galliera, Genova, Italy.

Wolf-Hirschhorn syndrome (WHS) is a contiguous gene syndrome resulting from partial 4p deletion. The currently considered WHS critical region (WHSCR) is restricted to the 165 kb interval in 4p16.3 defined by the loci D4S166 and D4S3327. Three WHS candidate genes have been independently described: WHSC1 and WHSC2 fall within the WHSCR, LETM1 flanks, being outside, the WHSCR. We analyzed a total of 9 patients carrying a terminal 4p16.3 microdeletion. Phenotypically, all of them presented with typical facial appearance, mild mental and growth retardation and seizures. Congenital malformations were absent, head circumference was normal in two occasions. Although genotype-phenotype correlations in WHS mostly depend on the deletion size, we found that the shared WHS phenotype is defined by the association of all the following signs: typical facial appearance, mental retardation, growth retardation and seizures. Genetically, the deletion varied in size from 1.3 to 2.4 Mb. The currently defined WHSCR was fully preserved in the patient carrying the 1.3 Mb deletion, that included LETM1. The unique reported patient with an interstitial deletion restricted to the WHSCR presented with a quite atypical WHS phenotype, lacking growth retardation and, more importantly, with no seizures. The few reported interstitial deletions, preserving LETM1, also resulted in an atypical WHS phenotype, lacking seizures. On our observations, the distinctive WHS phenotype maps distally, and it is completely outside the currently defined WHSCR. LETM1 turns to be the strongest candidate gene for seizures in this condition.

Cytogenetic Expression of Fragile Site Belong X Chromosome (FRAXA) in Patients with Speech Delay and Normal or Borderline IQ. *M. Diaz-Garcia, G. Garcia Sanchez.* Laboratorio de Genetica, InCH/CNR.

Fragile X syndrome is the most common inherited form of mental retardation. The syndrome is characterised by moderate to severe mental retardation, macroorchidism, large ears, prominent jaw and speech delay. In the Instituto de Comunicacion Humana of Mexico, we decided to search for the presence of FRAXA in a population of 433 individuals with normal intelligence (IQ) or borderline (70-80) and speech delay. The patients were selected through consultation of genetics to them realised their clinical history and diagnosis of psychological, speech, audiology etc. We performed chromosome analysis through three induction methods in order to identify FRAXA, were analysed per patients 300 metaphases. All the patients were diagnosed with speech delay: preservation, echolalia, jargon, stutter and articulation and omission errors. The most patients presented characteristics of common behaviour: emotional lability, short lapses of attention and low tolerance to the frustration. The majority of patients had been present alterations in one or both ears and others alterations phenotypic common at the syndrome. All the patients had antecedent hereditary of speech delay. In the chromosome analysis 422 were negative FRAXA and 7 positive FRAXA with different percentage in the expression. However with the application of the cytogenetic techniques we can't identify the carrier FRAXA and may be in some patients the alterations it is masked, whereby it requires the use of methodology applied in Molecular Biology to detect permutation or full mutation of trinucleotide repeat expansion of the FMR1 gene.

Subtelomeric FISH detects cryptic anomalies in a family with a boy with chimerism and a large balanced t(4;5).

R.E. Ensenauer¹, S. Jalal², R. Meyer², D. Babovic-Vuksanovic¹. 1) Dept Medical Genetics, Mayo Clinic, Rochester, MN; 2) Cytogenetics Laboratory, Dept Pathology and Laboratory Medicine, Mayo Clinic, Rochester, MN.

Testing for cryptic abnormalities by the use of subtelomeric FISH probes has become an important diagnostic tool in the work up of patients with mental retardation, dysmorphic features and congenital malformations. In such cases about 3 % of subtelomeric abnormalities appear to be inherited from one of the parents carrying a balanced chromosomal rearrangement. We report a 3-month-old boy who was diagnosed with ambiguous genitalia, dysmorphic features and developmental delay. Standard chromosome analysis on blood revealed a chimeric karyotype of 46,XY,t(4;5)(q31.1;q14)[46]/46,XX[4]. The boy had intra-abdominal gonads that were testicular by biopsy. He presented with multiple dysmorphic features, marked hypotonia, developmental delay, poor growth and relative macrocephaly. Physical exam of his 2.5-year-old sister also indicated hypotonia, significant developmental delay, relative macrocephaly and the same dysmorphic stigmata. In addition, she had several congenital malformations, including pulmonary valvular stenosis and pineal cyst. Her karyotype was found to be 46,XX. Due to the similar phenotype of the siblings, subtelomeric FISH studies were performed. In addition to the known karyotypic abnormalities, the boy was found to have a derivative chromosome 5 with 5pter deletion and a 17pter duplication, which was also detected in his sister. FISH probes for the critical cri du chat region on 5p15.2 were present in both siblings. Whereas the mother's karyotype was normal, chromosome analysis of the father revealed a subtle balanced t(5;17)(p15.31;p13.1) confirmed by subtelomeric FISH. Analysis of this interesting family demonstrates the utility of subtelomeric FISH in the diagnosis of cryptic chromosome anomalies in patients for whom previously identified chromosomal findings appear insufficient to explain the phenotypic anomalies observed.

Cytogenetic Evaluation of a Hormonal Drug Mestranol in Human Lymphocytes In vitro. *M.E. Ahmad¹, G.G.H.A. Shadab², M.A. Azfer²*. 1) Anatomy, AIIMS, New Delhi, India; 2) Zoology, AMU, Aligarh, UP, India.

Cytogenetic evaluation of a commonly used synthetic estrogen, Mestranol, was carried out in human peripheral blood lymphocytes in vitro. Chromosomal aberrations (CA) and sister chromatid exchanges (SCE) were used as genetic end points. Final concentrations of the drug were determined after observing its effects on Mitotic Index. The study was carried out both in the presence as well as in the absence of rat liver metabolic activation system (S9 mix). The lymphocytes were exposed to three different concentrations of the drug i.e. 10, 25 and 50mg/ml for three different durations i.e. 24, 48 and 72 hours. The drug was found to affect the genetic material both in the presence and absence of S9 mix. It induced chromosomal aberration and increased the SCE frequency at significant level in human lymphocyte chromosomes. In the absence of metabolic activation, maximum value for CA (27.00%) was observed at 25mg/ml concentration for 72h exposure duration. Further with an increase in the concentration this value decreased to an insignificant level in comparison to the normal control value (3.00%) particularly at higher durations, probably due to the death of cells. Again in the presence of S9 mix, maximum value for CA (29.50%) was observed at 25mg/ml concentration which was highly significant statistically in comparison to the normal control value. The drug Mestranol increased the SCE frequency in the presence as well as in the absence of S9 mix at 25mg/ml to a significant level (5.38 ± 0.180 and 5.04 ± 0.224 respectively) and the frequency decreased with an increase in the concentration. Thus it was concluded that the drug Mestranol and possibly its metabolites are genotoxic beyond a particular concentration in human lymphocytes.

Prader-Willi syndrome resulting from an unbalanced translocation: characterization by array CGH. P.D.

Cotter^{1,2}, *S.M. Bitts*¹, *L.G. Dietz*¹, *D.G. Albertson*³, *V.A. Cox*², *K.A. Rauen*^{2,3}. 1) Division of Medical Genetics, Childrens Hospital Oakland, 747 Fifty Second Street, Oakland, CA; 2) Department of Pediatrics, Division of Medical Genetics, University of California San Francisco, San Francisco, CA; 3) Comprehensive Cancer Center, University of California San Francisco, San Francisco, CA.

The etiology of Prader-Willi syndrome is variable. The majority of cases are the result of microdeletions in proximal chromosome 15. The remainder are the result of maternal uniparental disomy of chromosome 15, imprinting center defects, and balanced or unbalanced chromosome rearrangements involving chromosome 15. We report a patient who presented with multiple congenital anomalies including microcephaly and dysmorphic craniofacial features of a high, posteriorly slanted forehead, hypoplasia of the supraorbital ridges, epicanthal folds bilaterally and a short nose with a depressed nasal bridge and bulbous tip. The patients ears were mildly low-set with thickened, overturned superior helices and prominent antihelices. His mouth had down-turned corners, a thin tented upper lip and he was retrognathic. He had scrotal hypoplasia with bilateral cryptorchidism. Neurologically, he was severely hypotonic and had mild contractures at the knees, bilaterally. Cytogenetic analysis showed a *de novo* 45,XY,der(5)t(5;15)(p15.3;q13),-15 karyotype. In effect, the proband had monosomies of 5p15.3→pter and 15pter→15q13. Methylation PCR analysis of the promoter region of the *SNRPN* gene showed only the maternal allele, consistent with the PWS phenotype. Similar to other patients with PWS resulting from unbalanced translocations, the proband's phenotype is more severe, also reflecting the contributions of the associated monosomies. Array CGH confirmed deletions of both distal 5p and proximal 15q and provided more accurate information as to the size of the deletions. This case illustrates the utility of array CGH in characterizing structural chromosome abnormalities.

A dic(19) chromosome with an interstitial duplication of 19p13.1 in a patient with hypotonia and mild dysmorphic features. *D.B. Flannery, S.M Delaney, A.S Kulharya.* Dept Pediatrics, Sect Genetics, Medical Col Georgia, Augusta, GA.

Stable dicentric chromosomes are rarely seen as constitutional chromosome abnormalities. The majority of dicentric chromosomes in humans occur as marker chromosomes derived from chromosomes 15 or 22 or as Robertsonian translocations. For a dicentric chromosome to be mitotically stable through successive cell divisions, the centromeres have to be either very closely situated so as not to disrupt the spindle formation or one of the centromere becomes latent or inactive. We present a case with an unusual abnormality of chromosome 19. The patient is a two-year old male who was evaluated for hypotonia and dysmorphic features. Chromosome analysis demonstrated a male karyotype with additional material on the short arm of a chromosome 19. FISH with a panel of whole chromosome paint probes and subtelomeric probes showed that the additional material was derived from chromosome 19 itself. The presence of a very dark G-band similar in intensity to that of the centromere was not compatible with a direct or inverted duplication of 19p. C-banding demonstrated a C-positive band at 19p13.1 suggesting the presence of a second inactive centromere. The parental karyotypes were normal. This patient therefore has a small duplication of the p13.1 region resulting from a dicentric chromosome. Duplications and deletions of chromosome 19 are very rare for both arms of this chromosome. Two cases of partial trisomy of 19 are reported that resulted from abnormal segregation of a balanced translocation. Only one case of partial trisomy resulting from interstitial duplication of 19p has been reported. The interstitial duplication seen in our patient has not been reported previously. Several mechanisms may lead to the formation of a dicentric chromosome. These include meiotic recombination within a paracentric inversion loop, isochromatid break with U-shaped rejoining, and mitotic recombination. The small size of the second centromere implies that the stability of this abnormal chromosome in our patient may be due to the deletion of most of the active centromeric sequences in the second centromere.

Ring Y chromosome and several cell lines in a patient with growth delay and gonadal dysgenesis. M.

DesGroseilliers^{1,2}, F. Fortin¹, E. Lemyre^{2,3}, N. Lemieux^{1,2}. 1) Pathology and Cell Biology, University of Montreal, Montreal; 2) Research Center, Ste-Justine Hospital, Montreal; 3) Service of Medical Genetics, Ste-Justine Hospital, Montreal, Canada.

Ring Y chromosomes are unstable during cell division. Therefore, most reported patients are mosaics, usually including a 45,X cell line. An uneven number of sister-chromatid exchanges in the monocentric ring chromosomes leads to dicentric ring chromosomes. Depending on the breakpoints (proximal or distal to SRY) and the level of mosaicism, the phenotype of the ring Y patients vary from normal males or females to intersex individuals and sex ambiguities. We present here the case of a 19 year-old male who was referred, at age 11, for growth delay. Other clinical features included hypospadias, cryptorchidism, and gonadal dysgenesis. Karyotypes on the left (96%) and right (62.5%) testicular tissue showed two cell lines: a predominant 45,X and 46,X,r(Y)(p11.3q12). The GTG-banded karyotypes on PHA-stimulated lymphocytes showed the same cell lines, the ring Y chromosome being seen in 76% of the metaphases analyzed. FISH done 8 years later with probes SRY (Sex Region of the Y chromosome), 91H4.5 (recognizing Yp11.2), DYZ3 (specific for the centromeric region of the Y chromosome), and DYZ1 (recognizing Y heterochromatin in Yq12) showed an increase in the 45,X cell line (60.6%) and a reduction in the monocentric 46,X,r(Y) cell line (35.5%). Of the 259 metaphases analyzed by FISH, three more cell lines were found: one with a double dicentric ring (8 cells), one with two double dicentric rings (1 cell), and another one with a quadruple tetracentric ring (1 cell). FISH with the all-telomeres probe was negative, thus the formation of the ring involved breakpoints at both ends of the Y chromosome. Since probes SRY and DYZ1 were positive, the breakpoints occurred in Yp11.3 (distal to SRY) and Yq12. Thus, very few euchromatic material has been lost. Therefore, we propose that the clinical manifestations of the patient is more likely to be the result of the rising 45,X cell line rather than to the deletion of the Y chromosome (This research was supported by grants from Reseau de Medecine Genetique Appliquee-FRSQ).

Craniosynostosis and MCA/MR with 7p microdeletion: evidence for a second locus in 7p15. *P. CALLIER¹, J. PUECHBERTY², P. BLANCHET², G. LEFORT¹, F. PELLESTOR³, P. SARDA².* 1) Cytogenetics Laboratory, CHU Arnaud de Villeneuve, Montpellier, France; 2) Genetics Unit, CHU Arnaud de Villeuve, Montpellier, France; 3) Institute of Human Genetics, CNRS UPR 1142, Montpellier, France.

Craniosynostosis as a part of Multiple Congenital Anomalies and Mental Retardation (MCA/MR) are often associated with chromosomal microdeletion in particular of the chromosome 7p. To date, only a few molecular studies have been performed in order to characterize the area of chromosome 7 involved in the non syndromic craniosynostosis. High-resolution analysis have suggested subbands 7p21-22 as the craniosynostosis locus region (CRS1) and a probable second locus (CRS2) located in the more proximal region. We report the study of two new cases of children affected by craniosynostosis associated with MCA/MR (short stature, dysmorphic facial traits, malformed small ears, cardiac defect, skeletal changes, mental retardation) and subtle deletion of the chromosome 7p. Molecular cytogenetic investigations, using YACs and BACs probes (locus D7S1895, D7S1936, D7S1438, D7S2369, D7S632), have been performed on cytogenetics preparations from these two children. In the first patient, a deletion has been evidenced in the region 7p15.2- 7p21.2. The gene "Twist" is localised in this domain. The second patient displayed a smaller deletion 7p15.1 - 7p15.3. This region could be candidate for a second craniosynostosis locus region CRS2 in 7p15 region.

Excess of the short arm of chromosome 22 resulting in a duplication 22q13.3 in a girl with severe growth retardation: a possible pitfall in cytogenetics. *D. Genevieve¹, P. Sachs³, C. Borie¹, O. Dupuy¹, M. Raoul², M.L. Jacquemont², Y. Sznajer², C. Pignal¹, A. Thaly¹, M. Vitu¹, C. Baumann², P. Evrard³, A. Verloes², P. Eydoux¹.* 1) Unite de cytogenetique; 2) Unite de genetique clinique; 3) Service de neurologie pediatrique, Hopital Robert Debre, Paris, France.

Duplication 22q13 resulting in segmental trisomy 22 has been rarely reported. The phenotype of the patients carrying such duplications depends on the chromosome bands involved. Patients with a proximal duplication q11-q12, or with a trisomy 22, have a phenotype resembling cat eye syndrome. Duplication q12-q13 results in a different phenotype. We report on a girl born at 36 WG to unrelated healthy Indian parents. Caesarean section was performed because of IUGR and abnormal fetal rhythm. Birth weight was 1960 g (-2 SD), birth length was 40 cm (- 3 SD) and OFC was 31 cm (- 2 SD). Severe feeding difficulties were noted in the neonatal period. At age 3, there was severe mental retardation, growth retardation, microcephaly, facial dysmorphism, small hands and feet and an ASD. Blood karyotyping showed an excess of the short arm of chromosome 22, identified as a duplication 22q13.3 with subtelomeric FISH analysis. Only 6 cases with pure trisomy 22q13.3 have been reported. Reviewing these reports and our case, we conclude that patients with duplication 22q13.3 may have a recognizable phenotype, namely severe mental retardation, pre and post natal growth retardation, microcephaly, facial dysmorphism and visceral malformations. A putative growth regulatory gene may account for intra-uterine and post-natal growth retardation in duplication 22q13.3 and overgrowth in the microdeletion 22q13.3 syndrome. Additional euchromatic material on the short arm of acrocentric chromosomes may be easily mistaken for a variant. A careful conventional and FISH analysis is warranted in case of such findings.

Nondisjunction studies in trisomy 13. *M. Bugge*^{1,2}, *M.B. Petersen*^{2,3}, *M. Bak*¹, *C.A. Brandt*³, *J.M. Hertz*³, *L. Tranebjaerg*³, *C.D. deLozier-Blanchet*³, *G.B. Petersen*³, *C. Lundsteen*³, *J. Lespinasse*³, *K. Rasmussen*³, *M. Mikkelsen*².
1) Wilhelm Johannsen Centre for Functional Genome Research, University of Copenhagen, Denmark; 2) The John F. Kennedy Institute, Glostrup, Denmark; 3) The International Trisomy 13 Nondisjunction Collaborative Study.

The origin of nondisjunction in human trisomy 13 has previously been studied using DNA polymorphisms, but in a very limited number of cases and it has not been possible to determine the parental origin in all cases. We have investigated the parental origin of the additional chromosome in 57 cases of free trisomy 13 using 18 microsatellite DNA polymorphisms covering the length of chromosome 13q. The 57 cases were 29 prenatal, 26 postnatal, and 2 spontaneous abortions. The karyotypes were 23 of 47,XX,+13 and 34 of 47,XY,+13. In 50 cases the additional chromosome was of maternal origin, and in 7 cases of paternal origin. The addition of more DNA markers will enable the study of altered recombination associated with chromosomal nondisjunction, as previously described in other trisomies.

Functional disomy of distal Xq due to a der(Y)t(X;Y) in a male with severe congenital anomalies. *J.M. Gastier^{1,2}, I. Calloway¹, M.T. Millard¹, M. Ross¹, A. Thomas¹, P. Baker², J.D. Iams³, J. Atkin^{4,5}, G.D. Wenger^{1,2}.* 1) Dept of Laboratory Medicine, Columbus Children's Hosp, Columbus, OH; 2) Dept of Pathology, Ohio State Univ, Columbus, OH; 3) Division of Maternal Fetal Medicine, Ohio State Univ, Columbus, OH; 4) Division of Molecular and Human Genetics, Columbus Children's Hosp, Columbus, OH; 5) Dept of Pediatrics, Ohio State Univ, Columbus, OH.

Functional disomy of the X chromosome is known to be associated with severe phenotypic abnormalities, most commonly in association with a small ring X chromosome lacking XIST. These females present with additional features beyond a Turner syndrome phenotype. Rare cases of males with a duplicated X have been reported, frequently due to a recombinant pericentric inversion or inherited from the mother. We report an extremely rare case of nearly pure functional disomy of the distal long arm of the X chromosome due to a derivative Y chromosome arising from an X;Y translocation. Chromosome analysis was performed on amniotic fluid from a 20 week, 5 day fetus with ultrasound abnormalities including diaphragmatic hernia, abnormal spine, and thoracic mass. Maternal serum screening indicated a 1:14 risk for trisomy 18. Prenatal Aneuvysion FISH and testing for Smith-Lemli-Opitz Syndrome showed no abnormalities. G banding revealed pale material on the Y chromosome. FISH and molecular analysis confirmed the presence of the SRY locus on Yp and absence of the heterochromatin on distal Yq. FISH analysis with subtelomeric probes for Xp/Yp and Xq/Yq showed a normal hybridization pattern on the Y chromosome, suggesting an interstitial deletion of the Y chromosome or addition of distal Xq material. FISH using a whole chromosome paint confirmed that the material is derived from the X chromosome. The karyotype was described as 46,X,der(Y)(t(X;Y)(q27.3;q11.2)). The infant was delivered at 38 weeks and expired soon after birth. Clinical findings included hypoplastic heart, lungs, and ribcage. Radiological findings were similar to spondylothoracic dysplasia. To our knowledge, this is the first case of functional disomy for distal Xq due to a t(X;Y).

Association of a balanced autosomal translocation, t(1;12) (q34.1;q22) with mental retardation in a Han Chinese family from Taiwan. *C.H. Chen*^{1,2}, *C.C. Hung*², *K.F. Lee*², *J.S. Fang*². 1) Dept Psychiatry, Tzu-Chi General Hosp, Hualien City, Taiwan; 2) Institute of Human Genetics, Tzu-Chi University, Hualien City, Taiwan.

Mental retardation is characterized by the delayed and suboptimal development of general cognitive function, which is usually defined by the below-average of intelligence quotient. Mental retardation affects approximately 2-3% of general population, and its etiology is multifactorial. Genetics plays an important role in the etiology of mental retardation, and several genes involved in the syndromic and non-syndromic mental retardation have been identified. We identified a Han Chinese family from Taiwan with mental retardation through a referred child for evaluation of mental insufficiency. In this family, the mother is moderately mentally retarded, while the father is normal. They are not consanguineous. Two of their three boys were also found to have moderate mental retardation. No physical abnormalities were found in the mentally retarded individuals. Cytogenetic studies revealed that all three affected subjects have a balanced reciprocal autosomal translocation, t(1;12) (q34.1;q22). This translocation was found in the father and their normal child. The translocation was further confirmed by fluorescence in situ hybridization (FISH) using probes from chromosome 1 and 12. This chromosomal translocation associated with mental retardation in this family is a novel one, not reported in the literature. Further molecular studies of cloning the breakpoint sequences, and characterization of its effect should bring new insight into the mechanism of mental retardation in this family.

Phenotypic and Molecular Cytogenetic Characterization of a Girl with Mosaicism for Terminal Deletions of Chromosome 5p. *K.M. Allan¹, M. Perle², J.G. Pappas¹*. 1) Human Genetics Program, Department of Pediatrics, New York Univ Sch Medicine, New York, NY; 2) Cytogenetics laboratory, Department of Pathology, New York Univ Sch Medicine, New York, NY.

We describe an three-month old girl with a karyotype 46,XX,del(5)(p14)[14]/46,XX,del(5)(p15.1)[6] and Cri-du-Chat syndrome. She presented with weight, height and head circumference between the 3rd and 10th percentile for age. The clinical examination revealed downslanting palpebral fissures, broad nasal bridge, hypertelorism, epicanthal folds, micrognathia and cat like cry. The family history was not contributory. The peripheral blood karyotype detected mosaicism for two cell lines, each with a different deletion of part of the short (p) arm of chromosome 5; no normal cells were seen. Molecular cytogenetic (FISH) studies were also performed using in situ hybridization with fluorescent-labelled chromosome specific DNA probes for the short arm of chromosome 5 band p15.2 and the 5p telomere (Oncor, Inc D5S23 chromosome 5p15.2-specific probe and VYSIS, Inc TelVysion 5p telomere probe). Analysis of metaphase cells was consistent with the G-banding analysis and confirmed the loss of regions 5p15.2 and the telomere of chromosome 5p in each cell line. To our knowledge this is the second report of mosaicism for two cell lines each with del(5p) (P.C. Mainardi et al, J Med Genet 2001, 38: 151-158). The breakpoints in our case are different from the published case. Recent genotype-phenotype correlation studies have defined two deletion critical regions, one for the major clinical features of Cri-du-Chat syndrome in 5p15.2 and the other for the cat cry in 5p15.3. Both these regions are deleted in the two populations of cells identified in this patient; this is consistent with the clinical presentation.

Chromosomal damage frequency in hospital personnel exposed to low levels of ionizing radiation. *I. Ceja-Andrade*¹, *A. Corona-Rivera*^{1,2}, *T.A. Garcia-Cobian*¹, *L. Bobadilla-Morales*¹, *J.R. Corona-Rivera*^{1,4}, *A. Aceves-Escarcega*³, *E. Corona-Rivera*¹. 1) Laboratorio de Genetica Humana, Universidad de Guadalajara, CUCS, Guadalajara, Jalisco, Mexico; 2) OPD, Hospital Civil de Belen, Unidad de Citogenetica; 3) Instituto Jalisciense de Cancerologia (IJC), SSA; 4) OPD, Hospital Civil Juan I Menchaca, Div. de Pediatia.

Occupationally exposed personnel to ionizing radiation (OEP), may behave an increased potential risk of genomic damage. Spontaneous and induced chromosome aberration biomonitoring to evaluate low level of ionizing radiation effect is still open to discussion. The aim of this work is to evaluate chromosomal aberrations frequency in hospitalary OEP exposed to less than 30 mSv scored per year of ionizing radiation. Six POE working at radiotherapy or nuclear medicine departments for at least one year at Hospital Civil de Belen and IJC were included. Controls were matched by age and sex. Questionnaire and consent were fulfilled by them. Chromosomes were obtained by lymphocyte cultures from basal and 1.5 Gy radiated samples. At least 250 cells were scored per individual. Basal chromosome aberrations were increased in OEP (5.25%; 61/1161) vs. controls (1.07%; 19/1500. $P=0.04$ Wilcoxon test), mainly chromosome and chromatid breackages (31/1161) and tetradials (19/1161). Statistical increase was observed in basal versus radiated samples, but no differences were observed between OEP and control radiated samples (OEP 117/1373 8.5% vs control 132/1493 8.8%). Dicentrics were observed only in radiated cells (OEP 14/1373; controls 9/1493), and no rings were observed in any condition. Increased stable aberrations in basal cultures of OEP, evidences chronicle effect damage. Unstable aberrations such as dicentrics in radiated samples, reflect acute radiation effect. Such findings are compatible with an adaptative response of OEP to repair damage efficiently, subsequent to acute radiation stimuli. This procedure was able to detect low dose radiation effect in OEP and may be considered to evaluate laboral safety conditions.

Molecular cytogenetic detection of a (Y;22) translocation in an infertile 45,X male. *S. Brisset¹, A. Aboura¹, M. Misrahi², J.C. Soufir³, V. Izard⁴, R. Frydman⁵, G. Tachdjian¹.* 1) Department of Genetics, Hopital Antoine Beclere, Clamart, France; 2) Department of Molecular Biology, Hopital Bicetre, Le Kremlin Bicetre, France; 3) Department of Andrology, Hopital Bicetre, Le Kremlin Bicetre, France; 4) Department of Urology, Hopital Bicetre, Le Kremlin Bicetre, France; 5) Department of Obstetrics and Gynecology, Hopital Antoine Beclere, Clamart, France.

Previous cases with (Y;autosome) translocations have been reported in association with male infertility. The azoospermic factor (AZF) on long arm of Y chromosome, which is critical for spermatogenesis, may be affected secondary to a microdeletion, rearrangement or complete loss as a result of the translocation mechanism. We describe a new case with a de novo translocation t(Y;22). A 36-year-old male with azoospermia was found to have a 45,X karyotype. Further cytogenetic examination revealed a mosaic 45,X/46,X,+mar. Fluorescence in situ hybridization (FISH) was performed using the following probes: centromeric probes specific for chromosomes X,Y and 14/22, whole chromosome painting probes for chromosome 22 and chromosome Y and DiGeorge locus probe. FISH showed a derivative chromosome Y containing the short arm, the centromere and a small proximal part of the long-arm euchromatin of the Y-chromosome and the long arm of a chromosome 22. The breakpoint on the chromosome 22 occurred in the region just below the centromere. Thus, the small marker included the short arm and the centromere of chromosome 22. This small chromosomal fragment was unstable and lost in the cell line 45,X,der(Y)t(Y;22). Microdeletion analysis of the Y chromosome was performed using STS-PCR approach. Twenty different STS corresponding to the three distinct AZF loci (AZFa, AZFb and AZFc) and to the heterochromatic distal Yq region were amplified. AZFa was present and AZFb and AZFc were deleted. This unbalanced translocation t(Y;22) generated a long arm Y deletion with loss of the AZFb and AZFc regions and Yq heterochromatin region. Our case shows the importance to combine cytogenetic and molecular approaches in the diagnosis of male infertility, especially for genotype-phenotype correlation.

Subtelomeric chromosome abnormalities in South Carolina. *B.R. DuPont, J.S. Collins, R.S. Saul, C.E. Schwartz, R.E. Stevenson.* Greenwood Genetics Ctr, Greenwood, SC.

Fluorescence in situ hybridization (FISH) analysis of chromosome subtelomeric areas has enhanced the search for the underlying etiology in patients with idiopathic mental retardation. Previous studies have shown between 4% and 23% of children with moderate to severe retardation have a subtle chromosome abnormality using subtelomeric FISH probes. The largest study (Knight et al., 1999) found approximately 7% of patients had an unbalanced telomere rearrangement. A subsequent analysis of their data [29 affected, 110 controls] demonstrated that the prenatal onset of growth retardation and a positive family history for mental retardation are good indicators for subtelomeric analysis (STA) (deVries et al., 2001). The Greenwood Genetic Center Cytogenetics Laboratory initiated STA in 2000. To date, we have analyzed 166 people with developmental delay. We found subtelomeric abnormalities in 17 patients (8M, 9F), 14 Caucasian, 1 African-American, 1 Hispanic and 1 Indian. They ranged in age at testing from 2 months to 63 years, with 7 below the age of 9 and 4 above the age of 50; birth weights fell into normal ranges. Clinical features and abnormal test results that occurred in more than one of these individuals included facial dysmorphism (16/17), skeletal abnormalities (4/12), CNS abnormalities (6/9), cardiac abnormalities (6/13), vision abnormalities (4/13), cranial image abnormalities (8/12), and other abnormalities (10/12). The chromosome aberrations included two with 1p-, 2q-, 3q-, 8p-, 8p+, 9p-, 14q-, 15q-, 22q+, t(3;7), der(4)t(4;7), der(4)t(4;11), der(11)t(11;18), der(13)t(5;13), der(14)t(7;14), and der(19)inv(19). Five of these rearrangements were familial in origin, four were de novo, and results on the others were pending. In reviewing the causes of mental retardation in 7600 persons in South Carolina, we found 2513 with moderate to severe MR with unknown causation and an additional 324 with MR and a family history. If these two groups are combined, we might expect a retrospective analysis to find as many as 285 STA abnormalities using the 10% estimate found in our population.

Duplication of 15q24 and panic disorder - Is it real? *S.L. Christian, J. Lyons, F.J. McMahon, E.S. Gershon.* Dept Psychiatry, Univ Chicago, Chicago, IL.

In a recent study three types of dup(15)(q24) were observed in 7 families with panic and/or anxiety disorder comorbid with joint laxity (Gratacos et al. Cell 106:367-379, 2001). Dup(15)(q24q26) and dup(15)(q26q24) involving the telomeric region of the chromosome, as well as, dup(15)(q22q24) were observed in a total of 72% of the affected individuals. In a followup study 67/69 individuals with panic disorder undiagnosed for joint laxity showed one of the three types of dup(15)(q24) for a frequency of 97%. Based on these data we analyzed a series of 10 families collected as part of a National Institute of Mental Health study on the genetic basis of panic disorder for the presence of dup(15)(q24). Cell lines were not available for these initial studies, so microsatellites from the 15q22-q26 region were analyzed to check for either the presence of 3 alleles or a dosage difference between 2 alleles. The distal third of chromosome 15 contains multiple copies of segmental repeated regions, termed LCR15, that are similar to the duplicated genomic segments that rearrange to cause del(15)(q11q13) in Prader-Willi and Angelman syndromes. Therefore, 13 microsatellites including 3 from the reported region of duplication were selected to examine the single copy regions between 10 LCR15s on 15q22-qter. The results of the microsatellite analysis using 3 markers within the reported region of duplication were normal in all 10 families. Additionally, three alleles were not detected for any marker across the entire q22-qter region in any of these families. However, one marker, D15S818, located proximal to the reported region of duplication, displayed possible dosage differences in one allele that may indicate a duplication in this region. To further test the 15q24 region for the presence of duplications, cell lines from an additional 30 patients with panic disorder have been acquired for FISH analysis. In these cases BACs from the single copy regions between the 10 LCRs on 15q22-qter will be analyzed to test for duplications of 15q24.

An unusual de novo derivative/recombinant (14) from a likely germ line rearrangement,t(12;14), contributing to a partial trisomy 14q32.2@14qter. *J. de Oliva Ramirez*¹, *F. Jaquez*¹, *M. Varma*², *S. Kleyman*², *M.J. Macera*², *A. Babu*². 1) Robert Reid Hospital, Santo Domingo, Rep. Dominicana; 2) Div. Mol. Med. and Genet., Dept. of Med., Wyckoff Heights Med. Center, Brooklyn, NY.

A 4 1/2 year old girl was referred for cytogenetic evaluation because of wide fontanelles, macroglosia, preauricular fistula, constipation and non cyanotic congenital cardiopathy. She had mental retardation, with high implantation scarce hair, scarce eyebrows and eyelashes, strabismus, short wide elevated bridge, bulbed nose tip with anteverted nasal nostrils, fine lips, elongated mouth, high and narrow palate. A systolic murmur on the left parasternal border and pectus excavatum. Prominent peri-umbilical tissue, patent umbilical ring, rectus abdominis diathesis and patellar depression. 5th finger clinodactyly, long fingers and skin hyper-elasticity. Cytogenetic analysis of her peripheral blood revealed an abnormal 46,XX,?rec(14)t(12;14)(q21.3;q32.2), with an unusual secondary constriction at what appeared to be the 14q and 12q fusion point. Fluorescence in situ hybridization (FISH) using whole chromosome paints (wcp) for chromosome 12 and 14 confirmed the presence of a chromosome 12 segment in the long arm of der/rec chromosome 14, however, no detectable signal for wcp 14 was seen on the derivative chromosome 12. Telomere specific probe for chromosome 12 q (TelVysion 12q) hybridized to the distal qter of the normal homologue and the der/rec 14. Probe for telomere associated sequences for chromosome 14 (Telvysion 14q) showed signal over the normal 14, no signal over the del(12) but two separate signals in close proximity on the abnormal 14, suggesting a duplication of the 14q32.2 up to and including the telomere associated sequences. This contributes to a partial trisomy of 14 14q32.2@14qter. The karyotype was finally designated as 46,XX,der(12)t(12;14)(q31.3;q32.2).ish ?rec(14) (14pter@14q32.3@14q32.3::14q32.3@14q32.2:12q21.3@12qter)(wcp12+,wcp14+,tel14++). Both of the parents were cytogenetically normal, suggesting a possible multi-step de novo rearrangement. Possible mechanism(s) giving rise to such a complex derivative/recombinant chromosome rearrangement are described.

Subtelomere Deletion of 10q: Greater Frequency in the Population. *I.K. Gadi¹, P.N. Mowrey¹, P. Singh-Kahlon¹, P.R. Papenhausen¹, M. McDonald², P. Jayakar³, C. Bullen¹, J.H. Tepperberg¹.* 1) Dept Cytogenetics, Laboratory Corp of America, Res Triangle Pk, NC; 2) Duke University Medical Center, Durham, NC; 3) Miami Children's Hospital, Miami, FL.

Deletions of distal chromosome 10q appear to be relatively rare with only about 25 cases reported in the literature. We describe three cases with terminal deletions of 10q identified from a total of 1300 FISH subtelomere cases analyzed. Each case was submitted as a follow-up to a previously reported normal karyotype. Case one was a 3-month-old female with microcephaly, cupped ears, sloping forehead, hypertelorism, short stature, PDA, ASD, and abnormal kidneys. Subtelomere and retrospective cytogenetic analysis showed a de novo terminal deletion at 10q26.1. Case two was a 2.5-year-old female with microcephaly, preauricular sinuses, skin tags and bilateral epicanthal folds, broad nasal bridge, smooth philtrum, strabismus and developmental delay. FISH and cytogenetic analysis revealed an extremely subtle terminal de novo deletion at 10q26.3. The third case was a 5-year-old male with microcephaly, hypotonia, short stature, hydronephrosis, strabismus, and global developmental delay. The FISH and cytogenetic analysis revealed a very subtle terminal deletion at 10q26.3. Parental chromosome analyses are pending. Some of the common features reported with apparently larger 10q terminal deletions are growth retardation, psychomotor retardation, triangular face, hypertelorism, cryptorchidism, urinary tract anomalies and hypoplastic kidneys. Our patients appeared to have many of the features reported in the literature suggesting that the genes responsible for the common features may be located distal to 10q26.1. The three subtle 10q subtelomere deletions detected by FISH suggest a hot spot for subtle or cryptic 10q terminal deletions. Such deletions, essentially below the resolution of conventional G-band analysis, confirm the efficacy of subtelomere testing in globally affected patients with apparently normal karyotypes.

Familial MR associated with a subtle duplication in 4p16.3 which includes the WHSCR. *T. Drumheller, R. Vandergon, P. O'Lague, T. Treisman, E. Roeder.* Dept Cytogenetics, Dept Genetic Medicine, Childrens Hospital Central Cal, Madera, CA.

A duplication in distal 4p was identified in a mother and daughter who have mild mental retardation, minor dysmorphic features, tall stature, a normal to large head size and aggressive behavior. Initial chromosome analysis performed on the mother in 1993 reported a normal karyotype. However, a recent study of the daughter revealed a chromosome 4 with extra material at the end of its short arm. Fluorescence *in situ* hybridization (FISH) analysis using a probe for the 4p telomere region showed a normal pattern of hybridization signals. Commercial probes for the area of the Wolf-Hirschhorn critical region (WSCR) consistently showed a brighter signal on one chromosome 4 that could be resolved as 2 signals on elongated metaphase chromosomes. FISH performed on interphase nuclei consistently demonstrated 3 signals for the WHSCR probe. Follow-up studies showed the same duplication in the mother and in a newborn half-sister. The phenotype is mild compared to that described for the 4p Duplication syndrome. The subtle appearance of the duplication underscores the need for careful chromosome analysis at high resolution. A multitelomere screen would not have identified this abnormality. Eagerly anticipated new technologies, such as comparative genomic hybridization (CGH) analysis of micro-arrayed clones, will undoubtedly help identify such interstitial chromosome abnormalities.

Interstitial deletion of 9p in a patient with infertility. *E.H. Cho¹, Y.M. Kim¹, H.M. Ryu^{1,2}, Y.H. Cho³, S.Y. Park¹*. 1) Laboratory of Medical Genetics, Samsung Cheil Hosp, Seoul, Korea; 2) Obstetrics and Gynecology, Samsung Cheil Hosp, Seoul, Korea; 3) Department of Medical Genetics, College of Medicine, Hanyang University, Seoul, Korea.

9p22-p23 was reported as a critical region for the 9p-deletion syndrome that includes dysmorphic facial features and moderate to severe mental retardation. We present a 34 years old woman who referred for facial anomalies with micrognathia, mild mental retardation and infertility. Conventional GTG banded chromosome analysis indicated interstitial deletion in 9p. Subsequent high resolution and reverse banding were interpreted as 46,XX,del(9)(p22.3p23). Further comparative genomic hybridization (CGH) analysis and fluorescence in situ hybridization (FISH) analysis were performed to confirm the interstitial deletion. Results of fluorescence in situ hybridization (FISH) analysis using 9p telomeric probe and whole-chromosome painting probe and specific probe for chromosome 9 were compatible with cytogenetic interpretation. CGH profile revealed lack of chromosomal material at that region.

Prenatally detected triploidy/trisomy 7 mosaic. *M.J. Huggins¹, J.A. Ramsay^{2,3}, J. Xu^{2,3}*. 1) Obstetrics and Gynecology; 2) Pathology and Molecular Medicine; 3) Laboratory Medicine, Hamilton Health Sciences and McMaster University.

We present a rare case of mosaicism of triploidy and trisomy 7 detected prenatally. A 33-year-old woman was referred at 20 weeks gestation because of asymmetric IUGR of a singleton fetus (~17 weeks size) with a probable endocardial cushion defect. Amniocentesis performed following ultrasonography was analyzed by interphase FISH and routine karyotyping. Interphase FISH with Vysis AneuVysion probe set specific to chromosomes 13, 18, 21, X, and Y was performed on uncultured amniocytes. Analysis of 50 interphase nuclei for each probe showed at least 70% of the cells had 3 representative signals indicative of triploidy: nuc ish Xcent(DXZ1x3)[35/50],13q14(RB1x30)[42/50],18cen(D18Z1x3)[38/50],21q22(D21S259x3)[42/50]. Analysis of 21 in situ colonies showed an abnormal female karyotype mosaic for triploidy and trisomy 7: 69,XXX[8, 38%]/47,XX,+7[13, 62%]. The couple requested pregnancy termination. Postmortem examination of this female fetus identified craniofacial dysmorphism, including a conical shaped cranium, small chin, low set ears, and a flattened nasal tip with a prominent nasal groove. There were overlapping fingers on both hands, and bilateral rocker bottom feet with toe syndactyly. An endocardial cushion defect of the heart was confirmed and the left ventricle was hypoplastic. Additional findings included bilateral single lobed lungs, early microcystic changes of the kidneys, hypoplastic ovaries and mild microencephaly. These findings are consistent with triploidy. Follow-up cytogenetic analysis of 70 cultured cells from the fetal tissue showed 69,XXX[60, 86%]/47,XX,+7[10,14%], confirming the prenatal cytogenetics findings. Maternal and paternal karyotypes were normal. To our knowledge, this is the first case report of triploidy/trisomy7. Further DNA investigations may help clarify whether it originates from a single zygote (i.e. mosaicism) or fusion of different zygotes (i.e. chimera).

Deletion 3p25.3 in a mother and daughter with normal phenotype. *G.A. Jervis, P. Newkirk, B.G. Kousseff.* Regional Genetics Program, Univ South Florida, Tampa, FL.

JT, a 36 year old Caucasian woman, G2P1001, had an amniocentesis during her first pregnancy which revealed, 46,XX,del(3)(p25.3). JT was found to have the same terminal deletion. JT had FISH analysis using multiple probes for chromosome 3 to rule out a translocation or inversion. Five metaphase cells were scored using a whole chromosome 3 paint probe (Oncor, Inc) and all cells showed complete hybridization over the entire length, with no other hybridization signals on other chromosomes. Two different sets of subtelomeric probes specific for the short arm of chromosome 3 were hybridized independently to metaphase cells (D3S1443/ D3S1444, Oncor, Inc; D3S4559, Vysis), using a chromosome 3 centromere probe (D3Z1) to identify the chromosome in each hybridization reaction. Ten cells were analyzed with each probe set and all cells demonstrated a deletion of the terminal end of 3p. Skin biopsy revealed the same result without mosaicism. JT's parents had normal karyotypes. Of interest, JT's mentally retarded sister had a de novo unbalanced translocation, 46,XX,add(8).ishder(8)t(4;9)(q31.1-23.2)(wcp4+,wcp+8). JT is a pediatrician, without dysmorphic features. JT's daughter, AT, is a beautiful Eurasian girl, who at 15 months of age was developing normally with weight at 25th centile; height at 30th centile and head circumference at 50th centile. With her current pregnancy, JT is having CVS due to the 50% risk for her fetus to have 3p deletion. The phenotypic expression of this deletion may vary due to genomic imprinting and may result in physical consequences. Without genomic imprinting, the deleted segment may be genetically inert and of no clinical significance. Terminal deletions of 3p have been reported and most involved loss of the 3p25 band. The most common features included low birth weight (70%), severe postnatal growth retardation (100%), severe mental retardation (100%), microcephaly (80%), brachycephaly, and unusual facies (Gorlin, 2001). We present a mother and daughter with 3p25.3 deletion and apparently normal phenotype. This suggests that the critical region for the phenotype of 3p deletion syndrome lies within the region 3p25 to 3p25.3.

Partial trisomy 22 resulting from an extra chromosome 22 with an interstitial deletion. *A.S. Kulharya, S.M. Delaney, D.B. Flannery.* Dept Pediatrics, Medical Col Georgia, Augusta, GA.

Partial trisomies for the distal region of chromosome 22 have been described as unbalanced products resulting from segregation of a reciprocal translocation with another chromosome. Most markers derived from chromosome 22 are either dicentric, with two copies of the proximal region that result in Cat Eye syndrome, or they are products of 3:1 nondisjunction of t(11;22) resulting in der(22) syndrome with partial trisomy for distal 22, both with characteristic phenotype. We present a patient with partial trisomy 22 for the distal region resulting from an extra chromosome 22 with an interstitial deletion of the 22q11.2 region. Since the 22q11.2 region is prone to various kinds of rearrangements at a higher frequency than any other chromosome region it is surprising that such marker chromosomes have not been reported previously. The patient was evaluated at one day of age and has been followed for the past one year. She has a broad forehead, almond shaped eyes, cleft palate, short neck with redundant skin, wide spaced nipples, posteriorly rotated low set ears and metatarsus adductus. The nails on the halluces are very hypoplastic. A pneumothorax was treated with chest tubes. Chromosome analysis demonstrated an extra satellited marker chromosome in all the metaphases analyzed. The G-banding and FISH analysis with various probes revealed the karyotype to be: 47,XX,+der(22)(pter->q11.1::q13.1->q13.1->qter). The probe D22S75 that hybridizes to the 22q11.2 region was deleted in the additional chromosome. However, a signal for the probe specific for the ARSA gene in 22q13.1 region was observed on this chromosome. The parental karyotypes were normal. Our patient has few features of complete trisomy 22, such as webbed short neck and cleft palate which have been observed in patients with duplications of the distal 22q. However, the only feature common among our patient and patients with der(22) syndrome is cleft palate, which is unusual as both have partial trisomy of the same region of chromosome 22. This case provides a genotype phenotype correlation in case of over expression of genes in distal region of chromosome 22 without the involvement of another chromosome.

SEGREGATION OF A t(1;3) TRANSLOCATION IN MULTIPLE AFFECTED FAMILY MEMBERS WITH BOTH TYPES OF ADJACENT-1 SEGREGANTS. *C. Kozma¹, A. Slavotinek², J. Meck¹*. 1) Department of Pediatrics/Departemnt of Obstetrics and Gynecology, Georgetown University, Washington,DC; 2) National Human Genome Research Institute, National Institute of Health, Bethesda, MD.

A subtle familial balanced translocation involving the terminal regions of 1q and 3p was identified in a large family by high-resolution karyotype analysis and confirmed by fluorescence in situ hybridization (FISH) analysis. In this family, segregation of a balanced t(1:3)(q42.3;p25) chromosome translocation in two phenotypically normal sisters led to two types of viable unbalanced complements. The proband inherited the derivative chromosome 3 resulting in partial trisomy of 1q and partial monosomy of 3p. A paternal uncle and cousin had the reciprocal rearrangement with a derivative of chromosome 1 resulting in partial monosomy for 1q and partial trisomy for 3p. While profound mental and physical retardation and congenital heart defects were characteristic for both rearrangements, facial dysmorphism was quite distinct for each imbalance. Individuals who had the derivative chromosome 3 had a long face, wide eyebrows, small palpebral fissures, hypertelorism, prominent glabella, a large tip of the nose, long philtrum with thin upper lip, and low set-ears. In contrast, family members with the derivative of chromosome 1 had a tall forehead with bifrontal narrowing, full and large cheeks, and large simple ears. Since the translocated segments are small and approximately equal in size in this family, it is not surprising that viability was seen in individuals with both types of adjacent-1 segregation. In this kindred, the ratio of normal to abnormal individuals born to balanced carriers is believed to be 1:1.5. This suggests that the recurrence risk for carriers is at least as great as 50%.

Complex chromosome rearrangement in a case of assisted reproduction by IVF-ICSI. *C. Lostau*¹, *M. Orera*¹, *P. Blanco*², *C. Puertas*², *M.D. Lillo*¹, *C. Alonso*³. 1) Genetics, H. Gregorio Maranon, Madrid, Spain; 2) Biochemistry, H. Gregorio Maranon; 3) Clinical Analysis. H. de la Princesa.

INTRODUCTION: The widespread use of assisted reproduction has raised questions about the potential risks of the procedures and the effect in the fitness of the offspring. Intracytoplasmic sperm injection has been specially controversial given the lack of sperm selection. **MATERIAL AND METHODS:** 36 years old pregnant woman that underwent in vitro fertilization with intracytoplasmic sperm injection. Both the ovum and sperm were obtained from unknown donors. The husband is azoospermic with a 46 XY karyotype. She has regular cycles and her karyotype is 46 XX. The patient comes to our Genetic Unit, because of an elevated risk for Downs syndrome. The karyotype of the amniocytes revealed a single cell line with a complex rearrangement involving chromosomes 4,7 and 9 that was described as 46 XX, rcp (4;7) (q21;p15) rcp (7;9)(q23;p22). We confirmed the same karyotype in cord blood. We were able to obtain clinical data of the ovum donor, including the karyotype that was normal. The sperm sample had been purchased by the IVF clinic in a private sperm bank that was unable to identify the donor nor to provide data with the exception of a normal sperm count. We informed the patient that the phenotype of the fetus was unpredictable. We designed a follow up program that included sequential ultrasounds up to the 26th gestational week and a Doppler assisted ultrasound in the 22nd week. Providing that all the results were normal, the patient decided to continue the pregnancy. In the 38th gestational week she delivered a phenotypically normal girl, with APGAR 7-9, that weighted 2.800 gm. The girl is 14 months old and her development is within normal limits. **DISCUSSION:** The case illustrates most of the difficulties that can be encountered in the management of gestations attained by assisted reproduction. The impossibility to identify the sperm donor, rendered the phenotype prediction unattainable. Finally, it is important to emphasize the fact that the decision to continue the pregnancy was based in the apparent cytogenetic balance and the absence of ultrasound anomalies.

Chromosomal abnormalities in epithelial and blood cells of children with two types of Inflammatory Bowel Disease. *N.T. Holland¹, P. Harmatz², Y. Wu¹, J. Bae¹, R. Momi¹, D. Golden¹, J. Cooper³, J. Madden², C. Chen¹, A. Hubbard¹, M. Heyman³.* 1) Division of Environmental Health Sciences, University of California, Berkeley, Berkeley, CA; 2) Children's Hospital Oakland Research Institute, Oakland, CA; 3) Department of Pediatric Gastroenterology, Hepatology and Nutrition, University of California, San Francisco, CA.

Inflammatory Bowel Disease (IBD) includes two primary diagnoses: Crohn's disease and ulcerative colitis (UC). Both types of IBD are characterized by inflammatory infiltrates in the gastrointestinal tract, folate deficiency and an increased risk of cancer. Though genetic predisposition is suggested, the pathological mechanism remains unknown. The goal of this prospective case control study involves a longitudinal assessment of biomarkers of genetic damage in 31 IBD patients (19 CD and 12 UC) and 23 controls. The objective is to establish whether IBD in children is associated with an increased level of cytogenetic abnormalities, and whether it can be improved by folate supplementation. IBD subjects and controls were matched for age (12 years) and sex (56% males). Blood, urine and buccal samples were collected twice, first at the time of initial diagnosis and after one month of treatment and folate supplementation (IBD patients) or only folate supplementation (controls). Cytogenetic damage was assessed by micronucleus (MN) assay. Genetic endpoints in human lymphocytes included frequencies of MN and bridges. Cell death was assessed by percentage of apoptotic and necrotic cells and cell proliferation was measured by replicative index. CD and UC patients were different for most of the endpoints and they had a higher level of damage than controls. Treatment and folate supplementation had a positive effect on the levels of cell death, and decreased cytogenetic damage in IBD patients. Control subjects benefited from folate supplementation as indicated by a decrease of cytogenetic damage in their lymphocytes and epithelial cells. Supported by grants from Lucille Packard Foundation, Crohn's and Colitis Foundation of America and NIH (M01 RR01271).

A complex chromosomal rearrangement in a girl with mental retardation and distinctive dysmorphic features.

M.H. Haddadin¹, L.A. Morsberger¹, A.L. Hawkins¹, M.M. Cohen², R.S. Amato³, C.A. Griffin¹, A.D. Kline². 1) Departments of Pathology and Oncology, The Johns Hopkins University School of Medicine; 2) Harvey Institute for Human Genetics, Greater Baltimore Medical Center, Baltimore MD 21204;; 3) Eastern Maine Medical Center, Bangor, ME.

We report a 4 year old female with a de novo complex chromosomal rearrangement and a distinctive phenotype. Her medical history is significant for having been a twin at 35 weeks gestation, breech presentation, with feeding problems and poor growth as an infant, gastroesophageal reflux disease, peripheral pulmonic stenosis, omphalocele, high myopia and severe mental retardation. She is small for her age with microcephaly, posteriorly sloping forehead, shallow orbits, long palpebral fissures, prominent nose, wide mouth, absent uvula, along with kyphosis, brachydactyly, bridged palmar crease and hypertonia. Peripheral blood lymphocytes revealed a karyotype of 46,XX,t(1;12)(p22.3;q21.3),inv(6)(p24q23),t(7;18)(q11.2;q21.2) in all cells. Parental chromosomes and those on her twin were normal. Spectral Karyotyping (SKY) and FISH with whole chromosome paints for chromosomes 1, 6, 7, 12, and 18 did not reveal additional chromosomal rearrangements. However, prometaphase G-banding analysis suggests the inverted chromosome 6 may contain a cryptic duplication, deletion, or other rearrangement which might be causative for the observed phenotype. Additional studies are under way to elucidate the nature of the abnormality.

Comparison of three cases of deletion and duplication in 5p. *K.M. May, D. Saxe, A. Yearell, C. Taylor, K. Uhas.*
Emory University School of Medicine, Department of Pediatrics, Division of Medical Genetics, Atlanta, GA.

The frequency with which structural abnormalities occur in any given chromosomal location may be directly related to the positions of repetitive DNA sequences within the region. The short arm of chromosome 5 has been described as one area that is prone to rearrangement on that basis. We present three unusual and unrelated cases of live born individuals with deletion and duplication of 5p. As is the case with most chromosome rearrangements which contain inverted duplications, all three cases also have terminal deletions. The first case has a deletion of p15.31 and duplication of p13.3 to p15.31. The second case has a terminal deletion at p15.1 and a duplication of p12 to p15.1. The third individual has two cell lines with different structural abnormalities of chromosome 5. One cell line contains a terminal deletion at p15.1 without duplication, and the other line has a deletion at p15.31 and an inverted duplication of p12 to p15.31. These three cases have both monosomy and trisomy for varying amounts of 5p. The three cases have been characterized with FISH probes in the 5p region to more accurately determine the extent of imbalance. We compare the phenotypes with features associated with deletions and duplications of 5p, and as expected, there is overlap in each case with both monosomy and trisomy.

1p36 deletion syndrome: Refinement of a 2 Mb critical region. *K. Kurosawa*¹, *H. Kawame*², *Y. Ochiai*³, *A. Akatsuka*³, *M. Kobayashi*³, *N. Okamoto*⁴, *K. Imaizumi*¹, *Y. Kuroki*¹. 1) Kanagawa Children's Med Ctr, Yokohama, Japan; 2) Nagano Children's Hospital, Nagano, Japan; 3) Tokyo Metropolitan Kita Med Ctr, Tokyo, Japan; 4) Osaka Maternal & Children's Med Ctr, Osaka, Japan.

1p36 deletion syndrome is a newly delineated MCA/MR syndrome characterized by mental retardation, growth delay, epilepsy, congenital heart defects, characteristic facial appearance, and precocious puberty. We here report on 7 cases with the disorder identified by FISH screening with D1Z2 among MCA/MR. All the cases had normal karyotype of standard GTG banding. All have severe to profound mental retardation. Feeding difficulty is common to the cases. Five of 7 have intractable epilepsy and 2 are free from seizures. Two of 7 have dilated cardiomyopathy. To define the chromosomal deletion at the molecular level in the 1p36 deletion syndrome, we analyze 7 cases by FISH with BACPAC genomic clones in the 1p36 region. The common deletion is about 2 Mb between RP11-304C7(D1S3672) and RP4-785P20(NBR). The severity of clinical symptoms is correlated with the deletion size, demonstrated by two cases with profound mental retardation who have 9 Mb deletion. Haploinsufficiency of potassium channel beta-subunit (KCNAB2) are thought to be responsible for the intractable seizures found in the disorder, but it is not the case for our 3 of 7 cases. 1p36 deletion syndrome is one of the most frequent terminal deletion syndrome, account for 0.5-0.7% of MR. All our cases were recognized as 1p36 deletion by clinical features, and confirmed by FISH with D1Z2. Refinements of critical regions is important for the search for the causative genes for the syndrome.

Ring 2 chromosome: structural analysis by FISH. *T. Kosho*¹, *K. Matsushima*², *T. Sahashi*³, *R. Muto*⁴, *N. Mitsui*², *H. Sogajima*³, *H. Ohashi*⁵. 1) Department of Pediatrics, Saitama Municipal Hospital, Saitama, Saitama, Japan; 2) Department of Clinical Laboratory, Saitama Children's Medical Center, Iwatsuki, Saitama, Japan; 3) Department of Pediatrics, Nagoya Daini Red Cross Hospital, Nagoya, Aichi, Japan; 4) Department of Pediatrics, Tokyo Women's Medical University, Shinjuku, Tokyo, Japan; 5) Division of Medical Genetics, Saitama Children's Medical Center, Iwatsuki, Saitama, Japan.

We report a female of ring 2 chromosome with fine structural analysis by FISH. She was born after 33 weeks' pregnancy, which was complicated by intrauterine growth retardation and oligohydramnios. Birth weight was 1,276 g (-1.7 SD), length 38.0 cm (-2.3 SD), and head circumference (OFC) 26.0 cm (-2.1 SD). She exhibited respiratory distress syndrome, small ventricular septum defect (VSD), and hyperbilirubinemia in the neonatal period. She was fed through nasogastric tube until six months of age, because of poor sucking. At 19 months of age, she demonstrated severe proportionate growth retardation (weight 5,476 g (-5.3 SD), height 66.5 cm (-4.8 SD), and OFC 39.5 cm (-5.0 SD)) but her motor and mental development was normal. Her clinical features included mild hypertelorism, low and broad nasal root, thick upper and lower lips, flat occiput, and clinodactyly of bilateral fifth fingers. VSD was closed spontaneously. She suffered from frequent lower respiratory infections and eczema. Chromosome analysis using peripheral blood lymphocytes revealed 46,XX,r(2)(p25.3q37.3) constitution in 66/100 cells studied. Mitotic instability of the ring was observed in the other cells. FISH analysis using chromosome-specific subtelomeric probes (2ptel, 2qtel) showed no loss of sequences specific for subtelomeric regions of 2p and 2q. This is the ninth case of ring 2 chromosome and the first report in which fine structural analysis by FISH was performed. The breakpoints at 2pter and 2qter existed distal to chromosome-specific subtelomeric probes. The etiology of severe growth retardation without major malformations may be related not to loss of chromosomal materials but to instability of ring chromosome.

Frequent rearrangements between low copy repeats on 22q11 (LCR22) and telomeric bands of translocation partner chromosomes. *B.E. Morrow¹, E. Spiteri¹, K. Wakui², V. Pulijaal³, S. Minoshima⁴, N. Shimizu⁴, L.G. Shaffer².*
1) Dept Molecular Genetics, Albert Einstein Col Medicine, Bronx, NY; 2) Baylor College of Medicine, Houston, TX; 3) Ob/Gyn, Montefiore Medical Center, Bronx, NY; 4) Keio University, Tokyo, Japan.

The chromosome 22q11 region is susceptible to rearrangements resulting in three different congenital anomaly disorders, velo-cardio-facial syndrome/DiGeorge syndrome (VCFS/DGS), der(22) syndrome and cat-eye syndrome (CES). Meiotic homologous recombination events between two blocks of low copy repeats on chromosome 22 (LCR22s) mediate recurrent rearrangements associated with VCFS/DGS and CES. The translocation in carriers of the constitutional t(11;22) translocation is mediated by double strand breaks in AT-rich palindromes on both chromosomes 11q23 and 22q11, within a third LCR22. Malsegregation of this translocation leads to der(22) syndrome. Therefore, both homologous and non-homologous recombination events between LCR22s mediate recurrent rearrangements on 22q11. In addition to these recurrent rearrangements, non-recurrent, unique rearrangements on 22q11 have been identified, in particular, reciprocal translocations. We analyzed cell lines derived from fourteen different individuals with non-recurrent reciprocal translocations by genotype analysis, FISH mapping and somatic hybrid studies to determine whether there are common features among them. We found that five occurred in the same LCR22 as for the t(11;22) translocation implicating the same AT-rich palindromes. In addition to these cases, four others had chromosome breakpoints in the vicinity of different LCR22s, while five were in non-LCR22 sequences. The breakpoints on the partner chromosomes were all located in their most telomeric band, half in the unique regions and half in the vicinity of distal telomere associated repeats (TARs). Therefore, most of the translocation breakpoints occurred in highly dynamic regions of the genome, 22q11 and telomeric bands. Understanding the molecular basis for susceptibility to rearrangements on 22q11 can serve as a model for genomic disorders on other chromosomes as well.

Clinical features associated with an add(18)(q21) representing partial duplication of chromosome 18. K.J.

Harrison¹, C. Forster-Gibson². 1) Department of Pathology and Pediatrics; 2) Department of Family Medicine, Queen's University, Kingston, ON, Canada.

A 44 year old caucasian male was seen for genetic assessment of developmental disability. Birth history was of a 10 day post-term induced vaginal delivery with low forceps use but no reported injury. Bilateral club feet and pes cavus were identified at birth. As an infant he was hard to feed and had frequent constipation. Additional features included bilateral atresia of the ear canals, left moderate mixed hearing loss, left fibular hypertrophy, urachal cyst and anomalous 1st and 2nd ribs. Medical problems have included recurrent otitis media, pneumonia, asteatotic exzema, dshydrosis, chronic paralytic ileus, epilepsy and factor VIII hemophilia. On examination, growth parameters were normal. He had a wide mid-face with prominent cheeks; thin, pointed nose with an upturned tip; a flat, short philtrum; thin upper lip; dental malocclusion; abnormal ear shape; wide-spaced nipples; long sternum; narrow hands and brachydactyly. He had a high-stepping, ataxic gait. G-banded chromosome analysis identified a de novo 46,XY,add(18)(q21) karyotype with an extra G-positive band at the terminal end of the chromosome. Fluorescence in situ hybridization (FISH) studies using a whole chromosome paint probe specific for chromosome 18 identified the add(18)(q21) to be entirely chromosome 18 derived. The nature of the chromosome rearrangement could not be discerned by G-banding analysis. The extra G-positive band could represent a duplication of 18q12.1 or 18q22.1 material, although it is most likely part of a complex rearrangement. Molecular cytogenetic analysis using comparative genomic hybridization will provide additional information concerning the genetic imbalance involved with this rare chromosome 18 rearrangement.

Characterization of supernumerary marker chromosomes of chromosome 22 origin and associated with normal phenotype. *H.E. McDermid¹, N. Spinner², S. Timshel³, C.H. Gravholt⁴, U. Friedrich⁴.* 1) Dept Biological Sci, Univ Alberta, Edmonton, AB, Canada; 2) Div of Human Genet & Mol Biol, Children's Hosp Philadelphia, Philadelphia, Pa; 3) JF Kennedy Institute, DK-2600 Glostrup, Denmark; 4) Aarhus Kommunehospital/Aarhus University, 8000 Aarhus C, Denmark.

Supernumerary marker chromosomes (SMC) can be associated with both normal and abnormal phenotype, presumably dependent upon the amount and region of the genome in excess. In particular, small SMCs of chromosome 22 origin can be associated with the cat eye syndrome, characterized by defects of the heart, eyes, anus, kidneys, face and mental retardation. This creates a dilemma when an SMC is found prenatally, since its size is not necessarily indicative of whether it will be associated with an abnormal phenotype. We have therefore used FISH to characterize the SMCs of 4 apparently normal individuals and one fetus of unknown phenotype. Each SMC had previously been identified as originating from either chromosomes 14 or 22. These SMCs varied considerably in size, but all were smaller than a G-group chromosome. With chromosome 22-specific centromeric probes D22Z2 and D22Z4, FISH analysis showed that 4/5 SMCs were of chromosome 22 origin. However, because there was significant variation in the strength of the signal of both probes, including a normal chromosome 22 which was negative for both probes, the absence of signal from D22Z2 and D22Z4 cannot be taken as definitive proof of chromosome 14 origin of the remaining SMC. For the 4 SMCs with confirmed chromosome 22 origin, we performed FISH using the cosmid probes N89E2 (closest known unique probe to the centromere) and N107D6 (located in the 1.5 Mb pericentromeric region of 22q11). All four SMCs were negative for both probes, indicating that they contain only centromeric DNA. Therefore, this FISH analysis allows one to distinguish between SMCs which contain only centromeric DNA and are associated with normal phenotype, and previously characterized SMCs which contain at least the first 3 Mb of 22q11 and are associated with cat eye syndrome.

Mosaicism for two different Robertsonian translocations associated with infertility. *L. Martelli¹, D.B. Dentillo¹, J.F. Cuzzi¹, S.A. Santos¹, R.J. Ferreira¹, A.C.C. Nassr², V.M. Motta², E.S. Ramos¹.* 1) Dept Genetics, School of Medicine of Ribeirao Preto - University of Sao Paulo, Brazil; 2) Division of Genetics, Sinha Junqueira Maternity, Ribeirao Preto, SP, Brazil.

The great majority of Robertsonian translocations involve nonhomologous chromosomes and the 13;14 translocation is considered the most common single rearrangement in human beings. Those involving the fusion of homologs are rare. There is an excess of Robertsonian heterozygotes among couples who present recurrent spontaneous abortions. We reported a young, healthy nonconsanguineous couple referred for genetic counseling because of four miscarriages between 8th and 10th weeks gestation. The family history was negative for congenital anomalies. Cytogenetic studies performed on peripheral blood lymphocytes using GTG, CBG, NOR and high resolution bandings revealed a mosaicism for two different translocations: 45,XY,der(13;14)(q10;q10) in 54% of cells and 45,XY,der(13;13)(q10;q10) in 46% of metaphases, without normal diploid clone. The wife's karyotype was normal. Double-colour FISH technique using 13q plus 14q painting probes confirmed the diagnosis. According to the literature, the population frequency for the t(13;13) is 3% and for the 13;14 translocation is around 33%. In the nonhomologous translocation, such as rob(13q14q), there are two options for obtaining gametes: the alternate segregation, which produces normal and balanced gametes and the adjacent segregation producing two types of disomic and two types of nullisomic gametes. Homologous Robertsonian translocation leads to generation of only nullisomic and disomic gametes, essentially a 1:0 segregation, and no normal conceptuses can be produced. We did not find any previous description in the literature about mosaicism for two translocations involving two different chromosomes in somatic cells. In this case, the cytogenetic investigation was essential for the genetic counseling, resulting in indication for preimplantation genetics diagnosis. Supported by FAEPA-HCFMRP, University of Sao Paulo.

Developmental Genome Anatomy Project (DGAP): Mapping Genes That Cause Congenital Anomalies. S.R.

*Herrick*¹, *A.F. Bosco*¹, *G.A.P. Bruns*^{3,6}, *R. Eisenman*³, *C. Farra*^{1,6}, *H.L. Ferguson*^{1,2}, *J.F. Gusella*^{2,6}, *A.W. Higgins*^{1,6}, *B.R. Korf*^{1,2,6}, *A.H. Ligon*^{1,6}, *N.T. Leach*^{1,6}, *E. Lemyre*^{4,7}, *H.G. Kim*^{2,6}, *R.L. Maas*^{1,6}, *M.E. MacDonald*^{2,6}, *S. Michaud*^{1,6}, *A.M. Michelson*^{1,5,6}, *B.J. Quade*^{1,6}, *R.E. Williamson*⁶, *C.C. Morton*^{1,6}. 1) Brigham & Women's Hospital, Boston, MA; 2) Massachusetts General Hospital, Charlestown, MA; 3) Children's Hospital, Boston, MA; 4) Hopital Ste. Justine, Montreal, QUE; 5) Howard Hughes Medical Institute; 6) Harvard Medical School, Boston, MA; 7) University of Montreal, Montreal, QUE.

DGAP was established to identify developmentally important genes by analyzing samples from patients with balanced chromosomal rearrangements and at least one major congenital anomaly. We hypothesize that in a subset of these patients a gene critical in human development will be disrupted or dysregulated by the breakpoint and cause the abnormal phenotype. DGAP consists of four phases: collection of patient samples and detailed clinical histories; FISH-mapping of the breakpoints using BACs at ~1 Mb intervals; sequence analysis and candidate gene identification in the breakpoint regions; and functional analysis of candidate genes in model organisms (mouse and *Drosophila*). We have formed a growing international network of collaborators among clinical cytogeneticists, clinical geneticists and genetic counselors and now have over 100 cases in our database from patients with a variety of developmental defects and apparently balanced rearrangements. We have FISH-mapped 45 breakpoints using a collection of BACs with ~1 Mb resolution. Eleven of these have been localized within single clones, and FISH with both overlapping clones and PCR products has further narrowed the regions of interest. In six cases candidate genes have been identified and are now undergoing detailed molecular analyses. Eight additional breakpoints have been flanked by closely spaced BACs and are also being assessed molecularly. Cytogenetic, clinical, and FISH data for each case can be accessed at our website, <http://dgap.harvard.edu>. As DGAP evolves, and additional breakpoints and candidate genes are identified, we believe it will be a powerful resource for scientists in the genetics and developmental biology communities.

Prenatal diagnosis of a trisomy 21 fetus with an unusual familial t(15;21) translocation. *K.C. Kim¹, K.E. Jackson^{1,2}, G. Pridjian^{1,2,3}, R. Mao⁴, M.M. Li^{1,2}.* 1) Hayward Genetics Center; 2) Department of Pediatrics; 3) Department of OB-GYN, Tulane University School of Medicine, New Orleans, LA; 4) DNA Diagnostic Laboratory, University of Utah, Salt Lake City, UT.

A pregnant woman at 14 weeks gestation was referred for prenatal diagnosis because of advanced maternal age. Cytogenetic studies revealed the presence of an extra chromosome 21 and a satellited marker chromosome reported as 48,XX,+21,+mar. The pregnancy was terminated a week later and the result was confirmed in the fetal tissues. Parental chromosomal studies found that the father carried an unusual 15/21 translocation and a minute chromosome described as 46,XY,t(15;21)(q11.2;p13). FISH using probes D15Z1 and SNRPN showed that the minute chromosome [der(15)] was positive for the D15Z1 and negative for the SNRPN while the der(21) was positive for the SNRPN and negative for the D15Z1. These results confirmed that the t(15;21) breakpoints were on 15q11.2 and 21p13, unlike the traditional robertsonian translocations. FISH studies on the fetus demonstrated that the marker was in fact the der(15) inherited from the father. This extra copy of the chromosome 15 centromere region would have no significant phenotypic consequences since the marker did not contain the PWS/AS region. Genetic counseling uncovered that two paternal uncles of the fetus were diagnosed with Down syndrome. However, they are not available at present time for study. To determine the parental origin of the extra chromosome 21, polymorphic DNA markers on chromosome 21 were studied. Two markers were informative; the parents were heterozygous for both markers, while the fetus was homozygous for both markers. This ruled out meiosis I nondisjunction from either parent. Therefore, the extra 21 must have arisen from either meiosis II nondisjunction or early stage postzygotic nondisjunction. In addition, the balanced translocation may have played a role in the development of the trisomy 21 based on the family history of multiple Down syndrome patients. Future studies on the maternal uncles may shed more light on determining if and how the balanced translocation might have been involved in the chromosome 21 nondisjunction in the fetus.

FISH characterization of a rec(13) in a child with mild MR and his half-sibling with two structurally rearranged chromosomes 13. *S. Mehra, L. Christ, C. Curtis, S. Schwartz.* Center for Human Genetics and Department of Genetics, Case Western Reserve University and University Hospitals of Cleveland, Cleveland, OH.

Pericentric inversions of chromosome 13 are rare with most cases ascertained either through fetal loss or congenital anomalies. In general, the frequency of inversions is estimated to be 1.4 per 1000 varying between 0.3 to 5.0 per 1000 cases. In this study, we describe a six-year old child with mild mental retardation, developmental delay and learning disabilities. He was found to be FRAXA negative with a male karyotype but with a rearrangement of chromosome 13, which appeared to include a duplication of 13q31-qter and a deletion of 13p12-pter regions. The origin of the additional material was confirmed by FISH using a painting probe for chromosome 13. Further studies revealed that his father had a normal karyotype but his mother carried a balanced inversion of chromosome 13. FISH with an acrocentric beta satellite probe showed a hybridization pattern, confirming the rearrangement was an inversion rather than a shift of 13q31-qter into 13p12 and involved a break at p12 within the short arm in the mother. Thus the recombinant chromosome 13 [rec(13)dup(13q)inv(13)(p13q31)mat] in the child arose as a result of meiotic recombination between the normal 13 and inv(13) in the mother. It is likely that the phenotypic abnormalities in the patient derive from imbalance in 13q31-qter. The proband has a half-sibling who was unexpectedly found to have two chromosome 13 structural rearrangements; specifically a balanced inversion similar to his mother's and a balanced translocation, t(13;15)(q12.1;q13) inherited from his father. Thus in both chromosomes, the segment 13p12-13q12.1 is involved and could be expected to disrupt meiotic pairing. This is an interesting and instructive case for several reasons including: (1) The presence of a recombinant chromosome resulting from a maternal inversion; (2) A maternal inversion could be differentiated from a shift of chromosomal material by the use of a satellite DNA probe; and (3) The fortuitous finding of two rearrangements in the half-sib, which has serious implications for pairing and possible future fertility problems in this individual.

A familial interstitial duplication of 22q11.2 with distinct craniofacial and digital anomalies. *S.J. Hased, D. Hopcus-Niccum, L. Zhang, S. Li, J.J. Mulvihill.* Dept Pediatrics/Genetics, Univ Oklahoma Medical Ctr, Oklahoma City, OK.

Refined FISH analysis can reveal undetected chromosomal rearrangements. A patient was referred with cleft palate, hydronephrosis, and minor dysmorphic features, including low set, posteriorly rotated ears, down-slanting palpebral fissures, mandibular micrognathia, and brachymesophalangia. Routine chromosome analysis identified no abnormality of chromosome 22; FISH analysis with the TUPLE1 probe disclosed an interstitial duplication of 22q11.2. Family history showed two older full siblings: a brother with asthma, allergies, ADHD, oppositional defiant disorder, and learning problems and a sister with hydronephrosis and mild delays. Both siblings had similar facial features and were said to resemble the father and several members of his family. Indeed, the father had the same distinctive facial features; he had some post high school education and was in the armed services. He had one full brother and one full sister with developmental delay. Two female first cousins of the father also had hydronephrosis. One half-sister of the paternal grandfather had a cleft palate and died of a respiratory infection at three months of age. The patient's parents had no miscarriages. Subsequently, both older siblings of the proband and their father were found to have interstitial duplications of the TUPLE1 probe. On the initial testing, FISH analysis of metaphase chromosomes did not reveal the duplication, although, on review, the area appears brighter on one chromosome in each metaphase spread. However, FISH analysis of interphase spreads clearly showed three TUPLE1 probe sites with two chromosome specific identification probes in each interphase cell. This family illustrates the utility and need for careful analysis of interphase cells even in samples where good quality metaphases are available and may represent a novel craniofacial syndrome. *TUPLE1.*

Recurrent Miller-Dieker syndrome caused by paternal transmission of a de novo cryptic reciprocal translocation involving chromosomes 16 and 17. *K. Krabchi¹, M. Bronsard¹, R. Laframboise², R. Drouin¹.* 1) Dept. of Medical Biology, St Francois d'Assise Hospital, Laval University, Quebec, Canada; 2) Dept. of Pediatrics, Service of medical genetics, CHUQ, CHUL, Quebec, Canada.

We report non-consanguineous parents with three conceptions with Miller-Dieker syndrome (MDS) out of six pregnancies. The first conception resulted in the perinatal death of a baby with pathognomonic clinical manifestations of MDS. The second and fifth pregnancies ended with a spontaneous abortion. A clinically normal daughter was born in the third pregnancy. Our investigations focused on the proband, who was the fourth conception. This pregnancy resulted in the perinatal death of a baby girl born at full term but with clinical and neuropathological features of MDS. The mid-trimester ultrasound evaluation had shown a slight intrauterine growth delay, polyhydramnios and multiple heart defects. After birth, brain malformations (lissencephaly) were detected by magnetic resonance imaging. GTG-banding studies performed on amniotic fluid cells of the proband were normal. High-resolution (more than 550 bands per haploid genome) GTG-banding analysis of the chromosomes of the parents was normal. Fluorescence in situ hybridization (FISH) using D17S379 marker locus probe specific to MDS/LIS1 was performed on the fibroblasts of the proband and showed a microdeletion affecting the band 17p13.3. We used specific subtelomeric probes to show a de novo paternal cryptic translocation $t(16;17)(q24.3;p13.3)$ that gave rise to the 3:1 segregation unbalanced translocations detected in the conceptions. The sixth pregnancy was interrupted after the same unbalanced karyotype was detected by amniocentesis. The affected conceptions inherited a derivative chromosome 17 with trisomy for 16q24.3 to 16qter, and monosomy for 17p13.3 to 17pter. Facial, skeletal and brain anomalies (agyria) consistent with MDS were found. This pedigree underlines the importance of considering cryptic chromosome anomalies when more than one child presents with congenital anomalies and dysmorphisms. The identification of such cryptic anomalies is critical for informed genetic counseling.

Paternal balanced translocation, t (1p: 19q)(p32; q13.4) associated with recurrent fetal loss - A case report. *D.S. KRISHNAMURTHY, N. AL-TORKI, L. BASTAKI, R.I. AL-BALLOL, S.A. AL-AWADI.* CYTOGENETICS, KUWAIT MEDICAL GENETICS CENTER, SULAIBIKAT P.O., KUWAIT.

Balanced/Unbalanced structural aberrations (deletions/translocations) involving short arm of chromosome 1(1p) are very rare. Unbalanced structural rearrangements (duplications/deletion) are often incompatible with fetal survival and are associated with an increased risk of prenatal loss. Healthy consanguineous couple (First cousins) were referred for cytogenetic investigations because of 5 consecutive abortions. Karyotype of the wife showed normal 46,XX. A balanced translocation, t (1p:19q)(p32: q13.4) was observed in the husband. The couple have two normal male and a female sibs. The family history is unremarkable. The fact that there is no living child associated with deletion/duplication of 1p implies that partial trisomy 1p could be lethal or can result in early fetal loss/stillbirth. The effect of this rare translocation will be discussed in light of other cases reported in the literature involving chromosome 1p and other autosomes/sex chromosomes.

Breakpoint junction fragments in Prader-Willi and Angelman syndrome (PWS/AS) deletion patients reveal variable breakpoints within large duplicons. *S.K. Mewborn¹, N.L. Miley¹, J.A. Fantes^{1,2}, R.L. Brown¹, M.G. Butler³, S.L. Christian⁴, D.H. Ledbetter¹.* 1) Dept of Human Genetics, Univ of Chicago, Chicago, IL; 2) MRC Human Genetics Unit, Western General Hospital, Edinburgh; 3) Children's Mercy Hospitals, Univ of Missouri-Kansas City School of Medicine, Kansas City, MO; 4) Dept of Psychiatry, Univ of Chicago, Chicago, IL.

Genomic duplicons have been implicated at the breakpoints of many contiguous gene deletion syndromes. The most characterized are those mediating Charcot-Marie-Tooth disease type 1a (CMT1A) or hereditary neuropathy with liability to pressure palsies (HNPP) duplications and deletions. Duplicated sequences of 24 kb map to the breakpoints in direct orientation, implicating homologous recombination with a single hotspot within the duplicons as the mechanism. A similar mechanism has also been implicated in deletions of proximal 17p resulting in Smith-Magenis syndrome (SMS). In contrast, large duplicons (450 kb) with >98% homology have been mapped to the breakpoints in PWS/AS patients and appear inverted in orientation. Pulsed field gel electrophoresis (PFGE) analysis has been performed to screen 24 PWS/AS patients for junction fragments. Using three enzymes and seven probes, we have detected seven junction fragments in our patients. These junction fragments are variable in size indicating that breakpoints are not identical across patients as seen in CMT1A and SMS. Large duplicons flanking the Williams-Beuren syndrome (WBS) deletion region at 7q11 also appear to be largely inverted in orientation. Recently a polymorphic inversion of the WBS region has been identified in parents of some deletion patients. We have identified three PWS/AS patients with apparently identical junction fragments. These three patients may indicate the presence of a particular hotspot within the duplicon or a predisposing factor such as an inversion in the parents. These results indicate that a hotspot or precise breakpoint is responsible for the deletions of some patients, while a more random distribution of breakpoints throughout the duplicon may be responsible for the more variable junction fragments seen in other patients.

Cryptic subtelomeric rearrangements: report of two new cases. *E. Lemyre*^{1,2}, *J. Michaud*^{1,2}, *N. Lemieux*³, *F. Tihy*¹.
1) Medical Genetics Service, Hosp Ste-Justine, Montreal, PQ, Canada; 2) Dept of Pediatrics, University of Montreal, PQ, Canada; 3) Dept of Pathology, University of Montreal, PQ, Canada.

Cryptic subtelomeric rearrangements explain a significant proportion of cases with mental retardation. FISH with probes specific to the subtelomeric regions from each chromosome arm was performed on patients with mental retardation and dysmorphic features. We present 2 interesting cases where unbalanced subtelomeric rearrangements were found. The first case is an 18-year-old boy with severe mental retardation associated with metopic craniosynostosis, cleft palate, ASD, pre-axial polydactyly, arachnodactyly, scoliosis, deafness and facial dysmorphism. FISH for subtelomeric regions revealed the unbalanced product of a maternal translocation resulting in partial monosomy 9p and partial trisomy 10p. The predominant phenotypic expression seen in this patient corresponds mostly to monosomy 9p syndrome. The second case is a 2-year-old boy with moderate developmental delay associated with a constellation of malformations evocating cranio-cerebello-cardiac syndrome (3C syndrome): corpus callosum and cerebellar hypoplasia, enlarged cisterna magna, ASD and peripheral pulmonary stenosis, hypertelorism and other dysmorphic features. FISH for subtelomeric regions revealed the unbalanced product of a paternal translocation resulting in partial monosomy 6p and partial trisomy 10q. We can speculate that a certain number of patients with characteristics of 3C syndrome may have a cryptic rearrangement involving one of these regions. Diagnosis of these cryptic rearrangements allowed genetic counseling and had a great impact on these families.

A girl with velocardiofacial phenotype and complex chromosome rearrangements involving 8p and 10p. L.K.

Tomc¹, T. Heshka^{2,3}, L. Zwaigenbaum¹, S. Eastwood¹, J. Xu^{2,3}. 1) Pediatrics; 2) Pathology and Molecular Medicine; 3) Laboratory Medicine, Hamilton Health Sciences and McMaster University.

We report a 4-year old girl with a velocardiofacial syndrome (VCF)-like phenotype and a de novo, apparently balanced complex chromosome rearrangement. She initially presented for assessment of velopharyngeal insufficiency due to hypernasal speech. She has distinctive facial features (long face, broad nasal bridge, and protuberent ears with simplified helices), bifid uvula, strabismus and joint laxity. She is developmentally delayed, with performance on language testing approximately 2 S.D. below the mean expected for age. She has significant difficulty with sensory regulation and perseverative behaviours. The karyotype is characterized by the presence of two derivative chromosomes; 46,XX,der(8)(10pter->10p12.32::8p12->8qter), der(10)(8pter->8p21.3::10p12.32->10p11.23::8p21.3->8p12::10p11.23->10qter). The der(8) is a result of translocation of the segment 10p12.32-pter onto 8p12. The der(10) has two 8p segments collectively from 8p12-pter in that the segment 8p21.3-pter is translocated onto 10p12.32 and the segment 8p12-p21.3 is inserted at 10p11.23. FISH analysis showed no microdeletion of the major locus at 22q11.2 nor for the minor locus at 10p13p14. This case suggests that in addition to identified loci at 22q11.2 and 10p13p14, aberrations at 8p12, 10p11.23 or 10p12.32 could lead to VCF phenotype.

Phenotypic and Molecular Cytogenetic Characterization of a Child With a Terminal Deletion of 7q [del(7)(q36.2)]. *J.G. Pappas¹, E. Reich¹, K. Allan¹, L.E. McMorrow², M. Perle², H.E. Wyandt³, J.M. Milunski³.* 1) Human Genetics Program, Dept of Pediatrics New York Univ, Sch of Med, New York, NY; 2) Cytogenetics Laboratory, Dept of Pathology, New York Univ, Sch of Med, New York, NY; 3) Center for Human Genetics and Dept of Pediatrics, Boston University School of Medicine, Boston, MA.

We describe a girl that presented in infancy with large midline cleft lip and palate, gastroesophageal reflux and chronic constipation. Clinical examination at one year of age revealed microcephaly, bifrontal prominence, midline cleft palate, short and narrow palpebral fissures, depressed and broad nasal bridge, hypertelorism, bifid tip of the nose, widely spaced inverted nipples and tapering fingers. The neurological examination and the developmental evaluation were normal. The gastroesophageal reflux and constipation were successfully treated with antacids. The family history was not contributory. Chromosome analysis of peripheral blood cells by G-banding was normal. Fluorescent in situ hybridization (FISH) was performed using DNA probes specific for the subtelomeric ends of each chromosome arm (Vysis, Downers Grove, IL). Results revealed apparent negative hybridization of the probe, pcp7, to the long arm of one chromosome 7 homologue in the proband. Hybridization with a painting library, specific for chromosome 7 (Vysis), painted both chromosomes 7 over their entire length. No evidence of hybridization of 7 sequences was seen elsewhere in the genome. Hence, these results indicate a deletion in the terminal band of 7q. High resolution G-banding revealed apparent terminal deletion in band 7q36.2. The parental karyotypes were normal. To our knowledge this is the first report of del(7)(q36.2). There are 19 published cases with larger terminal deletions of 7q (R.S. Verma et al. Clin Genet 41:82-86, 1992). The phenotypic features of our case were common features among the published cases. These features along with developmental delay constitute the deletion 7q syndrome. Our case has the smallest deletion associated with the features of deletion 7q syndrome. The critical region of deletion 7q syndrome is probably in the distal portion of 7q36.

Prenatal Diagnosis of an Inherited Heterochromatic Variant Chromosome 4. *A.L. Zaslav¹, J. Jacob¹, G. Pierno², A. Fougner², F.Y. Alexander², D. Blumenthal³, J.E. Fox³.* 1) Dept Pathology, Long Island Jewish Medical Ctr, New Hyde Park, NY; 2) SonoScan Genetic Services, Forest Hills, NY; 3) Dept Pediatrics, Schneider Children's Hospital, New Hyde Park, NY.

Heterochromatic chromosome polymorphisms have been extensively reported. The majorities are associated with C-band-positive regions located on chromosomes 1, 9, and 16. We report a prenatal case of an unusual heterochromatic variant on chromosome 4. Amniocentesis was performed on a 35-year-old white female for AMA. The karyotype was 46,XY,add(4)(q35)?. One chromosome 4 homolog had an additional dark band at the terminus of the long arm. Parental chromosome analysis revealed that the chromosome 4 was maternally inherited. The mother and fetus were both Q and C-banding positive and NOR and DAPI Distamycin staining negative. FISH using the TelVysion 4q telomere probe was positive, FISH using Y and 9 WCP (Vysis Inc., Downers Grove, IL), 13/21, 14/22, and 15 alpha-satellite (Oncor, Gaithersburg, MD) were all negative. High-resolution ultrasound at 19 weeks revealed no apparent fetal anomalies. Based on these findings, it appears that this chromosome 4 was a rare heterochromatic variant. Heterochromatic variants have been demonstrated to have no phenotypic effect on carriers. Additional FISH studies are in progress. Follow up and confirmation studies after birth will also be performed to characterize this extra genetic material. This case illustrates the importance of reporting unusual variant chromosomes for genetic counseling issues. To the best of our knowledge, this is the first report of a heterochromatic variant involving part of the long arm of chromosome 4 in a phenotypically normal mother and an apparently normal fetus.

Disease associated balanced chromosome rearrangements (DBCR): Report of 2 new cases. *V.S. Tonk¹, H.E. Wyandt², X. Huang², N. Patel¹, M. Kukolich¹, L.H. Lockhart³, G.R.V.N. Velagaleti³*. 1) Department of Pediatrics, Texas Tech University, Lubbock, TX; 2) Center for Human Genetics, Boston University School of Medicine, Boston, MA; 3) Department of Pediatrics, University of Texas Medical Branch, Galveston, TX.

Disease associated balanced chromosome rearrangements (DBCR) causing truncation, deletion, inactivation or overexpression of specific genes are instrumental in identifying and cloning several disease genes and are estimated to be much more common than anticipated. In one survey the minimal frequency of combined balanced de novo reciprocal translocations and inversions causing abnormal phenotype is estimated to be .17%, a six-fold increase compared to the general population suggesting a causative linkage between the abnormality and the observed phenotypic traits. Here, we report two new cases of apparently balanced de novo translocations resulting in developmental delay and dysmorphic features. Case 1 involves an 8.5-year-old female referred for mild developmental delay and autistic behavior. She was small with dysmorphic facial features, bifid uvula, pigmentary anomalies and hyperextensibility. Chromosome analysis showed a complex karyotype involving the chromosomes 3, 8 and 18. FISH studies with paint and telomere probes confirmed the complex nature of the karyotype 46,XX,t(3;18;8)(q13.1;q22.2;q21.2). Case 2 involves a 17-year-old male with severe developmental delay and mental retardation. He was small at birth and later diagnosed with profound hearing loss, partial blindness, and a seizure disorder. On examination at age 17 years, he was small with synophrys and gynecomastia. Chromosome analysis showed a reciprocal translocation 46,XY,t(3;7)(q26.2;p15.1). FISH studies with telomere and paint probes confirmed the diagnosis. Majority of the DBCRs are associated with mental retardation and since more than 70% of the genes are known to express in human brain, DBCRs offer a large-scale resource for karyotype-phenotype correlations.

Genetic proof of unequal meiotic crossovers in reciprocal deletion and duplication of 17p11.2. *C.J. Shaw, J.R. Lupski.* Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX.

A number of common microdeletion syndromes have been shown to result from non-allelic homologous recombination (NAHR) within region-specific low-copy repeats (LCRs). The reciprocal duplications are predicted to occur at the same frequency; however, probably because of ascertainment bias and expected milder phenotypes, only few cases have been described. We previously identified seven patients with dup(17)(p11.2p11.2), the reciprocal of the Smith-Magenis syndrome (SMS) deletion (Potocki et al, Nature Genetics 2000). In 90% of SMS cases, identical ~ 3.7 Mb deletions in 17p11.2 have been identified. These deletions are flanked by large ~200 kb highly homologous directly oriented LCRs - proximal and distal SMS-REPs. The third middle SMS-REP is inverted with respect to them and maps inside the commonly deleted genomic region. To investigate the parental origin and to determine whether the common deletions and duplications arise by NAHR between the proximal and distal SMS-REPs, we analyzed the haplotypes of 13 SMS families and four dup(17)(p11.2p11.2) families using microsatellite markers directly flanking the SMS common deletion breakpoints. Eight deletions are paternal and five are maternal in origin. Five of the deletions are due to an interchromosomal exchange event, while eight are due to an intrachromosomal event. Of the four dup(17)(p11.2p11.2) cases, two duplications are paternal and two are maternal. Two duplications are due to an interchromosomal exchange event and two are intrachromosomal. When pooled with previously published data on six dup(17)(p11.2p11.2) cases, seven of ten duplications are paternal and three are maternal in origin. Six of the duplications are due to an interchromosomal exchange event, while four are due to an intrachromosomal event. Our data indicate that reciprocal deletion and duplication 17p11.2 result from unequal meiotic crossovers. These rearrangements occur via both interchromosomal and intrachromosomal exchange events between the proximal and distal SMS-REPs and there appears to be no parental origin bias associated with both common SMS deletions and the reciprocal duplications.

Novel Subtelomeric Rearrangements of Human Chromosomes Detected by Telomere FISH. *R. Saleki, C. Bacino, J. Wu, M. Santini, R. Naeem.* Mol. & Hum. Genetics, Baylor Col Medicine, Houston, TX.

Fluorescent in situ hybridization technique using a complete set of telomere specific probes (Telomere FISH) is routinely used to detect cryptic submicroscopic rearrangements that are otherwise undetectable by conventional cytogenetic methods. By revealing novel subtelomeric rearrangements, Telomere FISH can contribute to our understanding of their clinical significance. Here we report four new cases with rare abnormal telomeric regions. We present two cases in which the derivative chromosomes contained two distinct telomeric signals in tandem. In one case the 16q telomere signal was observed adjacent to the 21q telomere signal on a derivative chromosome 21. In the second case the long arm of a derivative chromosome 10 contained signals for 18p telomeric probe distal to its intact 10q telomeric region. In both cases, the breakpoints appear to be distal to the telomeric probe region. Abnormal telomeres represent a de novo event or are inherited from a parent with balanced translocation. In rare cases, the same abnormal telomeres are present in an affected proband and an unaffected parent. These telomeric rearrangements are commonly interpreted as normal rare variants with no influence on the phenotype. We report two cases that represent rare trisomic variants of subtelomeric regions. In the first case, a child with mental retardation and her unaffected mother were trisomic for the 4p telomeric region. The second case was observed in amniotic cells where G-banding had identified a paracentric inversion of the long arm of one chromosome 4. Telomere FISH indicated that fetus and the healthy father were both trisomic for 1p and monosomic for 4q telomeric regions. We present a summary of the reported rare variant telomeres from our lab and others and propose that a more detailed investigation might be necessary before their influence on the phenotype of proband can be dismissed. Theoretically, genetic phenomena such as genomic imprinting, sex specific effect, and further loss of telomeric integrity are few possibilities that might explain the inconsistency of the phenotypic expression of an abnormal telomeric region in the so called rare variants.

Submicroscopic telomere deletions of chromosome 9q. *D. Stewart¹, E. Zackai¹, A. Huang¹, L. Medne¹, K. Russell¹, E. Rossi², R. Tenconi³, B. Anderlid⁴, M. Nordenskjöld⁴, K. Gripp⁵, L. Nicholson⁵, N. Spinner¹, I. Krantz¹ and cytogenetics.* 1) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Biologia Generale e Genetica Medica, Univ di Pavia, Pavia, Italy; 3) Dipartimento di Pediatria, Univ. di Padova, Padova, Italy; 4) Dept of Molecular Medicine, Clinical Genetics Unit, Karolinska Inst., Stockholm, Sweden; 5) DuPont Hospital for Children, Wilmington, DE.

We report 3 new cases of the 9q telomere deletion, a novel chromosomal syndrome that has not been characterized. Patient 1 was a 2.5 y/o boy with developmental delay, relative microcephaly (small head relative to other growth parameters), hypotonia, coarctation of aorta with subaortic valve stenosis and a VSD. Dysmorphic features included coarse, flat facies, down-slanting palpebral fissures, a high arched palate, tented upper lip, and protruding tongue. Patient 2 was a girl with a DORV, mitral and aortic stenoses and a VSD. Dysmorphic features included relative microcephaly, bifrontal narrowing, arched eyebrows, a short, hirsute forehead, overfolded helices, small mouth and chin, a tented upper lip, high arched palate, flat occiput and a short neck with extra skin. She died at 8 weeks of complications from cardiac surgery. Autopsy revealed severe periventricular leukomalacia. No other structural abnormalities were found. Patients 1 and 2 had a de novo 46,XX, del(9)(qter) karyotype identified by telomere analysis. Patient 3 was a 2.5 y/o with acquired microcephaly, developmental delay, posterior plagiocephaly, epicanthi, high and wide nasal bridge and tip, right cryptotia, thickened left superior helix, tented upper lip, and micrognathia. Telomere analysis showed a de novo 46,XY,der(9)t(9;8)(qter;qter) karyotype. Review of 7 cases of 9q telomere deletions with our cases revealed that all patients had developmental delay, 3/10 had hypotonia, and 3/10 had relative microcephaly. Common dysmorphic features included hypertelorism, eyebrow and ear abnormalities, high arched palate, and tented upper lip. Cardiac malformations, seen in two patients, were severe. The deletion sizes and breakpoints of several patients are currently being determined in our laboratory.

Characterization of breakpoints on chromosomes 4 and 15 in a patient with Prader-Willi syndrome with an unbalanced translocation. *M.C. Varela, G.M.P. Lopes, C. Fridman, C.P. Koiffmann.* Dept Biol, Univ Sao Paulo, Sao Paulo, Brazil. mcvarela@ib.usp.br.

The Prader-Willi syndrome (neonatal hypotonia, poor sucking, hyperphagia, obesity and characteristic behavior) is caused by deletions of 15q11-q13, maternal uniparental disomy of chromosome 15 or imprinting defects. Chromosome 15 structural rearrangements have been described in ~5% of the patients with a typical or atypical PWS phenotype. A PWS patient with severe mental retardation and an unbalanced translocation $t(4q; 15q)$ was studied to characterize the extent of the deletions and to correlate with the severity of the phenotype. The patient was an 8 year-old boy, first child born at term by cesarian section when the mother was 32 and the father 35 years of age; birth weight was 2500g, birth length 50cm and neonatal hypotonia with poor suck were noticed. He walked at 46/12 years and hyperphagia and obesity began at 16/12 years of age. At 8 years of age he had severe mental retardation, behavioral problems and no speech; weight was 45kg (above 97 centile), height 1.22m (25 centile) and PC 53.5 (98-p-50 centile). Foot length was 13.5cm (below 3rd centile), whole hand measurement was 14cm (25 centile). Patient's karyotype was 45,XY,-15,der(4)t(4;15)(q35;q13) and FISH with probes D15S11/CEP15-D1521 (Vysis) detected the deletion. Both parents had normal karyotypes. The patient was diagnosed by SNURF-SNRPN exon 1 methylation assay, and the deletion extents were investigated by microsatellite analysis of markers D4S2924, D4S426, D4S1652 (4qter) and D15S1002, D15S1048, D15S1019, D15S165, D15S1031, D15S1043, D15S1010 (15q13-q14). The deletion on chr4q was distal to D4S1652 and on chr15 between D15S1031 and D15S1010. The severe phenotype in our patient could be attributed to the extent of the deletion larger than usually seen in PWS patients (between D15S1002 and D15S1048). Although the unbalance of the derivative chr4 cannot be excluded as another cause of the severe phenotype, the breakpoint was located in the subtelomeric region near the telomere, a region described as one with the lowest gene concentrations in the Human Genome. Support: FAPESP, CEPID, CNPq.

Apparently stable dicentric chromosome resulting from a whole chromosome translocation identified on an amniocentesis. *M.B. Smith¹, T. Gonzales¹, N. Casellas-Castillo², J.B. Ravnar¹, S. Schwartz³, S.A. Berend¹.* 1) Genzyme Genetics, Santa Fe, NM; 2) Santurce, Puerto Rico; 3) Case Western Reserve University, Cleveland, OH.

Chromosomes with two active centromeres are generally thought to be unstable throughout the cell cycle due to the breakage that occurs when the centromeres are attracted to opposite poles. Normal segregation can occur when the spindle apparatus from a single pole binds to both centromeres, pulling both centromeres to the same pole. Stable dicentric chromosomes generally either contain one active and one inactive centromere, or the centromeres are closely spaced and work together as a single centromere. Here we present a patient referred for amniocentesis due to a positive maternal serum screen indicating an increased risk for Down syndrome. Cytogenetic analysis revealed a dicentric chromosome resulting from a translocation between the short arms of one chromosome 14 and one chromosome 20, generating a chromosome that appeared to contain an entire chromosome 20 attached to the distal short arm of chromosome 14. The reciprocal product of this translocation was not present. After further investigation with fluorescence in situ hybridization, the derivative chromosome was found to contain centromeres from both chromosomes with ribosomal RNA present between them. The subtelomere of the short arm of chromosome 20 was not present on the derivative chromosome: 45,XY,dic(14;20)(p11.2;p13).ish dic(14;20)(D20Z1+,D20S1157-,rRNA+,D14Z1/D22Z1+). Parental chromosome analyses were normal. The patient elected to continue the pregnancy after a level four ultrasound showed no apparent anomalies; however, there were early signs of growth retardation. This translocation results in monosomy for the distal region of the short arm of chromosome 20. The phenotype for deletions encompassing this region is vague; however, clinical features reported for patients with larger deletions from band 20p12 include short stature, mental retardation with seizures, deafness, vertebral anomalies, tetralogy of Fallot, and optic atrophy. Such cases will help delineate the characteristics and stability of dicentric chromosomes.

Origin of X Chromosome in Familial 47,XXX: Evidence for Maternal Susceptibility for Recurrent Meiosis II

Non-disjunction. *O. Reish*^{1,2}, *T. Berryman*², *T.R. Cunningham*³, *C. Sher*¹, *W.S. Oetting*^{3,4}. 1) Genetic Inst, Assaf Harofeh Medical Ctr, Zerifin, Israel; 2) Sackler School of Medicine, Tel Aviv University, Tel Aviv, Israel; 3) Department of Medicine, University of Minnesota, Minneapolis, MN; 4) Institute of Human Genetics, University of Minnesota, Minneapolis, MN.

We determined the meiotic origin and the stage of non-disjunction of the extra X chromosomes in two sisters with 47,XXX chromosomal complements. Segregation of the X chromosomes in all family members was analyzed using X-linked short tandem repeat polymorphic (STRP) markers. Densitometric analysis of two STRP markers confirmed that both sisters had three copies of the X chromosome and the extra X chromosomes were maternally derived. Both sisters did not share the same maternal homologue suggesting that the recurrent trisomy is non-homologous X chromosome specific. Haplotype analysis demonstrated a reduction to homozygosity for all markers examined, covering the entire length of the X chromosomes in both sisters. These findings suggested that the extra X chromosomes have derived from meiotic II (MII) non-disjunction following a nulitransitional meiotic I (MI). A lack of X chromosome recombination in the extra chromosomes of both sisters suggests a maternal genetic defect leading to an erratic recombination at MI. As a recurrence of MII non-disjunction of X chromosome is rare, it is possible that for a second event to occur in maternal gametes, an additional risk factor such as increased maternal age, as occurred in the second sister, is required. This information may contribute to further understanding of mechanisms leading to X chromosome non-disjunction. It may also assist the clinician in more accurate counseling of couples with a previous X chromosome trisomy in future pregnancies.

Engineering chromosomal rearrangements in mice to model del(17)(q21q23) and Down syndrome. *Y.E. Yu¹, M. Morishima², A. Pao¹, Y. Qi¹, S. Rivera¹, A. Baldini^{1, 2}, A. Bradley^{1, 3}.* 1) Dept of Molec & Human Genetics; 2) Dept of Pediatrics (Cardiology), Baylor College Med, Houston, TX; 3) Sanger Institute, Cambridge, UK.

del(17)(q21q23) is a rare human deletion disorder with the phenotypes of craniofacial abnormalities, esophageal atresia, and heart defects, such as septal defects and overriding aorta (Marsh et al., *J. Med. Genet.*, 2000, 37, 701). Our group has generated many hemizygous deletions in the syntenic regions on mouse chromosome 11 using chromosome-engineering technology (Yu & Bradley, *Nature Review Genetics*, 2001, 2, 780). Similar heart defects were detected in mice that carry one of the deletions, which spans 5 cM and is located between Mpo and Chad. Importantly, mice carrying both the deletion and the reciprocal duplication were normal. Thus, these mutant mice can provide a model system for the genetic dissection of this human chromosomal region. Down syndrome is caused by human trisomy 21. Because of the existence of highly conserved linkage groups between human chromosome 21 and three segments of the mouse genome on chromosomes 10, 16, and 17, we have started engineering a new mouse model of Down syndrome by generating duplications of these segments. The selected endpoints of the duplications are located immediately outside the mouse chromosomal segments that are conserved on human chromosome 21. At this moment, we have nearly completed the duplication on mouse chromosome 10 and have also started constructing the rearrangement on mouse chromosome 17 in mouse embryonic stem (ES) cells. The endpoints of the duplication on mouse chromosome 16 have also been determined. The engineered ES cells will be used to establish mice with triple hemizygous duplications. This model can provide tissues for analyzing the developmental consequences of human trisomy 21 and can also be used for the development of novel therapeutical interventions. We also intend to engineer smaller overlapping duplications within the mouse chromosomal regions that conserved with the trisomic human chromosome 21 regions to identify the causative gene(s).

Program Nr: 749 from 2002 ASHG Annual Meeting

Disease Associated Balanced Chromosomal Rearrangements in 2000 Cytogenetic Analyses. *K. Prabhakara, A. Radha Ramadevi.* Diagnostics Division, Centre for DNA Fingerprinting & Diagnostics, ECIL Road, Hyderabad 500 076, India.

Disease associated balanced chromosomal rearrangements (DBCRs), which disrupt, delete or inactivate specific genes have been instrumental in positional cloning of many disease genes. We report here DBCRs found in our 2000 cytogenetic analyses in the referred population. The cytogenetic analysis was done in GTG-banded metaphases and fluorescence in-situ hybridization (FISH) was carried out whenever needed for the molecular cytogenetic characterization of the abnormality. DBCRs was detected in four cases: de novo pericentric inversion of chromosome 4 in a boy with piebaldism and mental retardation; familial 9;11 translocation and XX sex reversal in a phenotypic boy with dysmorphic features, delayed development and cryptorchidism; 5;13 translocation in an oligozoospermic male; familial 11;21 translocation in a female child with regression of milestones and mental retardation. The frequency of DBCRs in this referred population was 0.2 percent. Identification of DBCRs has greater implication in the characterization of disease genes in breakpoint regions involved in the chromosomal rearrangement.

Correlation between cytogenetic, fluorescence in situ hybridization and clinical findings in two cases of ring chromosome 4. *C.E. Uria Gomez, R. Garcia Cavazos, D.G. Mayen Molina, M.J. Zavaleta Abreu.* Depto. de Genetica, Inst. Nal. de Perinatologia, Mexico D.F. Mexico.

The ring chromosomes are cause of malformations, mental and growth retardation. The presence of ring chromosome 4 is a rare event. When the ring is complete, subtelomeric sequences are intact, and this cytogenetic finding is described as ring syndrome. We present two cases of ring chromosome 4 and discussed the cytogenetic, FISH, and clinical findings. The first case is a 4 year-old boy who was born at term from healthy non consanguineous parents. At birth the patient present bilateral preaxial polydactyly. He showed growth retardation, prominent sagital suture, microcephaly, midfacial hypoplasia, hirsutism, narrow forehead, low-set ears and narrow palate. The second case is a 18 months boy who was born at term from healthy non consanguineous parents. He showed intrauterine growth retardation, microcephaly, bilateral microtia, septal defect ventricular, clinodactyly of fifth finger and psychomotor retardation. **METHODS.-** Cytogenetic studies were performed in peripheral blood lymphocytes. FISH was performed using telomeric probes for chromosome 4. **RESULTS.-** Chromosomal analysis in the first case showed 46,XY,r(4)(p16.3q35.2) in 81/100 metaphases observed. Mitotic instability of the ring was observed in the rest of the cells. With GTG bands it seems that there was not material lost, however only one signal corresponding to 4qtel was observed by using FISH, so the 4ptel region was deleted. Chromosomal analysis in the second case showed 46,XY,r(4)(p16q35) in 92/100 metaphases observed. Mitotic instability of the ring was observed in the rest of the cells. With FISH the signals of 4ptel and 4qtel were absented in the ring chromosome. **DISCUSSION.-** We excluded the presence of ring syndrome because the 4ptel region was deleted in the first case and 4ptel and 4qtel as well in the second. The clinical findings support this. Probably the clinical findings are the results of both, the deleted material and the instability of the ring. We did not exclude some association with the Wolf-Hirshhorn syndrome, since in both cases the 4pter region is deleted.

Three cases of rare inversion of chromosome in couples with recurrent abortion. *H.W. Seol¹, H.J. Koh¹, S.K. Oh^{1,2}, D. Hwang³, Y.M. Choi^{1,2}, S.Y. Moon^{1,2}.* 1) Cytogenetics Lab., Institute of Reproductive Medicine and Population, Medical Research Center, Seoul National University, Seoul, Korea; 2) Department of Obstetrics and Gynecology, College of Medicine, Seoul National University; 3) Hamchoon Women's Clinic, Seoul, Korea.

Since the advent of new banding technique, diverse chromosome variants have been detected as well as subtle structural rearrangements and inversion. The risk of abnormal pregnancy outcome in a inversion carrier is a consequence of the formation of gametes with partial duplication and partial deletion, which in turn result from a crossover occurring within the inverted segment during meiosis. These chromosome variants have been found in increased frequency in association with reproductive failure. In a couple with experience of five fetal losses, a maternal pericentric inversion of chromosome 5 (46,XX,inv(5)(p15;q11)) was ascertained through conventional cytogenetic analysis and fluorescent in situ hybridization (FISH) with LSI Cri-du-Chat(5p15.2) probe (VYSIS, USA). A paternal pericentric inversion of chromosome 9 (46,XY,inv(9)(p24q12)) was analyzed with TelVysion 9p probe in a couple with three fetal losses. And in a couple with two fetal losses, a maternal paracentric inversion of chromosome 13(46,XX,inv(13)(q13q22)) was confirmed with LSI 13(13q14) probe. Therefore couple who had experienced repetitive fetal losses have to be examined parental chromosomal analysis and genetic counseling such as prenatal diagnosis should also be considered in subsequent pregnancy.

Craniosynostosis and congenital heart anomalies associated with a maternal deletion of 15q15-22.1. *P.G. Wheeler, N. Shur, J. Cowan.* Dept Pediatrics, Div Genetics, Tufts Univ Sch Medicine, Boston, MA.

Interstitial deletions of 15q outside of the Prader-Willi/Angelman region (15q11.2-13) are uncommon. To date there have been 2 reports of individuals with paternal deletions in 15q15-22.1 with one case having craniosynostosis (del 15q15-22.1) and the other congenital heart disease (del 15q15.2-21.2). We report on a female infant with a maternal 15q15-22.1 deletion. This infant was noted at birth to have turribrachycephaly secondary to congenital craniosynostosis. In addition, a variant of tetralogy of Fallot was found as was unusual overlapping of the 3rd, 4th and 5th toes. She had a tall, prominent forehead, depressed nasal bridge and downslanting palpebral fissures. She had initial hypotonia and follow-up at 8 months indicates developmental delay. Karyotype analysis found a de novo maternal deletion of 15q15-22.1. Our patient shares some features with the previously reported paternal deletions of this area, but her problems are more severe than in either case. Since she is the first reported maternal deletion of this area, the possibility of imprinting as an explanation for her increased severity has to be considered. The presence of craniosynostosis in 2 individuals with this deletion also implies that an area critical for sutural function is in 15q15-22.1. The child with congenital heart disease and the 15q15.2-21.2 deletion did not have craniosynostosis implying that the critical area for sutural formation may be either in 15q15-15.2 or 15q21.2-22.1. There has been one report of a mutation in fibrillin 1 (15q21.2) leading to Shprintzen-Goldberg syndrome (craniosynostosis plus Marfanoid habitus). But, other individuals with deletions encompassing 15q21.2 have not been reported to have craniosynostosis and thus 15q15-15.2 may be the most likely region for a gene involved in suture function.

Molecular characterization of mosaic tetraploidy in chorionic villi tissue from a missed abortion. *J. Van Brunt*¹, *R. Mao*³, *A. Fauchaux*⁴, *M.M. Li*^{1,2}. 1) Hayward Genetics Center; 2) Department of Pediatrics, Tulane University School of Medicine, New Orleans, LA; 3) DNA Diagnostic Laboratory, University of Utah, Salt Lake City, UT; 4) Professional Medical Co., LaPlace, LA.

The generation of tetraploid cells through the failure of mitotic division is a common artifact in long-term cultures of chorionic villi. This culture-induced mosaicism makes it difficult to distinguish constitutional tetraploidy from pseudotetraploidy. When both the diploid and tetraploid cell lines are female, the interpretation is further complicated by the possibility of maternal cell contamination (MCC). A POC specimen from a missed abortion at 9 5/7 weeks gestation was received for cytogenetic analysis. Chorionic villi were cultured for chromosome analysis. Two hundred metaphases were analyzed and the results showed that 70% of them were tetraploid (92,XXXX), 24% diploid (46,XX), and 6% octaploid. In order to rule out the culture artifact, we carefully screened all the primary cultures and compared the percentage of tetraploid cells in this case with that of CVS cultures from a normal pregnancy (22 %) and published data (4-58%). Since tetraploid cells were present in all the primary cultures of this case at a much higher percentage, it is unlikely that these cells were due to culture artifacts. To rule out MCC and to explore the mechanisms of tetraploidy formation, we studied nine polymorphic DNA markers in DNA samples from the chorionic villi cultures and parental blood samples. Five of the nine markers were informative. The chorionic villi sample displayed two alleles, one maternal and one paternal, for each informative marker. These results ruled out MCC since this would result in 3 alleles for informative markers. Trispermy, or a diploid egg fertilized by a diploid sperm, is not likely to be the cause of the tetraploidy as this would result in 3 or 4 alleles for informative markers. Therefore, this constitutional mosaic tetraploidy is most likely the result of postzygotic duplication. Because the fetal tissue was not available for the study, we could not determine if the pregnancy wastage was caused by placental insufficiency only or by tetraploidy in both the placenta and the fetus.

A child having mosaicism for an extra ring chromosome 16 and normal development. *U.T. Sundaram¹, K. Turner¹, P. Papenhausen², J. Bodurtha¹, C. Jackson-Cook¹.* 1) MCV Campus of VCU, Richmond, VA; 2) LabCorp RTP, N.C.

Through the use of FISH the complete characterization of extra structurally abnormal chromosomes (ESC) has expanded, thereby allowing for the recognition of new clinical entities resulting from partial trisomic imbalances. We report a case with mosaicism for an extra ring chromosome 16. The female proband presented at 6 months of age with a unilateral transverse palmar crease and epicanthal folds, and was referred for genetic evaluation to rule out Down syndrome. Her growth and development were age appropriate. A standard GTG-banding chromosome study showed that she had a mosaic complement with an ESC in 20% (7 of 34 cells) of the lymphocytes scored. Based on FISH & GTG-banding, the marker was further defined as a ring [r(16)(p13.3q22)]. Parental chromosomes appeared normal. Follow-up studies at 2.5 years of age showed no developmental delay. Her height and weight were in the 90th percentile and she had no dysmorphic findings. A FISH analysis at 2.5 y.o., using cultured and uncultured lymphocytes, as well as buccal mucosa cells, showed no significant difference in the proportion of cells having the r(16), which was now present in only 1.4%, 3.5%, and 2.7% of cells, respectively. To date only 5 other cases of an extra r(16) have been reported, including 4 patients with mosaicism (3 ascertained prenatally; 1 postnatally) and 1 with an extra r(16) in all cells (postnatally ascertained). The clinical findings in these patients have varied, ranging from a normal phenotype (a child with 90% mosaicism) to severe mental retardation with microcephaly and other anomalies (a case with 75% mosaicism). The observed disparity in clinical outcome for these cases showed no clear correlation between phenotypic severity and mosaicism level and/or breakpoint involved in the rings. Thus, until more information is obtained to better understand the causes of the variation in phenotypic outcome, providing accurate genetic counseling for individuals having an extra r(16) will remain a dilemma.

Deletion 3p25 in a mother and child. *S. Sklower-Brooks¹, J. Pappas², C. Duncan¹, M. Genovese¹, H. Gu¹, E.C. Jenkins¹.* 1) NYS Institute for Basic Research Staten Island, NY; 2) Dept. of Pediatrics NYU School of Medicine New York, NY.

A mother and her infant with del(3)(p25) were identified due to dysmorphic findings in the infant. Born at 36 weeks by C-section due to breech position, to a G2P1 30 y/o, her birth weight was 2800g. Pregnancy was complicated by morning sickness. Because of tachypnea she was admitted to the NICU and craniosynostosis was considered but ruled out. A karyotype was requested. She was discharged on the third day of life. At 2 weeks of age she had mild facial asymmetry, overriding sutures, deep periorbital creases, epicanthal folds, mildly downslanted palpebral fissures and micrognathia. At 1 mo. her growth parameters were normal. Based on the literature, genetic counseling was provided to the family that the child would likely have significant developmental disability. The mother was subsequently found to have the identical deletion on chromosome 3. No evidence of a translocation was present by G-banding, FISH with wcp3 & a 3p telomere probe. The karyotype of the baby girl is 46,XX,del(3)(p25.3).ish 3(wcp3x2),del(3)(p25(D4S4559-))(mat). About 30 cases of 3p25 deletion have been reported. Classic features of the syndrome include, characteristic facies, microcephaly, mental and growth retardation. Tazelaar et al, 1991 reported on an affected mother and son with 3p25 deletion. Another case has been reported of a prenatally detected, parentally transmitted del3p25.3 with no phenotypic effect (Knight et al, 1995) and we recently learned of a similar case identified during infertility work-up in which the normal father carries the deletion (S.Fallet, personal communication). Despite extensive cytogenetic evaluation no cryptic translocation was detected in the mother, although this is certainly a possibility. This family illustrates a genetic counseling dilemma. Careful assessment of the breakpoint appears critical in the 3p-syndrome. These three cases likely have breakpoints distal to the genes responsible for the syndrome. Further molecular testing with probes from the deleted region might provide an explanation for the lack of phenotype. (Supported in part by the NYS Office of Mental Retardation and Developmental Disabilities).

Partial trisomy 13 due to a der(13)t(13;13)(p11.2;q22) translocation. A. Santiago-Cornier¹, S. Carlo¹, M. Borges², V. Franceschini¹, S. Kleyman³, M.J. Macera³, A. Babu³. 1) Genetics Division, Ponce school of Medicine, Ponce, PR; 2) San Juan Bautista School of Medicine, San Juan, PR; 3) Division of Molecular Medicine and Genetics, Department of Medicine, Wyckoff Heights Medical Center, Brooklyn, NY.

A 7 month old baby girl was referred for genetic evaluation because of a cleft palate, polydactyly of fingers, broad and adducted thumbs, broad big toes, borderline low set ears, thin lips, bulbous nose tip and mild hypertonicity. She was born to a 21 year old G3P2A1 mother after an uneventful pregnancy and vaginal delivery. Peripheral blood chromosomal analysis was performed to rule out suspected mosaic trisomy 13. Cytogenetic analysis revealed additional material in the short arm of chromosome 13 with band homology to the short arm (p) of chromosome 9 as well as the distal long arm (q) of 13. Fluorescence in situ hybridization (FISH) using whole chromosome paints (wcp) for 9 and 13 revealed that the additional segment was derived from 13. Based on G-band patterns and FISH observations the karyotype was designated as 46,XX,der(13)t(13;13)(p11.2;q22).ish der(13)(wcp9-,wcp13+). Parental peripheral blood has been requested to perform cytogenetic analysis to determine if the der(13) is a product of an unequal segregation of a familial balanced translocation or the de novo appearance of an unbalanced derivative chromosome. There have been about twenty reported cases of partial trisomy 13 due to a duplication of 13q22 to qter. The clinical findings included among others, prominent forehead, epicanthic folds, low set dysplastic ears, frequent polydactyly, high palate and inguinal hernias. Major malformations, described for full trisomy 13 were not common in these cases, however, cleft lip and cleft palate were reported. The mild presentation of this child prompted the initial diagnosis of a possible mosaic trisomy 13. The clinical features in this case are consistent with partial trisomy of 13 and are presented in an effort to elucidate phenotype and genotype relations.

Clinical, Somatic Cytogenetic and Molecular (AZF Microdeletions) evaluation of 133 men with Idiopathic Azoospermia or Oligospermia. *J.M. Pina-Neto¹, R. Bisinella¹, R.C.V Carrara¹, E. Sartoratto².* 1) Dept Genetics, Fac Medicine Ribeirao Preto, Sao Paulo, Brazil; 2) Molecular Genetics Center, University of Campinas (UNICAMP), Campinas, Sao Paulo, BRAZIL.

The objective was to investigate the frequency of somatic chromosome abnormalities and AZF microdeletions in patients with idiopathic azoospermia or oligospermia. Were studied 133 men evaluated at University Hospital of Faculty of Medicine of Ribeirao Preto, BRAZIL. The somatic karyotype was obtained by lymphocyte culture and analyzing 100 GTG metaphases and the AZF microdeletions were evaluated through PCR multiplex using 28 STSs specific for intervals 5 and 6 of the Yq11 region (Henegariu et al., 1994). In 13/133 patients (approx. 10%) we detected a somatic chromosomal anomaly (6 patients with 47,XXY karyotype, 2 with a mosaic 47,XXY/46,XY, 2 with a balanced 13q/14q translocations, one male 46,XX, one 45,X-11%;/46,X,+frag-89%, one 46,XY/47,XY,+i(22p)-10%. The microdeletions of AZF genes were detected in 9/133 patients (6.77%), with all AZF genes (a,b,c) involved in microdeletions. This work reinforces the importance of genetics studies before male submission to assisted fertilization techniques.

Three examples of complex chromosomal rearrangements (CCRs): Family studies and FISH analysis. *G.D. Wenger^{1,3}, E. Hamelberg¹, M. Millard¹, G.E. Herman², J.M. Gastier^{1,3}.* 1) Lab Medicine, Children's Hosp, Columbus, OH; 2) Pediatrics, Ohio State University; 3) Pathology, Ohio State University.

CCRs, defined as those involving 2 or more chromosomes and at least 3 breakpoints, are rarely seen in constitutional karyotypes. The probability that an essential gene is disrupted or that subtle gain or loss of sequences occurs during generation of the CCR increases with the number of breakpoints. Familial CCRs tend to have fewer breakpoints, involve fewer chromosomes (cs) than those that are not familial, and are transmitted frequently through females. We report two familial and one de novo cases of CCRs. CCR1 was identified in a newborn with multiple congenital anomalies. The mother (G13P7) had a 3 break rearrangement involving one cs 6 and both the short and long arms of one cs 10. Previous pregnancy loss specimens had two different unbalanced karyotypes. The infant's unbalanced karyotype included a rec(10). CCR 2, ascertained through a 1 year old child with macrocephaly, developmental delay, and deafness, involved an insertion and translocations between cs 2, 3, and 8. The mother and an older normal sib each had the balanced CCR in which 2p21-p25.1 was inserted into cs 8 at q24.1, and the segment distal to the insertion point was exchanged in an apparently balanced reciprocal translocation with 3p. The infant had an unbalanced cs complement including the der(3) and the der(8), and two normal cs 2 homologs, resulting in partial trisomy for 2p. CCR3 was identified in a newborn with cleft palate, brain abnormalities, and cardiac defect. Conception had followed insemination with donor sperm; a previous pregnancy conceived using the same sperm donor resulted in a normal offspring. The CCR involved cs 2, 5, 6, 8, and 10, with apparently balanced reciprocal translocations between 2q and 5q, and between the short arm of the same cs 5 homolog and 8q; an interstitial deletion of 6q; and an inverted duplication of 10p, resulting in partial trisomy for 10p and partial monosomy for 6q. The maternal karyotype was normal. These rare cases provide opportunities to observe meiotic behavior of complex rearrangements, as well as presenting challenges for analysis and nomenclature.

Construction of a natural panel of 11p11.2 deletions. *K. Wakui*¹, *L. Potocki*^{1,2}, *C.D. McCaskill*¹, *P.-L. Kuo*³, *M. Irons*⁴, *J.T. Hecht*⁵, *L.G. Shaffer*¹. 1) Molecular & Human Genetics, Baylor College Medicine, Houston, TX; 2) Genetics, Texas Children's Hospital, Houston, TX; 3) OB/GYN, National Cheng-Kung University Medical College, Tainan, Taiwan; 4) Genetics and Metabolism, Children's Hospital, Harvard Medical School, Boston, MA; 5) Pediatrics, University of Texas Medical School at Houston, Houston, TX.

The Potocki-Shaffer syndrome (PSS, OMIM#601224) is a contiguous gene deletion syndrome caused by deletion of multiple genes within the short arm of chromosome 11 [del(11)(p11.2p12)]. The full spectrum of PSS has been delineated to include mental retardation, multiple exostoses, biparietal foramina, minor craniofacial anomalies and genital anomalies in males. The presence of multiple exostoses is associated with deletion of the *EXT2* gene and the presence of biparietal foramina has been shown to be associated with deletion of *ALX4*, both within 11p11.2. Specific genes related to mental retardation or other abnormalities have yet to be identified. We constructed a BAC/STS map of 11p11.2-p12 including the *EXT2* and *ALX4* regions using eight deletion patient cell lines by FISH and STS analyses. The extent of the largest deletion is about 10 Mb. The smallest deletion includes only the *EXT2* gene. This patient has isolated multiple exostoses and not PSS. The most distal breakpoint in the PSS patients we analyzed is about 41.5 Mb from the p terminus and the proximal breakpoint is about 49.5-50 Mb from the p terminus (close to the 11cen). Seven patients have deletion of both *EXT2* and *ALX4* regions. One patient is deleted for *EXT2*, but not *ALX4* by FISH analysis. However, this patient has biparietal foramina, and disruption of *ALX4* at the proximal deletion breakpoint is suspected. Five patients from three families have no mental retardation. Thus, the gene(s) related to mental retardation may be located either between 45.7-50.0 Mb and/or 41.3-44.3 Mb from the p terminus. Further delineation of the breakpoints will refine the regions in which to search for the gene(s) causing the mental retardation and the craniofacial features of the syndrome and may uncover sequences susceptible to chromosome rearrangement.

Two Cases of Interstitial Duplications Detected Only by Interphase FISH. *P.R. Papenhausen¹, P. Singh-Kahlon¹, S. Griffin¹, P. Stone¹, K.K. Rogers², J.E. Rosini³, I.K. Gadi¹, J.H. Tepperberg¹, P.M. Mowrey¹.* 1) Dept Cytogenetics, Labcorp of America, Res Triangle Pk, NC; 2) Cytogenetics, UNC-Chapel Hill, Chapel Hill, NC; 3) REFUAH Health Center, Spring Valley, NY.

A seven-year-old boy was referred for microdeletion FISH (DiGeorge/VCF) secondary to coarctation of the aorta, microcephaly, hypotelorism, low set ears, and developmental delay (mild MR, 25th percentile height and weight). There was a language disorder with skills >3 yrs below normal for age. During the course of routine metaphase analysis using the D22S75 probe (Vysis, Inc.) it was apparent that three separate signals were discernable in 47/50 interphase cells, although normal signals were observed in metaphase analysis. High resolution G-banding follow-up showed normal appearing 22 homologues. A second familial study involved a 5-year-old boy referred for hyperactivity and aggressiveness and his 14-year-old MR sister. Both had a small increase in the size of the terminal 1p36.1 euchromatin. FISH for the subtelomere (CEB108/T7) was normal, but follow-up analysis for the more proximal (1p36.1) p58 and midi satellite probes showed that both of these loci were duplicated. The duplications were again apparent only in interphase analysis, demonstrating the enhanced resolution available at interphase. Interestingly, further familial studies of a normal sister and the borderline retarded mother also showed the apparent duplication. The mother had abnormal teeth and an elfin-like face, but this was not seen in the children. Continued studies of this family are planned to include maternal relatives. Cases with duplications of the commonly deleted segments in microdeletion syndromes have been expected from the postulated meiotic misalignment mechanism, but possibly because of mild phenotypes few have been detected. Another reason could be that these are also below the resolution of metaphase FISH. The associated heart defect in case 1 may initiate FISH analysis in similar cases and interphase vigilance may help reveal a new syndrome. Case 2 also demonstrates the utility of interphase FISH, but will require further familial follow-up to establish phenotypic effects.

Distal Xp deletion associated with unbalanced X-rearrangement in patients with dysmorphism, short stature and Leri-Weill dyschondrosteosis. *S.K. Tan¹, Y.S. Choy², A. Mekesat¹*. 1) Department of Cytogenetics, Kuala Lumpur Hospital, Kuala Lumpur, Malaysia; 2) Genetic Unit, Pediatrics Institute, Kuala Lumpur Hospital, Kuala Lumpur, Malaysia.

Very distal deletion of short arm of chromosome X results in the loss of SHOX gene and therefore short stature with or without Medelung deformity in an individual. However, the deletion may not be seen in routine karyotyping but would be strongly suspected in X-rearrangement involving the distal p arm of X chromosome particularly so if there is mesomelic dwarfism clinically. Here, we described 3 patients with such deletion proven by FISH using TelVysion XpYp spectrum green probe. The first patient is a 5 year old girl with severe short stature, Medelung deformity, dysmorphic facies, atrium septal defect, ocular albinism and global developmental delay associated with 46,X, der(X)t(X;17)(p22.3;p13). Another patient, a 2-year-old boy presented with similar problems had undescended testes in addition due to dup(X)(p22.1-22.3). The third patient was clinically a perfect girl with just short stature and complete female genital organs but karyotype showing der(X)t(X;Y)(p22.3;q12). IGF1 and GH levels after GH stimulation were normal.

How telocentric mouse chromosomes are. *C.C. Lin^{1,3}, Y.C. Li¹, C. Lee²*. 1) Department of Life Sciences, Chung Shan Medical University, Taichung, Taiwan; 2) Department of Pathology, Brigham and Woman's Hospital, Harvard Medical School, Boston, MA, USA; 3) Department of Laboratory Medicine and Pathology, University of Alberta, Edmonton, Alberta, Canada.

Telocentric is the term implying that a chromosome has a centromere located at the end of the chromosome arm. Unfortunately, this terminology has an inherent problem since no normal eukaryotic chromosome is truly telocentric. Mouse chromosomes in general were considered to be telocentric. However some recent publications still described them as telo/acrocentric. In this investigation, we used 4 DNA probes for multi-color FISH studies to determine how telocentric the mouse chromosomes are. These included mouse major and minor satellite DNAs, mammalian telomeric DNA and whole chromosome painting probes for mouse chromosomes 4, 5 and 13 specifically. Hybridization signals on metaphase chromosomes showed that mouse minor satellite DNA (centromeric DNA) was closely associated or co-localized with telomeric sequence in one of the terminal ends of mouse chromosome. Fiber-FISH study further demonstrated that mouse minor satellite DNA is organized as single contiguous array closely associated with telomeric DNA array in those specific mouse chromosomes examined. Our study suggested that a mouse centromere can be located within 10 kb from the telomere of the mouse chromosome. This study was supported by a grant from the National Health Research Institute (NHRI- EX91-8933SL) of Taiwan.

Isolation and identification of a novel centromeric satellite DNA family highly conserved in several mammalian species. *Y.C. Li¹, C. Lee², W.S. Chang¹, S.Y. Li¹, C.C. Lin^{1,3}*. 1) Department of Life Sciences, Chung Shan Medical University, Taichung, Taiwan; 2) Department of Pathology, Brigham and Woman's Hospital, Harvard Medical School, Boston, MA, USA; 3) Department of Laboratory Medicine and Pathology, University of Alberta, Edmonton, Alberta, Canada.

In an attempt to amplify cervid centromeric satellite II DNA from the genomes of Indian muntjac and Chinese muntjac, a pair of primers derived from the white tailed deer satellite II DNA clone (OvDII) yielded a prominent ~1 kb PCR product (in addition to the expected 0.7 kb satellite II DNA fragments) in both species. The ~1 kb products were cloned, sequenced, Southern blot analyzed and FISH-studied to reveal that the ~1 kb cloned sequences indeed represent a previously unknown mammalian satellite DNA family which now designated as cervid satellite IV DNA. ~1 kb PCR clones were also obtained from the genomes of the black tailed deer and Canadian woodland caribou with similar primer pairs. Extremely high sequence conservation (over 90% homology) was observed among the clones generated from all four deer species and PCR-Southern hybridization experiments further verified the co-amplification of two kinds of satellite DNA sequences with a same pair of primers. This satellite DNA was found to co-localize with CENPs at the kinetochore by simultaneously FISH and immunofluorescence study. Due to its highly sequence conservation and close association with kinetochores, the newly identified satellite DNA may have a functional centromeric role. This study was supported by a grant from the National Health Research Institute (NHRI-EX90-8933SL) of Taiwan.

Chromosome-specific variation in telomere lengths & somatic cell aneuploidy acquired with aging. *R. Rehder, L. Corey, C. Jackson-Cook.* VCU, Richmond, VA.

Two proposed hallmarks of genomic instability are telomere shortening and increased chromosomal aneuploidy. To test the hypothesis that somatic cells acquire genomic changes as one ages (>50 y.o.), we compared: (1) aneuploidy levels in cells from different tissues (lymphocytes & buccal mucosa cells) and growth conditions (cultured vs. uncultured lymphocytes) using interphase FISH; (2) chromosome arm-specific telomere lengths (using a semi-quantitative Q-FISH based method); and (3) chromosome-specific acquired aneuploidy levels to telomere lengths. To date, we have scored the above attributes in 15 females (ages 52-72). In all cell types and females studied, chromosomal loss exceeded gain, with chromosomes having large heterochromatic regions (qh+) being lost with the highest frequency [chromosomes 16 (4.2%) and 9 (3.4%) based on both CEP & distal long arm probes; thus showing true loss rather than fusion of the qh+ regions], followed by chromosomes 17 (3.1%); X (2.7%); and 1 (2.6%). Differences in aneuploidy frequencies (loss but not gain) were also seen between tissues, with loss of chromosomes 1 and 17 being significantly lower in buccal mucosa cells compared to lymphocytes ($p < 0.01$). Cultured and uncultured cells also differed, with X chromosome loss being nearly twice as frequent (4.6% vs. 2.7%) in the cultured cells ($p < 0.01$). For chromosome-specific telomere lengths, differences were seen between females and chromosomes ($p < 0.0001$), with 21p, 14p, and 22p having the longest, while 4p and 2q had the shortest telomeres. This latter finding is of particular interest given recent reports of a variant for a deletion of the 2q subtelomeric region. As expected, average telomere length decreased with increasing age. Although some individuals showed a clear trend toward increased acquired aneuploidy levels with shortened telomere length (p or q arm), no consistent pattern between these traits has yet emerged. In summary, we detected individual and chromosome-specific differences in acquired aneuploidy frequencies and telomere lengths. This information could be helpful for designing tests (mutagen, health or pharmacogenetic applications) to screen for individual differences in susceptibility to change in the human genome.

Spectral karyotyping on 25 constitutional marker chromosomes. *P. Guanciali Franchi*^{1,2}, *E. Morizio*^{1,2}, *D. Fantasia*^{1,2}, *M.M. Rinaldi*⁴, *L. Cristini*³, *A. Simonelli*³, *A. Giannotti*⁵, *F. Lonardo*⁶, *A. Turci*⁷, *A. Zatterale*⁸, *M.G. Ciavarella*^{1,2}, *R. Mingarelli*⁹, *L. Stuppia*^{1,2}, *G. Calabrese*^{1,2}, *G. Palka*^{1,2}. 1) Scienze Biomediche, University of Chieti, Chieti; 2) Serv Genetica Umana, Pescara Hospital, Pescara; 3) S. Citogenetica, Frosinone; 4) Genetica Medica, Ospedale Cardarelli, Napoli; 5) Genetica Med, Ospedale Bambin Gesù, Rome; 6) Genetica Medica, Benevento Hospital, Benevento; 7) Citogenetica, Ravenna Hospital, Ravenna; 8) S. Citogenetica ASL-NA1, Napoli; 9) CSS-Mendel, Rome, Italy.

Constitutional marker chromosomes (MCs) are often associated with mental retardation and phenotypic abnormalities. Their characterisation is often difficult, expensive and time consuming, especially when MCs are found in prenatal diagnosis. Spectral karyotyping (SKY) has allowed a precise and rapid classification of chromosomal rearrangements with a single hybridisation of 24 chromosome painting probes. We report on a study of 25 cases of MCs found at pre- or postnatal diagnosis using SKY analysis. Eleven cases were detected at amniocentesis and 14 in postnatal tests performed for repeated miscarriages, or congenital malformation with or without mental retardation. In 10 cases SKY analysis allowed to classify MCs as der(22), in 7 of which with normal phenotype, while in 1 case associated with repeated abortions, in 1 with mental retardation, and in the last patient with anal atresia and cat-eye syndrome critical region duplication. Five cases showed MCs which SKY defined as invdup(15). In 3 of these there was normal phenotype with no involvement of Prader-Willi/Angelman syndrome (PWS/AG) critical region, while in the other 2, duplication of PWS/AG critical region was found by FISH on invdup(15) associated with mental retardation and other dysmorphisms. The remaining cases, all phenotypically abnormal, showed involvement of chromosomes 2, 3, 5, 13, 16, and 18. SKY analysis provided a fast and reliable tool for the identification of all MCs, highly important in the eleven MCs cases found at amniocentesis. Moreover, in combination with FISH using locus specific probes, SKY approach allowed a finer clinical and prognostic evaluation of patients, reducing genetic counselling dilemmas.

Ring chromosome 4 with deafness, developmental delay, and type 2 diabetes mellitus. *P.R. Blackett, S. Li, J.J. Mulvihill.* Pediatrics, University of Oklahoma, Oklahoma City, OK.

Ring formation of chromosome 4 usually has a predominant loss of distal 4p including the Wolf-Hirschhorn syndrome region [WHS]. We describe a case with r[4] in a girl who presented without features of WHS; she had mild developmental delay, deafness, short stature, obesity, and onset of type 2 diabetes in adolescence. Karyotype analysis revealed a monocentric ring chromosome 4 in 20 cells, 46XX,r[4][p16q35]. Parental karyotypes were normal. FISH analysis with telomeric 4p and 4q probes failed to detect 4p and 4q signals. A DNA probe corresponding to the WHS region showed 2 copies of the signal. Hybridization with the FGFR3 probe revealed a single band with the same intensity in samples from the patient and patient's mother excluding a deletion. We conclude that the 4p junction was distal to the WHS and FGFR3 loci but proximal to the D4S3360 marker. The 4q breakpoint was close to the telomere. The phenotype seems different from previous patients with 4p- or r[4], which have had more distal 4p deletion. The phenotype including skeletal findings and early onset of type 2 diabetes is inconsistent with other cases with 4p deletions. The findings suggest that the selective absence of distal genes on 4p could have lead to the phenotype including obesity and/or type 2 diabetes.

A complex family history and unusual FISH telomere findings. *E. Mak-Tam, W.S. Meschino, D. Allingham-Hawkins, A. Angelo, E. Capua, A. Mok, G. Rasiuk, P.R. Wyatt.* Dept Genetics, North York General Hosp, Toronto, ON, Canada.

The proband was referred to the genetics clinic at 3 years and 9 months. She had dysmorphic features, microcephaly, global developmental and language delay. She had deep-set eyes, a prominent nose with wide nasal bridge and mild micrognathia. She was similar in appearance to her mother who also was dysmorphic, microcephalic and significantly delayed. A four-generation pedigree showed an extensive maternal family history including schizophrenia and developmental delay with symptoms in the maternal grandmother and almost all maternal aunts and uncles of the proband. Only one maternal aunt has a normal phenotype. Chromosome, Fragile X and FISH for 22q11.2 results were all normal. FISH using the VYSIS telomere Xp/Yp probe showed an additional signal on the q terminal of one X chromosome in addition to the normal Xq telomere. This cryptic subtelomeric duplication of Xp (or homologous Yp sequences) was confirmed with probes from a second manufacturer (Cytocell). This unusual X chromosome was also present in the proband's mother. A maternal first cousin presented with developmental delay, speech problems and ADHD was also seen in the clinic. His karyotype was found to be 47,XYY. Unexpectedly, both he and his clinically normal mother were found to carry the same duplicated X. It is not clear if this X is clinically significant or a familial variant. One ambiguous finding is the presence of the duplicated X in both the proband's affected mother and her normal sister. A possible explanation is differential X inactivation in the two sisters. X inactivation studies have been recommended. Analysis of additional family members may also be informative. Inversion of an X chromosome in a family member from a previous generation may be a possible origin of this duplicated X. Neither VYSIS nor Cytocell report the existence of a variant such as the one described and no similar cases could be found in the literature. Documentation of similar cases is important to further our understanding of clinically significant subtelomeric changes and benign polymorphic variants.

Trisomy 17p resulting from isochromosome formation and whole arm translocation. *C.D. Martinhago¹, F.R.P. Souza², V.M. Motta³, A.C.C. Nassr³, L.A.F. Laureano¹, E.S. Ramos^{1,2}, L. Martelli^{1,2}.* 1) Medical Genetics, HCFMRP, University of Sao Paulo, Ribeirao Preto, SP, Brazil; 2) Dept.Genetics, School of Medicine of Ribeirao Preto - University of Sao Paulo, Brazil; 3) Division of Genetics, Sinha Junqueira Maternity, Ribeirao Preto, SP, Brazil.

Short arm isochromosome formation concomitant with translocation of an entire long arm is a rare mechanism of establishing of partial trisomy. We present a case of trisomy 17p and translocation 15p;17q. The propositus, a female newborn, is the second child born to young healthy nonrelated couple. There was no family history of congenital malformations. She was delivered by caesarian section, weighting 2,370g, showing a single umbilical artery, respiratory distress and gastroesophageal reflux. The physical examination revealed brachycephaly, triangular facies, prominent eyes secondary to hypoplastic supraorbital ridges, short and upward palpebral fissures, prominent nasal bridge with short nose and long philtrum, posteriorly rotated ears, micrognathia, webbed neck, widely spaced nipples, long fingers, clinodactyly of 5th finger, bilateral transversal palmar crease and muscular hipotrophy. PDA was diagnosed by echocardiogram. On recent examination (11 months), she presented psychomotor retardation and marked growth deficiency. Cytogenetic studies performed on peripheral lymphocytes using GTG, CBG and high resolution bandings revealed trisomy 17p due to an isochromosome 17p and a concomitant translocation between chromosomes 15 and 17. The parental studies were normal. Double-colour FISH using 17 telomeric probes and 15q plus 17 Whole Chromosome Painting probes confirmed the origin of the isochromosome and the chromosomes involved in the rearrangement. The final karyotype was 46,XX,-15,-17,+der(15)t(15;17)(p13;q11.2),+i(17)(p10). Isochromosomes can contain two identical and one nonidentical copy of the trisomic segment, representing an example of partial uniparental isodisomy with phenotypic consequences. In this case, molecular and nerve conduction studies become obligatory to confirm the early diagnosis of CMT1A disease, mapped on 17p11.2. Supported by: FAEPA-HCFMRP, University of Sao Paulo.

Dysmorphic features, extra chromosome material and multi-color FISH. *M.M. Li^{1,2}, K.E. Jackson^{1,2}, K.C. Kim¹, H. Andersson^{1,2}.* 1) Hayward Genetics Ctr; 2) Department of Pediatrics, Tulane Univ School Med, New Orleans, LA.

The presence of extra chromosome material of unknown origin is one of the major causes of birth defects. Accurate characterization of these unbalanced chromosome rearrangements is critical in clinical diagnosis and genetic counseling. Here we present two patients with dysmorphic features: 1) a de novo supernumerary marker chromosome (SMC) 5 and 2) a de novo partial trisomy 2p and small accompanying 18q deletion characterized by multi-color FISH (M-FISH). Case 1 was born at 34 weeks gestation. She was noted at birth to have epicanthal folds, a flattened nasal bridge, small ears and short fifth digits. Cardiac ECHO uncovered a secundum ASD. At age 18 months, she has demonstrated motor and cognitive delay. Cytogenetic studies revealed a karyotype of 47,XX,+mar[15]/46,XX[5]. M-FISH showed that the marker was derived from chromosome 5. The marker was further defined by FISH using a whole chromosome 5 painting probe and chromosome 1/5/19 a-satellite probe to be composed of the chromosome 5 centromere and the pericentric region. Case 2 was referred for chromosome study because of "Edward syndrome-like" dysmorphic features and severe development delay. Cytogenetic studies revealed a karyotype of 46,XY,add(18)(q23). M-FISH showed that the extra material was from chromosome 2. FISH with chromosome 2 telomere probes and the *N-myc* probe confirmed that the extra material originated from 2p and that the patient had three copies of the *N-myc* gene. Marker chromosomes derived from chromosome 5 are rare; only two cases have been previously reported and both are de novo and mosaic. The common features include epicanthal folds, flat faces, abnormal ears and development delay. Over 50 cases of partial trisomy 2p with or without an accompanying deletion have been reported. The common anomalies include a high forehead, wide depressed nasal bridge, hypertelorism and musculoskeletal defects. At least four cases of partial trisomy 2p associated with neuroblastoma have been reported indicating that germline duplication of 2p, giving rise to three copies of the *N-myc* gene may have predisposed the patients to the development of neuroblastoma.

Prenatal diagnosis of de novo balanced translocation between chromosome Y and 11. *Y.M. Kim¹, J.M. Kim¹, M.H. Lee¹, H.M. Ryu², S.Y. Park¹.* 1) Lab Medical Genetics, Samsung Cheil Hosp, Seoul, Korea; 2) Obstetrics and Gynecology, Samsung Cheil Hosp, Seoul, Korea.

We report a de novo balanced translocation between chromosome Y and 11 in prenatal diagnosis. The patient was referred for amniocentesis due to increased risk for Down syndrome at 16 wks of gestation. Karyotype of fetus revealed 46,X,t(Y;11)(q12;q23.2) by high-resolution GTG and RBG banding. The parents have a healthy girl and their karyotypes were both normal. Amniocentesis and percutaneous umbilical blood sampling were done at 21.2 wks of gestation for FISH (fluorescence in situ hybridization), CGH (comparative genomic hybridization) and PCR. FISH confirmed the breakpoint at the Yq12 region and CGH did not show any chromosomal amplification or loss. The targeted fetal sonography finding showed no definite evidence of fetal congenital anomaly with normal male external genitalia. DNA analysis using Y specific STS revealed the presence of SRY loci and euchromatic portions of the long arm including AZFa, b and c. Extensive counseling on potential of infertility and other congenital abnormalities was done. The parents wanted to continue the pregnancy and further examination will be followed.

FISH of kidney touch preparation: a useful approach to chromosome studies of products of conception. *J. Xu, J. Bourgeois.* Pathology and Molecular Medicine, and Laboratory Medicine, Hamilton Health Sciences and McMaster University.

We report use of FISH of touch preparation in analysis of 2 unusual cases of intrauterine fetal demise (IUFD). FISH with probes (AneuVysion, Vysis) specific for chromosomes 13, 18, 21, X, and Y was performed on intact nuclei from touch preparations of kidney section of the abortuses. Case 1 was of a 32 week gestational age IUFD with phenotypic features of triploidy and advanced maceration. Attempt to culture the macerated skin and tendon tissues failed, giving rise to no results from the routine cytogenetic method. FISH analysis of 50 interphase nuclei for each probe showed at least 86% of the cells had 3 representative signals, confirming clinical diagnosis of triploidy. Case 2 was an IUFD at 20 weeks gestational age in a 41 year old women. Only an external fetal and placental examination was granted. The external phenotypic features were suggestive of trisomy 21. G-banding analysis of 91 cells from a long-term (30-day) amnion culture showed a mosaic for 2 female cell lines, 46,XX (22%) and 92,XXXX (78%). FISH was performed to rule out possibility that the tetraploid cells result from a long-term culture. It showed that at least 84% (42/50) interphase cells for each probe had signals indicative of diploidy and less than 6% of the cells had signals indicative of tetraploidy. This finding indicates that the tetraploid cells seen in G-banding and FISH likely a result of technical artifact and background noise, respectively. The normal female karyotype is likely representative of the fetus. Our results show that FISH of kidney touch preparation could be invaluable for chromosome studies, genetic counseling and clinical management of those cases with clinical indication of common numerical aberrations that 1) have advanced maceration and very low likelihood of successful culture; and/or 2) need additional information for more accurate interpretation of a routine result.

FISH Analysis of Female Carriers of X-linked Chronic Granulomatous Disease Deletions. *K.C. Simon¹, D. Noack², J. Rae³, J.T. Curnutte³, V. Kolev¹, J.K. Blancato¹.* 1) Oncology, Georgetown University, Washington, DC; 2) The Scripps Research Institute, La Jolla, CA; 3) DNAX Research Institute, Palo Alto, CA.

Chronic granulomatous disease (CGD) is a rare inherited disease in which microbial killing ability is impaired due to a deficiency in NADPH oxidase activity. Proper functioning of NADPH oxidase is essential for reduction of oxygen to superoxide (O₂⁻) and conversion to compounds that kill bacteria and fungi (1). CGD patients are diagnosed at an early age and usually present with recurrent, severe infections and in many cases development of granulomas (2). Diagnosis of probands is made by measuring oxidative burst using dihydrorhodamine (DHR) assays in which oxidative burst capabilities of circulating neutrophils and monocytes are detected through the conversion of DHR to fluorescent rhodamine 123 (3). CGD is inherited as an X-linked or an autosomal recessive disorder with an incidence of 1/200,000 live births (2). All forms involve mutations of one of the four subunits of NADPH oxidase (p67*phox*(1q25), p47*phox*(7q11.23), p22*phox*(16q24) and gp91*phox*(Xp21.1)). X-linked transmission accounts for 70% of all CGD cases and is caused by a variety of mutations in the gp91*phox* subunit(CYBB) of cytochrome b558 (1). Carriers of large deletions in CYBB are undetectable by DNA sequencing; therefore we developed a FISH assay for carrier analysis of females and molecular confirmation of affected probands with deletions of exons 2-13 of the CYBB gene. FISH cosmid contig probes from PCR products of CYBB were tested on control lymphocytes and samples from families with possible CYBB deletions based on DHR analysis and lack of PCR amplification with CYBB specific primers (spanning the coding region) in the probands. We analyzed 4 carriers and 3 normal female samples from families to assess deletion of CYBB and were able to reliably determine carriers from non-carriers using the FISH contig probe to this region. This assay will represent a novel approach to screening carriers whose mutations may otherwise go undetected. 1. Segal et al. 2000. *Medicine (Baltimore)* 79:170-200 2. Winkelstein et al. 2000. *Medicine (Baltimore)* 79:155-169 3. Woodman et al. 1985. *Blood* 85:231-241.

Chromosome Specific Aneuploidy Rates in Pregnancy Loss: Use in Development of FISH Protocols When Tissue Culture Fails. *E. Sicinska*^{1,2,3}, *A. Thomas*¹, *P.M. Miron*^{1,3}. 1) Dept Pathology, Brigham & Women's Hospital, Boston, MA; 2) Dept Cancer Biology, Dana-Farber Cancer Institute, Boston, MA; 3) Harvard Medical School, Boston, MA.

Cytogenetic analysis of pregnancy loss is often crucial in determining cause and assessing future risk. In cases for which assessment of metaphase chromosomes is not possible, FISH can be a powerful adjunct for detection of targeted numeric abnormalities. While interphase FISH has the advantage of forgoing specimen culture, this analysis requires selection of probes to target particular chromosomes of interest. Ideally, the selection of probes should be optimized to minimize the number of hybridization reactions used to detect an abnormality. Frequently, the only clinical data available for a specimen are gestational age and maternal age. It is well established that gestational age contributes to the distribution of chromosome abnormalities as this distribution is significantly different in first trimester losses than in late second trimester and third trimester losses. However, the probability of a particular chromosome abnormality for a given gestational age has not been well defined. We determined the distribution of numerical chromosomal abnormalities by gestational age among 877 specimens shown to have at least one numeric abnormality by analysis of G-banded metaphase chromosomes. Our data show that the distribution of anomalies does change significantly throughout the first 15 weeks of gestation. For example, trisomy 16, the most common abnormality in early losses, comprised more than 40% of the abnormal specimens at 6 weeks gestation, but only 10% of specimens at 12 weeks gestation. The percentage of trisomy 22, the second most common abnormality in early losses, remained fairly constant over the first 12 weeks gestation, comprising 10-15% of the abnormal specimens. Trisomy 15 was the third most common aneuploidy until 10 weeks gestation when it was then surpassed by trisomy 21. Our data suggest that multiplex FISH, when used for aneuploidy detection, should incorporate varying probe cocktails depending on the developmental age of the pregnancy loss.

Juxta-subtelomeric small deletions: a cytogenetic pitfall? *D. Sanlaville, M. Prieur, O. Raoul, M.C. De Blois, P. Gosset, T. Attie, A. Munnich, S.P. Romana, M. Vekemans, C. Turleau.* Dept Genetics, Hopital Necker Enfants Malades, Paris, France.

Subtelomeric imbalances are found in 6% of patients with unexplained mental retardation and a normal karyotype at a 550-bands level. However, in these patients, high-resolution karyotypes and comparative genomic hybridization (CGH) have also shown a significant number of interstitial imbalances. We recently observed using high resolution banding an unexpected number of apparently terminal deletions in patients with unexplained mental retardation. These small deletions concerned various chromosome ends: 2q, 4p, 5p, 6p, 6q, 8p, 9p and 20q. Clinical and cytogenetic data will be provided. In all these cases, FISH using commercially available subtelomeric probes was normal. Interstitial deletions were subsequently confirmed using either band specific probes or microsatellite markers. In conclusion, juxta-subtelomeric chromosome imbalances are a significant cause of mental retardation. They may be missed if suboptimal banding analysis is considered acceptable in conjunction with commercially available subtelomeric FISH screening. Suspected terminal deletions must not be rejected on the basis of a normal subtelomeric FISH analysis. Clinical evaluation and high resolution karyotypes are key-factors for the detection of small chromosomal imbalances. Moreover, it is important to consider juxta-subtelomeric imbalances when setting diagnostic tools such as CGH microarrays.

Delineation of cryptic subtelomeric duplications: Implications for an under-reported but important abnormality.

S. Schwartz^{1,2}, *L. Christ*², *M. Eichenmiller*¹, *C.A. Curtis*^{1,2}, *J.B. Jeng*¹, *M.D. Graf*^{1,2}. 1) Department of Genetics, Case Western Reserve University, Cleveland, OH; 2) Center for Human Genetics, University Hospitals of Cleveland, Cleveland, OH.

Over the past few years, several studies have shown the importance of cryptic deletions involving the subtelomeric regions of chromosomes. These studies have revealed that approximately 2-8% of cases with unexplained MR/developmental delay, without a cytogenetic abnormality detected with routine analysis, could be due to a subtelomeric deletion. However, during this same time there have been very few reports examining the role of subtelomeric duplications. Over the past 10 years we have studied over 100 cases of de novo duplications, to better understand the phenotype-karyotype correlations and implications of different duplications. Utilizing both high-resolution chromosomal analysis and metaphase and interphase fluorescence in situ hybridization, with single copy BAC probes, we have identified 7 cryptic subtelomeric duplications (involving 6p, 11p, 8p, 16p, 18q and Xq). The majority of these range in size from 2-5 Mb, are usually within 3Mb of the telomeric region of the chromosome, and could not be detected without a combination of high-resolution chromosomes and FISH. To better understand these cases we have developed BAC maps characterizing each duplication and in two cases have identified duplication of specific genes accounting for the phenotypic abnormalities.

Based on the findings from these studies we have gained additional insights concerning the implication of duplicated material and can conclude the following: (1) similar to cryptic deletions, we have shown that there are also clinically relevant cryptic subtelomeric duplications; (2) because of the difficulty in detecting these duplications, they are likely to be under-ascertained; (3) BAC contigs constructed from the human genome data indicates that most of our duplications are less than 5 Mb; and (4) in two cases a further analysis of the duplicated region has elucidated genes responsible for the phenotypes.

A Case of 22q13.1 Deletion as a Result of Asymmetrically Dicentric 22. *Y.M. El-Gohary¹, U. Surti^{1,2}, E. McPherson^{1,2}, J. Hu^{1,2}, S. Kochmar¹.* 1) Genetics Department, UPMC Magee-Womens Hospital, Pittsburgh, PA; 2) University of Pittsburgh, School of Medicine, Pittsburgh, PA.

The patient was the 2750 gram, 50 cm, OFC 34 cm, male product of an uncomplicated full term pregnancy in a 30 year old G4 P3 mother. Chromosome studies were done because of minor anomalies including camptodactyly, mild micrognathia, minor asymmetry of the ears, inability to extend the fingers and overlapping toes. The karyotype of the patient is 46,XY,dic(22;22)(q13.1;q11.21). The derivative bisatellited dicentric chromosome 22 occurred denovo, as it was not found on analysis of parental bloods. Fluorescence In Situ Hybridization (FISH) using paint probes (Vysis Inc.) revealed positive signals covering the entire derivative dicentric #22 chromosome. Also FISH analysis was done using the DiGeorge chromosome probe 22q11.2 region (TUPLE1) and a marker probe 22q13.3 region (ARSA). The normal #22 chromosome showed the presence of both the critical region (TUPLE1) and the marker region (ARSA). The derivative dicentric #22 chromosome was found to contain one signal of the critical region (TUPLE1) but the absence of the (ARSA) marker region. Because the Stalk and Satellite areas on either side of the derivative #22 chromosome were not identical, this derivative chromosome more likely resulted from an unbalanced translocation between the q arms of two #22 chromosomes resulting in a partial monosomy for the segment 22q13.1 to qter, and a partial trisomy for a very small segment of 22pter to 22q11.21. On follow-up at one month, the patient's facial appearance remained mildly unusual, due mainly to his small chin, the hands remained somewhat clenched and his feet had improved since birth. He was growing normally, but delay is expected based on reports of other patients with deleted 22q13. In previous reports, the phenotype of distal del 22q has been non-specific with normal to accelerated growth, minor facial anomalies, hypotonia and developmental delay. Our patient did not show any features of trisomy 22 or Cat Eye syndrome, presumably because there is little euchromatin in the region of partial trisomy.

Mosaicism and endometrial adenocarcinoma in an adult Turner syndrome patient. *B.K. Goodman, V. Golembiewski-Ruiz, C.A. Tirado, P.S. Kishnani, T.T. Stenzel, J.M. Lancaster, S.J. Robboy.* Depts of Pathology, Pediatrics and Obstetrics and Gynecology, Duke Univ Medical Ctr, Durham, NC.

A 35-year-old female with Turner syndrome presented with a one-month history of significant GI symptoms, weight loss and an enlarged uterus. A CT scan showed ascites, omental thickening and a right adnexal mass. The patient was on hormone replacement, taken since 13 years of age. Following a genetics consult, peripheral blood was sent for chromosome analysis to exclude the presence of a Y-bearing cell line that could predispose to gonadoblastoma. The patient underwent gross tumor removal and surgical staging. Her karyotype was mosaic 45,X[13]/46,X, idic(Y)(q11.2)[37]. FISH analysis further defined the character of the small isochromosome, showing signals for SRY (Yp11.3) at each end, the presence of two copies of Y centromeric (alpha-satellite) sequences and the absence of satellite III sequences (Yq12). Thus, a Y-derived chromosome was present that contained only the most proximal long arm sequences, which could include the region implicated in predisposition to gonadoblastoma. FISH analysis also detected a cell line with two X chromosomes in 2% of nuclei, not detected by chromosome analysis. Pathologic examination showed a primary endometrial adenocarcinoma, FIGO grade 2, with mixed endometrioid, serous and mucinous features and metastases to the left ovary, omentum and lymph nodes. Peritoneal dissemination likely occurred by retrograde transmission via the fallopian tube. Both ovaries were small. Molecular analysis using PCR for the amelogenin locus on the Y chromosome confirmed the presence of the Y-bearing cell line in frozen tissue from the left and right ovaries. Molecular and FISH analyses of additional archived tissues are in process. Normal-appearing ovaries and uterus have been reported in patients with Turner syndrome. Endometrial carcinoma has also been reported both with and without hormone replacement therapy in young Turner syndrome patients. This case and others underline the importance of thorough cytogenetic evaluation for chromosomal mosaicism in Turner syndrome and the increased risk of endometrial carcinoma, as well as gonadoblastoma.

Cytogenetic and FISH analysis of an interstitial 1q42.3-q44 deletion. V. Golembiewski-Ruiz, C.A. Tirado, K. Curesky, J. Goldstein, A. McKonkie-Rosell, M.T. McDonald, B.K. Goodman. Departments of Pathology and Medical Genetics, Duke University Medical Center, Durham, NC.

1q distal deletion syndrome is most often associated with cleft palate, flat nasal bridge, strabismus, hypotonia, severe mental retardation and seizure disorders. We report a 33 month-old girl with a previous karyotype of 46,XX,del(1)(q42.3). Maternal peripheral blood karyotype was normal and a paternal sample was unavailable. An extended family history showed no history of mental retardation, birth defects or translocation. Prenatal ultrasound had shown multiple brain cysts. Delivery was at 37 weeks gestation, and the neonate remained hospitalized for poor feeding and low birth weight. In order to further define the deletion in this patient, we performed FISH analysis using the Vysis chromosome 1 subtelomeric probe set. Both short and long arm loci were intact. To determine whether this was only a deletion or whether material from another chromosome was involved, we performed multicolor FISH (M-FISH) analysis. There was no apparent material derived from any other chromosome. In order to confirm the interstitial nature of the deletion, we used an investigational 1q subtelomeric probe located slightly more proximally in the subtelomeric region of 1q. This locus was also intact. Patients with 1q distal deletions have been reported with brain cysts, midline defects and psychomotor delays. To our knowledge, a subtle interstitial deletion of chromosome 1 bands q42.3-q44 such as that defined in this case has not been reported. A more proximal interstitial deletion, 1q42.1-q42.3, was reported with mild phenotypic effects. Our patient presented with similar features to many of those observed in patients with both terminal and interstitial 1q deletions. These include frontal bossing, cleft palate, flat nasal bridge, hypertelorism, strabismus, severe developmental delay and seizures. A previous brain MRI showed bifrontal atrophy. Our results show that the molecular cytogenetic tools now available will assist in defining deletions such as this and, as in this case, may further localize the critical region for the deletion 1q phenotype.

Interstitial deletion of chromosome 4p in a three-generation family with minimal phenotypic effects. S.L.

*Dagenais*¹, *B.A. Cox*², *L. Stempek*², *J.W. Innis*¹, *H. Carels*³, *J. Robertson*⁴, *D. Roulston*², *T.W. Glover*¹. 1) Depts. of Human Genetics and Pediatrics, Univ. of Michigan, Ann Arbor, MI; 2) Dept. of Pathology, Univ. of Michigan, Ann Arbor, MI; 3) Family & Community Medicine, Michigan State College of Osteopathic Med., East Lansing, MI; 4) Henry Ford Hosp., Detroit, MI.

We describe a three-generation family that shows segregation of an interstitial deletion (p14p15.1 or p15.1p15.2) on the short arm of one chromosome 4 homolog but with minimal apparent phenotypic effects. Concern began when the proband was not speaking at age 16-18 months. Formal evaluation demonstrated a delay in expressive language and motor development with hypotonia and a positive Babinski reflex. The child had normal receptive language, hearing, brain MRI, and Fragile X DNA testing. At 44 months, her fine motor testing indicated an age equivalent of 31 months with delays in eye-hand coordination and manual dexterity. The proband's GTG banded karyotype was 46,XX,del(4)(p14p15.1 or p15.1p15.2). The karyotypes of the paternal grandfather, mother, and younger sibling also showed the same 4p interstitial deletion in all cells. The maternal grandfather exhibited normal motor and language development. The mother showed no developmental problems and performed well in college. The proband's younger sister was normal at 24 months in all developmental aspects. To confirm and characterize the deletion, BAC clones mapping to the 4p13-p15.3 region were used for FISH on metaphase spreads from the proband and mother. Based on FISH results and the draft map for human chromosome 4, the deletion size is <5Mb in a relatively gene-poor euchromatic region that is flanked by gene-rich regions. The phenotype associated with this deletion is extremely mild, but may include genes that when haploinsufficient can lead to delay of language and motor functions with variable expressivity. At least 20 individuals have been reported to have 4p interstitial deletions and compared with our family, these individuals have more serious phenotypic effects, which are likely due to different deletion breakpoints involving additional chromosome segments and genes.

Subtelomeric and locus specific FISH as adjunct to conventional cytogenetics elucidate chromosome rearrangement in a de novo complex variant of Wolf-Hirschhorn syndrome. *N.S. Mitter¹, T.T. Brown², G.B. Bromage², M.E. Mangual², J.S. Morales², W.L. Flejter², S.L. Gersen² and Dianon Systems, Inc.* 1) NeoGenomics, Inc., Naples, FL; 2) Dianon Systems, Inc., Stratford, CT.

Wolf-Hirschhorn (WHS), a contiguous gene syndrome, is associated with a deletion of a 165kb critical region in chromosome band 4p16.3. Some cases with small deletions have more severe presentations while others with large deletions have mild clinical features. One explanation for this phenomenon could be in the etiology of the deletion. Cryptic unbalanced translocations between 4p and other chromosomes may appear as deletions of 4p, but with a mixture of features associated with both the deleted 4p and the duplicated genetic material. The use of subtelomeric and region/locus specific FISH probes can help elucidate the exact chromosomal rearrangement involved. This was illustrated for a 2-day old female, referred for cytogenetic analysis for a suspicion of trisomy 18. GTW banding revealed a faint G-positive band in the telomeric region of the short arm of one chromosome 4, interpreted as add(4)(p16.3). FISH analysis with probes for the subtelomeric regions of chromosome 4 showed the absence of a signal on one 4p. Analysis with Vysis ToTelVysion revealed a presence of the 8p telomeric region on 4p as well as two normal chromosomes 8. This was confirmed with the use of WCP8 probes. Similar analyses on parents revealed normal karyotypes and FISH signals. The child, therefore, had an unbalanced de novo rearrangement with a monosomy for distal 4p and a trisomy for distal 8p. Subsequent FISH analysis showed a deletion of the WHS critical region on the der(4p). The final karyotype was: 46,XX,add(4)(p16.3).ish der(4)t(4;8)(p16.3;p23)(D4S3359-,D4S2930+,D8S504+,WHSCR-). The clinical phenotype of distal trisomy 8p includes minor facial anomalies, hypotonia and developmental delay. The proband has mild abnormalities seen in both WHS and distal trisomy 8p (orbital hypoplasia, wide anterior fontanel, dysplastic ears, short bulbous nose) and others that are limited to WHS (triangular face, high arched palate, retrognathia, hypotonia). Family was counseled for a low recurrence risk and follow-up evaluations.

Tetrasomy 9q11-q22.1 in an infant with cleft palate and multiple anomalies. *E.W. McPherson^{1,2,4}, K. Neiswanger¹, M.J. Buckley¹, U. Surti^{3,4}.* 1) Cleft Palate Craniofacial Center, Univ of Pittsburgh School of Dental Medicine; 2) Dept of Pediatrics, Univ of Pittsburgh School of Medicine; 3) Dept of Pathology, University of Pittsburgh School of Medicine; 4) Dept Genetics, Magee Womens Hosp, Pittsburgh, PA.

The proband was the product of an uneventful pregnancy and delivery to a 22 yo G2P1-2. At birth, he was in the 3-10% for weight, length, and head circumference and had a complete bilateral cleft of the hard and soft palate. His facial appearance was unusual with retrognathia, short palpebral fissures, beaked nose with short columella, small mouth, and large, low set ears. He was hypertonic, and had arthrogryposis with wrist flexion and ulnar deviation, camptodactyly, single palmar creases, hammer toes of the hallux, overlapping toes, and metatarsus adductus. He suffered several fractures without known trauma. By one year, his hands had improved, and he was beginning to sit, roll, reach for toys, and say mama. His length and weight were normal, but he had mild microcephaly. His family history was unremarkable. Karyotyping revealed tetrasomy for chromosome 9q13-q22.1, due to a triplication on one chromosome 9 with the normal chromosome complement on the other. FISH utilizing whole chromosome paint for chromosome 9 demonstrated that all of the extra chromosomal material was derived from chromosome 9, for a karyotype of 46,XY, trp(9)(q13q22.1). ish trp(9)(q13q22.1)(wcp+).

While there are several reports of trisomy for different segments of 9q, to our knowledge this is the first report of a patient with partial tetrasomy 9q. Our patient shares several phenotypic features with the trisomy 9q cases, including microcephaly, beaked nose, narrow palpebral fissures, micrognathia, cleft palate, hand and foot abnormalities, and developmental delay. The aneuploid region is similar to that in a patient with trisomy 9q13-q22.1 evaluated for MR, behavioral problems and minor dysmorphic features (Luke et al., AJMG 40: 57, 1991). Partial tetrasomy 9q in our patient appears to cause multiple anomalies similar to trisomy 9q with moderate developmental delay.

A rare case of mosaicism for paternal UPD 9 in a dizygotic twin pregnancy. *K.A. Kaiser-Rogers¹, W.P. Robinson⁴, J.F. Knops⁵, D. Vargo², C.A. Livasy³, J. Bailit², K.W. Rao^{1,3}.* 1) Dept Pediatrics; 2) Dept Obstetrics & Gynecology; 3) Dept Pathology & Lab Medicine, Univ North Carolina, Chapel Hill, NC; 4) Dept Medical Genetics, Univ British Columbia, Vancouver, BC, Canada; 5) Genzyme Genetics, Santa Fe, NM.

In this report we describe the first published case of paternal uniparental disomy (UPD) for chromosome 9. Amniocentesis and karyotyping of a dizygotic twin pregnancy were performed because twin "A" had an enlarged, molar appearing placenta. Growth of twin "A" also lagged 1 week behind its normal appearing twin, "B". Although both twins had a 46,XX karyotype, twin "A" appeared to have two cell lines. In one cell line both chromosome 9 homologues contained a large heterochromatic (qh) region (LL), while 1 large and 1 small heterochromatic region (LS) were seen in the other cell line. Both chromosome 9 homologues within twin "B" had a small heterochromatic region (SS). While both the "SL" and the "SS" cell lines could be explained by normal Mendelian segregation of the paternal "LS" and maternal "SS" homologues, the "LL" cell line in twin "A" could not.

As the pregnancy progressed, twin "A's" growth (22nd centile) continued to lag behind that of twin "B" (58th centile), and at 28 weeks gestation liver cysts were seen. Following the in utero death of twin "A" at 34 weeks gestation, twin "B" was delivered and is currently alive and well. Cytogenetic and molecular studies performed after delivery on the placenta of twin "A", were consistent with mosaicism for a cell line (LL) with complete paternal uniparental isodisomy (UPiD) for chromosome 9. The results obtained from the newborn cord blood were inconclusive. In addition to being the first report of paternal UPD9, this case also represents a rare example of mosaicism for euploid cell lines with UPD and normal biparental inheritance. We speculate that paternal UPD9, especially when present in nonmosaic form, may be lethal in utero. Alternatively, homozygosity for a recessive mutation caused by UPiD9 may be the basis for the clinical findings in twin "A". Absence of a maternal UPD9 affect suggests the latter may be more likely.

Two Cases of Partial Trisomy 13q with Different De Novo Structural Cytogenetic Anomalies and Their Clinical Manifestation. *I. Llano, M.J Zavaleta, R. Melendez, R. Garcia- Cavazos, M. Aguinaga.* Genetics, Inst Nacional Perinatologia, Mexico, Mexico.

Several partial 13q syndromes have been described in the literature, most of them as the result of an unbalanced translocation inherited from a progenitor. Depending on the point of breakage there are widely variable clinical manifestations, the distal deletions being the most severe. Here we report two unrelated cases of patients with distal trisomy 13q due to de novo structural rearrangements involving chromosome 13. Case 1.- 46,XY,homodic(13)(pter--cenq32::q12-cen-pter) and with molecular cytogenetic techniques: 46,XY,homodic(13).ish(CEP13x2)(WCP13+)(LSIx2)(D135327-). Case 2.- 46,XY,add(15)(p13) and with molecular cytogenetics: 46,XY,add(15)(p11).ish dup(13)(qter-q22)(WCP 13+)(D135327+). With these two cases we remark the importance of the clinical examination and correlation with the cytogenetic studies in every patient and his family in the genetics clinic. Even though we now have more sophisticated molecular tools, it is important not to forget the usefulness of the cytogenetic study in almost all of our dysmorphic patient.

A preliminary study to assess the predictive value of a low-resolution genomic microarray in detecting chromosomal imbalances and DNA copy number polymorphisms. *J. LAPIERRE¹, D. SANLAVILLE¹, J. KANG², P. GOSSET¹, C. OZILOU¹, M. Le LORCH¹, C. TURLEAU¹, M. MOHAMMED², S. ROMANA¹, M. VEKEMANS¹.* 1) Departement de genetique, Hopital Necker-Enfants Malades, PARIS, FRANCE; 2) Spectral Genomics Inc., Houston, TX.

Microarray-based comparative genomic hybridization (array-CGH) has been successfully used in the detection of both acquired and constitutional chromosome imbalances. Since these arrays comprise of discrete large-insert genomic clones such as BACs, they may also be used to detect DNA copy-number polymorphisms across the entire genome, which may otherwise be undetectable by conventional cytogenetic methodologies. We decided to test the capacity of a commercially available genomic microarray in detecting constitutional chromosome imbalances as well as its utility in detecting DNA copy-number polymorphisms across the genome. The array chosen for this study was a first generation microarray comprising of 1003 BAC and PAC clones (Spectral Genomics Inc.). DNA samples from patients with well characterized chromosome aberrations as well as from known normal references were tested in a blinded fashion. In accordance with the protocols established for use with these arrays, between 500ng-1g of Cy5 labeled test DNA was co-hybridized with Cy3 labeled reference DNA (forward reaction). Similarly, an equal amount of Cy3 labeled test DNA was independently co-hybridized with Cy5 labeled reference (reverse reaction). While aberrations for which clone coverage was available were detected, our findings suggest that although these arrays were initially designed to offer on average a 3Mb coverage of the genome, the resolution within particularly the subtelomeric regions is lower than 3Mb. The utility of the dye-reversal approach was highlighted by the analysis of one of the known normal reference samples. Importantly, DNA copy number polymorphisms for a single clone on 7q and 16q were observed in both our normal and abnormal DNA samples. Further studies using appropriate DNA clones are in progress to confirm these findings.

Molecular cytogenetic identification of a chromosome 8 derived supernumerary marker chromosome: a clinical description. *J.J. MacKenzie^{1,2}, K.J. Harrison^{1,2}*. 1) Dept of Pediatrics, Queen's University, Kingston, ON, Canada; 2) Dept of Pathology, Queen's University, Kingston, ON, Canada.

A 7 year old boy with developmental delay, inattention and poor coordination was identified to have a karyotype of 47,XY,+mar[21]/46,XY[20].ish der(8)(wcp8+,TelVysion 8p-). He had a prominent forehead, triangular chin, broad nasal root, everted lower lip, arched palate, prominent ears, and increased plantar creases. Initial cytogenetic analysis of 41 G-banded metaphases identified a small metacentric supernumerary marker chromosome (SMC) in 20/41 cells. C-banding identified a single positive centromere region. Paternal chromosome studies (50 cells) were normal. Since the origin of the SMC could not be discerned from the G-banded analysis, it was established using a panel of whole chromosome paint probes (Chromosome Multiprobe-Octochrome). The marker hybridized positively with the wcp probe specific for chromosome 8 and was confirmed using a single wcp8 probe (Vysis). Comparative genomic hybridization studies indicated a possible gain of 8p and 8q material but this was equivocal. The SMC did not hybridize with the TelVysion 8p telomere specific probe. The karyotype was revised to 46,XY,+mar[21]46,XY[20].ish der(8)(wcp8+,TelVysion 8p-). SMCs are a cytogenetic and clinical dilemma, particularly when the chromosome origin cannot be identified or they present in mosaic form. Some phenotypes have been characterized for SMCs derived from chromosomes 9,12,15,18 and 22. The reported features of the few cases identified with SMC 8 overlap with trisomy 8 mosaicism. This case presents a rare clinical condition and illustrates the use of multiple techniques to determine the chromosome origin of the SMC. Probe availability or low level mosaicism can impede the resolution achieved with FISH and PCR, so additional techniques are essential for detailed evaluation. Currently, SMC outcome generalizations can be made based mode of origin, chromosome origin and overall size, but correlation of specific clinical and cytogenetic data provides more predictable phenotypic information which can be applied to counselling and health management.

True fetal mosaicism for a supernumerary *de novo* ring chromosome. *J.M. Meck¹, A. Wray¹, A. Ghidini¹, B. Gorman¹, P. Vallejo¹, T. Dennis², B. Haddad³.* 1) Dept Obstetrics/Gynecology, Georgetown Univ Hospital, Washington, DC; 2) NHGRI/NIH, Bethesda, MD; 3) Dept. Oncology, Georgetown Univ Med Ctr, Washington, DC.

Assessment of the consequences of a *de novo* marker chromosome found prenatally is among the most difficult challenges that a geneticist must face. The best assessments require a thorough classical and molecular cytogenetic workup and excellent prenatal diagnostic testing. We report here on a case in which a small *de novo* supernumerary ring chromosome with apparent euchromatic material was found in 27% of amniocytes at amniocentesis performed for advanced maternal age. Genetic counseling of the couple included a discussion of possible molecular cytogenetic approaches to chromosome identification which included microdissection, SKY, and standard FISH testing. The ring chromosome was lost in subcultures, making FISH diagnosis difficult. The couple elected to have a targeted 2-D and 3-D sonogram, fetal echocardiogram, fetal blood sampling, and a repeat amniocentesis. Both the sonogram and fetal echo were normal. The ring chromosome was found in 10% of fetal lymphocytes, and in 43% of colonies from the repeat amniocentesis. The marker did not hybridize to FISH probes for SNRPN or the centromeres of chromosomes 15, X or Y. The couple was counseled that the FISH results ruled out the marker as being derived from (1) the chromosome which is the most common source of markers (chromosome 15); and (2) chromosomes for which there is substantial prognostic information (X, Y, and 15). Due to the advanced gestational age (23 weeks), uncertainty as to the significance of the mosaicism and its extent in other tissues, the couple elected to have a pregnancy termination without additional testing (SKY, microdissection). Results from the autopsy as well as further molecular cytogenetic evaluation of the marker will be presented. Cases such as this are important in order to establish a genotype/phenotype correlation for other such diagnostic dilemmas.

Phenotypic diversity associated with idic(15) marker chromosomes. *S. Mann¹, D. Liu¹, N. Wang¹, L. Wang¹, N. Dorrani¹, L. Espana², C. Williams-McGovern², C. Fernandez², A. Lopez-Singh², M. Jimenez², M. Sigman², C. Schanen³.* 1) Dept Human Genetics, UCLA, Los Angeles, CA; 2) Neuropsychiatric Institute, UCLA, Los Angeles, CA; 3) Nemours Research Programs, A.I. duPont Hospital for Children, Wilmington DE.

The most common cytogenetic abnormalities observed in autistic probands are aberrations of chromosome 15, specifically 15q11-q13. These duplications frequently take the form of supernumerary pseudoisodicentric marker chromosomes, idic(15). Although they clearly impart a major risk for autism, the phenotypic consequences of these duplications are remarkably variable, but often include some degree of mental retardation, neurologic symptoms, and facial dysmorphisms.

A cohort of 18 probands with idic(15) chromosomes were clinically assessed for abnormalities commonly associated with idic(15) including measures of cognition, language, play and specific testing for autism. Detailed molecular and cytogenetic analyses were performed to identify the extent of the duplicated material. Parental inheritance and methylation status were also ascertained.

Most of the idic(15) chromosomes are structurally stereotyped arising from exchanges through a series of common breakpoints, which allow the critical portion of 15q to be divided into A, B, C regions. However, several were found to be asymmetric leading to trisomy rather than tetrasomy of the involved segments. Comparison of data from probands whose duplications include only AB versus ABC material indicates that autism, seizures, hypotonia and dysmorphisms occur at similar frequencies in both groups. Surprisingly, one autistic female was found to have a paternally derived duplication. Severe cognitive and language deficits occurred in both groups, with some improvement in language scores with age. Within groups, however, there was marked variability in performance. These data underscore the molecular diversity that likely underlies the difficulties in determining genotype-phenotype correlations in idic(15) probands.

Supported by the M.I.N.D. Institute Research Program and NIH HD35470.

Mosaic, SNRPN positive, Inversion Duplication 15 without Phenotypic Effect in a Mother and Daughter. *E.D. Wood, A. Patel, K.J. Blakemore, G. Stetten.* Johns Hopkins University, Baltimore, MD.

Inversion duplication of chromosome 15 [inv dup (15)] is the most common supernumerary marker chromosome detected during routine karyotyping. The phenotype ranges from normal to severely mentally retarded, related to size of the marker and presence of the SNRPN region. Case reports of both non-mosaic, SNRPN positive cases and mosaic, SNRPN negative cases have been published. An abnormal phenotype has been associated with the SNRPN positive cases in most reports. There are no previously published cases of individuals mosaic for a SNRPN positive inv dup (15). We report a mosaic SNRPN positive inv dup (15) in an apparently unaffected mother and daughter ascertained through prenatal diagnosis. An amniocentesis was performed in a 30 year old G1P0 for a choroid plexus cyst at 20 weeks. Analysis showed that 6/16 (38%) of the amniocyte colonies contained a supernumerary, bisatellited, pseudodicentric marker chromosome identified as a SNRPN positive inv dup (15). Additional FISH studies revealed the inv dup (15) to be positive for D15S11 and D15S10 region, and negative for GABRB3. The maternal karyotype was also mosaic for the same marker in 6/20 (30%) of peripheral lymphocytes. Grandparental karyotypes were normal. Despite similar findings in an apparently normal parent, concerns regarding fetal outcome persisted due to the possibility of UPD 15, the unpredictable effects of imprinting in this region of chromosome 15, and the association between SNRPN positive inv dup (15) markers and abnormal phenotypes. UPD studies revealed normal, biparental inheritance. While most de novo inv dup (15) markers in the literature are of maternal origin, the origin of the de novo marker in the mother is still under investigation. The mother is phenotypically normal with no history of developmental delay. Her daughter, now 17 months old, is non-dysmorphic and showing normal development.

Familial translocation with partial trisomy of 9q34 and 22q11: an expansion of the genomic disorders of 22q11.

A.L. Shanske¹, K.L. David², V.R. Pulijaal³, S. Gogineni³, B.E. Morrow⁴. 1) Ctr Congenital Disorders, Children's Hospital at Montefiore, Bronx, NY; 2) Genetics/Department of Pediatrics, Metropolitan Hospital Center, New York, NY; 3) Department of Pathology, Montefiore Medical Center, Bronx, NY; 4) Department of Molecular Genetics, Albert Einstein College of Medicine, Bronx, NY.

Region 22q11 is a model for disorders caused by chromosomal rearrangements involving large regions (Lupski, 1998) because it is involved in a number of relatively common chromosome disorders including VCFS/DGS, CES, and the der(22) syndrome. Nonhomologous recombination followed by meiotic nondisjunction results in the der(22) syndrome. Usually, this involves a nondisjunctional event in a carrier of a constitutional t(11;22) translocation. We have identified a patient with a der(22) syndrome secondary to the malsegregation of a maternal (9;22) translocation. He is a 9 year old son of double first cousins. His mother lost 7 first trimester pregnancies and a male infant who survived only hours. He underwent unsuccessful glaucoma surgery at age 3 and the repair of a VSD at 5 years. His development has been delayed. His physical examination revealed a microcephaly, a synophrys, low anterior hairline and abnormal pinna. He wears a left eye prosthesis and his speech is often unintelligible. An abnormal peripheral leucocyte karyotype was recorded: 47,XY,+der(22)t(9;22)(q34.3;q11.2)mat.ish +der(22)t(9;22)(q34.1;q11.2)mat(WCP9x2,ABLx2,D9S325x3, D22S75x3,ARSx3). Our patient does not have the somatic features of der(22) resulting from a t(11;22). He does have some features associated with CES; including a congenital heart defect and eye abnormality. He lacks the more typical eye and ear anomalies seen in CES. VCFS/DGS and CES result from homologous recombination between blocks of low-copy repeats (LCR22) and der(22) from nonhomologous recombination between AT-rich palindromes. Non-recurring translocations involving 22q11 have been reported but little is known whether or not they preferentially occur in the same LCR. Molecular analysis of this family will help clarify the importance of LCR22 and AT-rich palindromic sequences.

Inherited mosaic supernumerary marker chromosome (SMC) 8 in a patient with mental retardation: a potential counseling challenge. *M.T. Velinov¹, H. Gu¹, M. Genovese¹, C. Duncan¹, S.S. Brooks², E.C. Jenkins¹*. 1) Cytogenetics, IBRDD, Staten Island, NY; 2) Human Genetics, IBRDD, Staten Island, NY.

A 30-year-old male with mental retardation, long narrow face and high arched palate presented with mosaicism for a small SMC in 90% of his peripheral blood cells. The SMC was shown by multiplex FISH analysis to have originated from chromosome 8. This individual's phenotypically normal mother exhibited the same SMC in 8% of her cells. One additional family with inherited SMC-8 in two affected children has been reported to date (Rothenmund et al. *Am J Med Genet*, 72:339, 1997). In this report one phenotypically normal parent also exhibited low level mosaicism for the marker chromosome 8. These two families illustrate the potential difficulties that may occur in genetic counseling, since at present it is impossible to establish a specific cut off in the mosaicism level for SMC-8 that would result in an abnormal phenotype. The size and chromosomal origin of each SMC is crucial for the effect on phenotype. In addition, inherited SMC's from unaffected and non-mosaic parents typically do not result in abnormal phenotypes. However, families have been reported with poor reproductive history or children with congenital abnormalities/mental retardation in which one of the parents is mosaic for SMC. Accordingly, the reported family supports the concept that phenotypically normal individuals who are mosaic for SMC have higher reproductive risk compared to those with SMC in all cells. Potentially harmful SMC may be "silent" in the parent with low-grade mosaicism, but may have observable phenotypic expression in the fetus/child since it would be present, at least initially, in all fetal cells. We suggest that the inheritance of SMC from a mosaic parent is associated with higher risk for an abnormal phenotype. [This work was supported in part by NYS Office of Mental Retardation and Developmental Disabilities].

Family with three Prader-Willi syndrome siblings carrying a paternally inherited deletion of SNRPN. P.D.

*Storto*¹, *L. Gourash*², *M.N. Netzloff*¹, *U. Surti*³, *S. Das*⁴, *K. Cluck*⁴. 1) Dept Pediatrics/Human Develop, Michigan State Univ, East Lansing, MI; 2) Prader-Willi Syndrome/Behavioral Disorders Program The Children's Institute, Pittsburgh, PA; 3) Pittsburgh Cytogenetics Laboratory, University of Pittsburgh Center for Human Genetics and Integrative Biology, Pittsburgh, PA; 4) Department of Human Genetics, University of Chicago, Chicago, IL.

We describe a family with three Prader-Willi syndrome children; a daughter born in 1977, and two sons born in 1982 and 1984. By age 10, the first son was suspected of having the syndrome due to his clinical history (premature birth, hypotonia, respiratory distress, neurological deficit, epicanthal folds, cryptorchidism, hyperactivity, IQ of 80, small build, small hands and feet, food-seeking behavior by age 3, and increased weight gain). A high-resolution karyotype analysis was performed in 1992, and was normal (no deletion in region 15q11-q13). His sister was also tested at that time, as she had some PWS features (decreased fetal activity, hypotonia at birth, rapid weight gain, small hands and feet, failure to thrive, attention deficit disorder, IQ of 55, and delayed motor development). Her hi-res karyotype was also normal. Additional testing was requested on the first son; In 1994, two FISH probes, GABRB3 and D15S11, were used to detect submicroscopic deletions. The results were negative. In 2001, the first son was re-tested by both FISH SNRPN probe and methylation tests. These tests were positive. The second son (with a history of cryptorchidism, speech delay, hyperactivity and attention deficit, but negative for decreased fetal activity and hypotonia) was also tested by FISH, and was also positive for a SNRPN deletion. Subsequent testing of family members included the sister and the father of the three children, both testing positive for a SNRPN deletion. The father is asymptomatic, presumably carrying the deletion on his maternal chromosome 15 (as a de novo deletion, as his mother tested negative for the SNRPN deletion). This family is of interest due to the variability in expressivity of the identical deletion, the relatively small size of the deletion (which did not include the D15S10 locus), and the fathers normal phenotype.

FISH variants with D15Z1 in clinical cases. *S.H. Shim*¹, *A. Pan*¹, *X.L. Huang*¹, *V.S. Tonk*², *H.E. Wyandt*¹. 1) Center for Human Genetics, Boston University School of Medicine, Boston, MA; 2) Department of Pathology, Texas Tech University Health Sciences Center, Lubbock, TX.

Interphase FISH analysis using alpha-satellite probes for centromere identification has been suspect because of occasional heteromorphism and because of shared sequences, especially between chromosomes 13 and 21 and between chromosomes 14 and 22. Classical satellite III (D15Z1) in the short arm of chromosome 15 reportedly also cross-hybridizes with other acrocentric chromosomes about 10% of the time. We present our experience with cross-hybridization of D15Z1 in clinical cases referred for Angelman (AS) or Prader-Willi syndromes, for autism to rule out duplication of 15q12, or to identify a supernumerary marker chromosome. D15Z1 is commercially available in dual-color probe mixtures in combination with D15S10, D15S11 or SNRPN (Vysis, Downers Grove, IL). Of 38 clinical cases studied with at least one of these probe mixtures, 9 showed an extra signal with D15Z1 on a chromosome 14 and one case showed absence of the D15Z1 signal from 15p. Three of the nine cases with an extra signal on chromosome 14 have additional chromosome abnormalities, including two with a supernumerary marker derived from 15 and one case with der(Y)t(Y;15). Two sibs referred for possible AS show an extra signal on a chromosome 14 in one sib but not in the other. The overall frequency of 23.7% with a signal on chromosome 14 and the high percentage of positive cases (33.3%) with structural abnormalities suggest an unusual correlation with the presence of the D15Z1 signal on chromosome 14. However, in one case with a maternally derived idic(15), the variant 14 was paternal in origin. The absence of the variant 14 in one of the two sibs referred for AS, also make it unlikely the D15Z1 variants have any causative role in any of the clinical or structural chromosome abnormalities studied.

Preeclampsia and confined placental mosaicism. *P.J. Yong, S. Langlois, P. von Dadelszen, I.J. Barrett, D.K. Kalousek, W.P. Robinson.* Depts of Medical Genetics, Obstetrics, and Pathology, UBC, Vancouver, BC.

Confined placental mosaicism (CPM) is present in ~2% of pregnancies and may contribute to the etiology of preeclampsia in cases where the fetus appears karyotypically normal. We sought to determine whether there was an association between preeclampsia and CPM of trisomy 16 (CPM16). Data were collected from a sample of prenatally diagnosed CPM16 pregnancies that continued past 20 weeks, consisting of 6 cases diagnosed in Vancouver and 30 cases from other centres. The clinical definition of preeclampsia from the Australasian Society for the Study of Hypertension in Pregnancy (2000) was used. The prevalence of preeclampsia was 14% (5/36). In the general population, preeclampsia is cited to occur in 3-5% of pregnancies, which was confirmed by control data from BC Womens Hospital. Using 5% as the background prevalence, the relative risk (RR) for preeclampsia in CPM16 was 2.70 ($p = 0.04$). This is a conservative estimate, however, since obstetric data were missing for some cases. Considering the 14 cases where an explicit statement was made about the presence or absence of preeclampsia, the prevalence was 36% (5/14) ($RR = 7.14$, $p < 0.01$). Since poor trophoblast invasion is associated with preeclampsia, the level of trisomy in trophoblast isolated from term placenta was compared between the 5 cases with preeclampsia and the 31 other cases. The cases with preeclampsia had a higher level of trisomy in the trophoblast: 86% +/- 9% vs 55% +/- 9% (mean +/- SE, $p = 0.05$). The preeclampsia cases also had a higher frequency of males (80% vs 21%, $p = 0.02$), and a trend towards higher frequency of maternal uniparental disomy of chromosome 16 (upd(16)mat) (60% vs 34%, $p = 0.27$). There were no significant differences in clinical outcome, except for a higher risk of hypospadias among the preeclampsia cases (100% vs 17%, $p = 0.05$). This supports previous reports of an association between hypospadias and preeclampsia. Our results suggest that trisomy 16 trophoblast may have a poor invasive phenotype. Furthermore, trophoblast that are XY and/or upd(16)mat may have reduced proliferation, increasing the proportion of trisomic trophoblast, and thus, the risk of preeclampsia.

A molecular cytogenetics study of 21 patients with Neonatal Diabetes Mellitus. *C. Borie¹, O. Dupuy¹, D. Genevieve¹, N. Bondeux¹, N. Collot¹, S.P. Romana², M. Polak³, P. Eydoux¹.* 1) Biologie du Developpement, Hospital Robert Debre, Paris, France; 2) Cytogenetics, Hospital Necker-Enfants-Malades, Paris, France; 3) Endocrinology, Hospital Robert Debre, Paris, France.

Neonatal Diabetes Mellitus (NDM), a hyperglycemia appearing within the first month of life and requiring insulin therapy, is a rare disease (1/400,000 live births). Features of this disease include intra-uterine growth restriction, macroglossia, umbilical or inguinal hernia. In half of the cases, neonatal diabetes is transient, disappearing within 6 months. In these patients, there is a predisposition to insulin resistant diabetes. Duplication and inverted duplications within chromosome bands 6q22-23 have been demonstrated in association with NDM; paternal isodisomy of the same region has been shown in other patients. PLAGL1, an imprinted gene located in this region is a candidate gene for NDM. We have tested 21 patients with NDM using conventional cytogenetics and FISH with a probe encompassing PLAGL1. A chromosome rearrangement was barely visible on metaphase chromosomes, but interphase FISH clearly showed a duplicated signal on interphase chromosomes on patients with a duplication demonstrated at the molecular level. The results of this study will be presented. We conclude that interphase FISH is a simple test to diagnose NDM. It may be used in association with molecular diagnosis.

Prenatal Diagnosis by nuc ISH: Patient selection criteria and an analysis of findings. *S.A. Farrell, M.D. Speevak, J. Wilkins.* Dept Lab Medicine, Credit Valley Hosp, Mississauga, ON, Canada.

Nuclear fluorescence in situ hybridization (nuc ISH) now is a commonly used technique for the rapid detection of fetal aneuploidies in amniotic fluid cells. However, the expense, technical time and equipment consumption is high. To conserve laboratory resources, we developed a strategy for selection of patients who could benefit most from this procedure. The Genetics clinic at The Credit Valley Hospital established the following criteria for the selection of patients for nuc ISH. Criteria 1: Late gestation (>21 weeks) and late maternal age (LMA) or screen positive Maternal Serum Screen (MSS) result and late gestation. Criteria 2: A risk of 3% or greater for a chromosome abnormality based on LMA or MSS. Criteria 3: Ultrasound findings highly suggestive of a chromosome abnormality or 2 ultrasound soft signs and late gestation. Over a six month period, nuc ISH was performed on amniotic fluid specimens from 49 patients, representing 8% of the total amniotic fluids tested during that period. Nine (18.4%) patients qualified under category 1; 30 (61.2%) patients qualified under category 2 and 10 (20.4%) patients qualified under category 3. The abnormal nuc ISH findings were: 0/9; 5/30 (16.7%) and 4/10 (40%) respectively. A 100% detection rate of chromosome abnormalities supported the cut-off risk of 3% as compared to a detection rate of 37.5% with a 5% risk cut-off. This analysis justifies the appropriateness of the selected risk criteria. The use of strict selection criteria is a valuable tool, ensuring consistency, fairness, and increased predictability of impending abnormal results.

Detection of chromosomal rearrangements with single copy FISH probe arrays. *J.H.M. Knoll, P. Angell, P.K. Rogan.* Children's Mercy Hospital & Clinics, Kansas City, MO 64108.

Single copy FISH (scFISH; Rogan et al. *Genome Res* 11:1086, 2001) is a technique that quickly generates probes for chromosomal in situ hybridization to sequence-defined genomic intervals. DNA fragments suitable as hybridization probes are generated by long PCR amplification of single copy sequences deduced from the human genome draft sequence. A nick-translated 2 kb fragment is adequately and reliably visualized by indirect immunolabeling. Intervals of at least this length are separated in the genome by an average of 20-30 kb. We have designed and hybridized probes from 21 disease intervals on 15 different chromosomes (Knoll et al. *AJHG* 67S:157, 2000; Rogan et al. *EJHG* 9: 95, 2001). Chromosome breakpoints and gene disruptions in acquired and inherited disorders can be detected and refined by scFISH at a resolution comparable to Southern hybridization and fiber-FISH, neither of which preserve higher-order chromosome structure. We delineate breakage intervals by pooling various combinations of probes derived from an ordered array of single copy sequences adjacent to the breakpoint. We have designed and produced a set of scFISH probes to delineate chromosome 9 breakage intervals in 9;22 translocation-positive chronic myelogenous leukemia, as large deletions proximal of *ABL1* are often associated with a poor prognosis. To increase the throughput of probe synthesis for other chromosomal regions, probe design was automated by developing software to select primers for amplification of scFISH products based on the coordinates of disease intervals in the genome draft assembly. Long PCR reaction conditions were also optimized for preparation and amplification of multiple probes in parallel (96-well format), and amplicons were purified either by reamplification of gel-separated products or by preparative HPLC. These streamlined procedures were used to concurrently design and amplify probes for 24 distinct subtelomeric regions. These probes were selected based on their proximity to chromosomal ends, and therefore should detect subtle, terminal unbalanced rearrangements.

High rate of non-informative FISH patterns is a significant limiting factor in pre-implantation genetics. *R.R. Higgins, J. Ahmad, W. Wyatt.* Allina Cytogenetics Laboratory, Abbott Northwestern Hospital, Minneapolis, MN.

Pre-implantation genetic testing utilizing FISH is performed on blastomeres and sperm to provide genetic information to couples with known balanced chromosome abnormalities. Two examples demonstrate significant FISH signal artifact, due to technical difficulties in processing and random overlap of same color signals, is inherent and prevalent in as high as 50% of our results. Example 1: a couple with the male carrying an $\text{inv}(10)(\text{p}13\text{q}26.1)$. Commercial 10p-arm (green) and 10q-arm (red) sub-telomere probes in conjunction with a centromere 10 (aqua) probe were utilized. The signal pattern for normal/balanced inversion nuclei in sperm was 1 red/1 green/1 aqua (1R1G1A) and in blastomeres was (2R2G2A). The signal patterns for the recombinant $\text{rec}(10)\text{dup}(10\text{p})\text{inv}(10)(\text{p}13\text{q}26.1)$ was in sperm (0R2G1A) and in blastomeres (1R3G2A). The signal patterns for the recombinant $\text{rec}(10)\text{dup}(10\text{q})\text{inv}(10)(\text{p}13\text{q}26.1)$ was in sperm (2R0G1A) and in blastomeres (3R1G2A). FISH was performed on 200 sperm: 67.5% displayed a normal/balanced inversion result, 23.0% displayed a recombinant result and 9.5% were non-informative. 10 blastomeres from 2 cycles of stimulation were studied: 40% displayed a normal/balanced inversion result, 10% displayed a recombinant result and 50% were non-informative. Example 2: a couple with the male carrying a $\text{t}(4;8)(\text{p}14;\text{q}24.13)$. Commercial 4p-arm (green) and 8q-arm (red) sub-telomere probes in conjunction with a centromere 4 (aqua) probe were utilized. A signal pattern for normal/balanced translocations was in sperm (1R1G1A) and in blastomeres (2R2G2A). The 16 signal patterns for the disjunction products were determined. FISH was performed on 200 sperm: 34.5% displayed a normal/balanced translocation result, 65.5% displayed an abnormal result and 0.0% was non-informative. FISH was performed on 10 blastomeres from 1 cycle of stimulation: 40% displayed a normal/balanced inversion result, 30% displayed an abnormal result and 30% were non-informative. A high rate of non-informative patterns is a significant limiting factor in pre-implantation genetics and a significant number of blastomeres are needed to obtain enough informative blastomeres for implantation.

Program Nr: 798 from 2002 ASHG Annual Meeting

Submicroscopic deletion 9(q34.4) and duplication 19(p13.3) identified by subtelomere specific FISH probes. *D.I. Quigley, K. Kaiser-Rogers, A.S. Aylsworth, K.W. Rao.* Depts of Pediatrics and Genetics, University of North Carolina, Chapel Hill, NC.

Submicroscopic rearrangements involving chromosome ends are responsible for a number of cases of previously unexplained mental retardation and multiple congenital anomalies. We have studied a patient with mental retardation, significant microcephaly, alopecia totalis and other anomalies who carries an unbalanced product of a cryptic reciprocal translocation involving chromosomes 9 and 19. FISH studies using subtelomere specific probes revealed a derivative chromosome 9 that is missing 9q subtelomeric sequences that are replaced by 19p subtelomeric sequences. The patient has partial monosomy 9q and partial trisomy 19p. The patient inherited the derivative 9 from his father, who carries an apparently balanced, cryptic, reciprocal translocation involving the terminal regions of 9q and 19p. To our knowledge, this is the first report of a patient with the two very rare chromosomal rearrangements, partial monosomy 9q and partial trisomy 19p. This case demonstrates the utility of subtelomere specific FISH probes for detecting cryptic subtelomeric rearrangements in patients with idiopathic mental retardation and normal appearing karyotypes.

Deletion analysis of Smith-Magenis syndrome patients toward further delineation of the SMS critical interval.

C.N. Vlangos¹, R.E. Lucas¹, D.K.C Yim², S.H. Elsea^{1,3}. 1) Graduate Program in Genetics, Michigan State University, East Lansing, MI; 2) Department of Pediatrics, Kaiser Permanente Medical Care Program, Honolulu, HI; 3) Departments of Zoology and Pediatrics and Human Development, Michigan State University, East Lansing, MI.

Smith-Magenis syndrome (SMS) is a congenital anomalies/mental retardation disorder and possible contiguous gene deletion syndrome associated with an interstitial deletion of chromosome 17p11.2. The SMS phenotype includes mental retardation, developmental delay, distinct facial anomalies, sleep disturbance, and behavioral abnormalities. The typical deletion carried by >90% of SMS patients is ~4-5 Mb. Using patients with various deletions spanning chromosome 17p; the SMS critical interval is currently narrowed to ~1.0-1.5 Mb of DNA, and contains ~30 known genes and ESTs. To date there has not been a gene identified that is responsible for any of the major characteristics seen in the SMS phenotype, though the gene(s) causing the phenotype are thought to map to this critical interval. In order to further narrow the SMS critical region and determine possible genotype:phenotype correlations, we are searching for patients carrying smaller or abnormal deletions involving 17p11.2. Using fluorescent *in situ* hybridization (FISH), we have completed analysis of 15 patients for deletion of chromosome 17p. Of the 15 patients analyzed, three were found to carry novel deletions involving 17p. Two patients were found to carry larger than average SMS deletions, while the third patient carries an abnormally sized deletion with a breakpoint located within the current SMS critical region. This patient has typical SMS features, and this deletion allows for further refinement of the distal end of the SMS critical interval. Refinements such as this will help to reduce the large number of positional candidate genes currently being studied. Further studies are underway to determine the role, if any, the positional candidate genes may play in the SMS phenotype. In addition, studying patients with these slightly different deletions along 17p may help to explain some of the subtle differences seen in the SMS phenotype.

Program Nr: 800 from 2002 ASHG Annual Meeting

Familial variation in alpha satellite regions of chromosomes 18, X and Y can result in inconclusive or false prenatal interphase FISH results. *E.J.T. Winsor, E.M. Wood-Burgess.* Pathology and Laboratory Medicine, Mount Sinai Hosp, University of Toronto, Toronto, ON, Canada.

Commercially available FISH probes are widely used for rapid prenatal diagnosis of common trisomies. In a study of 778 patients using AneuVysion(Vysis) probes on uncultured amniotic fluid or CVS, three patients had an inconclusive result because of a small alpha probe signal (two for chromosome 18 and one for X). Variation in the size of chromosome 18 alpha satellite has previously been reported as a reason for false negative results (Tepperberg J et al.2001; Thilaganathan et al.2000; Weremowicz S et al.2001). Similar variations have been reported using alpha satellite probes for the X and Y chromosomes (Tsuchiya K et al.2001; Tepperberg J et al.2001).

Conclusion: Variation in the size of the alpha satellite region of chromosomes 18,X and Y can result in inconclusive,false negative or false positive prenatal interphase FISH results. These inherited variations may be more common than previously recognized and should be considered when prenatal ultrasound findings are consistent with Trisomy 18 or when there are no ultrasound abnormalities and FISH results indicate 45,X. Use of locus specific probes would reduce these limitations.

Genotype-phenotype correlation in patients with NF1 microdeletion syndrome: identification of candidate genes for mental retardation. *P. Riva¹, M. Venturin¹, P. Guarnieri¹, F. Orzan¹, F. Natacci², C. Gervasini¹, P. Colapietro¹, A. Bentivegna¹, M. Stabile³, R. Tenconi⁴, M. Upadhyaya⁵, C. Hernandez⁶, L. Larizza¹.* 1) Dept Biol & Genetics, Univ Milan, Milan, Milan, Italy; 2) Medical Genetics Unit, ICP Milan, Italy; 3) Medical Genetics Service, H Cardarelli, Naples, Italy; 4) Dept Pediatrics, Univ Padua, Italy; 5) Dept of Medical Genetics, Univ of Wales, Cardiff, Wales UK; 6) Molecular Genetic Unit, H Ramon y Cajal, Madrid, Spain.

NF1 microdeletion syndrome is determined by haploinsufficiency of NF1 gene and its flanking regions in 17q11.2. As indicated in previous studies microdeleted patients (pts) show a more severe phenotype than that observed in classical NF1 pts. To address a phenotype-genotype correlation we have undertaken a study aimed at: 1) grouping the pts on the basis of their extra-NF1 clinical signs; 2) searching candidate genes involved in the outcome of severe phenotype. As NF1 microdeleted pts account for 5-8% of NF1 mutations, we combined the clinical and genetic evidence from 15 of our pts with that concerning 77 similar published cases to evaluate the frequency of each parameter versus the classical phenotype. By means of statistical analysis we found that the most prevalent extra-NF1 clinical signs are mental retardation (MR), heart disease (HD) and dysmorphism. Conventional and fiber FISH analysis allowed our pts to be grouped on the basis of deletion type: REP (1.5 Mb del) and BL (del > 1.5 Mb) which distal and proximal boundaries were marked by 271K11-474K4 and 252O24-1J8 respectively. By using bioinformatics we established the deletion gene content: out of 23 genes, one or several of the following genes, CREME9, CENTA2, OMG, EVI2A, KIAA1821, included in both deletion types and of the five genes in the BL deletion, CDK5R1, ZNF207, NJMU-R1, ACCN1, MYO1D, might be implicated in MR. In particular CDK5R1, involved in the development of cerebral cortex, is currently processed for mutation analysis on pts with non X-linked unspecific MR. Only the JJAZ gene appears a suitable candidate for HD; additional genes with unknown function might be identified by expression and bioinformatic studies.

Genomewide screening with automated fluorescent genotyping to detect cryptic cytogenetic abnormalities in children with idiopathic mental retardation. *M. Rio¹, V. Cormier-Daire¹, S. Lyonnet¹, J. Amiel¹, D. Sanlaville¹, D. Bacq², M. Vekemans¹, A. Munnich¹, L. Colleaux¹.* 1) INSERM U393, et Departement de Genetique Hopital Necker-Enfants Malades, Paris, France; 2) Centre National de Genotypage, Evry, France.

Mental retardation (MR) is the most common developmental disability, affecting largely 2% of the general population. However, its origin remains poorly understood. The causes of MR are diverse, but chromosomal rearrangements are believed to account for 4 - 28% of cases. Because no practical way for screening the entire genome is available at present, efforts have first focused on rearrangements involving subtelomeric regions. We previously developed an efficient strategy based upon automated fluorescent genotyping to test for telomere integrity. This strategy detected about 9 % of cryptic subtelomeric deletions or duplications and 1.4% of uniparental disomies in patients with idiopathic syndromic MR.

Since telomere screening is a first step towards the goal of analyzing the entire genome for chromosomal rearrangements in MR, we decided to extend our strategy to 400 markers evenly distributed along the chromosomes to detect interstitial anomalies. Similarly to telomeric genotyping, the genotype of the affected child was compared to the parental genotypes seeking for irregular allele inheritance. A total of 100 individuals were tested. Results for 45 children have already been analysed and 7 interstitial anomalies were found : 6 deletions and 1 parental disomy. Our data demonstrate that fluorescent genotyping is a sensitive and cost-effective method that not only detects small interstitial rearrangements but also provides a unique opportunity to detect uniparental disomies.

This study emphasizes the value of fluorescent genotyping as a systematic screening approach for the detection of interstitial aberrations. In addition to its clinical relevance, this study will hopefully allow the delineation of new contiguous gene syndromes and the identification of new imprinted regions.

Chromosomal Analysis, Y-microdeletion Detection and their Implications on Subfertile ICSI Men Candidates.

*S.M. Tayel*¹, *K. Homouda*². 1) Cytogenetics Unit, Department of Anatomy, Faculty of Medicine, University of Alexandria, Egypt; 2) Department of Obstetrics and Gynecology, Ain Shams Faculty of Medicine, Egypt.

One hundred and thirty two subfertile candidate men for ICSI treatment were subjected to chromosomal analysis and Y chromosome microdeletion detection prior to ICSI. Sex chromosome aberrations in pure and mosaic forms were diagnosed in 6 cases (4.5%). Y- microdeletion detection in the AZFc region was detected in 3/126 males (2.4%). Fertilization and implantation rates were significantly reduced in subfertile men with AZFc microdeletion ($P < 0.05$) when compared to those with no deletion. As Y- deletion is genetically transmitted from subfertile men to their male offspring via ICSI, genetic counseling and reproductive options have to be offered to those men before ICSI treatment. Preimplantation genetic diagnosis and female sex selection may present another strategy for infertile men with Y- microdeletion to avoid fathering a son with the same fertility problem.

Preimplantation Genetic Diagnosis (PGD) for translocation carriers. *S.W. Cheung¹, W.S. Wun², M.L. Cooper¹, S.C. Angus², A.A. Ybarra¹, J.R. Nichols¹, G.M. Grunert².* 1) Dynagene, Houston, TX; 2) Obstetrical and Gynecological Associates, Houston, TX.

Preimplantation Genetic Diagnosis (PGD) was used for translocation carriers at risk of transmitting chromosome abnormalities to offer the possibility of selectively transferring unaffected embryos. We report three cases in which one spouse is a reciprocal translocation carrier. They are [1] t(3;15)(q26.2;q22.3), [2] t(4;13)(q34;q12) and [3] t(3;15)(q29;p13). Fluorescent in situ hybridization (FISH) for the detection of chromosome abnormalities was utilized prior to embryo transfer. Following In Vitro Fertilization, embryo biopsy was performed on all embryos with 5 cells or greater on day 3. All blastomeres were subjected to two rounds of multicolor FISH for chromosomes 13, 16, 18, 21, 22, X and Y (Vysis) followed by a third round of multicolor FISH for the detection of unbalanced translocations. A three-color scheme consisting of one telomeric probe each for the short and long arm of one translocation chromosome (labeled with Spectrum Green and Orange respectively from Vysis) and a third telomeric probe for one arm of the second translocation chromosome (Texas Red from CytoCell) were used in all cases. This approach enables us to distinguish the balanced signal pattern from that of the unbalanced signal pattern simultaneously in a given blastomere. Therefore it allows for detection of all unbalanced products of meiotic segregation. Only one cell was biopsied and only normal or balanced embryos were transferred. All patients underwent genetic counseling to discuss the risks and benefits of the testing prior to the PGD procedure. A total of 39 embryos in 3 cycles were biopsied. Following FISH analysis, 3 embryos were undiagnosed. Of the 36 embryos that were diagnosed, 10 embryos (27.7%) had a normal complement of the chromosomes tested, and 26 (72.3%) were determined to be chromosomally abnormal (numerical and structural). Three transfers were performed, resulting in one live birth and one ongoing pregnancy. Detailed analysis of the 36 biopsied, normally developing embryos obtained from the three reciprocal translocation carriers will be presented.

Custom Probes for PGD of Acrocentric Chromosome Rearrangements: Use of the BAC Resource Consortium.

P.M. Miron^{1, 4}, S. Herrick¹, C.C. Morton^{1,2,4}, J. Stoler^{3,4}, L. Wilkins-Haug^{2,4}, S. Weremowicz^{1,4}. 1) Dept Pathology, Brigham & Women's Hosp, Boston, MA; 2) Dept Obstetrics & Gynecology, Brigham & Women's Hosp, Boston, MA; 3) Dept Pediatrics, Massachusetts General Hospital, Boston, MA; 4) Harvard Medical School, Boston, MA.

Interphase FISH analysis can be used to detect unbalanced products of meiotic segregation in reciprocal translocation carriers. In such investigations, two probes that flank (or one probe that spans) one of the translocation breakpoints must be employed to detect all unbalanced products resulting from 2:2 segregation. Reciprocal translocations involving acrocentric chromosomes present special problems for probe selection because of extensive DNA homology among acrocentric chromosomes in both the short arm and centromere sequences. We studied a translocation, t(14;21) (q12;q21), present in the male partner of a couple interested in PGD, that required probe development. As both chromosomes involved in the translocation are acrocentric, unique probes were unavailable for the short arm and centromeric sequences. Furthermore, because of the proximity of each breakpoint to its respective centromere, no locus-specific probe mapping proximally to the breakpoint on either long arm was commercially available. The BAC Resource Consortium provides a vast repertoire of FISH-verified human BACs that can be employed for probe development. One of these clones mapping in the region on chromosome 21q proximal to the breakpoint was selected for probe development and used in combination with the Vysis LSI 21 probe mapping distally to the translocation breakpoint. Hybridization to metaphase chromosomes in the translocation carrier verified that the BAC probe mapped proximally to the breakpoint on 21q. A spontaneous pregnancy precluded PGD, but use of these probes permitted the option of CVS for early chromosome analysis, which otherwise would not have been recommended because of the subtlety of this translocation. As illustrated by this case, the extensive collection of clones from the BAC Consortium provides a powerful resource for probe development in FISH diagnostic strategies for both PGD and prenatal diagnosis more generally.

Molecular characterization, IQ and executive functioning in a sample of Turner syndrome cases from Australia.

*V. Anderson*¹, *D.L. Thiselton*², *K. Howard*¹, *R. Dobb*¹, *K. Mill*³, *R. Ribble*², *R. Williamson*³, *B. Riley*². 1) Dept. of Psychology, University of Melbourne, Melbourne, Victoria, Australia; 2) Depts. of Psychiatry and Human Genetics, Virginia Commonwealth University, Richmond VA; 3) Murdoch Children's Research Institute, Royal Children's Hospital, Flemington Road, Parkville, Victoria, Australia.

We collected a sample of 104 cases of Turner syndrome (TS) for replication of previously reported findings suggesting imprinted, X-inactivation escaping loci affecting behavior on the X chromosome. For 73 cases where DNA was available, we characterized the X chromosome structure, and monosomic or disomic status using a panel of 12 evenly spaced microsatellite markers. 38 cases were monosomic; 24 were maternal in origin (45,Xm), 7 were paternal in origin (45,Xp) and 7 could not be determined because parental samples were not available. 35 cases were disomic. 8 had p-arm and 2 q-arm deletions on the paternal chromosome, and 10 had p-arm deletions on the maternal chromosome. 4 p-arm and 1 q-arm deletions could not be assigned parental origin. 10 cases show a complex pattern and are being further characterized. IQ results were in the normal range (Mean 101.16, SD 12.61) and cases did not differ from controls for either verbal or performance measures. In general, cases performed significantly less well on tests of executive functioning compared to controls. Specifically, selective attention and ability to sustain attention was impaired. Cases showed deficits on the contingency naming task (CNT) and controlled oral word association test (COWAT). When compared to the normative sample TS girls performed significantly less well on accuracy of copy, recall and organisational ability. The pattern of performance exhibited by the (45,Xp) and (45,Xm) were very similar both on measures of IQ and executive functioning. These findings are not in accordance with previous reports, suggesting that (45,Xp) females cannot be distinguished from (45,Xm) females by their performance on these tests.

Trisomy 15q11.2-qter resulting from unbalanced translocation t(X;15)(q22.3;q11.2) in a phenotypically normal girl.

I. Hansmann¹, C. Baldermann¹, U. Lieser², M. Hesse³, A. Kuechler⁴, T. Liehr⁴, H. Thiele¹, M. Hagemann¹, E. Fiedler¹, B. Horsthemke⁵, J.R. Lupski^{6,7}, P. Stankiewicz⁶. 1) Institut fuer Humangenetik & Medizinische Biologie; 2) Universitaetskinderklinik, Halle/Saale; 3) Suedharzkrankenhaus, Nordhausen; 4) Institut fuer Humangenetik & Anthropologie, Jena; 5) Institut fuer Humangenetik, Essen, Germany; 6) Depts. of Molecular & Human Genetics; 7) Pediatrics, Baylor College of Medicine, Houston TX.

Only a few unbalanced X;autosome translocations associated with a normal phenotype are known. We report a twin girl with minor growth retardation but no other phenotypic features, in whom a nearly complete trisomy 15 due to a *de novo* unbalanced translocation t(X;15) was identified prenatally (nuchal translucency). Karyotyping, M-FISH and multicolour banding revealed an unbalanced karyotype 46,X,der(X)t(X;15)(q22;q11.2) in the female twin and a normal karyotype in the male twin. At 1 year the girl's development does not differ significantly from her twin. In all cells, BrdU studies showed late-replication of the der(X) with variable spreading onto the translocated 15q. The paternal origin of the der(X) was verified by the CGG-repeat analysis in *FMRI* and the *AR* methylation assay. The 15q11.2 breakpoint was mapped between cen15 and the PWS/AS region. Microsatellite analysis revealed that the additional 15q material is an identical copy of the paternal chromosome 15. The *SNRPN* locus on the derivative chromosome is unmethylated, although X-inactivation appears to spread onto the translocated autosomal DNA. By FISH, BAC clone RP11-483F6 was found to span the Xq22.3 breakpoint. This BAC contains significantly more LINE1 elements (44.69%) than clones in flanking Xq segments. Recently, Bailey et al. (2000) proposed that L1 elements may serve as DNA signals for X-inactivation propagation along the normal X. We hypothesize that in X;autosome translocations, spreading of X-inactivation may be mediated only from specific regions of the X chromosome. Clusters of specific DNA domains such as LINE1 sequence may serve as target e.g. for histone proteins, which in turn enable *cis*-propagation of the XIST-RNA from X onto the autosome.

Evidence for sequence specificity in the association of XIST RNA with chromatin. *L.L. Hall¹, C.M. Clemson¹, J. McNeil¹, M. Byron¹, K. Wydner², A.F. Smit³, J.B. Lawrence¹*. 1) Cell Biology, U. Mass. Medical School, Worcester, MA; 2) Department of Obstetrics/Diagnostic Genetics, UMDNJ-Robert Wood Johnson Medical School, New Brunswick, NJ; 3) The Institute for Systems Biology, 1441 North 34th Street, Seattle, WA.

Whether XIST RNA is indifferent to the sequence content of the chromosome is fundamental to understanding its mechanism of chromosomal inactivation. Transgenic Xist RNA appears to associate with and inactivate an entire mouse autosome. Here, the relationship of human XIST RNA to autosomal chromatin is investigated in cells from two patients carrying X;autosome translocations in the context of trisomy for the involved autosome, where there is no selection against autosomal inactivation. Since such trisomies are lethal in early development, the normal or mild phenotypes of the X;14 and X;9 trisomic patients demonstrates that the translocated autosomes were inactivated. Surprisingly, our analyses show that in cultured primary fibroblasts from adult patients, XIST RNA does not associate with most of the involved autosomal material, as it does the X-chromatin. The bulk of the translocated autosome is hypoacetylated and later replicating than the normal autosome, supporting that inactivation hallmarks were present beyond the region associated with XIST RNA. However, several observations indicate that the autosomal inactivation is less complete or stable than X inactivation, which our results suggest is due to a deficient interaction with XIST RNA. These findings reveal a fundamental difference in the affinity of XIST RNA for autosomal versus X chromatin. Further evidence for sequence specificity comes from a reproducible banding pattern of the Xist RNA as it detaches from murine mitotic X chromosomes, indicating higher affinity of Xist RNA for early-replicating R-bands enriched for genes and SINE elements. This specificity of XIST/Xist RNA may point to novel sequence motifs involved in chromosome architecture and genomic regulation.

Expression profile of the human inner ear genes and the identification of candidate genes for genetic deafness.

Z.Y. Chen^{1,2}, *C.C Morton*^{2, 3}, *D.P. Corey*^{4, 5}. 1) Neurology Dept, Massachusetts General Hosp, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Department of Pathology, Brigham and Women's Hosp, Boston, MA; 4) Neurobiology Dept, Harvard Medical School, Boston, MA; 5) Howard Hughes Medical Institute.

Despite the progress in the human genome project and the efforts to identify the genes expressed in the mammalian inner ear, our knowledge of the genes expressed in the inner ear is very limited. Microarray technology has provided a powerful tool that can be used to study the inner ear gene expression. Oligonucleotide array was used to survey genes expressed in the fetal human inner ear. Sub-tissues (the organ of Corti, the ligament) from the inner ear were collected to evaluate the regional expression patterns. In total ~27,000 genes and ESTs were classified as being expressed in at least one of the samples, representing 43% of ~62,000 genes and ESTs surveyed. A majority of genes were found to be expressed in all the tissues, with a subset of genes showed distinct patterns associated with each sub-tissue. Other human tissues were also studied using the same chip set in order to identify the inner ear enriched genes. The tissues included the human brain, heart, kidney, testis and retina. ~2600 (4% of total number of genes surveyed) genes were identified as the inner ear enriched, being either expressed in the inner ear only, or predominantly expressed in the inner ear. Gene ontology representation showed many enriched genes encode for signal transducers, enzymes and transporters. Of 39 deafness genes on the chip 41% came from the inner ear enriched genes, indicating that other genes within the group are more likely to be involved in many forms of deafness. We have mapped all the inner ear enriched genes and their mouse orthologs to the human and mouse chromosomal locations, respectively. This approach will result in the enrichment of candidate genes for deafness by as much as 10 fold. In addition our work also identified genes enriched in other human tissues, thereby providing candidate genes for genetic disorders involving those tissues.

Identification of novel genes involved in the regeneration of inner ear hair cells. *M.G. de Silva*¹, *M. Hildebrand*^{1, 2}, *J. Aloe*¹, *T. Klockars*¹, *H.-H. Dahl*^{1,3}. 1) Murdoch Childrens Research Institute, Royal Children's Hospital, Melbourne, Victoria, Australia; 2) Department of Biochemistry, University of Melbourne, Melbourne, Victoria, Australia; 3) Department of Paediatrics, University of Melbourne, Melbourne, Victoria, Australia.

Hearing loss is the most common sensory condition in our population often resulting from inner ear hair cell degeneration due to genetic abnormalities or environmental insults. In the bird, hair cells can regenerate resulting in restored hearing function. In the mature mammalian inner ear however, hair cells are not replaced once damage has occurred leading to permanent hearing deficits. Our aim therefore, is to identify factors required for hair cell regeneration. Microarrays offer a tool for sensitive, quantitative and efficient analysis of expression changes in thousands of genes in the one experiment. Our microarray analyses of the Soares NMIE library, consisting of 1536 cDNA clones isolated from the mouse inner ear have successfully identified several novel inner ear specific transcripts. In addition we have validated the technology by detecting transcripts that are known to be important in inner ear function such as Collagen II, alpha 1, Collagen I, alpha 2 and Otoconin 90. We are applying this technology to identify factors vital to the process of differentiating an ES cell to an inner ear hair cell. Several growth culture conditions, exposure to EGF, BDNF, NT-3, aFGF, bFGF and conditioned media from cochlea cell explants, have been selected for the examination of gene expression variations as the ES cell population moves along the differentiation pathway. RNA isolated from differentiating cells has been screened by RT-PCR for the expression of the hair cell markers Brn3.1, and myosin vi and viia. In addition the RNA was reverse transcribed incorporating the fluorescent dyes Cy3 or Cy5. The parental ES cell line is used as a reference base and was labelled with the alternate dye prior to co-hybridisation. Using the Soares NMIE library array we have been able to follow expression changes in inner ear-specific transcripts and select genes with interesting expression profiles for further examination.

The Role of FOXI1 in Pendred Syndrome. *K.A. Kolln¹, S. Enerback², R.J.H. Smith¹.* 1) Molecular Otolaryngology Research Laboratories, University of Iowa, Iowa City, IA; 2) Medical Genetics, Department of Medical Biochemistry, Goteborg University, Goteborg, Sweden.

Statement of Purpose. Pendred Syndrome (PS) is an autosomal recessive disorder characterized by severe-to-profound sensorineural hearing loss (SNHL), thyroid goiter and temporal bone malformations (dilated vestibular aqueduct (DVA) and Mondini malformation). Mutation screening of the causative gene, SLC26A4, has facilitated diagnosis, however in many individuals with this phenotype no SLC26A4 mutations are found. In other persons, only a single SLC26A4 mutation is detected. These findings suggest genetic heterogeneity and/or epistatic interactions with other genes. Recently, cochlear abnormalities and SNHL were demonstrated in mouse mutants with targeted deletions of a winged helix transcription factor, Foxi1. In situ hybridization studies of Foxi1 showed that this gene is expressed in the endolymphatic duct and sac in a pattern similar to that seen with Slc26a4. Further studies have shown that Slc26a4 expression is absent in Foxi1 ^{-/-} mutants. Based on these observations we hypothesized that mutations in FOXI1 cause PS in humans. Methods Used. We screened a cohort of 133 families with a PS phenotype who were negative for SLC26A4 mutation screening. Summary of Results. We identified eight single nucleotide polymorphisms (SNPs) in FOXI1. Four SNPs (276: G®A; 969: G®C; 1011: G®A; 1041:C®T) are wobble bases, causing no change of amino acids. Four nucleotide changes (674:C®T, 724:C®A, 769:G®C, 797:G®A) identified in three affected persons result in missense mutations (T199I, P216T, R231G, R240Q) in FOXI1. In mutation screening of 153 random controls, P216T was detected in two individuals. While only two changes are conserved across species (T199I and R240Q), all cause significant alteration in size and polarity of the amino acids. Conclusion. Based on these data, we calculate that mutations in FOXI1 are responsible for 10% of the PS genetic load and are one-fifth as common as mutations in SLC26A4. (Supported in part by R01-DC02842 to RJHS).

Analysis of the ear and craniofacial region in mouse models of VCFS/DGS. *S. Nowotschin¹, S. Raft², J.S. Arnold¹, J. Liao¹, D.E. Febres¹, T. Van De Water³, B.E. Morrow¹.* 1) Molecular genetics, Albert Einstein College of Med, Bronx, NY; 2) Neuroscience, Albert Einstein College of Med, Bronx, NY; 3) University of Miami, Miami, FL.

Patients with velo-cardio-facial syndrome/DiGeorge syndrome (VCFS/DGS) are characterized by defects in the derivatives of the pharyngeal arches. Included among the major malformations of the first and second arches are facial dysmorphism, velo-pharyngeal insufficiency, chronic otitis media, outer ear malformations and submucous cleft palate. In addition, some have conductive or sensorineural hearing loss as well. Genetic complementation studies revealed that one of the genes hemizygotously deleted on 22q11, termed *Tbx1*, is a strong candidate for cardiovascular defects in mouse models. *Tbx1* is a member of the T-box containing family of transcription factors expressed in the otic vesicle and pharyngeal arches. Pathological studies were performed in *Tbx1* heterozygous and homozygous embryos as well as in bacterial artificial chromosome (BAC) transgenic mice overexpressing human *TBX1*. By otocyst stages of ear development, the otic epithelium (rudiment of the sensory organs and VIIIth cranial neurons) is hypoplastic in homozygous mutants, while the ganglion is enlarged. During otocyst stages, areas of epithelial neurogenic gene expression domains are expanded nearly 2-fold in null animals, suggesting a role for *Tbx1* in regulating the otocyst epithelial/neuronal cell fate decision. BAC transgenic mice had hypoplasia of the sensory organs and chronic otitis media, both found in VCFS/DGS patients. In addition to the ear, *Tbx1* homozygotes and BAC transgenic mice had a cleft palate. To determine the basis of these, we are examining staged embryos by in situ hybridization with molecular probes for the cochlea, vestibular system and ganglion, including *Pax2*, *Hmx2/Hmx3* and *NeuroD*, respectively. We are also investigating the expression pattern of *Col2a1* to study craniofacial development. We believe that these mice serve as a model to understand the molecular basis of ear and craniofacial disorders associated with VCFS/DGS and more common non-syndromic disorders.

Gene expression profiles of regenerating sensory epithelia in the chick inner ear. *R.D. Hawkins¹, S. Bashiardes¹, N. Saccone¹, D. Messina¹, M.E. Warchol², M. Lovett¹*. 1) Washington University, St Louis, MO; 2) Central Institute for the Deaf, St Louis, MO.

Damage to sensory hair cells (HCs) of the inner ear can result in acquired deafness and balance disorders. Mammals cannot replace damaged cochlear HCs, but avian sensory HCs can regenerate if damaged. These new HCs are derived from the underlying supporting cells of the epithelia. Unless such damage occurs, the HCs of the avian cochlea remain in a quiescent state. However, the nearby HCs of the chick utricle are normally in a constant process of regeneration and apoptosis. We are employing cDNA and oligonucleotide microarrays to pinpoint the gene expression changes that occur during this regenerative process and in the process that occurs after sound or drug damage to the cochlea. Our cDNA arrays consist of amplicons for either 400 genes expressed in the inner ear, or for a more random collection of ~8,000 sequence-verified cDNAs. Our custom oligonucleotide array contains 50mers for >1700 transcription factor (TF) genes (comprising all known TFs plus several new TFs). We have derived multiple comparative expression profiles from the few tens of thousands of cells that comprise the (two-cell thick) sensory epithelia of the cochlea and utricle. Among the most significant differences we have observed are increases in SMAD2, beta amyloid, SPARC, TBX2 and KIT expression levels in the proliferating utricle. In the quiescent cochlea BMP4, GATA3, gelsolin, syndecan4, and FOXF1 are upregulated. We have validated many of these observations by a combination of RNA in situ and quantitative real time PCR. We are also generating profiles from sensory epithelia at various timepoints after damage (either in vivo or in vitro). Preliminary data indicate that the TFs FHL1, JUNB, LAF4, and LDOC1 are upregulated early during the regeneration process. Interestingly, several genes that show changes are either known deafness loci or map close to as yet uncloned loci for hearing loss. These findings should prove useful in identifying new markers for the developing and regenerating sensory epithelia, for identifying regenerative pathways and for deriving candidate disease loci.

Fgf-3 and Fgf-10 in mouse inner ear development. *T.J. Wright, S.L. Mansour.* Dept Human Genetics, Univ Utah, Salt Lake City, UT.

Otic development initiates early in development when signals from the hindbrain and mesoderm induce a region of ectoderm to thicken, forming the otic placode. The placode then invaginates and forms a vesicle that undergoes cellular differentiation and morphogenesis, resulting in a mature inner ear. Studies of mice, chick, and zebrafish have implicated several signalling molecules, including fibroblast growth factors (Fgfs) 3 and 10 in these processes.

Mice carrying targeted mutations in *fgf-3* or *fgf-10* have shown that these genes play important roles in inner ear development. In mice that lack *fgf-3*, induction of the placode and formation of the otocyst occur normally, but defects were observed in the induction of the endolymphatic duct and the subsequent morphogenesis of the otocyst as well as in the formation of the otic ganglion. However, the penetrance and expressivity of the mutant phenotype varied, suggesting that other Fgfs and/or their receptors might also play roles in otic development. Indeed, *Fgf-10* is expressed in the developing ear and *Fgf-10* mutants have small inner ears. This hypothesis was also strengthened by the finding that mice homozygous for a targeted disruption of *fgfr2IIIb*, which encodes the preferred receptor for Fgfs-3 and -10, have an ear phenotype similar to, but more severe and penetrant than those of *fgf-3* and *fgf-10* mutants.

To determine the combinatorial roles of these molecules, we have generated mice that lack both Fgf-3 and Fgf-10. Surprisingly, the double mutant embryos lack otic vesicles. These embryos do not show otic expression of the placode marker *Pax-2* and expression of three additional placode markers are mislocalised. Hindbrain patterning as assessed by in situ hybridisation analysis of *Hoxb1* and *kr* expression in rhombomeres 4-6 in the double mutants is normal. In addition, an intermediate otic phenotype is present in embryos with 3 mutant alleles. Further characterisation of otic development and ganglion formation in double mutant embryos and those with three mutant alleles is underway. These results suggest that Fgf signalling plays a direct role in placode specification.

Cluster analysis of gene expression dynamics in differentiating C2C12 myoblasts. *K. Tomczak*^{1,3}, *M. Ramoni*^{2,3}, *D. Sanoudou*^{1,3}, *M. Han*^{1,3}, *A. Kho*^{2,3}, *I.S. Kohane*^{2,3}, *A.H. Beggs*^{1,3}. 1) Genetics Division; 2) Informatics Program; 3) Children's Hospital, Harvard Medical School, Boston, MA.

We used expression profiling to assay gene expression in mouse C2C12 myoblasts induced to differentiate through addition of fusion media (day 0). Triplicate cultures were analyzed on days -2, -1, 0, 2, 4, 6, 8 and 10 for expression patterns of 24,422 probe sets using Affymetrix MG_U74 Av2 and Cv2 microarrays. Fold comparisons and cluster analysis were performed to identify genes with coordinate expression patterns and variable expression levels between proliferating and differentiating cells. Immunofluorescence and western blotting are being used to establish that protein levels of selected genes correlate with mRNA expression measured by the arrays. We used CAGED (<http://genomethods.org/caged>), a Bayesian program for the analysis of time-ordered microarray experiments, to identify 13 unique clusters. Three clusters best met the normality criteria of the standardized residuals and showed the most dramatic changes with time. Cluster 1 contains 8 probe sets whose expression levels decreased with average fold difference of 87. They all represent genes that are expressed in proliferating cultures and are scored "absent" by Affymetrix MAS 5.0 in differentiated/contact-inhibited ones. Conversely, cluster 13 includes 5 mRNA sequences that are found only in fusing cells with 593 fold up-regulation, on average. Four of these highly up-regulated transcripts represent known muscle genes and one is an EST. Cluster 2 contains 90 mRNA sequences that are also up-regulated over the time course. Not surprisingly, 56 are known muscle genes with 21 sarcomeric proteins (e.g. 9 myosins, 6 troponins) and 11 membrane proteins (e.g. 3 sarcoglycans). More interesting are 34 mRNAs not known to be involved in muscle differentiation. Among them are 18 ESTs with no homology to any known genes. These unknown genes represent new differentiation-induced transcripts whose further characterization will allow a better understanding of muscle differentiation. Moreover, our model can be used as a baseline to compare with C2C12 cells expressing various mutant genes involved in myopathic disorders.

Direct Genetic Influence on Brain Sexual Differentiation. *P. Dewing*¹, *T. Shi*¹, *B. Bowling*¹, *S. Horvath*⁴, *E. Vilain*^{1,2,3}. 1) Human Genetics, UCLA, Los Angeles, CA; 2) Dept of Pediatrics, UCLA, Los Angeles, CA; 3) Dept of Urology, UCLA, Los Angeles, CA; 4) Dept of Biostatistics, UCLA, Los Angeles, CA.

The central dogma of sexual differentiation of somatic tissues is based on the primary dependence on testicular secretions by the developing fetus. This concept of hormonal control of sexual differentiation has been applied to brain sexual dimorphisms, where testosterone, directly or via local conversion to estradiol, promotes the induction of masculine patterns of neural and behavioral development, while preventing feminine patterns of differentiation.

A great deal of experimental evidence from several decades of research supports the role of gonadal steroids being solely responsible for inducing brain sexual differentiation. By acting on neural development, testosterone and its metabolites cause male and female brains to develop slightly differently. Here we propose an alternative theory that sexual differences between male and female brains are also the result of direct actions of genes on the induction of sexually dimorphic patterns of neural development. Using microarrays and confirmatory RT-PCR, we have detected at least seven murine genes which show differential expression between male and female developing brains at E10.5, before any gonadal hormone influence. Three of these genes are enhanced in females and four in male. The identification of genes differentially expressed between male and female brains prior to gonadal formation suggests that genetic factors directly influence brain sexual differentiation.

Central apnea in newborn mice with homozygous SLC5A3 gene deletion. *G.T. Berry¹, R.B. Buccafusca¹, S.W. Wu¹, J.R. Ren², L.G. Gonzales¹, P.B. Ballard¹, J.G. Golden¹, J.G. Greer².* 1) The University of Pennsylvania School of Medicine, CHOP, Philadelphia, PA; 2) University of Alberta, Edmonton, Alberta, Canada.

Myo-inositol (Ins) has been long held to play a special role in brain metabolism because both Ins and its polyphosphoinositide derivatives that are important in membrane signaling are exceptionally abundant in nervous tissue. The Na⁺/Ins cotransporter (SLC5A3 or SMIT) can maintain a high millimolar concentration gradient of cellular Ins and is highly expressed in brain and spinal cord of the embryo and fetus, as well as placenta. In order to gain more insight into the role of the Ins in brain metabolism, we generated a homozygous targeted murine SLC5A3 gene deletion model. All SLC5A3 (-/-) animals expire shortly after birth because of hypoventilation at which time whole body Ins levels were reduced by 84%. Necropsy studies were normal. We utilized an in vitro brain stem-spinal cord -diaphragm preparation to examine the inspiratory motor discharge of 18.5 pc fetuses following SLC5A3 (+/-) X SLC5A3 (+/-) matings. Electrophysiological recordings were also obtained from medullary slice preparations, consisting of a putative ventrolateral respiratory rhythm-generating center, the pre-Bötzinger complex (PBC). The screening for potential mutants with an abnormal respiratory motor pattern was double-blinded. A total of 3 SLC5A3 (-/-), 65 (+/-) and 10 (+/+) newborn mice were studied. Diaphragm EMG recordings from only the SLC5A3 (-/-) pups had irregular respiratory rhythm patterns with 3-8 apneas of 15 to 60 second durations per 10-minute period. Direct recordings of brainstem neuronal population discharge within the PBC demonstrated that the irregular rhythms were present in the center, rather than simply reflecting a failure of transmission of inspiratory drive to motoneuron populations. The lethal hypoventilation can be explained on the basis of central apnea due to a deficit in the brain rhythm-generating center, close to or at the PBC. The homozygous SLC5A3 gene deletion model demonstrates the critical importance of Ins in the physiology of the nervous system, as well the essential nature of the SLC5A3 transporter in establishing an Ins concentration gradient in the fetus.

Novel Developmentally Regulated Gene Circuits in Murine Brain Regions: A Template for Understanding Dysfunction and Tumorigenesis. *E.A. Donarum¹, S. Hautaniemi², J. Graff¹, Y. Cheng¹, S. Mousses², O. Kallioniemi², J. Natale¹, D.A. Stephan^{1,2}.* 1) Research Center for Genetic Medicine, Childrens Research Institute, Washington, DC; 2) Cancer Genetics Branch, National Human Genome Research Institute, NIH, Bethesda, MD.

The gross anatomic changes of the developing brain have been well documented, and to a large extent, correlated with specific brain dysfunction. Dysfunction (tumorigenesis as well as cognitive difficulties) without major structural damage is less well understood. Despite the great advancements in biological knowledge, the developmental pathogenetics underlying most brain phenotypes are not known. Here, we investigate the normal developmental gene regulation program in an in vivo murine model using cDNA array expression profiling of 11,264 genes (BMAP clone set). Four murine brain regions were micro-dissected and expression profiled in quadruplicate at high-density time points between birth and maturation. Waves of gene expression correlating with known anatomic/structural changes were identified. We specifically focused on the expression changes that were known to be involved in axonal migration and myelination, and defined a cohort of genes and ESTs that are temporally correlated with these events. A novel SOM analysis tool was applied to assign novel functions to these gene/EST clusters. This analysis provides a template against which to compare expression profiles of different neurologic tumors (glioma, ependymoma, medulloblastoma) and behavioral murine models (neurofibromatosis) of human disease so that we can rapidly identify developmental stage-specific pathologic expression correlates. For more information on the use of cDNA microarrays as a gene expression platform, refer to <http://microarray.cnmcresearch.org>.

Tumor Suppressor PTEN is a Negative Regulator of TrkA Signalling. *S.A. Moussatov¹, J.M. Roberts², M. Sugiultzoglu², D.W. Pfaff¹, M.G. Kaplitt^{1,2}.* 1) Lab Neurobiology/Behavior, Rockefeller Univ, New York, NY; 2) Dept. of Neurosurgery, Weill Medical College of Cornell Univ., New York, NY.

The tumor suppressor PTEN has distinct spatial and temporal patterns of expression in the nervous system. However, its role in regulating neuronal functions is poorly understood. We have overexpressed PTEN in rat pheochromocytoma PC12 cells, a neuronal in vitro model, and found it to inhibit several NGF-mediated effects. While survival was significantly reduced, neurite outgrowth and NGF-induced growth arrest were blocked. We have shown that activation of the MEK/MAPK signaling pathway by NGF, a major pathway that regulates neuronal differentiation in PC12 cells, was hampered by PTEN. Upregulation of AKT and its downstream targets, which are involved in both survival and differentiation, were also significantly reduced. In addition, PTEN overexpression prevented the expected elevation of peripherin mRNA in response to NGF-induced differentiation. This phenomenon is known to be mediated by PLC-gamma signaling, suggesting that PTEN might negatively regulate this pathway as well. In search of the mechanisms of PTEN action on the above cascades, we have discovered that PTEN dramatically inhibits phosphorylation of the kinase domain of the NGF high affinity receptor TrkA at Tyr674/675. Consistent with this observation, the phosphorylation of TrkA at Tyr490, critical for the activation of the MEK/MAPK cascade, was also significantly reduced. To our knowledge, this is the first evidence of negative regulation of multiple signal transduction pathways by PTEN at the level of a neurotrophin membrane receptor. Given the fact that NGF elicits a wide variety of responses in PNS and CNS both during embryogenesis and in adulthood, our findings suggest a role for PTEN in modulating neuronal differentiation, synaptic function, plasticity and survival.

Functional and genetic interactions between Doublecortin and LIS1 in neuronal migration. *T. Tanaka*¹, *C. Paczkowski*¹, *F.F. Serneo*¹, *S. Sasaki*³, *M.J. Gambello*², *S. Hirotsune*³, *A. Wynshaw-Boris*², *J.G. Gleeson*¹. 1) Dept Neurosciences, Univ California, San Diego, La Jolla, CA; 2) Dept Pediatrics and Medicine, Univ California, San Diego, La Jolla, CA; 3) Center for Genome Medical Science, Saitama Medical School, Hidaka, Saitama, Japan.

Neurons destined for the cerebral cortex migrate hundreds of cell-body distances to reach their final destination. Neuronal migration is dependent upon *doublecortin* (*DCX*) and *lissencephaly-1* (*LIS1*), as humans with mutations in either gene display defective migration. Here we show that *Lis1* and *Dcx* function on a common pathway in neuronal migration. We adopted a cerebellar granule cell migration assay system with retroviral transduction of either wild type proteins or fluorescently-tagged proteins to study the effect of gene overexpression and to determine the subcellular localization of these proteins during cell migration in vitro. To study the effect of loss of function of *Lis1*, we utilized neurons from *LIS1* deficient mice. *LIS1* deficient neurons displayed a dose dependent decrease in migration distance. Overexpression of *Lis1* or *Dcx* in wild type neurons resulted in increased neuronal migration distance. *Dcx* overexpression rescues the migration defect in *LIS1* deficient neurons. These results suggest that *LIS1* and *DCX* have dosage-sensitive effects on neuronal migration in both deficiency and overexpression, and genetically interact.

Supported by the Epilepsy Foundation of America (T.T.), Searle Scholars Program, the Klingenstein Foundation and the NINDS (J.G.G).

Mutations in the EGF-CFC genes, *CFC1* and *TDGF1*, cause congenital cardiovascular malformations in humans.

*J.D. Karkera*¹, *E. Roessler*¹, *M.V. Ouspenskaia*¹, *J. Dela Cruz*¹, *E. Goldmuntz*², *P. Bowers*³, *J. Towbin*⁴, *J. Belmont*⁴, *M.M. Shen*⁵, *M. Muenke*¹. 1) Medical Genetics Br, NHGRI/NIH, Bethesda, MD; 2) The Children's Hospital of Philadelphia, PA; 3) Yale University College of Medicine, New Haven, CT; 4) Baylor College of Medicine, Houston, TX; 5) CABM, MMDNJ-RWJ Medical School, Piscataway, NJ.

EGF-CFC genes (*Cfc1*, *Tdgf1*, and others) are expressed during early vertebrate development and are implicated in the establishment of the axial midline and left-right axis formation. Recently, mutations in *CFC1* have been shown to cause laterality defects and transposition of the great arteries (TGA) in humans. In addition, *Tdgf1* was found to be involved in cardiogenesis during murine embryonic stem cell differentiation in culture. Our study consisted of 378 patients with a wide spectrum of cardiac anomalies: TGA, tetralogy of Fallot, truncus arteriosus, interrupted aortic arch, and atrioventricular canal. Screening for mutations in *CFC1* and *TDGF1* were conducted by PCR-dHPLC and each identified variants were subsequently sequenced to identify the nucleotide change. In addition to published mutations in *CFC1*, we have identified a single base pair deletion which was previously described to have loss of function in the zebrafish rescue assay, one splice site mutation, one variant in the Kozak sequence -5' untranslated region, seven missense mutations, two intronic variations in the splicing region, and four SNPs. In *TDGF1* we have identified two missense mutations (one each in EGF and CFC motif) and three SNPs. The identified deletion and missense mutations were not detectable among 200 chromosomes from normal controls. Preliminary data from functional studies and/or predicted protein alterations of some of the identified mutations in *CFC1* and *TDGF1* suggest a loss-of-function mechanism as a cause for cardiovascular malformations in humans. We are now testing the functional effects of previously unstudied variants in three assay systems: a) transfection into NIH 293 cells with a reporter readout, b) functional complementation in zebrafish embryos, and c) splicing analysis by RT-PCR in transfected COS cells.

Role of *FAST1* gene in the development of holoprosencephaly (HPE) and congenital cardiac malformations in humans. *M.V. Ouspenskaia*¹, *J.D. Karkera*¹, *E. Roessler*¹, *M.M. Shen*², *E. Goldmuntz*³, *P. Bowers*⁴, *J. Towbin*⁵, *J. Belmont*⁵, *M. Muenke*¹. 1) MGB, NHGRI/NIH, Bethesda, MD; 2) CABM/UMDNJ-RWJ Medical School, Piscataway, NJ; 3) The Children's Hospital of Philadelphia, Philadelphia, PA; 4) Yale University School of Medicine, New Haven, CT; 5) Baylor College of Medicine, Houston, TX.

Fast-1 (Fox-H1) is a transcriptional factor that in complex with Smad2 and Smad4 mediates TGF- β , Activin and Nodal signaling pathways. These factors control early development in vertebrates and are vital for specification of the anterior-posterior (AP) axis. Recent studies on murine *Fox-H1* knockouts show that embryos failed to pattern the AP axis, form the node, prechordal mesoderm, notochord and definitive endoderm. These mutant mice demonstrate aberrant anterior head structures and abnormal cardiac development. Based on these studies we screened 100 patients with familial holoprosencephaly (HPE) and 350 patients with congenital cardiac anomalies, including tetralogy of Fallot, transposition of the great arteries, double outlet right ventricle, interrupted aortic arch and atrioventricular canal. We characterized the intron-exon structure of human *FAST1* gene. Then using PCR-dHPLC, SNPs carrying variants were identified and sequenced. We have found 20 missense variants, two deletions, one 13 bp intronic insertion and several polymorphic variants. Three of these mutations were seen both in HPE and cardiac patients. None of the described mutations was found in 200 normal chromosomes. These mutations are present in the DNA-binding (Fork head) domain of FAST1 and in the SMAD interaction domain, which is involved in FAST1/SMAD2 interaction. To provide evidence for the predicted loss-of-function, the following functional studies are in progress: a) RNA injection into the Fast-1^{-/-} zebrafish mutant *schmalspur*, b) transfection into 293 cells with reporter read-out, and c) transfection followed by co-immunoprecipitation to assess interactions with SMADs and related co-factors. If confirmed by these studies, *FAST1* will be the first gene shown to cause midline (HPE) and laterality (abnormal cardiac looping) defects in humans.

Heart defects in X-linked heterotaxy: evidence for genetic interaction of *Zic3* with the TGF-beta signaling pathway. *S.M. Ware, K. Harutyunyan, B. Casey, J.W. Belmont.* Molecular & Human Genetics, Baylor College Medicine, Houston, TX.

Heterotaxy, the random assignment of visceral organs with respect to each other and the left-right axis, is characterized by complex congenital heart defects. Mutations in the zinc finger transcription factor *Zic3* cause X-linked heterotaxy, HTX1. Disruption of a critical asymmetric signaling pathway involving the TGF-beta family member *nodal* during early embryogenesis results in heterotaxy in animal models. We have investigated the interaction of *Zic3* and *nodal* in order to understand the role of *Zic3* in cardiac development and left-right axis formation. A targeted deletion in the murine *Zic3* locus has been created and we have previously shown that these knockout mice correctly model HTX1 (Development 129: 2293-2302, 2002). Embryonic lethality occurs in *Zic3* null mice due to both gastrulation defects as well as cardiac defects. In situ hybridization of gastrulation stage embryos indicates defects in migration through the primitive streak. Analyses of null embryos during the looping phase of cardiogenesis show abnormalities in approximately 70%, with ventral looping and dextrocardia as the predominant phenotypes as demonstrated by gross morphology, histology and in situ hybridization. In order to investigate the role of *Zic3* in the left-right axis pathway and the development of heterotaxy, we have intercrossed *Zic3* and *nodal* deleted heterozygous mice. *Zic3/nodal* double heterozygotes are born in significantly reduced numbers compared to heterozygous littermates. Embryonic lethality in the double heterozygotes occurs between 10.5 and 14.5 days post coitum and is associated with defects of cardiac looping which mimic those seen in the *Zic3* null mice. In contrast to *Zic3* null mice, *Zic3/nodal* double heterozygotes do not show an increased frequency of gastrulation defects. These results demonstrate that the development of heart defects in X-linked heterotaxy is a result of abnormal looping, and suggests that *nodal* signaling plays a critical role. The data further suggest that *Zic3* functions at multiple steps in the generation of left-right asymmetry, acting upstream of *T-brachyury* in the primitive streak and upstream of *nodal* in the lateral plate mesoderm.

Microarray Expression Analysis of Hepatic Transcripts of an IUGR Rat Model that Mimicks Human Syndrome
X. N.K. MacLennan, J.L. Hsu, T.D. Pham, A.E. Campos, A.R. Puri, R.H. Lane. David Geffin School of Medicine at UCLA, Mattel Childrens Hospital, UCLA, Los Angeles, CA.

Uteroplacental insufficiency is a common complication of pregnancy that causes low-ponderal-index intrauterine growth retardation (IUGR). IUGR is the basis for Barkers Fetal Origins of Adult Disease Hypothesis and predisposes the individual towards adult onset morbidities such as diabetes and dyslipidemia. Similar to humans, rats rendered IUGR via uteroplacental insufficiency develop insulin resistance and hypertriglyceridemia; moreover, the IUGR rat is characterized by persistent changes in hepatic gene expression and DNA methylation despite the transient nature of the initial insult. Therefore, the purpose of this study was to characterize patterns of gene expression in male IUGR rat liver versus control rat liver at day 21 of life. This project focused upon male rats at this age because they are more severely affected than female rats, but are not yet characterized by overt diabetes or dyslipidemia. Bilateral uterine artery ligation (IUGR) and sham surgery (Control) were performed to induce a well-characterized model of IUGR; litters were culled to six at birth (n=3 litters). RNA from day 21 IUGR and Control livers were used for global expression analysis using Affymetrix rat cDNA microarrays consisting of 8,784 transcripts. Uteroplacental insufficiency and subsequent IUGR increased or decreased transcript levels a minimum of two-fold in 133 and 128 genes respectively. Of particular interest, mRNA levels of enzymes involved in cholesterol biosynthesis were altered, including HMG-CoA reductase, squaline epoxidase, and 7-deoxycholesterol reductase. The promoters of these enzymes are characterized by Sp1 sites and GC richness which affect DNA methylation. Further analysis of this data identified a subset of important metabolic genes that may lend insight into the pathogenesis of in-utero programming, while suggesting possible specific targets for pharmacological intervention. This work was supported by NIH/NICHD K08HD01225 and R01HD41075.

Expression profiling in mouse neural development and differentiation. *P. Carotenuto¹, V. Aglio¹, A. Faedo², M. Cocchia¹, V. Avantaggiato¹, A. Andre¹, A. Ballabio¹, J. Rubenstein³, A. Bulfone², M. Zollo¹.* 1) TIGEM, TIGEM, Naples, Naples, ITALY; 2) SCRI, Dibit-HSR, Milan, ITALY; 3) CFNP, UCSF, San Francisco, USA.

The aim of the project is the identification and characterization of new genes specifically involved in the developing mouse telencephalon and potentially associated to human neurological disorders. Our approach combines gene array expression technology and murine subtractive cDNA library to isolate unique and specific genes preferentially expressed in the embryonic telencephalon. We have randomly sequenced 3168 cDNA clones (ESTs) from a cDNA subtractive library. Detailed sequence analysis of the selected cDNA clones by using public domain DataBases was performed, to verify the bonafide of the library, to identify human gene homologs, map and correlate them to neurological disorders; in particular, to date 28% have no public database match, and 19% correspond to genes with unknown function. A set of unique transcripts (1026) have been identified, selected and arrayed on glass coated slides. A series of experiments based on the potential of cell lines (P19, neuro2A, PC12) to be induced to differentiation into specific neuronal cell subtypes by Retinoic Acid (RA) or Neural Growth factor (NGF), have been performed. This strategy permitted us to isolate 110 genes that are differentially expressed before and after neuronal "in vitro" differentiation. To determine the spatio-temporal expression profile of 110 cDNAs, we have performed in-situ mRNA hybridization on mouse embryos (sagittal and coronal sections of E14.5 embryos and whole-mount E10.5 embryos) and adult brains. Moreover, experiments are undergoing for testing the value of this cDNA array in order to unravel the molecular defects of the developing brain of migration defect mice models.

Expression analysis supports the *CECRI* gene as a candidate for cat eye syndrome. S.A. Maier, H.E. McDermid.
Biological Sciences, Univ Alberta, Edmonton, AB, Canada.

Cat eye syndrome (CES) is a human genetic abnormality characterized by defects of the eyes, anus, heart, kidney and face, as well as mental retardation. It is associated with the duplication of a 2Mb segment of 22q11.2 called the CES critical region, which is thought to contain dose-sensitive genes responsible for the CES phenotype. One promising candidate gene is *CECRI*, which is a member of a growing family of novel growth factors. Homologues of human *CECRI* have been found in various organisms, including insects, pig, zebrafish, pufferfish and baboon, but not in mouse.

In order to further characterize the *CECRI* gene, an animal model was used to determine the spatial and temporal expression pattern of *CECRI* homologues during embryonic development. Since there is no mouse homologue of *CECRI*, the pig (*Sus scrofa*) was used as a model system. Northern analysis showed *Pig CECRI* expression in adult lung and spleen. This narrow expression pattern is being complimented by using the more sensitive method of RT-PCR. *In situ* hybridization of pig embryos ranging from 22 to 31 days (equivalent to approximate mouse ages 10.5 to 13.5 days) was also used to study expression. Two different *Pig CECRI* antisense RNA probes revealed low level staining in many tissues, with significantly darker staining in the kidney, heart, liver, back, and tubules of the gut. A sense control probe from the middle of the gene was negative for all stages tested. A second sense control probe from the 3' end of the gene showed striking expression in the liver only, indicating that antisense regulation may exist. The antisense expression pattern that was found in the pig model, primarily heart and kidney, is consistent with the tissues affected in human CES, suggesting that *CECRI* may play a major role in the development of symptoms involved in CES.

Repositioning of certain muscle-specific genes to the periphery of SC35 domains during development. C.V.

Johnson¹, K.P. Smith¹, P. Moen², L.S. Shopland¹, A. Imbalzano¹, I. de la Serna¹, J.B. Lawrence¹. 1) Cell Biology, Univ. of Mass. Med. School, Worcester, MA; 2) One Cell Systems, Inc. Cambridge, MA.

It has long been suggested that gene organization within the nucleus may facilitate the coordinate regulation of thousands of genes during development and differentiation of specific cell-types. Previous studies have shown that in a given cell-type certain active genes associate with SC35 domains, nuclear regions rich in RNA metabolic factors and excluded from heterochromatin. This organization is locus-specific and not a property of all active genes. For example, the myosin heavy chain gene is essentially always associated with SC35 domains in muscle cells, whereas the dystrophin gene/RNA are not. To better understand and establish the relationship of this organization to gene expression, it is important to investigate the distribution of the same genes in different cell-types during development. Here we investigate whether gene organization relative to SC35 domains is cell-type specific by following several muscle and non-muscle genes in fibroblasts, committed but proliferative myoblasts, and terminally differentiated muscle. While no change was seen for other loci, two muscle genes (human b-cardiac myosin heavy chain and myogenin) repositioned to the immediate periphery of an SC35 domain in differentiated muscle nuclei. Similar results were observed for mouse 3T3 cells induced to form muscle by introduction of MyoD. For those genes that changed position relative to SC35 domains, brief analysis of gene position relative to the chromosome territory or centric heterochromatin showed no repositioning relative to these structures. Results demonstrate a cell-type specific reorganization of specific developmentally regulated loci relative to discrete nuclear domains of RNA metabolic factors.

Mutation spectrum in the Opitz syndrome gene (MID1), its expression during human development and X inactivation pattern in severely affected females . L. PINSON, J. AUGÉ, S. AUDOLLENT, G. MATTEI, N. GIGAREL, A. MUNNICH, S. LYONNET, M. VEKEMANS, T. ATTIE-BITACH. Departments of Genetics, INSERM U393, Hospital Necker, Paris, FRANCE.

Opitz syndrome (OS) is a midline malformation syndrome characterized by hypertelorism, hypospadias, oral, oesolaryngotracheal and anal defects. A heart malformation is observed in 25% of patients. Recently, MID1 mutations have been identified in the X-linked form of the disease, while the gene of the autosomal dominant form on 22q11 remains unknown. Here, we report on the spectrum of MID1 mutation in our 14 OS patients series, X inactivation pattern in 3 severely affected females and the expression pattern of MID1 during human development. X inactivation pattern was studied in 3 severe OS females. A skewed pattern of inactivation (91/9%) in one girl strongly suggested X linked inheritance. SSCP analysis of the 9 exons of the MID1 gene followed by sequencing of 9 abnormal patterns detected mutations in 7/14 patients (5 familial and 2 sporadic cases). All were novel mutations except one (R495X) previously reported in one patient (Hum. Mol. Genet. 2000, 9 :2553-2562). Interestingly, both patients presented with vermis hypoplasia, a rare feature of OS. Two different MID1 changes were detected in a severely affected girl presenting a random pattern of X inactivation. Further experiments are underway to see whether the two changes are carried by the same or different alleles. Finally, in order to compare the pattern of MID1 expression with the clinical features of the disease, we performed in situ hybridization on human embryos. MID1 was mainly expressed in the central nervous system, oropharynx, oesotracheal epithelia, genital tubercle and anal membrane. MID1 expression was also observed in kidney, limb buds, but unlike the mouse, it was expressed in a restricted area of the heart interventricular septum, thus correlating with occasional features of the syndrome. This study supports the broad spectrum of MID1 mutations, the major involvement of MID1 in OS and confirms that vermis hypoplasia is a feature of the syndrome. Finally, expression studies suggest involvement of MID1 in human heart development.

EDA targets revealed by skin gene expression profiles of wild-type, Tabby, and Tabby EDA-A1 transgenic mice.

C.Y. Cui¹, M. Durmowicz¹, T.S. Tanaka¹, A.J. Hartung², T. Tezuka³, K. Hashimoto⁴, M.S.H. Ko¹, A.K. Srivastava², D. Schlessinger¹. 1) Laboratory of Genetics, NIA / NIH, Baltimore, MD; 2) J. C. Self Research Institute of Human Genetics, Greenwood Genetic Center, Greenwood, SC; 3) Department of Dermatology, Kinki University School of Medicine, Osaka, Japan; 4) Department of Dermatology, Wayne State University School of Medicine, Detroit, MI.

Mutations in the EDA gene cause Anhidrotic Ectodermal Dysplasia (EDA), with lesions in skin appendage formation. To begin to analyze EDA pathways, we have used expression profiling on 15,000-gene mouse cDNA microarrays, comparing adult mouse skin from wild-type, EDA-defective (Tabby), and Tabby mice supplemented with the EDA-A1 isoform, which is sufficient to rescue multiple Tabby phenotypes. Given the sensitivity of the current microarray system, 8,500 genes (60%) were estimated to be expressed, including transcription factors and growth-regulatory genes that had not previously been identified in skin; but only 24 (0.16%), one third of them novel, showed significant differences between wild type and Tabby. An additional 8 genes not included in the 15K gene set were shown to have expression differences by real time RT-PCR. Sixteen of 32 affected genes were restored significantly toward wild-type levels in EDA-A1 transgenic Tabby mice. Significant up-regulation in Tabby skin was observed for several dermal matrix genes, including *Col1a1*, *Col1a2*, *Col3a1* and *Sparc*. In contrast, down-regulation occurred for the NEMO/NF- κ B pathway, already implicated in skin appendage formation, and even more markedly for a second pathway, JNK/c-jun/c-fos and their target genes, that has not previously been clearly associated with skin development. These data are consistent with the regulation of the NF- κ B pathway by EDA, and support its involvement in the regulation of the JNK pathway as well.

The characterization of genes with different expression levels in mouse blastocyst inner cell mass cells and trophoctoderm cells. *J.C.F.M. Dreesen¹, M. Bras², J.G. Derhaag², J.C.M. Dumoulin², E. Coonen², H.J.M. Smeets¹, J.L.H. Evers², J.P.M. Geraedts¹, J. Herbergs¹.* 1) Clinical Genetics, Academic Hospital Maastricht, Maastricht, The Netherlands; 2) Obstetrics and Gynaecology, Academic Hospital Maastricht, The Netherlands.

The blastocyst represents the embryonic stage in which differentiation of embryonic cells into trophoctoderm (TE) and the inner cell mass (ICM) has occurred. Using immunosurgery and mechanical separation, ICM- or TE-cells can be divided and isolated from the blastocyst. In this study blastocysts were obtained from superovulated (C57BI/6XCBA)F1 mice in vivo fertilized by random-bred Swiss males. ICM- and TE-cells were isolated from single blastocysts. mRNA was purified and cDNA was transcribed and amplified with the SMART cDNA synthesis kit. Differential display PCR was performed on replicate ICM, TE samples and total blastocyst cDNA samples, followed by separation of the PCR fragments on a denaturing polyacrylamide gel. ICM- and TE-specific bands as well as shared bands present in ICM, TE and total blastocysts (controls) were isolated from the gel, amplified and sequenced. Sequences were annotated by BLAST searches in the commercial CELERA and public NCBI and MGD nucleotide sequence databases. 25 of the 52 isolated fragments could be directly sequenced and annotated according to NCBI nomenclature. Comparison of TE-cells with ICM-cells showed differential expression of five of 7 identified genes and 2 of 3 anonymous cDNA sequences. Furthermore, three control sequences equally expressed in the blastocyst, ICM- and TE-cells, showed consistent results with respect to sequencing and annotation. In conclusion we have isolated, sequenced and annotated sequences from transcripts differentially expressed in ICM- and TE-cells. Equal expression of control sequences showed the feasibility of this method. Differentially expressed genes are currently being confirmed and will be quantified by quantitative PCR analysis and evaluated for their role in blastocyst formation and implantation.

Isolating New Genes of Adrenal Development. *S. Ching*¹, *P. Dewing*¹, *E.R.B. McCabe*^{1, 2}, *E. Vilain*^{1, 2}. 1) Human Genetics, UCLA, Los Angeles, CA; 2) Pediatrics, UCLA, Los Angeles, CA.

In humans, abnormal development of the adrenal gland leads to severe adrenal insufficiency which is often fatal if untreated. Adrenal Hypoplasia Congenita (AHC) is an inherited disorder in which the development of the adrenal cortex is defective. It can be inherited as either an X-linked or autosomal recessive disorder, each characterized by a distinct histopathology. X-linked AHC is characterized by the cytomegalic persistence of fetal adrenal cortex that fails to differentiate into the adult zone. Affecting approximately 1 in 12,500 births, only about half of these cases can be explained by a mutation in the gene DAX-1, an unusual member of the orphan nuclear receptor superfamily, suggesting that there are additional genes involved in adrenal development. The purpose of these studies was to identify other genes involved in adrenal development, and therefore, candidates for cases of AHC not associated with DAX-1 mutations. During adrenal development in rodents, there is a period of dramatic reorganization of the adrenal cortex between 15.5 dpc and P0. We therefore isolated RNA from the adrenals of female mice at these timepoints to be used as probes for microarrayed genes and ESTs. Analysis of the microarray data produced a list of differentially expressed genes, from which several were chosen for further analysis. Two of these genes, serum amyloid P-component (SAP) and L-FABP (liver fatty-acid binding protein), showed a 10.3-fold and 13.4-fold increase, respectively. RT-PCR confirmed that there were highly significant differences in mRNA transcript levels between 15.5 dpc, P0 and P8, with a strong peak occurring around P0. SAP is a member of the pentraxin family of proteins which binds to apoptotic cells and interacts with membrane receptors on phagocytes to mediate phagocytosis. L-FABP belongs to the family of hydrophobic carrier proteins and has been implicated as a regulator of mitogenesis in rat hepatocytes. These results suggest that SAP and L-FABP are involved in remodeling the developing adrenal glands, and therefore in the pathogenesis of AHC.

Vsx1, a rapidly evolving paired-like homeobox gene is essential for retinal cone bipolar cell development. *R.R. McInnes¹, R.L. Chow¹, D.G. Birch²*. 1) Program in Developmental Biology, Research Institute, Hospital Sick Children, Toronto, ON, Canada; 2) Retina Foundation of the Southwest, Dallas, Texas.

VSX1 and CHX10 are closely related paired-like homeodomain transcription factors expressed in the vertebrate retina. Consistent with the retinal expression of Chx10 during both early and late stages of eye development, Chx10^{-/-} mice (and humans) have profound developmental eye defects: microphthalmia, blindness, poor proliferation of retinal progenitors, and an absence of both rod and cone bipolar cells, the major class of retinal interneurons. In contrast, Vsx1 is expressed only at late stages of eye formation, and solely in "OFF" and "ON" cone bipolar cells. Despite the absence of Vsx1 expression in adult mouse & human cornea, human VSX1 missense mutations are associated with the dominant corneal disorders posterior polymorphous dystrophy & keratoconus. To determine the role of Vsx1 in eye development and bipolar cell biology, and in the pathogenesis of the monogenic corneal disorders, we generated Vsx1^{-/-} mice with a tau-lacZ reporter gene knock-in. In Vsx1^{-/-} mice, cone bipolar cells were normally specified, since tau-lacZ expression was detected in a pattern characteristic of both "OFF" and "ON" cone bipolars. In the Vsx1^{-/-} retina, however, normal differentiation of cone bipolar cells was disrupted, since expression of the cone bipolar markers recoverin and caldendrin was lost, and the axonal termini of these cells were morphologically abnormal. Unexpectedly, no corneal expression was detected during mouse development and no adult corneal abnormalities were noted. We conclude that 1) Vsx1, unlike Chx10, is not required for early eye development, 2) Vsx1 is essential for the late differentiation program of retinal cone bipolar cells in mammals, 3) Vsx1^{-/-} mice and humans are likely to have serious vision defects due to the disruption in cone bipolar formation, 4) The role of Vsx1 in the cornea remains unclear, but the Vsx1^{-/-} mouse mutant will serve as a valuable model system into which the human VSX1 mutations can be introduced, to begin to explore the pathogenesis of the human corneal defects.

Tissue specific expression of type X collagen in hypertrophic chondrocytes is specified by *cis* elements in both the *Col10a1* promoter and second intron. Q. Zheng¹, G. Zhou¹, Y. Chen¹, A. Parker², B. Lee¹. 1) Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Respiratory and Inflammation Research Area, AstraZenica, Cheshire, United Kindom.

Type X collagen is a specific marker for hypertrophic chondrocytes and is altered in Schmid metaphyseal chondrodysplasia. Until recently, no transcriptional determinants specifying chondrocyte-specific type X collagen gene (*Col10a1*) expression have been identified. We have characterized the 4 kb murine *Col10a1* promoter region and demonstrated that it contains conserved *Runx2/Cbfa1* binding sites. We show that these *cis* elements bind RUNX2, an essential RUNT domain transcription factor required for osteoblast differentiation and chondrocyte maturation, and can mediate transactivation of the *Col10a1* minimal promoter both *in vitro* and *in vivo* in reporter transgenic mice. However, further analysis of our transgenic mice showed that the 4 kb element is required but not sufficient for high level tissue-specific expression, since the reporter was primarily localized in the lower hypertrophic zone. We hypothesized that additional positive and/or negative *cis* elements outside of this 4 kb promoter are required for high level specific expression throughout the zone of hypertrophy. We report that an 8 kb *Col10a1* region encompassing the same proximal promoter and large second intron can direct reporter gene (*LacZ*) expression throughout the zone of hypertrophy. A stable MCT cell line containing this *Col10a1* 8 kb element upstream of a reporter shows 7 fold up-regulation of reporter activity when cells undergo hypertrophy. Interspecies sequence analysis of *Col10a1* identified a highly conserved element that may serve as a tissue-specific enhancer within *Col10a1*. Electrophoretic mobility shift assay (EMSA) using nuclear extracts from hypertrophic MCT cells confirmed formation of a specific DNA-protein complex. The identification of additional transacting factors that regulate *Col10a1* will lead to a better understanding of skeletal dysplasias that affect metaphyseal long bone development.

Paternally transmitted recurrent tetragametic chimerism resulting in recurrent true-hermaphroditism. C.

Oddoux¹, V. Clarke¹, M.C. Clayton¹, M. MacGillivray², H. Ostrer¹. 1) Div Human Genetics, New York Univ School of Med, New York, NY; 2) Div Ped Endo, Buffalo Children's Hosp, Buffalo, NY.

This report describes a family displaying paternally transmitted predisposition to tetragametic chimerism. The family has 4 individuals affected with 46,XX true hermaphroditism spanning two generations and displays a paternal inheritance pattern. Previous Southern analysis of lymphocyte DNA ruled out the presence of a Y- to X- or autosomal translocation or of a Y-chromosomal inversion that could lead to recurrent translocations. Pathological examination of excised gonadal tissue from affected individuals indicated that they were in fact true hermaphrodites with ovotestes. Subsequent immunohistochemical studies of the paraffin-embedded gonadal tissue revealed a mosaic pattern of SRY gene expression. Here, we report short tandem repeat analyses of the blood and gonadal tissue of two affected individuals and their parents. Normal bi-parental inheritance of X-chromosomal and autosomal markers was observed in lymphocyte DNA from both individuals. Multiple Y-chromosomal markers were present in SRY-expressing gonadal tissues suggesting the presence of an intact Y-chromosome. Bi-parental inheritance of X-chromosomal markers was also observed in gonadal tissue; however, in some regions of the tissue, an additional maternal allele was observed. Most commonly the autosomal alleles observed in the ovotestes were the bi-parental alleles observed in lymphocyte DNA. In some instances, additional autosomal alleles of maternal or paternal origin, or both, were seen in the ovotestes. Occasionally, no autosomal alleles from one parent were present in the ovotestes. Taken together these data suggest that the paternally transmitted phenotype in this family is predisposition to formation of tetragametic chimeras. Tetragametic chimeras arising from sperm with different sex chromosomes develop as true hermaphrodites with ambiguous genitalia that brings them to clinical recognition. The observation that all alleles from one or the other parent may be lost in some parts of the tissue suggests that there is chromosomal instability in some cells.

Analysis of DNA-Binding Specificity of the Forkhead Transcription Factor FOXC1, a Gene Mutated in Axenfeld-Rieger Malformations. *T.C. Murphy, R.A. Saleem, M.A. Walter.* Ophthalmology/Medical Genetics, University of Alberta, Edmonton, Alberta, Canada.

FOXC1 is a developmentally important transcription factor. Mutations in FOXC1 lead to aberrant development of the anterior segment of the eye and increase the risk of early-onset glaucoma. In order to better understand the mechanisms of FOXC1 function and its role in ocular development, we have undertaken an analysis of the DNA binding specificity of FOXC1. FOXC1 has been shown to interact with an *in vitro* derived DNA binding site (GTAAATAAA), while the distantly related FOXH1 binds the *in vitro* preferred site TGTG/TG/TATT. We are using these differences in DNA-binding specificities in domain swapping experiments to define the amino acids of the forkhead domain that regulate the DNA binding specificity of FOXC1. The 21 amino acids immediately upstream of helix 3 in forkhead proteins have been suggested to be involved in the regulation of DNA binding specificity. We are using site-directed mutagenesis to convert these 21 amino acids within the FOXC1 cDNA to reciprocal amino acid positions from the forkhead domain of FOXH1. These 21 amino acids will be swapped stepwise in a series of three constructs each comprised of 7 amino acids from FOXH1. The effect of the FOXH1 amino acids within the context of FOXC1 forkhead domain will be tested by evaluating the relative affinities of the chimeric proteins for the FOXC1 and FOXH1 binding sites by electrophoretic mobility shift assays (EMSAs) and transactivation of luciferase reporter construct containing either the FOXC1 or FOXH1 binding sites. Preliminary results indicate that a FOXC1-H1 chimeric protein in which the anterior most 7 amino acids preceding helix three have been converted from FOXC1 to FOXH1 displays altered site specificity on a panel of oligonucleotides that are variants the FOXC1 binding site. Analyses of the remaining FOXC1-H1 chimeric proteins are in progress. This work will help to precisely delineate the specific residues involved in DNA site selection. A mechanistic understanding of how FOXC1 recognises and binds to DNA will be critical to defining the function of FOXC1 in the development of the eye.

Localization of the mouse *Tcm* gene to a 1Mb region on chromosome 4. *K.S. Wang*^{1,2}, *P. Grimes*², *A. Dutra*³, *J. Favor*⁴, *D. Stambolian*^{1,2}. 1) Department of Genetics, University of Pennsylvania, Philadelphia, PA; 2) Department of Ophthalmology, University of Pennsylvania, Philadelphia, PA; 3) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 4) GSF-Neuherberg, Institute of Mammalian Genetics, National Research Center for Environment and Health, Neuherberg, Germany.

Tcm (total cataract with microphthalmia) is an autosomal dominant mouse mutation recovered from an X-irradiated mouse. Initial characterization of the heterozygous *Tcm* mouse revealed total lens opacity, microphthalmia, iris dysplasia, and ventral coloboma. We have recently characterized the homozygous *Tcm* phenotype which results from a failure of ventral retinal development, leading to retinal dysplasia and subsequent anophthalmia. Variable brain abnormalities include hydrocephalus, cerebellar white matter cysts, and possible absence of the septum pellucidum. Spectral karyotyping analysis was done on *Tcm* mouse chromosomes and found to be normal. In this study, we report on the use of a mouse backcross breeding strategy (C3Hx102 x C57BL/6) with analysis of over 270 resultant progeny using microsatellite markers D4Mit101, D4Mit106, D4Mit235, D4Mit263, and D4Mit264 to localize *Tcm* to an approximately one megabase region on mouse chromosome 4. This locus is delineated by microsatellite markers D4Mit235 and D4Mit264 with *Tcm* mapping approximately 0.7 cM and 0.4 cM from each marker, respectively. We also report on the evaluation and exclusion of several candidate genes including *Mmp16*, *Cbfa2t1h*, and *Gem* by Southern and Northern analysis. Additional developmental characterization of the mutation is also presented to further define the timeframe in which the *Tcm* phenotype manifests.

Abnormal diaphragmatic development and pulmonary hypoplasia caused by an ENU-induced hypomorphic mutation of *Fog2*. K.G. Ackerman¹, B.J. Herron¹, C. Rao¹, H. Huang¹, R.P. Babiuk², J.A. Epstein³, J. Greer², D.R. Beier¹. 1) Genetics Div., Brigham and Women's Hospital, Boston, MA; 2) Div. of Neuroscience, U. of Alberta, Edmonton, AB; 3) Cardiovascular Div., U. of Pennsylvania Medical School, Philadelphia, PA.

We are screening progeny of ENU-mutagenized mice to identify recessive mutations causing developmental abnormalities similar to those seen in human congenital defects. In an examination of day 18.5 embryos we identified a mutation that results in severe pulmonary hypoplasia and abnormal diaphragmatic development. Specifically, while the diaphragm is intact, its dorsolateral portion fails to muscularize. Genetic mapping was used to localize the mutation to a 1.1 cM interval on chromosome 15. This localization facilitated the identification and examination of homozygous mice at earlier timepoints during embryonic development, which revealed that approximately half the mice homozygous for the mutation die *in utero* between day 12.5 and day 15.5. The affected mice have cardiac defects identical to those previously reported for a targeted mutation of Friend of Gata 2 (*Fog2*), which is in the recombinant interval. Molecular analysis identified a point mutation in a splice donor site that results in an insertion of 85bp of intronic sequences into the *Fog2* transcript, resulting in early termination and a severely truncated protein product. The causal role of the ENU-induced mutation was proven by demonstrating that it is non-complementing in a cross with a *Fog2*-null mutant mouse.

Our results demonstrate the utility of a phenotype-driven strategy for understanding the genetic contributions to mammalian development. The importance of *Fog2* for normal cardiac development has been previously shown, but its role in diaphragm and lung development was not recognized. Additionally, the fact that a defect in *Fog2* affects diaphragm, lung, and heart development may be relevant to the syndrome of congenital diaphragmatic defect (CDD) in humans, as CDD has been reported in 2 unrelated patients with balanced translocation breakpoints at 8q22.3, the location of human FOG2.

Expression and functional analyses of zebrafish *tgfb3*. *F.S.H. Cheah*^{1,5}, *E.W. Jabs*^{3,4,5}, *S.S. Chong*^{1,2,3,5}. 1) Pediatrics; 2) Obstetrics & Gynecology, and Laboratory Medicine / Molecular Diagnosis Center, National University of Singapore and Hospital, Singapore; 3) Pediatrics, Center for Craniofacial Development and Disorders, Institute of Genetic Medicine; 4) Medicine, and Plastic Surgery, Johns Hopkins University School of Medicine, Baltimore, MD; 5) Johns Hopkins Singapore, Singapore.

Transforming growth factors (TGFs) constitute one of the many extracellular signaling molecules that display a remarkable spectrum of effects on patterning, epithelial-mesenchymal interactions, cell proliferation, apoptosis, and chondrogenesis in both vertebrates and invertebrates. In particular, TGF β 3 is known to contribute to facial development, especially in palate formation. The nucleotide sequence of the full-length zebrafish *tgfb3* cDNA has not been determined, and its normal expression pattern during zebrafish development has not yet been characterized. Here we report the complete sequence of the zebrafish *tgfb3* cDNA and its embryonic expression pattern. In addition, *tgfb3* morphants were generated by antisense morpholino targeting technology. Day 4 post-fertilization morphants were generally shorter than their normal AB counterparts. Their ear vesicles were also smaller and some had an enlarged pericardial space. Alcian blue staining revealed malformation of both the head and pharyngeal arches. All neurocranial components, including the ethmoid plate and trabeculae, were severely reduced. Parachordal and auditory capsules were also absent. The first pharyngeal arch pair was severely reduced and malformed, the second to sixth pairs were severely shortened, while the seventh pair was completely absent. Furthermore, the basibranchial and hypobranchial elements were also absent. These data suggest that *tgfb3* may be involved in zebrafish craniofacial development.

Phenotypic characterization and positional cloning of craniofacial mutants generated from a recessive ENU mutagenesis screen. *B.C. Bjork*¹, *B.J. Herron*¹, *M.J. Justice*², *J.D. McDonald*³, *D.R. Beier*¹. 1) Division of Genetics, Brigham & Women's Hospital, Harvard Medical School, Boston, MA; 2) Baylor College of Medicine, Houston, TX; 3) Wichita State University, Wichita, KS.

ENU mutagenesis has proven to be a powerful means by which to generate single nucleotide mutations in mice. We are screening E18.5 embryos from ENU-treated mice for recessive phenotypes that resemble human congenital disorders. The screen is performed as an outcross to facilitate the rapid localization of mutant loci using a strategy of interval haplotype analysis. Among the large spectrum of phenotypic abnormalities we have identified are defects involving craniofacial development, including nonsyndromic and syndromic cleft primary and secondary palate.

Orofacial clefting is a major human congenital disorder with a complex etiology and a high incidence (1/500 to 1/2500 live births). Many known mouse mutants contain orofacial clefts as part of their phenotype, but the best models for human clefting are those with clefts in the absence of additional phenotypes. In an analysis of 54 families for recessive mutations, we identified four models of orofacial clefting including *cleft palate only 1* (*cpo1*; cleft secondary palate with no additional phenotypic abnormalities), *curly tail 2* (*ct2*; variable expression of cleft secondary palate, a curly or kinked tail and bent forelimbs) and *little chin* (cleft secondary palate and a small mandible that resembles the abnormalities observed in the Pierre Robin syndrome). Most recently, we identified *cleft lip/palate 1* (cleft primary and/or secondary palate with no additional phenotypic abnormalities). Critical regions of 500 kb on distal chromosome 4 and 8 cM on proximal chromosome 3 are defined for the *cpo1* and *ct2* mutations, respectively. Using novel polymorphic markers and the public mouse genomic sequence, we continue to refine these genetic intervals and to identify and prioritize candidate genes for mutation screening. We report the genetic localization, fine-mapping, developmental characterization and candidate gene screening for these ENU-induced recessive mutations.

Developmental mechanisms of congenital vertebral malformations in the *Dll3-pudgy* mouse mutant homolog of *DLL3*-spondylocostal dysostosis. K. Kusumi^{1,2}, M.S. Mimoto¹, K.L. Covello², S.A. Stevens¹, S.L. Dunwoodie³. 1) Division of Human Genetics & Molecular Biology, The Children's Hospital of Philadelphia, Phila., PA; 2) University of Pennsylvania School of Medicine, Philadelphia, PA; 3) Victor Chang Cardiac Research Institute, Darlinghurst, NSW 2010 & Department of Biotechnology and Biomolecular Sciences, University of New South Wales, Australia.

The notch ligand, delta-like 3 (*Dll3*), is disrupted in the mouse pudgy (*Dll3^{pud}*) and targeted (*Dll3^{neo}*) mutants and in the human vertebral segmentation disorder, spondylocostal dysostosis (SD, MIM 277300). Disruptions of delta-like 3 in both human and mouse are characterized by generalized axial vertebral and rib malformations. To identify the developmental origins of these defects, we have examined somitogenesis, the embryological process generating axial segments, in *Dll3^{pud}* mutants. *Dll3^{pud}* mutant embryos have defective epithelial somite segmentation and fail to form normal rostral-caudal somite domains, leading to vertebral malformations. Initiation of somite formation and *Lfng* dynamic expression is observed in mutants, but there is a failure to maintain cycling. The somite cycling genes *Hes1*, *Hes7*, and *Hey3* were also examined in mutant embryos, and major disruptions were observed both at the onset of segmentation and in mid-somitogenesis. These *Dll3^{pud}* results are consistent with observations of somitogenesis in the *Dll3^{neo}* null allele. In summary, the *Dll3* gene appears to be required for maintenance of normal cycling in somitogenesis and initial expression of some notch pathway genes. Given segmental defects observed in targeted mutations in many notch pathway genes, defects in these loci may be involved in the genetic etiology of human congenital vertebral malformations, including congenital scoliosis, congenital kyphosis, Klippel-Feil syndrome, and Jarcho-Levin syndrome, and VATER and VACTERL associations.

Influence of the ion channel polycystin-2 on organ morphogenesis and left-right axis development in mice. J.

Horst¹, A. Schweickert², C. Karcher², A. Fischer², M. Blum², B. Dworniczak¹, P. Pennekamp¹. 1) Institut fuer Humangenetik, Universitaetsklinikum Muenster, Germany; 2) Institute of Toxicology and Genetics, Forschungszentrum Karlsruhe, Germany.

The establishment of left-right asymmetry can be divided into initial breakage of symmetry, establishment of asymmetrical gene expression and transfer of this positional information to the developing organs. Embryological and genetic experiments revealed a conserved asymmetric signaling cascade, which during early embryogenesis transmits asymmetric cues from the embryonic midline to the lateral plate mesoderm and the forming organs. The central players in this scheme are four asymmetrically expressed genes: nodal, Lefty1 and Lefty2, and Pitx2c. Recently we have generated a Pkd2 knockout mouse. Pkd2 encodes polycystin-2, an intracellular Ca-release channel expressed in the ER membrane. In humans mutations in PKD2 account for 15 % of autosomal dominant polycystic kidney disease (ADPKD) which is one of the most frequently inherited monogenic diseases and affects up to 1:1000 individuals worldwide. ADPKD is characterized by progressive development of fluid filled cysts in the kidneys that frequently result in end-stage renal failure. Loss of Pkd2 causes recessive embryonic lethality. Pkd2^{-/-}LacZ^{+/+}-embryos develop whole body oedema and cysts in the kidneys, pancreas and liver and exhibit skeletal malformations. All mutant hearts analyzed so far exhibited structural deformations with abnormalities in trabecularisation and cardiac septation. Surprisingly, Pkd2 knockout mouse embryos displayed left-right positional defects: embryonic turning, heart looping and placement of abdominal organs were randomized and the lung showed right pulmonary isomerism. Lefty1, Lefty2 and nodal were not expressed in the left lateral plate mesoderm and Pitx2 was absent from heart and lung primordia and bilaterally expressed in body wall, mid and hindgut. The embryonic midline was present and normal levels of hnf3 and shh were expressed. We suggest that polycystin-2 acts upstream of the nodal cascade in left-right axis determination and that Pkd2 might be one of the master genes of the body plan.

Altered Expression of Late-Gestation-Lung 1 (LGL1) in a Rat Model of Bronchopulmonary Dysplasia (BPD). *K. Nadeau*^{1,2,3}, *R. Jankov*^{4,5,6}, *K.A. Tanswell*^{4,5,6}, *N.B. Swezey*^{5,6,7}, *F. Kaplan*^{1,2,3,8,9}. 1) Dept of Human Genetics; 2) McGill University, Montreal, QC, Can; 3) Mont. Child. Hosp. Res. Inst, Montreal, QC, Can; 4) Lung Biology and Medical Research Council Group in Lung Development; 5) Hospital for Sick Children Res. Inst., Toronto, ON, Can; 6) University of Toronto, ON, Can; 7) Dept. of Pediatrics and Physiology; 8) Dept. of Pediatrics; 9) Depts. of Pathology and Pediatrics, Harvard Med School, Boston, MA, USA.

Deficiency in terminal lung differentiation due to premature birth is a leading cause of morbidity in the newborn period (RDS), with sequelae that can extend into adulthood (BPD). Although multiple pathophysiologic mechanisms are likely to contribute to BPD, it is believed to be largely due to an arrest in alveolar development. LGL1 is a glucocorticoid induced and developmentally regulated gene cloned in our laboratory. It is maximally expressed in rat lung mesenchymal cells at fetal day 21, concordant with the onset of alveolar septation and augmented surfactant production. We therefore hypothesized that arrested alveolarization in BPD may be associated with altered expression of LGL1. To test this hypothesis, we investigated alterations in LGL1 RNA (northern analysis, n=2) and protein (immuno-histochemistry, n=1) in a rat model of BPD generated by exposing neonatal rats to 60% oxygen for 7, 10 or 14 days (n=4 litters/group). Control litters were exposed to air for the same time periods (n=4 per group). We observed decreased levels of LGL1 mRNA in the BPD rats compared to controls at each time point. A diminution in Ig11 protein level is apparent in control lungs between fetal days 7 and 14. These data confirm our original finding that Ig11 expression diminishes with time after its peak expression at fetal day 21. We showed by immunohistochemistry that Ig11 protein is further reduced in the BPD rats compared to controls at neonatal days 7 and day 14. We have previously shown that absence of Ig11 in the pseudoglandular lung affects lung branching. Our current findings support an additional role for LGL1 during the period of alveolarization. We speculate that deficiency of Ig11 contributes to the arrested alveolar partitioning observed in BPD.

Using cDNA Microarray Analysis to Understand Pathways Related to Waardenburg Syndrome. *S.R. Lipner¹, L. Kochilas², J.A. Epstein², B.E. Morrow¹, A. Skoultchi¹*. 1) Albert Einstein College of Medicine, Bronx, NY; 2) University of Pennsylvania Medical School, Philadelphia, PA.

Waardenburg syndrome (WS) is an autosomal dominant disorder with an incidence of 1 in 40,000 live births. Patients with WS have sensorineural deafness, pigmentation anomalies, cardiac and skeletal abnormalities and neural tube defects. WS1 and 2 are caused by loss of function mutations in Pax3. Mutations of Pax3 have been identified in splotch (sp) mouse strains and these mice have characteristics similar to WS patients. Heterozygotes have a white belly spot and homozygotes die at E13.5 with spina bifida, craniofacial abnormalities, conotruncal heart defects, and thymus and thyroid abnormalities. Many of the organs and tissues that are affected in WS patients and splotch mice are derived from neural crest cells. Another mouse strain that has defects in tissues derived from the neural crest is the Hoxa3 knockout mouse. Many of the defects seen in Hoxa3 homozygotes resemble those seen in Pax3 homozygotes. Hoxa3 homozygotes die at birth with craniofacial malformations, as well as cardiovascular, thymus, thyroid and parathyroid defects. We are interested in understanding the relationship between Pax3 and Hoxa3, including the downstream pathways in which their effects may intersect. Our approach is to use semiquantitative RT-PCR and cDNA microarrays to identify genes whose expression is changed in Pax3 and Hoxa3 mutant embryos. Our data indicate that Pax3 and Hoxa3 do not lie either upstream or downstream of each other. However, Hoxa3 and Pax3 may be in parallel pathways and regulate some of the same genes. One of these genes is Trp-2, which is expressed in migrating melanoblasts of mouse embryos beginning at E10.5. We believe that Trp-2 is activated by both Hoxa3 and Pax3, since this gene is downregulated in both types of knockout embryos. In addition, we have shown that Hoxa3 and Pax3 are coexpressed with Trp-2 in B16 melanoma cells. We are currently studying the mechanism by which these transcription factors regulate Trp-2 gene expression.

Gene expression profiles of human craniofacial development. *Y. Korshunova*¹, *R. Tidwell*¹, *R. Veile*¹, *D. Messina*¹, *C. Helms*¹, *M. Lovett*¹, *T. Attié-Bitach*², *J. Augé*², *S. Audollent*², *M. Vekemans*², *D. Ash*³, *J. Cai*³, *E.W. Jabs*³. 1) Washington Univ, St Louis, MO; 2) Hospital Necker Enfants Malades, Paris; 3) The Johns Hopkins Univ, Baltimore, MD.

Our consortium is profiling gene expression changes in human craniofacial development to identify new lineage markers, to identify important pathways and to pinpoint genes that might contribute to craniofacial disorders. We are using multiple methods to generate profiles from 25 microdissected structures spanning 4 weeks through 8.5 weeks of development. This collection of tissues includes many defined lineages. The example below illustrates data derived for the frontonasal prominence (FNP) lineage which eventually gives rise to the nose and parts of the upper lip. By analyzing multiple hybridizations to Affymetrix chips we identified 173 genes that are discretely expressed in four FNP structures. Sixty four genes, including the homeobox D9, the zinc finger 197, basic transcription factor 3 and homeobox D1 genes are specifically upregulated in the 4th week FNP. Twenty six genes are specific to the 5th week FNP including thrombospondin 2 and catenin delta 1. Thirty six genes are upregulated in the 6th week medial nasal prominence including thrombospondin 4 and zinc finger 267. Forty five genes are specific to the 6th week lateral nasal prominence. These include zinc finger 208 and basic transcription factor 2. We have also interrogated our own custom built microarray of 50mer oligonucleotides. This 1700 gene array corresponds to all known (and several previously unknown) human transcription factors. All pair-wise comparisons for the tissues in our collection were performed and revealed additional transcription factors that show differential expression profiles. For the FNP lineage, TBX21, BARX1, BAPX1, EMX2, SOX10, MNT, ID1 and BRPF1 show distinct temporal changes. Many of these changes have been validated by RNA in situ hybridizations to embryo sections and to whole mount mouse embryos. In the longer term, analysis of this dataset should prove useful as one route for identifying pathways and genes that contribute to common craniofacial defects such as cleft lip and palate.

***Cops3* is essential for murine embryonic development.** J. Yan¹, K. Walz¹, S. Carattini-Rivera¹, A. Bradley², J.R. Lupski¹. 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Sanger center, Cambridge, UK.

Cops3 is located in the common deletion interval for the Smith-Magenis Syndrome (SMS), a contiguous gene deletion syndrome. It encodes the third subunit of the COP9 signalosome, which is an eight-subunit protein complex and is similar to the regulatory lid of the 26S proteasome. The COP9 complex was originally identified as a repressor of light mediated development in plant and mutants of this complex are lethal after the seedling stage. Disruption of one of the subunits in *Drosophila* caused lethality at the late larval or pupal stages. In order to investigate its potential role in mammals and in the SMS phenotypes, we disrupted the murine *Cops3* by an insertional vector. The heterozygous mice appear normal, although the protein level is reduced. In 18 offsprings from the heterozygous mice intercrosses, no homozygous mice were observed. Embryos from heterozygous intercrosses were then examined. At 13.5 days postcoitum (dpc) and 10.5 dpc, no homozygous embryos were detected. At 9.5 dpc, morphologically abnormal embryos have been found, while at 6.5 and 7.5 dpc, all the embryos looked normal. It seems the *Cops3* homozygous embryos died between 7.5 dpc and 10.5 dpc. *Cops3* is crucial for maintaining the development of the embryo in mice. Further analysis is underway to reveal the cause of lethality.

Basic helix-loop-helix transcription factors Twist and Dermo1 during palatal, tooth, and calvarial development.

Y.L. Wang, W.A. Paznekas, L.E. Kotch, E.W. Jabs. Inst. Genet. Med., Johns Hopkins Univ., Balto., MD.

Twist and Dermo1 are closely related members of the family of basic helix-loop-helix (bHLH) transcription factors. The human TWIST (202AA) and DERMO1 (160AA) proteins have 66 percent AA identity. We sequenced these genes and found that nucleotides 127-159 and 173-483 of DERMO1 cDNA exhibit 93 and 89 percent identity to n199-231 and 299-609 of TWIST. The mouse Twist (206AA) and Dermo1 (160AA) proteins have 65 percent AA identity, and n127-158 and 168-483 of Dermo1 cDNA exhibit 90 and 87 percent identity to n199-230 and 306-621 of Twist (n1, first base of the start codon). We analyzed and compared the distribution of Twist and Dermo1 transcripts during mouse craniofacial development from E13.0-E17.0 in vivo by in situ hybridization with digoxigenin-labeled cRNA probes designed from nonhomologous regions of each gene transcript. Dermo1 and Twist exhibited similar dynamic expression patterns in the developing palate, tooth, calvarial bone and other craniofacial organs. They appeared to be expressed at sites of epithelial-mesenchymal interaction during palate and tooth development. At E13.0 both genes were expressed strongly in the mesenchymal and epithelial cells throughout the entire palate and tooth bud primordia. From E15.0 to E17.0 the expression in mesenchyme decreased and the transcripts were primarily located in palate-derived epithelial cells lining both oral and nasal cavities, as well as the tooth bud epithelium of the enamel organ. These data suggest that Dermo1 may play a complementary role in the same embryonic craniofacial processes as Twist, and given their spatial overlap in distribution they may play a role in the epithelial-mesenchymal interactions that dictate development of craniofacial organs. As both are expressed in osteoblastic cells and mutations in the TWIST gene were found in patients exhibiting the Saethre-Chotzen syndrome phenotype which includes premature fusion of the coronal sutures, we examined a 693bp region encompassing the coding sequence of DERMO1 in 33 patients classified as having Saethre-Chotzen syndrome or coronal craniosynostosis, no mutations or polymorphisms were revealed.

Program Nr: 847 from 2002 ASHG Annual Meeting

Expression of CTCF gene in preimplantation embryos. *A.F.L. Rios, D.C. Lemos, M.B. Fernandes, M.V. Andrea, R.B. Lobo, M. Mazucato, E.S. Ramos.* Dept Genetics, Fac Med Rib Preto - University of Sao Paulo, Ribeirao Preto, Sao Paulo, Brazil.

CTCF, a conserved factor, is involved in X chromosome inactivation and expression of imprinted genes. It plays a central role in the epigenetics and cell growth regulations, and perturbations of its functions occur in some forms of neoplasias. Experimentation with embryos has become an important breakthrough in medical research. However, it is also a source of controversy, because the ethical problems. We have identified in cattle a sequence of the CTCF gene. Molecular analysis and characterization of the sequence document homology to its human counterpart. In the present study, the RT-PCR was employed and transcripts were detectable during blastocyst stage. To our knowledge, this is the first report in the literature showing the expression of the CTCF in preimplantation embryos and the presence of this gene in bovines. Further studies are needed to identify the complete sequence of the bovine CTCF gene. To elucidate the biological importance of CTCF and its role in human diseases and normal development, it is important to study homologous genes in other animals. It is possible to culture large proportions of bovine preimplantation embryos; besides, it represents an important model for the investigation of fetal development. Supported by: FAPESP, CAPES, CNPq, FAEPA.

Gene Expression Studies of Embryonic Stem Cells Using RNA Amplification and Microarray Technologies. *T.D. Gallardo*¹, *R.E. Hammer*^{2,3}, *D.J. Garry*¹. 1) Dept Internal Medicine, Univ Texas SW Medical Ctr, Dallas, TX; 2) Dept Biochemistry, Univ Texas SW Medical Ctr, Dallas, TX; 3) Howard Hughes Medical Institute, Univ Texas SW Medical Ctr, Dallas TX.

Gene expression profiles of thousands of genes can now be examined *en masse* through cDNA and oligonucleotide microarrays. Many studies have reported gene expression changes in cell lines, primary cells and tissues. However, present applications of microarray technology do not include the study of gene expression from minimal numbers of cells or individual cell types residing in a given tissue. Such advances would greatly facilitate our understanding of complex interactions between neighboring cell populations. We demonstrate here that gene expression studies can be successfully performed using a T7-based RNA amplification method combined with microarray technology. Using this strategy we have successfully amplified RNA from 100 embryonic stem cells for analysis of gene expression using Affymetrix oligonucleotide microarrays. RNA was isolated from a range of 100 to 100,000 stem cells, submitted through two rounds of amplification and then compared by array analysis to a set of unamplified samples. We observed greater than 91% of the transcripts expressed were changed less than two-fold. We have performed each amplification in triplicate and found this method to be not only highly reproducible but also sensitive for low abundance transcripts. Using this strategy we have begun to define the genetic program of the SM-1 embryonic stem cell population and have identified a number of novel genes and previously characterized genes to be expressed in this population (Oct-4, SSEA-1, AlkPhos., GCNF, etc). We believe the utilization of these combinatorial technologies will enhance our understanding of the cellular and genetic programs associated with these stem cell populations.

Roles for growth differentiation factor 3 in energy metabolism. *C.W. Brown¹, S.D. Coleman¹, D.E. Houston-Hawkins¹, M.M. Matzuk²*. 1) Depts of Molecular and Human Genetics and Pediatrics; 2) Depts of Pathology, Molecular and Cellular Biology and Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Growth Differentiation Factor 3 (GDF-3) is a secreted protein that is a member of the transforming growth factor beta superfamily. It shares significant homology with the *Xenopus laevis* mesoderm-inducing factor, Vg-1. PCR analyses of tissues from the adult mouse demonstrated expression of GDF-3 in multiple sites, including adipocytes. To better understand the functional role of GDF-3, we created mice with a homozygous null mutation at the GDF-3 locus. We examined the potential role of GDF-3 in the adipocyte by analyzing energy metabolism in the knockout mice. Although only modest differences in body weight were observed between the knockout mice and controls maintained on regular laboratory chow, dramatic differences in weight gain were observed when the mice were given high fat diets, despite similar caloric intake. Control male and female mice and homozygous mutant males became obese on this regimen, whereas homozygous mutant females maintained normal weight curves. Although control mice developed glucose intolerance on the high fat regimen, GDF-3^{-/-} females maintained essentially normal glucose tolerance curves. These findings suggest potential important roles for GDF-3 in maintaining normal body fat composition and glucose homeostasis.

Knock-in mouse models for phenotypic comparison of the Apert syndrome Fgfr2 Ser252Trp and Pro253Arg mutations. *R. Xiao¹, D. Huso², C.P. Lerner³, W.A. Paznekas¹, J. Conover³, K. Yu⁴, D.M. Ornitz⁴, E.W. Jabs¹.* 1) Inst. Genet. Med., Johns Hopkins Univ., Balto., MD; 2) Dept. Comparative Med., Johns Hopkins Univ., Balto., MD; 3) The Jackson Lab., Bar Harbor, ME; 4) Dept. Mol. Biol. and Pharmacology, Washington Univ., St. Louis, MO.

Apert syndrome is an autosomal dominant disorder characterized by craniosynostosis, cleft palate, multiorgan system malformations with severe and symmetric syndactyly. The phenotype results from mutations in fibroblast growth factor receptor 2 (FGFR2). Two thirds of the patients have the Ser252Trp mutation while the other third have the Pro253Arg mutation. These gain of function mutations cause a change in the fibroblast growth factor ligand binding affinity and specificity. In limited human studies, it has been suggested that craniofacial abnormalities such as cleft palate are more severe with the Ser252Trp mutation while limb malformations are more severe with the Pro253Arg mutation. To understand the pathogenesis of this developmental disorder and to delineate phenotype-genotype correlations, we generated two mouse models with mutations at the conserved Ser or Pro residue of the mouse sequence. Gene targeting by homologous recombination followed by Cre/loxP-mediated recombination was performed. Ser252Trp heterozygous mutant mice had smaller body size, abnormal head shape, and bulging eyes. There was a high incidence of perinatal lethality. Mutant mice that died within 24-36 hours of birth showed multiple abnormalities. The lung lesions had lack of alveolar expansion and diffuse atelectasis with accumulation of proteinaceous fluid in the alveoli and mild dilation of the bronchioles. Cardiovascular abnormalities included dilation of the atria and great vessels at the base of the heart. There was diffuse, severe lymphoid necrosis and apoptosis in the thymus and mild luminal ectasia was found in the stomach and the intestine. In addition, mutant mice had structural abnormalities of the palate. Pro253Arg heterozygous mutant mice were observed to have syndactyly. These findings are consistent with some of the major congenital abnormalities described in patients with Apert syndrome.

Sonic hedgehog induces ectopic expression of zebrafish iroquois gene (ziro1b) during neural development. C.H.M. Yan, S.H. Cheng. Biology and Chemistry, City University of Hong Kong, Hong Kong, Hong Kong.

Vertebrate embryo development relies on complex molecular mechanisms to ensure correct spatial and temporal gene regulations for the production of orderly developed tissues and organs. During the development of the vertebrate brain, proneural and neurogenic genes are required for proper specification of neuronal precursors. The *iroquois* family of homeobox genes, first isolated in *Drosophila*, has been found to act as pre-pattern factors involved in patterning and regionalization of embryonic tissues in both vertebrates and invertebrates. The expression of *iroquois* genes is maintained by *hedgehog* (*hh*) signaling and its downstream mediator, *Cubitus interruptus*, in some domains of *Drosophila*, while such relationship is largely unknown in vertebrate systems. The Hh family of secreted signaling proteins has been found to be responsible for developmental patterning in a variety of systems such as the neural tube. In this study, zebrafish was chosen as the vertebrate model organism to investigate the regulatory mechanism of a member of *iroquois* genes (*ziro1b*) by *sonic hedgehog* (*shh*) in neural development. The expression of *shh* was manipulated by RNA injection into fertilized embryos. *In situ* hybridization analyses were carried out on injected embryos at various time points. Overexpression of *shh* induced ectopic expression of *ziro1b* gene, which is normally expressed in the midbrain and hindbrain of developing embryos. This suggests that *shh* may regulate *ziro1b* in neural development.

Defective SRY phosphorylation and DNA-binding ability caused by a non-HMG box SRY mutation in a family presenting variable sex-reversed phenotypes. *J.G. Assumpcao¹, C.E. Benedetti², A.T. Maciel-Guerra³, G. Guerra-Jr³, M.R. Scolfaro³, M.P. De Mello¹.* 1) CBMEG, Univ Estadual de Campinas, Campinas, So Paulo, Brazil; 2) Centro de Biologia Molecular Estrutural - Laboratrio Nacional de Luz Sncroton (LNLS), Campinas, SP, Brazil; 3) 3Grupo Interdisciplinar de Estudos de Distrbios da Diferenciaio do Sexo (GIEDDS) - Faculdade de Cincias Mdicas, Universidade Estadual de Campinas (UNICAMP), Campinas, SP, Brazil.

The *SRY* gene (sex-determining region of the Y chromosome) initiates the process of male sex differentiation in mammals. We describe here a novel missense mutation in the *SRY* gene, a G to T transversion, which changes an arginine to an isoleucine at codon 30 (R30I). This mutation was found in affected and non-affected members of a family, including the father, two siblings with partial gonadal dysgenesis, a phenotypic female with pure gonadal dysgenesis and three non-affected male siblings. The G to T base change was not found in the *SRY* sequence of 100 normal males screened by ASO-PCR. The R30I mutation is located upstream to the HMG box, within the ²⁹RRSSS³³ PKA phosphorylation site. We demonstrate that the phosphorylation of the SRY^{R30I} protein in vitro is negligible. We also show that the non-phosphorylated SRY^{R30I} protein is able to bind the target DNA as effectively as the wild-type SRY; however, when using phosphorylated proteins in gel mobility shift assays, the SRY^{R30I} protein exhibits reduced DNA-binding activity in comparison to the phosphorylated wild-type protein. Therefore, we suggest that the activity of the SRY^{R30I} is close to a threshold level in which its ability to induce testicular development in vivo would depend on the physiological conditions or interactions with other genetic factors. This could explain the three phenotypes (normal male, partial gonadal dysgenesis and pure gonadal dysgenesis) observed in the individuals carrying the R30I substitution. Financial Support: CNPq, FAEP-UNICAMP.

Mutations in *GDF1* are associated with congenital cardiovascular malformations in humans. *J.B. Mez¹, J.D. Karkera¹, E. Roessler¹, E. Goldmuntz², P. Bowers³, J.A. Towbin⁴, J. Belmont⁴, S.C. Ekker⁵, M. Muenke¹.* 1) Medical Genetics Branch, NHGRI/NIH, Bethesda, MD; 2) Division of Cardiology, Children's Hospital of Philadelphia and the University of Pennsylvania School of Medicine, Philadelphia, PA; 3) Department of Pediatrics, Yale University School of Medicine, New Haven, CT; 4) Pediatric Cardiology, Baylor College of Medicine, Houston, TX; 5) Arnold and Mabel Beckman Center for Transposon Research, Institute of Human Genetics, Department of Genetics, Cell Biology, and Development, University of Minnesota, Minneapolis, MN.

The transforming growth factor- β (TGF β) superfamily is a large group of structurally related, proteolytically cleaved polypeptides, that regulate the formation of the primary germ layers and the establishment of the body axes during gastrulation. Several (TGF β) family members (*Nodal*, *Lefty-1*, *Lefty-2*, and *Growth/differentiation factor-1 (Gdf1)*) in the Nodal signaling pathway have been implicated in left-right (L-R) patterning in the mouse. *Gdf1*^{-/-} mice show complex and variable cardiac malformations due to L-R axis anomalies including randomization of the great arteries, atrial and ventricular septal defects, and atrioventricular (A-V) canal. To test whether this gene is involved in L-R asymmetry in humans, we characterized the human *GDF1* gene and screened 378 patients with congenital cardiac anomalies including truncus arteriosus, tetralogy of Fallot, transposition of the great arteries, double outlet right ventricle, A-V canal, or interrupted aortic arch for mutations in *GDF1*. We identified the following changes that were apparently unique to patients with congenital cardiovascular malformations (and not present in 200 chromosomes from normal controls): one nonsense mutation, seven missense mutations including an invariant cysteine knot, three silent mutations, a variation in the 5' untranslated region and four intronic variations. To better understand the underlying mechanisms of *GDF1* mutations as one cause for cardiovascular anomalies in humans, functional studies in zebrafish are in progress utilizing morpholino-induced *Vg1* zebrafish mutants.

Nicotine and embryonic development in zebrafish. *S. Beiraghi, E. Beckman, D. Shiroma, S.C. Ekker.* The Arnold & Mabel Beckman Center for Transposon Research, University of Minnesota, Minneapolis, MN.

Children of mothers that smoke have an increased risk for a number of developmental abnormalities including low birth weight, craniofacial anomalies such as cleft lip and palate. Nicotine can exert multiple effects on early embryogenesis, including altered patterns of cellular mitosis, cell migration, and other gross developmental defects in mice. The zebrafish (*Danio rerio*) offers many advantages to the study of this problem because of external embryonic development and the multiple genetic tools now available to this model organism. In addition, there is substantial similarity between the early development of the zebrafish and mammals, including mechanisms that underlie craniofacial or skeletal structure, making this a significant vertebrate system to explore the early developmental defects due to teratogens or mutagens. Objective: To investigate the effects of L-nicotine on zebrafish during embryonic development. Methods: We performed a dose response profile and determined an LD50 (0.025%) and ED (0.0031%) of L-nicotine. These embryos displayed wide spectrum developmental abnormalities as determined using standard microscopy approaches for morphological criteria. Experimental group were bathed for 24 hours in L-nicotine with different concentration (0.025 %-0.0031%), and the control group were bathed in egg-water for the same duration. Three markers (OTX-2, MYO-D, GATA-1) was used in in situ hybridization to investigate the patterns of expression of anterior ectodermal, somitic mesodermal, and ventral mesodermal tissue derivatives. Alcian blue staining was used on 5 day larvae to follow development of the jaw. Results: Nicotine exposure in higher concentration (0.025%) resulted in embryos with a wide spectrum of severe malformations with an underdeveloped tail and jaw and a reduced number of somites, and subsequent complications in jaw formation. As the concentration of nicotine reduced, the anomalies were less severe, however, subtle physiological changes such as; slow heart rate in experimental groups. Conclusion: Our preliminary data supports the view that nicotine is a teratogen, particularly affecting early vertebrate embryogenesis.

Sequence variations in the dystrophin gene, biological consequences, and clinical correlations. *C.S. Richards¹, Y.P. Weng¹, D. Odenbaugh¹, G. Miller¹, D.R. Love², M.R. Hegde¹.* 1) Dept Molec & Human Genet, Baylor Col Med, Houston, TX; 2) School of Biological Sciences, University of Auckland, Auckland, New Zealand.

Duchenne/Becker muscular dystrophy (DMD/BMD) is an X-linked recessive neuromuscular disorder affecting approximately 1 in 3500 males with one-third of isolated cases resulting from a new mutation in the dystrophin gene. The dystrophin gene, located on Xp21 is greater than two megabases and encompasses 79 exons. Two-thirds of patients have structural mutations with approximately 60% having intragenic deletion mutations and 6% duplication mutations, which can be detected using multiplex PCR analysis and/or Southern blotting. The remaining one-third of the patients carry non-deletion/duplication mutations that escape detection by routine genetic testing performed in diagnostic molecular laboratories. These non-deletion/duplication mutations in sporadic cases are problematic in risk analysis for at-risk females, particularly the mother of the affected child. Thus, prenatal diagnosis in these types of families is inaccurate and problematic. We have developed an assay, which addresses this serious and immediate need. We have developed a comprehensive mutation analysis strategy for the entire dystrophin gene to identify not only whole exon deletion/duplication mutations, but also point mutations, small deletions and small insertions. The strategy involves amplification of all exons of dystrophin gene and analysis of each exon using denaturing high performance liquid chromatography (dHPLC). Missense mutations represent challenges in sequence interpretation and are often reported as unclassified variants. One strategy which may help resolve such interpretation dilemmas is the use of protein modeling. We intend to characterize each missense mutation identified in the dystrophin gene by sequence analysis and map it to the corresponding dystrophin protein domain and perform protein modeling. A better characterization of all sequence variations within the dystrophin gene will lead to a better understanding of the functional domains of the dystrophin gene and the relationship to disease phenotype.

Myosin VI and hereditary hearing loss: from mouse to man and back to mouse. *K.B. Avraham¹, N. Ahituv¹, G. Gasparini², Y. Raphael³*. 1) Dept. of Human Genetics & Molecular Medicine, Sackler School of Medicine, Tel Aviv University, Tel Aviv, Israel; 2) Genetica Medica, Dip. Patologia Generale, II Universite di Napoli and Tigem, Italy; 3) Kresge Hearing Research Institute, The University of Michigan, Ann Arbor, MI, USA.

The past few years have provided an explosion in our understanding of how the inner ear functions. This dramatic increase is due in large part to the genes found to be associated with nonsyndromic hearing loss. Since 1995, 27 genes have been found, and these have provided clues about auditory transduction, ion homeostasis, and inner ear development. In particular, mouse models for human deafness, with mutations in orthologous genes, have revealed essential information about the pathophysiology caused by these mutations. One group of proteins frequently associated with hearing loss are the myosins, three of which were discovered thanks to their corresponding mouse mutants. Myosins are molecular motors that move along actin filaments and have been implicated in various cellular functions such as cell movement, membrane traffic, and signal transduction. An intragenic deletion in myosin VI (*Myo6*) leads to deafness and vestibular dysfunction in Snell's waltzer mice. A genome scan on DNA derived from an Italian family with progressive dominant hearing loss revealed linkage to chromosome 6q13, the region containing the human *MYO6* gene (Melchionda *et al. AJHG* 2001). Subsequently, a missense mutation was found in the coding region of this gene, which replaces a cysteine with a tyrosine at residue 442 of the protein (C442Y). The following suggests that the deafness in this family is due to the *MYO6* missense mutation: the segregation of this mutation with the affected individuals in the family, the previous association of myosin VI with deafness, and the conservation of the mutated residue. We have now confirmed that this mutation is the cause of deafness in humans, since reproduction of this mutation in transgenic mice has revealed a similar progressive hearing loss. A morphological analysis of the transgenic mice demonstrates the pathophysiology of this mutation.

Eya4 and Its Interacting Partners. *Y. Zhang*¹, *S. Wayne*¹, *R.A. Friedman*², *G. Van Camp*³, *R.J.H. Smith*¹. 1) Molecular Otolaryngology Research Laboratories, University of Iowa, Iowa City, IA, USA; 2) House Ear Clinic and House Ear Institute, Los Angeles, CA, USA; 3) Department of Medical Genetics, University of Antwerp, Antwerp, Belgium.

Statement of Purpose. Our work identifying mutations in EYA4 in two families with DFNA10 implicates this gene as essential for normal auditory function. EYA genes, four of which are known in humans, are expressed in a wide range of tissues. The mutations we identified in EYA4 are predicted to affect the *eya* homologous region (*eyaHR*). Given the role of the *eyaHR* to EYA protein function, it is not surprising that these mutations have a phenotypic correlate. Neither is the association of late-onset hearing loss with transcriptional activators unprecedented, as mutations in POU4F3 are known to cause postlingual hearing loss at the DFNA15 locus (Vahava et al., 1998). What is surprising is the limited DFNA10 phenotype, especially when one considers the clinical impact of mutations in another EYA gene, EYA1. In this study, we determined the interacting partners of Eya4. **Methods Used.** We used RT-PCR to identify isoforms of Eya4 in total RNA isolated from multiple mouse tissues. To determine the normal functional partners of the Eya4 protein and to assess the impact of specific Eya4 mutations on these interactions, we used the yeast two-hybrid system and cell culture/transfection assays. **Summary of Results.** We identified three novel splice variants of Eya4 and demonstrated expression of Eya4 in multiple tissues. Based on these findings, we constructed several bait vectors by fusing select portions of the Eya4 coding sequence with a GAL4 DNA-binding domain; in addition, we made constructs that contain the two mutations associated with the DFNA10 phenotype. We used these constructs to test the interaction of Eya4 with prey constructs of Six1 and DACH, two proteins that are known to interact with Eya1 (Buller et al., 2001). To identify partners of Eya4 that are unique to the cochlea, we constructed a cochlear cDNA prey library. **Conclusion.** Eya1 and Eya4 show differing affinities for Six1 and DACH. Eya4 interacts with several cochlear-expressed proteins. (Supported by DC03544 to RJHS).

Mutation Screening of *TMC1* in DFNB7/11 Families. *T. Yang*¹, *R. Carmi*², *Y. Bayazit*³, *A. Ramesh*⁴, *K. Kurima*⁵, *B. Cable*¹, *K. Elbedour*², *C.R.S. Srisailapathy*⁴, *A.J. Griffith*⁵, *V.C. Sheffield*⁶, *R.J.H. Smith*¹. 1) Genetics Program, University of Iowa, Iowa City, IA, USA; 2) Genetic Institute, Soroka University Medical Center, Ben-Gurion University of Negev, Negev, Israel; 3) Gaziantep University, Department of Otolaryngology and Head and Neck Surgery, Kolejtepe, Gaziantep, Turkey; 4) Department of Genetics, University of Madras, Madras, India; 5) National Institute on Deafness and Other Communication Disorders, National Institutes of Health, Rockville, Maryland, USA; 6) Howard Hughes Medical Institute and Department of Pediatrics, University of Iowa, Iowa City, IA, USA.

Statement of Purpose. Autosomal recessive nonsyndromic deafness (ARNSD) is the most common form of congenital inherited deafness. A novel gene *TMC1* has been identified as being responsible for ARNSD at the DFNB7/11 locus. Mutations in this gene also cause autosomal dominant hearing loss at the DFNA36 locus (Kurima et al., 2002). We screened our DFNB7/11 families to determine whether mutations in *TMC1* were causally related to their hearing loss. **Methods Used.** Mutation screening of *TMC1* was completed using bi-directional sequencing. In addition, we used computational analysis of the genomic sequence that includes *TMC1* to predict additional potential exons. **Summary of Results.** We identified an R34X nonsense mutation in one Bedouin family and two unrelated Turkish families. In two other DFNB7/11 families, screening of the reported coding sequence of *TMC1* failed to reveal mutations that segregated with the deafness phenotype. This finding suggests the possibility of unrecognized or alternatively spliced *TMC1* exons that contribute to the DFNB7/11 mutation load. Sequencing of predicted exons has revealed a point mutation segregating with the deafness phenotype in an Indian family. **Conclusion.** Mutations at DFNB7/11 locus appear to be a relatively common cause of ARNSD. It is possible that there are novel splice variants of *TMC1* that are cochlear-expressed and causally related to deafness at this locus. (This research was supported by R01-DC02842 to RJHS.).

Spinocerebellar ataxia type 10 protein binds to Myosin phosphatase target subunit 1 (MYPT1). *S. Nagamitsu*¹, *R. Zhang*², *T. Matsuura*², *H.F Epstein*², *T. Ashizawa*². 1) Department of Pediatrics, Kurume University, Fukuoka, Fukuoka, Japan; 2) Department of Neurology, Baylor college of Medicine, Houston, TX.

Spinocerebellar ataxia type 10 (SCA10) is an autosomal dominant disorder caused by expansion of an unstable pentanucleotide ATTCT repeat in intron 9 of the *SCA10* gene. While the number of ATTCTs does not exceed 22 in normal subjects, affected individuals have ATTCT repeats ranging from 800 to 4,500 repeats. However, the mechanism by which the expansion mutation in this gene causes the disease phenotype is not understood. The *SCA10* gene encodes a novel protein known as E46L, which has no recognizable motifs or predicted structures. To gain insight into the function of this protein, the yeast two-hybrid system was utilized to identify proteins that interact with E46L. In the screening of 5 million yeast clones expressing human brain cDNA proteins, 25 clones were identified to interact with E46L; 9 of these 25 clones encoded myosin phosphatase target subunit 1 (MYPT1). This protein-protein interaction was confirmed by both in vitro protein binding assay and immunohistochemistry. E46L was localized in both nucleus and cytosol, and colocalized with MYPT1 mainly in the cytosol in the transfected PC12 cells. In vitro protein binding studies using truncated MYPT1 proteins suggested that E46L binds to the carboxyl terminal portion of MYPT1. Although this portion of MYPT1 includes phosphorylation sites, phosphorylation of MYPT1 was not affected by E46L. In transfected PC12 cells, over-expression of E46L with or without over-expression of MYPT1 did not cause any detectable morphological changes including neurite outgrowth. MYPT1 phosphatase activity on myosin light chain in the presence of E46L is currently investigated in our laboratory.

Potential Modifier Role of the R618Q Variant of Proa2(I)collagen in Type I Collagen Fibrillogenesis: In Vitro Assembly Analyses. *A.N. Vomund¹, S.R. Braddock², C.L. Phillips^{1,2}*. 1) Dept Biochemistry, Univ Missouri, Columbia, MO; 2) Dept Child Health/ Medical Genetics, Univ Missouri, Columbia, MO.

An arginine to glutamine substitution at amino acid position 618 in the triple helix of proa2(I)collagen (R618Q) was first reported in a patient with a variant of Marfan syndrome. This substitution was later identified in conjunction with a second mutation in a patient diagnosed with osteogenesis imperfecta. Yet, in both cases, R618Q was also present in unaffected or mildly affected family members, suggesting R618Q may represent a rare polymorphism. However, arginine₆₁₈ in the triple helix is conserved across a variety of species and fibrillar collagen types, suggesting it is functionally significant. We hypothesize that the R618Q allele of proa2(I)collagen may act as a modifier of connective tissue structure/function and is not a primary disease causing allele. To evaluate the functional significance of the R618Q allele, we isolated type I collagen from cultured dermal fibroblasts from control individuals and two unrelated individuals who were heterozygous for R618Q allele and evaluated triple helical stability and fibril assembly. We analyzed type I collagen helical stability by protease resistance under thermal denaturing conditions and by CD spectroscopy, and demonstrated that there were no statistical differences between control and R618Q containing collagen. We evaluated fibrillar assembly using an in vitro assembly assay, which demonstrated that fibrils containing R618Q collagen molecules exhibited more rapid fibril growth and no apparent fibril nucleation phase when compared with control in vitro assembled type I collagen fibrils. Further, electron microscopy analyses indicated that assembled R618Q fibrils have diameters, which are approximately 20 percent of in vitro assembled control type I collagen fibril diameters. These data suggest that R618Q containing collagen does not play a significant role in the triple helical stability of type I collagen, but points to a role for arginine₆₁₈ in fibril assembly, and supports the hypothesis that the R618Q variant may have a role in modifying connective tissue structure and function, and potentially in disease pathogenesis.

Pathogenic Molecular Signals Underlying Non-Union Skeletal Fractures. *K.E. Pearson¹, M. Bostrom¹, R. Hotchkiss², D.A. Stephan².* 1) Genetic Med, CNMC, Washington, DC; 2) Hosp. for Special Surgery, New York, NY.

Non-union skeletal fractures are characterized by their inability to heal six months after injury. Approximately 100,000 non-union fractures occur annually in the United States. Bone graft surgery is the most common form of treatment while other methods such as electrical stimulation are used to accelerate the natural bone healing process. Current therapies are extremely invasive, painful, and expensive. Left untreated, non-unions may cause advanced arthritis and loss of function in the affected limb. Here we aim to identify novel treatment options through a detailed understanding of the pathogenic process. Oligonucleotide arrays were used to identify the mechanisms that lead to lack of skeletal repair in non-unions. Biotynlated cRNA was generated from four normal fracture callus tissue samples and pooled and hybridized to two replicate Affymetrix chips. The same method was applied for five non-union callus samples. This pooling strategy physically normalizes inter-individual differences, allowing disease-specific correlates to be identified with a greater than 80% true positive ratio. Lists of upregulated and downregulated genes were produced to isolate genes with fold changes greater than two. The absence of genes responsible for the early inflammatory stage of healing may suggest the lack of infiltration of macrophages, monocytes, lymphocytes, and polymorphonuclear cells, which are responsible for the ingrowth of vascular tissue, formation of granulation tissue, and the migration of mesenchymal cells. Instead, non-union tissue is abundant in B-cell type-II response genes such as the various chains of immunoglobulins and B-lymphocyte chemoattractants, along with many extra-cellular matrix protein and skeletal muscle genes. Immunohistochemical staining of several unique non-union and normal frozen callus tissue samples was performed using antibodies against several upregulated and downregulated genes to confirm the array data. In vivo studies are underway. Our findings indicate that a lack of an inflammatory/immune response is the cause of non-union fractures in skeletal tissue. This insight allows directed therapeutics to be developed.

Mapping and identification of CRX - ataxin-7 binding domains and a novel ataxin-7 nuclear localization domain.

*S. Chen*¹, *G. Peng*¹, *X. Wang*¹, *A.C. Smith*², *L.Y. Li*¹, *S. Xu*¹, *B.L. Sopher*², *A.R. La Spada*². 1) Dept of Ophthalmology & Visual Sciences, Washington Univ, St Louis, MO; 2) Dept of Laboratory Medicine, Univ Washington, Seattle, WA.

Spinocerebellar ataxia type 7 (SCA7) is caused by a CAG repeat expansion. We recently showed that polyglutamine-expanded ataxin-7 directly interacts with cone-rod homeobox (CRX) protein and that SCA7 retinal degeneration may involve interference with CRX function. To characterize the CRX-ataxin-7 interaction, we generated CRX deletion constructs. In vitro co-ip studies using different N-terminal deletions established that the glutamine-rich and homeodomain regions of CRX are sufficient for interaction with ataxin-7. While deletion of the seven C-terminal glutamines (Q's) from the glutamine-rich domain diminished but did not eliminate the interaction, non-conservative mutagenesis of the two N-terminal homeodomain Q residues in this context abolished the ataxin-7 interaction. To evaluate ataxin-7, we generated N-terminal and C-terminal deletions of ataxin-7 with 92 Q's, and tested the ability of the ataxin-7 deletion proteins to repress CRX transactivation of a rhodopsin promoter-reporter construct in HEK293 cells. Importantly, C-terminal deletions of ataxin-7 92Q markedly reduced its ability to repress CRX transactivation. Analysis of subcellular localization of C-terminal deletions suggested that they were predominantly cytoplasmic, and thus unable to enter the nucleus and interfere with CRX function. When ataxin-7 92Q was truncated to a 147 aa N-terminal protein, nuclear localization became prominent, likely due to its small size, and was accompanied by a return of full repression. Analysis of the ability of ataxin-7 92Q N-terminal deletions to repress CRX-mediated transcription revealed that the Q tract of ataxin-7 is required for inhibition. Interestingly, loss of the first 25 amino acids of ataxin-7 significantly reduced the level of CRX interference. This finding suggests that the most N-terminal ataxin-7 amino acids either participate directly in the CRX interaction or that their loss alters the tertiary structure of ataxin-7 or its Q tract such that interaction with CRX is diminished.

The transcription factor SOX10 regulates PLP expression in the central nervous system. *M. Girard¹, N. Bondurand¹, N. Lemort¹, V. Pingault^{1,2}, M. Goossens^{1,2}.* 1) Genetics, INSERM U468, Creteil, France; 2) Laboratoire de Biochimie et Genetique Moleculaire, AP-HP, Hospital Henri Mondor, Creteil, France.

SOX10 is an essential factor in the enteric nervous system (ENS), melanocytes and glial cells development. Mutations in the SOX10 gene have been described in several cases of Shah-Waardenburg syndrome, a neurocristopathy characterized by the association of Hirschsprung disease (intestinal aganglionosis) and Waardenburg syndrome (pigmentation defects and sensorineural deafness). In accordance, it was shown that SOX10 controls expression of MITF and RET, which play important roles during melanocytes and ENS development, respectively. Some patients also present with myelination defects of the peripheral nervous system (PNS), which is in agreement with the demonstration that P0 and Cx32, two major proteins of the PNS, are controlled by SOX10. Nevertheless, these findings cannot explain the defects of the central nervous system (CNS), consistent with Pelizaeus-Merzbacher disease (PMD), observed in one patient. This suggests that SOX10 may regulate other genes involved in the myelination process of the CNS. To test this hypothesis, we sought the possible involvement of SOX10 in the regulation of expression of PLP and its alternative transcript DM20. Both proteins are major components of myelin in the CNS, and mutations of the PLP gene are associated with PMD. Here we show that SOX10 activates expression of the PLP gene in transfection assays, while SOX10 mutant proteins fail to transactivate this promoter, and that EGR2, another major regulator in the CNS, is also able to regulate the PLP promoter. These results were further confirmed by the study of a cell line expressing SOX10 in an inducible manner, where PLP and DM20 expression is upregulated when SOX10 is induced. Overall, our results provide insights into the regulation of PLP expression, and underline the importance of SOX10 during the myelination process. Our study may also improve our understanding of molecular mechanisms involved in the phenotypic features of some peripheral neuropathies.

Repair capacity of motor neurons in spinal muscular atrophy. *T. FRUGIER, R. OLASO, N. ROBLLOT, V. JOSHI, J. MELKI.* Molecular Neurogenetics Laboratory, INSERM E.9913, Evry University, GENOPOLE, Evry, France.

Mutations of the survival of motor neuron gene (SMN1) are responsible for spinal muscular atrophy (SMA), a common genetic cause of death in childhood. SMA is characterized by degeneration of motor neurons leading to progressive paralysis with muscular atrophy. The Cre-loxP recombination system has been used to direct deletion of the murine *Smn* exon 7 to neuronal tissue. Mutant mice display severe muscle paralysis leading to death within the first 4 weeks of age (Frugier et al., 2000). To evaluate the repair capacity of motor neurons, conditional expression of an intact human SMN cDNA at various times of the disease course has been carried by using the tetracycline-controlled transactivator (tTA system). A transgenic line expressing hSMN cDNA placed under the control of the tetO-CMV promoter (tetO-hSMN) has been generated and crossed to transgenic line expressing tTA under the control of the prion gene promoter (Prp-tTA, Tremblay et al., 1998). An induction or repression of the hSMN transgene expression has been observed in response to the absence or presence of doxycycline treatment respectively. We are currently crossing the appropriate progenitors to produce mice carrying Prp-tTA, tetO-hSMN transgenes and the deletion of SMN in neurons. Doxycycline will be stopped at various times of the disease course. We will evaluate the expression pattern of hSMN mRNA and protein and will examine the effect of hSMN transgene expression on SMA phenotype. In addition, elucidating the molecular mechanism involved in or associated with motor neuron repair through gene expression profiling studies should contribute to identify new therapeutic targets in SMA and possibly in other degenerative disorders.

Characterization of Torsin Related Proteins (Tor2A/Tor3A). *M.M. Caton¹, S. Jose¹, P. De Carvalho Aguiar¹, J. Hewett², X.O. Breakefield², L. Ozelius¹.* 1) Department of Molecular Genetics, Albert Einstein College of Med.; 2) Molecular Neurogenetics, Massachusetts General Hospital Charlestown, Ma.

Dystonia is a movement disorder, characterized by involuntary twisting movements and abnormal postures. Over 13 different genes have been implicated in various forms of primary, hereditary dystonia. The DYT 1 locus on human chromosome 9q34 is responsible for early onset dystonia (EOD). Inheritance of this gene is autosomal dominant with reduced penetrance (30-40%). DYT1 is a member of a gene family consisting of several other highly homologous genes. Two members, TOR2A and TOR3A/ADIR1 share about 45% homology at the amino acid level with DYT1. We are interested in characterizing TOR2A and TOR3A, as these genes are potential candidates for involvement in other forms of dystonia, could influence the penetrance of EOD, or may provide clues to the function(s) of the DYT1 gene. Northern analysis showed that both messages are widely expressed in peripheral tissues, as well as in various regions of the brain. Genomic sequence analysis showed that TOR3A mapped to chromosome 1 and TOR2A to chromosome 9. Analysis of exon:intron structure revealed that both genes are structurally similar to DYT1. Further EST database searches revealed that there are several isoforms of TOR2A, which are derived by alternative splicing. In order to determine whether these isoforms are present in cDNA of adult brain, we performed PCR amplification of Tor2a. We have identified two alternative splice variants containing open reading frames, the first encodes exons 2, 3, 4, 5, and the second, exons 2, 3, 5. In order to determine the cellular localization of TOR2A and 3A, the full-length cDNAs were cloned into expression vectors and transfected into 293T cells. Immunofluorescence staining showed that both proteins co-localize with antibodies for Protein Disulfide Isomerase (PDI) suggesting that similar to torsinA, Tor2a and 3a are resident in the endoplasmic reticulum. Finally, we are in the process of examining genetic markers located close to these genes on chromosome 1 and 9 in several large families with dystonia not linked to other known loci.

Functional characterization of genetic polymorphisms in the human serotonin receptor 1B (HTR1B) gene promoter. *J. Duan, A.R. Sanders, P.V. Gejman.* Schizophrenia Genetics Research Program; The University of Chicago; Chicago, IL.

HTR1B has been suggested to play an important role in multiple psychiatric disorders and conditions, and therefore many association tests have been published with varied results. Hence, our group initiated a systematic study of the functional correlations of genetic diversity in HTR1B and are reporting now the effect on transcription of polymorphisms located at the *in silico* predicted HTR1B promoter sequences. Using the TSSG program for recognition of human PolIII promoter region and start of transcription, we determined that a 5 segment (-1 to 1387) contains a putative functional promoter spanning a TATA box (TATAAA) from -911 to 906. This 5 segment also spans common variations, T-261G, A-161T, and -182INS/DEL-181 (insertion/deletion spanning 2 bp). We have used a SEAP (secreted alkaline phosphatase) reporter gene system to measure the transcription activity. We found that the putative promoter segment exhibited transcriptional activity after 96 hr of transfection in HCN-1A (human cortical neuron) and 48 hr of transfection in CHO-K1 (Chinese hamster ovary) cells. Interestingly, the haplotype -261G/-182INS-181/A-161 showed a 2-fold enhanced transcriptional activity compared with the haplotype T-261/-182INS-181/A-161. The effect was not detected with -261G/-182INS-181/-161T, which suggests that the -161T allele has a compensating negative effect on transcription. The TSSG program also predicted that A-161T and -182INS/DEL-181 fall into putative transcription factor (TF)-binding sites, and that the -261G allele generates a new TF-binding site (CCCMNSSS). To assess whether the functional effect of the alleles -261G and -161T could be explained by the modification of a specific binding to TF, we performed an electrophoretic mobility shift assay. The oligonucleotide probe spanning allele -261G showed specific binding to an unknown TF from nuclear extracts, but no specific binding was detected for T-261 allele. These results provide an explanation for the increase of the transcription activity of the promoter. Our experiments have relevance to the design and interpretation of association studies with HTR1B.

Gene structure and protein function studies for Sacsin. C. LeBlanc¹, J. Mercier¹, P. Lepage², T.J. Hudson², A. Richter¹. 1) Génétique Médicale, Hôp. Sainte-Justine; 2) Montreal Genome Centre, McGill Univ. Health Ctr.; Montreal, Canada.

Mutations in *sacsin* (g.6594delT (DT) and g.5254C®T, (C®T)) are responsible for autosomal recessive spastic ataxia of Charlevoix-Saguenay (C-S), (ARSACS/SACS MIM# 270550), a clinically homogeneous early onset disease. Different disease causing mutations have been described in other populations. Gene predictions of the Genome Project Working Draft at <http://genome.ucsc.edu/> suggest that coding regions 5' of the *sacsin* ORF are also part of the gene. Using 5' RACE and RT-PCR analyses combined with direct sequencing we determined that 9 other smaller exons likely are part of *sacsin*, making the genomic region close to 105 kbases. Experiments are underway to define the still elusive transcription start site. We can detect over 97% of disease alleles in C-S ARSACS patients. In 5 other patients with classical ARSACS phenotype from the C-S region, one disease allele is still undetected. We are now scanning the upstream exons in these patients for mutations.

To investigate the function of the *sacsin* protein we raised polyclonal Abs to two cloned polyHis-tagged *sacsin* fragments produced in a bacterial expression system. Western blotting of total protein from mouse brain and liver using both Abs revealed the presence of a >427 kDa protein band in brain that was absent in liver. The MW was estimated in comparison to dystrophin, detected by a monoclonal anti-dystrophin Ab. Western analysis of protein extracts from fibroblasts of ARSACS patients with DT/DT, DT/C®T and C®T/ C®T genotypes and controls showed the specific absence of the high molecular weight protein band. Immunocytochemistry using Ab to the C terminal portion of *sacsin* on control and patient fibroblasts shows reduced cytoplasmic localization of *sacsin* in patients. The intense granular staining with Ab to a more NH₂ terminal region suggests the presence of truncated *sacsin* in patient cells. Cell fractionation and immunohistochemistry with patient and control tissues are in progress. **Supported by the Canadian Institutes of Health Research.**

The expression of polyglutamine and $\alpha 1A$ -voltage-dependent calcium channel protein in the SCA6 brain. *K. Ishikawa, K. Ishida, H. Fujigasaki, K. Owada, H. Mizusawa.* Dept Neurology, Tokyo Medical & Dental Univ, Tokyo, Japan.

Spinocerebellar ataxia type 6 (SCA6) is a dominantly-inherited degenerative disease caused by a small expansion of the CAG repeat that encode polyglutamine tract in the $\alpha 1A$ -voltage-dependent calcium channel gene. By immunohistochemistry, two types of microscopic aggregations composed either of $\alpha 1A$ -calcium channel protein or polyglutamine have been identified in the cytoplasm of the cerebellar Purkinje cells that are predominantly affected in this disease. Importantly, these two types of aggregates are so far specific to SCA6 Purkinje cells, and have been shown not co-localize each other. To elucidate the precise nature of these aggregates, we examined frozen brain tissues of control human and SCA6 patients on western blot using antibodies against $\alpha 1A$ -calcium channel, calcium-binding protein calbindin-D28k, and expanded-polyglutamine. The expression of $\alpha 1A$ -calcium channel protein was demonstrated in the cerebral cortex, basal ganglia, hippocampus and the cerebellar cortex of both control subjects and patients with SCA6. On western blot, the expression level of the channel protein relative to that of calbindin-D28k, a marker for Purkinje cells in the cerebellum, was not obviously decreased in the SCA6 cerebellum. No aberrant band was detected in lysates from SCA6 brain tissues. Immunohistochemical staining also showed that immunoreactivity for anti-calcium channel antibody is not altered in Purkinje cell soma, nor in the molecular and granule cell layers of SCA6 cerebellum. Western blot for expanded-polyglutamine failed to detect any aberrant bands from the SCA6 brain tissue. The present study indicates that the small polyglutamine expansion do not alter the expression level of $\alpha 1A$ -calcium channel protein. The mechanism underlying the formation of polyglutamine aggregates in SCA6, which are mainly seen in the cytoplasm of Purkinje cells, may not be identical to that of polyglutamine aggregates in other polyglutamine diseases.

CLN3 modulates cell growth and apoptosis. *D.N. Persaud-Sawin¹, A. Van Dongen^{1,3}, R-M. Boustany^{1,2}.* 1) University Program in Genetics, Duke University, Durham, NC; 2) Department of Pediatrics, Duke University, Durham, NC; 3) Department of Pharmacology, Duke University, Durham, NC.

Juvenile Batten disease (JNCL) is an autosomal recessive disease that results from mutations in the CLN3 gene. The CLN3 gene coding sequence has 15 exons, and the translated protein consists of 438 amino acids. The most commonly observed mutation is a 1.02 Kb deletion in the genomic DNA. This deletion results in a truncated protein of 24KDa in size. This is due to the loss of amino acids 154-438, and the introduction of 28 novel amino acids at the carboxyl end. We demonstrate that compared to normal controls, CLN3 deficient lymphoblasts homozygous for this common deletion grow slower and show increased sensitivity to etoposide-induced apoptosis, supporting the notion that CLN3 may negatively regulate apoptosis. Using these JNCL lymphoblasts as a model system, we assess the effects of specific CLN3 mutations on cell growth and protection from etoposide-induced apoptosis. Protection from etoposide-induced apoptosis occurs and the observed growth deficiency is corrected, following transfection of these JNCL lymphoblasts with mutant CLN3 cDNA that includes exons 11 or 13. We show that deletion of the conserved region 184WSSGTGGAGLLG195, creates a growth phenotype similar to the JNCL patient cells. However, individual mutations within this region do not by themselves create diminished growth. We also show that mutations within glycosylation sites 71NQSH74 and 310NTSL313 and within the highly conserved amino acid stretches 291VYFAE295 and 330VFASRSSL337, result in slowed growth and susceptibility to apoptosis. These findings suggest that 1) glycosylation at the above two sites affects the impact of CLN3 on cell growth and apoptosis; and 2) the highly conserved stretches VYFAE and VFASRSSL may represent motifs essential for preserving the positive effect of CLN3 on cell growth and the negative regulation of apoptosis. This information may aid in the design of drugs or therapies for JNCL.

Negative Regulation of Tyrosine Hydroxylase Expression by the Tumor Suppressor PTEN. *J.M. Roberts¹, S.A. Moussatov², M. Sugiultzoglul¹, M.G. Kaplitt^{1,2}.* 1) Neurosurgery, Weill Med Col, Cornell Univ, New York, NY; 2) Lab. of Neurobiology and Behavior, The Rockefeller Univ., New York, NY.

PTEN is a tumor suppressor gene which is frequently mutated in a variety of cancers including high grade gliomas. Although wild-type PTEN is known to modulate cellular responses to growth factors by opposing the ERK/MAPK and PI3K/Akt pathways, its function in regulating gene expression is far less understood, particularly in non-neoplastic cells. While studying potential effects of PTEN on neuronal signal transduction, we unexpectedly discovered tyrosine hydroxylase (TH) expression to be profoundly down-regulated. PC12 cells are a rat pheochromocytoma line which has been widely used to study expression of neuronal genes, including TH, which is the rate-limiting enzyme in the synthesis of dopamine. As analyzed by western blot, stable PTEN overexpression in PC12 cells reduced TH protein levels by at least 20 fold. Not only was this effect consistent among several independent clonal isolates, it also appeared to be specific for TH expression, since several other house-keeping genes tested were not affected. In comparison to control cells, PTEN over-expressing cells revealed approximately a 100-fold decrease in TH mRNA as determined by quantitative PCR. This suggests that PTEN elicits its effects on TH protein expression mostly by modulating mRNA levels. We are currently conducting studies to identify potential elements in the rat TH promoter which may mediate this effect in PTEN-overexpressing cells. By affecting dopamine synthesis in neurons, this tumor suppressor may also serve to modulate neurotransmission. Thus, our findings suggest that the role of PTEN is more complex than has been previously believed.

Program Nr: 871 from 2002 ASHG Annual Meeting

Alternative transcripts of human brain-specific genes *MOB* and *CPLX 2*. *N.M. Raevskaya, I.P. Vladychenskaya, L.V. Dergunova, S.A. Limborska.* Human Molecular Genetics Dept, Inst. of Molecular Genetics, Moscow, Russian Federation.

Working on the project of the human brain-specific genes investigation we have obtained new in vitro and in silico data on structure and function of the human genes *MOB* and *CPLX 2*. Novel human brain-specific gene *MOB* coding the hypothetical transmembrane protein and located on the human chromosome 10 was demonstrated to span more than 219 kb. BLAST analysis supported by the results of RT-PCR has shown at least 11 exons and 10 introns to represent the genomic structure of *MOB* gene. Two alternatively spliced mRNA transcripts differing in their 5'-ends and possessing the same 3'-end were recognized in the human cerebellum mRNA samples. The length of the shorter transcript is estimated of 3,2 kb; 5'-end for this transcript is detected by means of RACE PCR. In *CPLX 2* gene, BLAST analysis has proposed the existence of an additional exon located within the intron 2 sequence at the distance of about 7 kb from the exon III. The resulting alternative transcript is thought to differ with its 5'-end from that for the previously described transcript. Alternative transcripts of the human complexin 2 gene differing with their 5'-ends encode the same protein product. We confirmed the existence of the predicted transcript using RT-PCR technique.

Gene Expression in Rhesus Monkey Brain. *B. Su*^{1,2}, *Y. Li*¹, *Y. Ma*³, *X. Zhang*³, *W. Huang*⁴, *L. Jin*^{2,4}. 1) 1.Key Laboratory of Cellular and Molecular Evolution, Kunming Institute of Zoology, the Chinese Academy of Sciences, Kunming, China; 2) 2.Center for Genome Information, Department of Environmental Health, University of Cincinnati, USA; 3) 3.Department of Neuroscience, Kunming Institute of Zoology, the Chinese Academy of Sciences, Kunming, China; 4) 4.National Genome Center at Shanghai, China.

Brain enlargement with improved cognitive skills is the most significant change during primate evolution and origin of our own species. It is widely believed that the prefrontal cortex (PFC) is the region in primate brains responsible for complex cognitive skills. In this study, we constructed a cDNA library from the PFC of a male rhesus monkey brain. The cDNA library contains about one million cDNA clones with insert size ranging from 500bp to 2kb. Our preliminary screening of sequencing 2,000 cDNA clones identified about 150 genes expressed in the rhesus monkey PFC with most of them also expressed in human brain according to previous studies, suggesting similar set of genes expressed both in human and rhesus monkey brains. The sequence similarity of the genes ranges from 90% to 97% between human and rhesus monkey confirming the suggested coding region sequence divergence between these two species.

Program Nr: 873 from 2002 ASHG Annual Meeting

The Induced Mutant Resource: New tools for neurological research. *S.F. Rockwood, L.E. Mobraaten, M.T. Davisson.* Induced Mutant Resource, Jackson Laboratory, Bar Harbor, ME.

Transgenic and targeted mutant mice have proven to be useful in a wide variety of neurological research applications. The Induced Mutant Resource (IMR) at The Jackson Laboratory was formed in 1992 to serve as a centralized facility for the collection and distribution of induced mutant mice to the scientific community. The IMR distributes a wider variety of induced mutants than any other repository, with neurological mutants representing approximately 20% of available stocks. Neurological mutants fall into one or more of four categories. *Basic Mutations* that don't represent specific disease models, but are useful in delineating the biological role of specific genes, represent the bulk of the IMR's neurological mutant collection. *Disease Models* that recapitulate aspects of Alzheimer's, Huntington's, Parkinson's and other diseases provide useful tools for the study of underlying causes and designing therapeutic strategies. *Cre Expressing* strains that utilize nestin or Purkinje cell protein 2 promoters are useful for generating tissue-specific deletion mutants. *Neuronal Imaging* mutants express a variety of fluorescent proteins allowing visualization of various neuronal subsets. Since its inception, the IMR has accepted over 870 different induced mutant mouse strains and distributes over 100,000 mice annually to the scientific community. Current growth in the IMR collection is approximately 60 new strains each year. Each strain accepted into the IMR is cryopreserved (sperm or embryo) to protect against accidental loss and genetic contamination. An online resource allows researchers to retrieve information related to phenotype, strain construction, husbandry and relevant citations. Researchers wishing to submit mutant strains for consideration in the IMR may use the form available at the IMR web site. The IMR database can be accessed at URL: <http://www.jax.org/resources/documents/imr/>.

The Induced Mutant Resource is supported by the National Center for Research Resources (RR09781/RR11081), National Institute for Allergy and Infectious Disease and The Howard Hughes Medical Institute.

PHR1 protein-protein interactions in retina and brain. *S. Xu, D. Valle.* Howard Hughes Medical Institute, Inst Genetic Medicine, Johns Hopkins Univ, Baltimore, MD.

PHR1 is a PH domain containing integral membrane protein predominantly expressed in primary sensory neurons, including photoreceptors, olfactory receptor neurons and the cochlear and vestibular hair cells (1). Using alternative promoters and alternative splicing, PHR1 encodes four isoforms: isoform 1 predominates in photoreceptors; isoform 4 in brain. Stimulated by this intriguing expression pattern, we produced a mouse lacking *Phr1* but found no obvious phenotype. We therefore turned to a yeast two-hybrid analysis, using PHR1 isoform 1 and isoform 4 as baits, to screen bovine retinal and human brain cDNA libraries, respectively. We found that PHR1 isoform 1 interacts specifically with itself and with carboxypeptidase E (CPE), while PHR1 isoform 4 interacts with the C-terminal, proline-rich region (PPr) of brain specific RGS9-2 (Regulator of G-protein Signaling 9-2). The latter agrees with the observation of Jones et al, who found PHR1 isoform 4 as an interactor with RGS9-2 bait (personal communication). To confirm these interactions, we co-expressed epitope-tagged versions of the interacting proteins in human HEK293 cells and used co-immunoprecipitation to detect interactions. We were able to confirm the self-interaction of the PHR1 isoform and the interactions of the appropriate PHR1 isoform with CPE and RGS9-2. Surprisingly, we also found interactions between PHR1 and its paralog, PHR2, raising a possibility that PHR1 and PHR2 form heterooligomers in certain cells. Our results define a system of *Phr1* interactors in neural cells and suggest additional studies to elucidate the function of PHR1. (1) Xu S, et al. PHR1 encodes an abundant, pleckstrin homology domain-containing integral membrane protein in the photoreceptor outer segments. *JBC* 1999 Dec 10;274(50):35676-85.

Detection of a large number of specific mRNA species in very few glial cells. *G. Yue¹, H. Wang¹, M. Luo¹, D. Frikker¹, K. Yin², J. Neubauer³, H. Li¹.* 1) Mol Gen & Microbio, CINJ-UMDNJ-RWJMS, New Brunswick, NJ; 2) Dept Cell Bio, UMDNJ-SOM, Stratford, NJ; 3) Dept Med, UMDNJ-RWJMS, New Brunswick, NJ.

Examining gene expression globally in single or very few cells in CNS is highly desired. The present study was designed to detect a panel of 58 mRNA species with a two-round RT-PCR/PCR protocol in few cells. 58 mRNA sequences relevant to hypothalamus function in the public database were selected for this study. Primers were designed for multiplex RT-PCR of the 58 mRNAs. Each primer pair was designed to flank a large intron sequence in the corresponding gene. If no intron information was available in the database for the rat, positions were based on available information of highly related genes in other evolutionarily closely related species. In this way, amplified products from mRNAs and from genomic DNA can be discriminated. Eight cells from a tumor cell line, C6 derived from rat brain glial cells, were used as starting material. RT-PCR was performed in the presence of the 58 primer pairs. Aliquots from the RT-PCR products were re-amplified separately with single primer pairs for each mRNA. In control reactions, each primer pair was used to amplify their target sequences in rat genomic DNA without reverse transcription. Single bands were detected with 19 (33%) pairs of primers while no comparable bands were detected in the controls indicating that these pairs of primers may have had their sequences separated by large introns in the rat genome. Amplification was detected in the RT-PCR products and the respective controls for 12 (21%) pairs of primers indicating that these primers may have had their sequences located in the same exons. No visible bands were detected from the amplification of both RT-PCR and respective controls with 21 (36%) primer pairs. It is likely that the sequences of these pairs flank large introns and these genes were not expressed at a detectable level or not expressed. Our results show that it is possible to analyze a large number of specific mRNA species in very few cells. The approach could be very useful for understanding the molecular mechanisms underlying the function of very few specialized cells in CNS.

Direct interaction between the Breast Cancer Tumor Suppressor Protein, BRCA1, and the Fanconi Anemia protein, FANCA. *A. Folias¹, M. Matkovic¹, D. Bruun¹, S. Reid¹, J. Hejna¹, M. Grompe^{1,2}, A. D'Andrea³, R. Moses¹.* 1) Dept. of Molecular and Medical Genetics, Oregon Health & Science University, Portland, OR; 2) Dept. of Pediatrics, Oregon Health & Science University, Portland, OR; 3) Dept. of Pediatric Oncology, Dana-Farber Cancer Institute and Dept. of Pediatrics, Childrens Hospital, Harvard Medical School, Boston, MA.

Fanconi anemia (FA) is a rare autosomal recessive disease characterized by skeletal defects, anemia, chromosomal instability and increased risk of leukemia. At the cellular level FA is characterized by increased sensitivity to agents that form interstrand crosslinks(ICL) in DNA. Six FA genes have been cloned and interactions among individual FANC proteins have been found. The FANCD2 protein co-localizes in nuclear foci with the BRCA1 protein following DNA damage and during S-phase, requiring the FANC A, C, E, and G proteins to do so. This finding may implicate the BRCA1 protein in DNA interstrand crosslink repair. Therefore, interactions between BRCA1 and the FANC proteins were investigated. Among the known FANC proteins, we find evidence for direct interaction only between FANCA and BRCA1. The evidence rests on three different techniques: yeast two-hybrid analysis, coimmunoprecipitation from in vitro synthesis, and coimmunoprecipitation from cell extracts. The interaction does not depend on DNA damage, thus FANCA and BRCA1 are constitutively interacting. The demonstrated interaction directly connects BRCA1 to the FA pathway of DNA ICL repair.

Tuberin Regulates Rho Activation, Cell Adhesion, and Cell Migration. A. Astrinidis¹, T. Cash¹, D. Hunter², C. Walker², J. Chernoff¹, E.P. Henske¹. 1) Dept. Medical Oncology, Fox Chase Cancer Ctr, Philadelphia, PA; 2) MD Anderson Cancer Ctr, University of Texas, Smithville, TX.

Tuberous sclerosis complex is a tumor suppressor gene syndrome characterized by benign tumors, seizures and mental retardation. Tuberin, the *TSC2* product, has a region of homology with Rap1GAP, and has been linked to cell cycle regulation, endocytosis, and steroid hormone function. Hamartin, the *TSC1* product, interacts with the ezrin-radixin-moesin cytoskeletal proteins, activates Rho, and promotes stress fiber formation. Hamartin and tuberin interact in vivo. Here we report that tuberin regulates cell adhesion, cell migration, and activation of Rho.

ELT3 cells, lacking endogenous tuberin, and MDCK cells, were transduced with a retroviral construct containing human *TSC2* cDNA. Tuberin expressing stable clones were selected in G418. Stable vector clones were used as controls in subsequent experiments. Tuberin-overexpressing ELT3 and MDCK cells exhibited increased attachment by 1.5-2 fold. The chemotactic migration of tuberin-expressing ELT3 cells was reduced by 60%. To define the biochemical pathways linking cell adhesion and migration with tuberin overexpression, Rho activation was assayed by Rhotekin pulldown. A 2-3 fold activation of Rho was present in MDCK and ELT3 cells overexpressing tuberin. Focal Adhesion Kinase (FAK), which is a downstream target of Rho, had increased phosphorylation by 2-4 fold in tuberin-overexpressing MDCK cells, and the total amount of FAK was decreased.

In conclusion, we demonstrate, for the first time, that tuberin expression increases cell adhesiveness and decreases cell migration. These changes are associated with increase in GTP-Rho and the phosphorylated fraction of FAK. These findings may have relevance to the pathogenesis of pulmonary LAM in patients with *TSC2* mutations.

Cloning and characterization of two novel human transcripts at the 9p12-p13 chromosomal region. *I. Eisenberg¹, M. Barash¹, H. Hochner¹, T. Kahan², T. Levi³, S. Mitrani-Rosenbaum¹.* 1) Molecular Biology, Hadassah Hospital, The Hebrew University-Hadassah Medical School, Jerusalem, Israel; 2) Bioinformatics Unit, The Hebrew University-Hadassah Medical School, Jerusalem, Israel; 3) Department of Genetics, Harvard Medical School, Boston, USA.

As part of the positional cloning strategy towards the successful identification of the gene causing Hereditary Inclusion Body Myopathy (HIBM, OMIM 600737) we have previously established a high throughput physical and transcriptional map spanning about 1Mb at the 9p12-p13 chromosomal region. Many studies have shown that multiple regions across the short arm of human chromosome 9 and in particular the region 9p12-p13 are functionally involved in a large number of common diseases such as lung cancer, hepatocellular carcinoma, papillary renal cell carcinoma, squamous cell head and neck cancer, bladder transitional cell carcinomas, melanoma, acute lymphoblastic leukemia, prostate cancer as well as in several rare diseases. Among the 25 distinct transcripts we mapped, 8 were previously characterized genes and 17 were ESTs of unknown function. Further analysis of two of these transcripts led to the identification and characterization of two novel genes. The first, C9orf19, encodes a conserved putative protein of 154 amino acids with an SCP-like extracellular protein domain. Its mRNA consists of 1.9kb widely expressed in adult tissues, most abundantly in lung and leukocytes. To gain insight into the biological function of C9orf19 gene, the putative protein was further analyzed for homologies and functional motifs. The second gene identified, RNF38 (RING finger protein 38), is a new member of the RING finger protein family. The complete mRNA consists of 6.8kb widely expressed in human tissues as a single transcript, most abundantly in testis. The predicted proline-rich protein consists of 432 amino acid residues with a coiled-coil motif, KIL motif and a RING-H2 motif at its carboxy-terminus. Further studies will determine the functional significance and biological role of these genes, which could be involved in one of the numerous human malignancies and other various diseases located in the p12-p13 segment of chromosome 9.

Understanding the Endothelial Function of Utrophin. *J.T. Ehmsen, A. Weir, K.E. Davies.* Functional Genetics Unit, Department of Human Anatomy and Genetics, University of Oxford, Oxford, England.

The critical role of the membrane-associated dystrophin-glycoprotein complex (DGC) in muscle is underscored by the large number of muscular dystrophies associated with mutations in its distinct protein components. Clinical and molecular correlations have helped identify the canonical members of the DGC in striated muscle, including dystrophin, the dystroglycans, sarcoglycans, dystrobrevins, syntrophins and sarcospan, and implicate a dual role in signaling and structural maintenance. Dystrophin-dystroglycan complexes are distributed in a number of nonmuscle cells as well, showing small variations on a theme in terms of associated proteins or isoform identities. Undertaking a survey of tissue-specific expression patterns of the two known utrophin isoforms, we have recently found that utrophin B is present exclusively in capillary endothelia. Vascular endothelia experience constant changes in hemodynamic stress and likely demand suitable protection against injury from repeated cycles of contraction and relaxation, yet must remain flexible enough to sustain a dynamic response. A utrophin-associated protein complex could participate in achieving this compromise. We are searching for the presence of other known dystrophin-associated proteins in endothelia using Western analysis, immunofluorescence, coimmunoprecipitation and yeast two-hybrid analyses to characterize specific interactions and to define potentially unknown binding partners of utrophin B. Dystrobrevin, syntrophin, and e-sarcoglycan have already been detected in endothelial cells, forming a group of candidate binding partners for endothelial utrophin B in at least some tissues. A closer examination of any subtle vascular defects in utrophin-deficient mice may also enhance our understanding of utrophin's endothelial function.

Mutations in the HERG ion channel: A novel link between long QT syndrome and sudden infant death syndrome. *M. Christiansen¹, N. Tonder², L.A. Larsen³, P.S. Andersen¹, H. Simonsen¹, N. Oyen⁴, J.K. Kanter⁵, J.R. Jacobsen⁶, I. Fosdal⁷, G. Wettrell⁸, K. Kjeldsen⁹.* 1) Dept Clinical Biochemistry, Statens Serum Inst, Copenhagen, Denmark; 2) Dept Internal Medicine, Hillerd Hospital, Hillerd, Denmark; 3) The Wilhelm Johanssen Centre for Functional Genome Research, Dept of Medical Genetics, Univ Copenhagen, Copenhagen, Denmark; 4) Dept of Clinical Genetics, Haukeland Hospital, Bergen, Norway; 5) Dept of Cardiology P, Gentofte University Hospital, Gentofte, Denmark; 6) Dept of Pediatrics, Rigshospitalet, Copenhagen, Denmark; 7) Dept of Pediatrics, Visby Hospital, Visby, Sweden; 8) Dept of Pediatrics, University of Lund, Lund, Sweden; 9) Medical Dept B, The Heart Centre, Rigshospitalet, Copenhagen, Denmark.

Sudden infant death syndrome (SIDS) remains - despite a dramatic decrease in prevalence during the last 15 years caused by the introduction of supine sleeping - the most important cause of death in children below 1 year of age. Prolonged cardiac repolarization, i.e. increased QT-time on the electrocardiogram, is a risk factor for SIDS. This has raised the interest for the role of congenital long QT syndrome in babies dying from SIDS. In a SIDS baby we identified a mutation, K101E, in the gene *KCNH2*, encoding the HERG potassium channel alpha-subunit. The mutation was - later - found associated with prolonged QT-time and the presence of torsade de pointes arrhythmia - a characteristic of long QT syndrome - in family members. Reduced HERG function, as may be seen in hypokalemia, drug-induced or sympathetic stimulation may be a common mechanism of arrhythmic death in children. A SIDS diagnosis should only be made after a careful genetic examination for mutations in LQTS associated genes. A screening of DNA from 120 SIDS patients for the mutation did not find more cases. Likewise no pore-associated mutations were found. Thus, classical Romano-Ward syndrome does not seem to play a major role in SIDS.

Identification of a Novel Alternatively Spliced isoform of human Fibulin-2 Gene Abundantly Expressed in Heart and Genetic Evaluation in Patients with ARVD. *D. Li, A.J. Marian, R. Roberts.* Dept Medicine/Cardiology, Baylor Col Medicine, Houston, TX.

We recently mapped a locus responsible for Arrhythmogenic Right Ventricular Dysplasia (ARVD) to 3p23. The disease is associated with apoptosis and fibrosis in the right ventricle and high incidence of arrhythmia and sudden death and is inherited as autosomal dominant. One of the genes mapped within the 8 cM region is fibulin 2. Fibulin-2 belongs to an emerging family of extracellular matrix proteins with a unique amino terminal extension as compared to other fibulins. Fibulin-2 is ubiquitously expressed in human tissues including the heart. To detect mutations such as those in splice junctions, it was necessary to determine the genomic structure of the gene. Analysis of the cDNA from human heart and other tissues by RT-PCR, showed two distinct bands differing by 140 base pairs. The sequence of the smaller band, identical to the previously reported cDNA, had ubiquitous expression in human tissues. The larger band with additional 140 base pairs had restricted expression with abundance in the heart, moderate in skeletal muscle and pancreas and a trace in the liver. Comparison of fibulin-2 cDNA sequence, with its genomic counterpart sequence, identified 17 exons. The larger band had an additional exon which in the genomic sequence was exon 9. Exon 9 had been spliced out of the smaller form. The predicted amino acid sequence encoded by exon 9 of human fibulin-2 is highly conserved across species with 95% identity to that of mouse fibulin-2. A complete exon-intron organization was derived and all exons and their flanking introns amplified and sequenced from patients DNA. Several polymorphisms were detected, but no disease-causing mutation responsible for ARVD was identified. Thus, there are two alternatively spliced transcripts of the fibulin-2 gene, one with 4,139 bp ubiquitously expressed in human tissues and another with 4,280 bp with restricted tissue expression but abundantly expressed in the heart. While the function of fibulin-2 remains to be defined, the distinct tissue expression of the two forms should accelerate further clinical and functional investigation.

Fang-1, Which Can Increase Expression of IRS1, is a Candidate Gene for Diabetes Mellitus. *Y. Chang, J. Zuo, Y. Li, F. Fang.* Department of Molecular Biology and Biochemistry, Institute of Basic Medical Science, Peking Union Medical College & Chinese Academy of Medical Sciences, 5 Dong Dan San Tiao, Beijing, P.R.China.

A novel gene, which is related to blood-glucose regulation and is named as Fang-1, was cloned by messenger RNA differential display. First, the blood glucose regulation model of rat was build with jugular vein right atrium intubations. One differentially expressed fragment was proved by slot blot and Northern blot analysis, and then full-length cDNA was cloned by screening the muscle cDNA library of rat, which has homologue in human. After transfecting Fang-1 into L-6TG cells, we found Fang-1 was localized in cytoplasm and cell nucleus. Overexpression of Fang-1 in CBRH7919 can up-regulate the expression of IRS1, the key factor related to glucose metabolism. Since Fang-1 itself was up-regulated after glucose stimulation *in vivo*, and it can also up-regulate the expression of IRS1, we propose that Fang-1 might be a novel candidate gene for diabetes mellitus and helpful to clarify the mechanism of diabetes mellitus.

Proteolytic inactivation of DNA ligase III during apoptosis converts the base excision DNA repair pathway into a cell-killing machine. *L. Bordone*², *C. Campbell*¹. 1) University of Minnesota, Dept. Pharmacology, Medical School, 321 Church St. SE Minneapolis, MN 55455; 2) MIT, Department of Biology, Cambridge MA.

Exposure of cells to anti-Fas monoclonal antibody (Fas) results in the proteolytic cleavage of DNA ligase III (Lig3). Lig3 participates in the base excision repair (BER) pathway, sealing nicks produced during the repair reaction. Loss of Lig3 would lead to the accumulation of chromosome single-strand breaks, which we hypothesized could contribute to the cell death induced by Fas. We further proposed that this DNA damage could contribute to the cell death observed following exposure of cells to Fas. We performed a series of experiments to test this hypothesis. We created cells that expressed protease-sensitive or protease-resistant alleles of Lig3 and found that while 73% of cells overexpressing a protease-sensitive allele died following exposure to Fas, cells overexpressing the protease-resistant allele were completely protected. We also used pharmacologic and genetic approaches to determine if blocking the BER pathway upstream of the introduction of nicks into the DNA phosphodiester backbone would protect cells from Fas-induced death. We found that 90% of cells pretreated with methoxyamine (MX), an inhibitor of APE1, the enzyme that introduces nicks into the DNA phosphodiester backbone during BER, survived treatment with Fas. In contrast, only 72% of cells that were not treated with MX prior to Fas exposure survived. We also found that 90% of cells transfected with antisense APE1 survived treatment with Fas, compared to 75% of control cells. These data are consistent with the hypothesis that Fas-mediated degradation of Lig3 converts the BER pathway from a cell protector that repairs DNA damage, to a cell-killer that generates DNA damage. We propose that the DNA single-strand breaks that accumulate in cells in which Lig3 has been degraded contribute to the death that follows exposure of cells to Fas. We have generated additional data indicating that inhibition of BER in this manner also occurs in cells subjected to serum starvation, suggesting that this may represent a common mechanism through which cells ensure efficient death in response to a variety of apoptotic stimuli.

Genomic Organization and Characterization of the Human ATX1 Homologue Involved in Copper Homeostasis.

P.-C. Liu, S.G. Kaler. Unit on Pediatric Genetics, Laboratory of Clinical Genomics, NICHD/NIH, Bethesda, MD.

Copper is an essential trace element that plays a critical role in the biochemistry of iron homeostasis, cellular respiration, antioxidant defense, neurotransmitter biosynthesis, connective tissue biosynthesis and pigment formation and is needed for the survival of all living organisms. Menkes disease and Wilson disease are inherited disorders of copper transport caused by mutations in copper ATPase genes *ATP7A* and *ATP7B*, respectively. Molecular genetic studies of these disorders have provided opportunities to better understand the mechanisms of cellular copper metabolism. In addition, studies in yeast have revealed a family of cytoplasmic proteins termed copper chaperones that bind copper ions and deliver them to specific cellular pathways. Biochemical studies of the copper chaperone *Atox1* showed interaction between this protein and the Menkes and Wilson disease copper transporters. While no disease-associated mutations have been reported in the human homolog of *Atox1*, mice with disruption of the murine homolog demonstrated perinatal mortality similar to that observed in the *brindled* mice (*Mo^{br}*), a mouse model of classical Menkes disease. In this study, we characterized the genomic structure of the *Atox1* human homolog. We identified 4 exons within a genomic distance of approximately 14 kb. The *Atox1* start codon is located in the 3' end of exon 1 and the termination codon is in exon 3. Characterization of the genomic structure of the *Atox1* human homolog will facilitate screening of this gene using genomic DNA, particularly appropriate in patients with Menkes or Wilson disease phenotypes who do not have molecular alterations in *ATP7A* or *ATP7B*.

Genetic basis for non-syndromic and syndromic, Blepharophimosis/Ptosis and Epicantus Inversus Syndrome

(BPES)-associated Premature Ovarian Failure (POF). *L. Crisponi¹, M. Uda^{1,9}, F. Chiappe², M. Deiana¹, G.L. Usala¹, M. Marongiu¹, P. Amati³, D. Bonneau³, F. Faravelli⁴, J. Tolmie⁵, L. Bisceglia⁶, M.R. Piemontese⁶, L. Zelante⁶, P. Gasparini⁶, G. Crisponi², L. Boccone², A. Iolascon⁷, A. Percesepe⁸, A. Forabosco⁸, G. Pilia¹ and FOXL2 study group.* 1) Inst Ric Talass Anemie Medit, Cons Nazion delle Ricerche, Cagliari, Italy; 2) University of Cagliari, Cagliari, Italy; 3) Service de Genetique Medicale, Poitiers, France; 4) Ospedale Galliera, Genova, Italy; 5) Duncan Guthrie Ins. Med. Genet., Glasgow, UK; 6) IRCCS, San Giovanni Rotondo, Italy; 7) University of Bari, Italy; 8) University of Modena, Italy,; 9) NIA, NIH, USA.

In Type I BPES (MIM110100) eyelid abnormalities are associated with Ovarian Failure leading to Female Infertility. We have recently cloned a winged helix/forkhead transcription factor gene, FOXL2, mutated in BPES. We report here a FOXL2 mutation screening on 43 BPES and 71 POF patients. Nonsense and frameshift mutations were identified on all 13 type I BPES families analyzed. Milder mutations were found in 9 out of 13 type II BPES patients with a typical hypomorphyc phenotype. We detected 9 FOXL2 mutations in 17 patients whose clinical type could not be determined. The 12 families with no apparent mutation could harbor either lesions outside the FOXL2 gene or mutations in another gene. In two such families linkage analysis excluded the involvement of the region containing FOXL2 in the pathogenesis. Mutations in the TWIST gene, involved in Saethre-Chotzen Syndrome (MIM101400) in which craniosynostosis is often associated with eyelid anomalies, have not been detected in any of the FOXL2 negative families. A possible role of FOXL2 in non-syndromic Female Infertility has been tested in 71 females with idiopathic POF. We analyzed the entire coding region, proximal promoter, 5UTR, and 3UTR. We have identified a missense, a promoter, a 5UTR and 3 different 3UTR mutations. The role of these mutations in the pathogenesis of this common disorder is currently under investigation with two complementary approaches: genetic (association studies) and functional analysis on the gene and its product.

Toward Temporal and Spatial Control of Retinal Gene Expression. *S.H. Tsang¹, M.L. Woodruff¹, M. Jiang¹, G. Fain¹, C.S. Lin², S.P. Goff², D.B. Farber¹.* 1) Jules Stein Eye Inst, UCLA Sch of Med, Los Angeles, CA; 2) Columbia U., New York, NY.

Purpose: The *Pdeg^{tm1}/Pdeg^{tm1}*, mutant mouse (carrying a targeted deletion of the gene encoding PDEg, *Pdeg*) lacks PDE activity and undergoes rapid retinal degeneration. An interaction between the inhibitory PDEg and catalytic PDEab subunits may be critical for the proper folding, conformation or stabilization of the PDE enzyme complex.

Unfortunately, the maldeveloped and truncated outer segments of the *Pdeg^{tm1}/Pdeg^{tm1}* mouse prohibit their use in biochemical studies. A fully developed photoreceptor that lacks PDEg will allow us to test if PDEg has a positive role in the formation of an active PDE complex. We will develop an inducible gene expression system that will make possible to delete or activate genes in an adult mouse. **Methods:** Fluorescence microscopy was used to monitor floxed-Pdeg--IRES-EGFP expression in the retina of mice carrying a modified allele of the PDEg gene (*Pdeg*). EGFP expression in single rods was detected in the suction electrode after stimulation at 488 nm. **Results:** Transgenic mouse lines were established using embryonic stem cells carrying a Pdeg floxed allele with an IRES-EGFP cassette introduced into its 3' end. To test the expression of this construct in 293T cells, in vitro, a CMV promoter was placed at its 5' end. EGFP fluorescence was detected after transfection. The floxed-Pdeg-IRES-EGFP cassette (without the CMV promoter) was then introduced into the mouse germline. Sections of retinas from the resulting mice showed that EGFP was specifically expressed in photoreceptor cells. In vivo, Cre-mediated site-specific recombination should result in loss of both *Pdeg* and EGFP expression. **Conclusion:** We have successfully used EGFP as a reporter for the expression of PDEg. The lines of floxed mice that we have generated will be utilized to monitor Cre-mediated recombination in photoreceptors. An inducible gene targeting system may allow us to address several previously unapproachable problems in sensory biology.

Growth hormone expression on mRNA level is significantly reduced in the brain of *Ndp*-knockout-mice. U.

Luhmann^{1,2,3}, S. Lenzner¹, S. Prietz¹, J. Landgrebe⁴, B. Lipkowitz¹, H.H. Ropers¹, W. Berger^{1,3}. 1) Max Planck Institute for Molecular Genetics, Berlin, Germany; 2) Free University Berlin, Berlin, Germany; 3) Present Address: Institute of Medical Genetics, University of Zurich, Switzerland; 4) Max Planck Institute of Psychiatry, Munich, Germany.

Norrie disease (ND, OMIM # 31060) is a rare X-linked recessive neurological syndrome characterized by congenital blindness, progressive deafness and mental retardation. It is caused by mutations in the *Ndp* gene (Norrie disease, pseudoglioma). Mutations in this genes were also observed in patients with exudative vitreoretinopathy, Coats disease and retinopathy of prematurity. The *Ndp* gene in mouse is expressed in the retina, the chochlea, the olfactory bulb and the Purkinje cell layer of the cerebellum. *Ndp* codes for a small extracellular protein of unknown function containing a cystine knot motif characteristic for several growth factors, including transforming growth factor beta. The expression pattern of *Ndp* in the eye and the ear corresponds to the progressive and degenerative morphological changes in these organs in the knockout mice. So far, no morphological alterations were described in the brain of knockout animals. To search for transcriptional changes in the brain of knockout mice we performed gene expression profiling by cDNA-microarrays. By comparative hybridisation of total brain RNA from one year old wildtype and knockout mice to a brain specific cDNA-microarray we identified several differentially expressed genes and confirmed differential expression of the Growth hormone (*mGH*) mRNA on Northern Blots and by RT-PCR. Using RNA from wildtype and *Ndp* knockout mice of different ages (P14, P21, P28, 3 month, 6 month and 1 year) we now show that the growth hormone mRNA expression is increased at P14 in *Ndp* knockout mice compared to wildtype, while it decreases from P21 onwards. Therefore, there seems to be a switch in GH expression in the brain between P14 and P21, the time when *Ndp* expression is enhanced. These findings suggest that there might be a relationship between the partially overlapping *Ndp* and the *mGH* expression in the brain. The *Ndp* mouse model may help to characterize this tissue-specific effect.

Analysis of histone H1 subtype associations with the Barr body. *W.H. Brooks¹, B. Hong¹, M.H. Parseghian⁵, B.A. Hamkalo⁴, T.P. Yang^{1,2,3}.* 1) Biochem & Molec Biology, Univ Florida, Gainesville, FL; 2) Center for Mammalian Genetics, Univ Florida, Gainesville, FL; 3) Division of Pediatric Genetics, Univ Florida, Gainesville, FL; 4) Molec Biology & Biochem, Univ California, Irvine, CA; 5) Peregrine Pharmaceuticals, Tustin, CA.

One of the two X chromosomes in each female mammalian somatic cell is transcriptionally inactivated to achieve dosage compensation between male and female cells for most X-linked genes. The resulting inactive X chromosome forms the late-replicating heterochromatic Barr body seen in female somatic cell nuclei at interphase. The molecular composition and structure of the Barr body are largely unknown with few molecular components currently identified. The linker histone H1, consisting of at least 8 subtypes in mammals, has been associated with the formation of higher order chromatin structure, chromatin condensation, and transcriptional silencing. Each of the H1 subtypes is encoded by a different gene and all show different expression patterns and cell type distributions. Using affinity-purified polyclonal subtype-specific antibodies and detection by indirect immunofluorescence, we have examined the association of three H1 subtypes with the Barr body. We find subtypes H^S-1, H^S-2, and H^S-3 are preferentially localized to the Barr body in human female fibroblasts. The accumulation of these histone H1 subtypes in the Barr body, along with the reported depletion of subtype H^S-2 in active chromatin, suggests a role for histone H1 in the structure, maintenance, and/or function of the Barr body in female nuclei.

Evolutionary analysis of a cluster of ATP-binding cassette (ABC) genes reveals multiple gene duplication, gene deletion and gene conversion events. *T. Annilo*¹, *Z.-Q. Chen*², *S. Shulenin*¹, *M. Dean*¹. 1) Human Genetics Section, Laboratory of Genomic Diversity, NCI-Frederick, MD 21702; 2) Intramural Research and Support Program, SAIC-Frederick, MD 21702.

The proteins of the ATP-binding cassette (ABC) superfamily utilize the energy of ATP hydrolysis to transport a wide variety of molecules across different cellular membranes. In humans, current annotation classifies 48 ABC proteins into seven subfamilies. While most of the ABC genes are dispersed in the mammalian genome, five ABCA subfamily genes (*ABCA5*, *ABCA6* and *ABCA8-10*) form a unique cluster on human chromosome 17q24. To investigate the evolutionary history of ABC transporters, we characterized the structure and expression pattern of the genes at the mouse conserved syntenic locus. Phylogenetic and comparative sequence analysis reveals that after the divergence of rodent and primate lineages, at least one gene has been lost in each genome. In addition, we found that both mouse and human clusters show evidence of a number of gene conversions, in several cases involving intron sequences. Analysis of exon-intron structures indicates that splice sites are more conserved than exon sizes and only those nucleotide insertions and deletions that do not disrupt the open reading frame within the established splicing pattern have been fixed in the course of evolution. Similarity of both the genomic organization and primary structure among the genes in this cluster suggests that the duplications generating the cluster occurred relatively recently compared to most of the ABC genes in the present-day mammalian genomes. For instance, the *Fugu rubripes* genome contains an ortholog of *ABCA5*, but not of any other member of the ABCA cluster. This also supports the hypothesis that *ABCA5* has been a founder gene of that cluster.

Expression of the gene for progressive ankylosis (ANK) during insulin-induced chondrogenesis in ATDC5 cells.

R. Zaka, G. Bonavita, S. Piera-Velazquez, C.J. Williams. Medicine, Thomas Jefferson University, Philadelphia , PA.

ANK codes for a transmembrane protein that appears to regulate intra- and extracellular levels of inorganic pyrophosphate. Missense mutations in ANKH, the human homologue of ANK, have been reported by us and others in the autosomal dominant arthropathy known as calcium pyrophosphate dihydrate deposition disease. To ultimately understand the impact of mutations in ANK on its function in chondrocytes and articular cartilage, we have chosen to use the ATDC5 cell line as a chondrogenic model system. ATDC5 is a clonal murine cell line established from a differentiated culture of embryonic cell-derived AT805 cells. When cultured in the presence of insulin, the cells undergo a program of chondrogenesis that includes the induction of chondrocyte-specific gene expression. Cells were plated at low density and grown as monolayers with and without the addition of insulin for a period of 28 days. Media were changed every other day and cells were harvested on days 1, 3, 7, 14, 21, and 28 for histochemical analyses and RNA isolation. Consistent with previous reports, we observed weak alcian blue staining of isolated clusters of cells by day 7 of culture of cells treated with insulin. By day 14, the alcian blue staining was strong in areas of densely packed multicellular nodules. Analyses of transcripts for cartilage-expressed genes by relative quantitative RT-PCR were consistent with the induction of chondrogenesis; for example, the expression of pre-chondrogenic collagen IIA was strong at early time points, whereas that of chondrocyte-specific collagen IIB predominated at day 14 and later time points. ANK transcript was present from day 1 of culture and was similar in cells with or without treatment with insulin. Since TGF β has been reported to significantly increase the production of extracellular inorganic pyrophosphate in chondrocytes, we also cultured the ATDC5 cells in the presence of insulin plus TGF β . We did not observe a significant increase in ANK expression in TGF β -treated cells compared to those treated with insulin only. These studies provide the foundation for future analyses of mutated ANK in the ATDC5 line. (Supported by AR44360 from NIH/NIAMS to C.J.W.).

Specific expression of Cre recombinase in kidney tubular cells of mice. *L. Tontsidou*¹, *K. Bilbilis*¹, *P. Pennekamp*¹, *B. Skryabin*², *H-J. Galla*³, *J. Horst*¹, *B. Dworniczak*¹. 1) Institut of Human Genetics, Institute of Human Genetics, UKM Muenster, Germany; 2) ZMBE Muenster, Institute of Experimental Pathology, Germany; 3) Institut fuer Biochemie, Muenster, Germany.

Autosomal dominant polycystic kidney disease (ADPKD) is one of the most common monogenic diseases in humans with an incidence of 1:600. The cardinal finding is the formation of fluid filled cysts in both kidneys - predominantly in the proximal tubules - frequently resulting in end stage renal failure. In the vast majority of cases, the disease is caused by mutations in PKD1 and/or PKD2. However, despite extensive research only little is known concerning the pathogenesis of ADPKD. Cystogenesis in ADPKD kidneys in humans is a focal process: patients inherit one germline mutation and acquire somatic mutations affecting the normal allele in a subset of cells (second hit). In the last couple of years conventional knockout mouse models for Pkd1 and Pkd2 have been generated. All of them are prenatal lethal making it impossible to analyze the pathogenesis of ADPKD after birth/over a longer period in adult mice. These limitations caused by embryonic lethality can be circumvented by conditional mutagenesis in which the loss of gene function is placed under temporal and/or spatial control. In order to establish this system we have generated a transgenic mouse line expressing the Cre-recombinase under the control of a truncated mouse type II GGT promoter. We expected that this promoter allows the spatial excision of loxP flanked genes in proximal tubular cells. The recombinase activity was demonstrated by crossing these mice with Cre- reporter lines (Z/AP and ROSA26). Both lines carry a marker gene whose expression requires excision of loxP flanked stop sequences. Using alkaline phosphatase histochemistry in Z/AP mice as well as b-Galactosidase histochemistry in ROSA26 mice we observed a strong and specific expression of Cre-recombinase in proximal tubular renal cells. This Cre transgenic mouse line, which induces efficient Cre-mediated excision of DNA in proximal tubules, should provide a useful genetic resource to elucidate the role of loxP manipulated genetic targets in cyst formation of ADPKD.

A mutation in FSHb as a possible cause of idiopathic hypogonadotropic hypogonadism. A.D. Clark^{1,2}, R.J. Sherins³, D.P Bick⁴, L.C. Layman^{1,2}. 1) Section of Reproductive Endocrinology, Infertility, & Genetics, Department of Obstetrics and Gynecology, Medical College of Georgia, Augusta, Georgia; 2) Neurobiology Program, Institute of Molecular Medicine & Genetics, Medical College Georgia, Augusta, GA; 3) Genetics and IVF Institute, Fairfax, Virginia; 4) Department of Genetics, University of Wisconsin.

Follicle stimulating hormone (FSH) is a pituitary protein consisting of a a and b subunit that is an important regulator of reproductive function in males and females. It is necessary for follicle maturation in females, spermatogenesis in males, and the aromatization of testosterone to estradiol. To date, four mutations in FSHb have been described which all resulted in varying degrees of pubertal development and low to undetectable FSH accompanied by elevated serum luteinizing hormone (LH). Idiopathic hypogonadotropic hypogonadism (IHH) is characterized by irreversible pubertal delay in patients with low serum levels of FSH and LH, and the absence of other endocrinologic abnormalities. It is conceivable that an inactivating mutation in FSHb could mimic the IHH phenotype of hypogonadism and delayed puberty. To investigate this hypothesis, the entire coding region of FSHb was analyzed by denaturing gradient gel electrophoresis (DGGE) in 76 patients with IHH and 20 controls for mutations in FSHb. Two unrelated IHH patients shared a sequence difference in FSHb exon two that was absent in all other patients and controls tested. Subsequent DNA sequencing showed both were heterozygous for a G®T substitution that results in an amino acid change of Ser1Ile. This sequence difference was introduced into a FSH expression vector and its bio- and immunoactivity was assayed *in vitro*. The Ser1Ile showed both decreased bio- and immunoactivity of FSH, indicating that it is a true mutation affecting FSH production *in vitro*. Our findings suggest that this mutation may be partly or completely responsible for the IHH phenotype in the individuals identified with this sequence difference. It is possible that the Ser1Ile might only be significant in the homozygous state, but we cannot exclude a dominant negative effect or modifying effects from other genes.

HNF-4 Alpha Enhances Expression of Human Glycerol Kinase in a Human Hepatocellular Carcinoma Cell Line.

S.V. Stepanian¹, S.T. Huyn¹, E.R.B. McCabe^{1,2}, K.M. Dipple¹. 1) Departments of Pediatrics and; 2) Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA.

Isolated glycerol kinase deficiency (GKD) is an X-linked inborn error of metabolism for which genotype does not correlate with phenotype. We hypothesize that phenotypic variability might be due to factors influencing GK expression. We have shown previously that an HNF-4a (HNF-4) consensus binding site exists between -433 and -451 bp (GK-HNF-4 site) and that this region is important for enhanced GK expression. The purpose of this study was to investigate the specificity and functionality of HNF-4 binding to the GK-HNF-4 site. To determine the specificity of HNF-4 binding to the GK-HNF-4 site, rat liver nuclear extract was used in a gel mobility shift assay with a radiolabeled GK-HNF-4 site and excess amounts of unlabeled HNF-4 consensus oligonucleotide. One band was effectively competed by excess unlabeled HNF-4 consensus oligonucleotide. Repetition using an unlabeled mutated oligonucleotide (mGKHNF-4), with a three base pair change in the GK-HNF-4 site, did not compete. Self-competition demonstrated specificity of the interaction. An HNF-4 antibody showed a supershift of the HNF-4-GK complex, indicating that HNF-4 binds to the GK-HNF-4 site. To explore the functionality of HNF-4 binding to the GK promoter, cotransfection of HepG2 cells with GK500LUC (-1 to -500 bp construct) or mutant GK500LUC construct (mGK500LUC) with an HNF-4 expression vector showed that HNF-4 increased expression of GK500LUC by 2 fold, while transfection of mGK500LUC led to diminished baseline luciferase activity. These data suggest that HNF-4 binds to the GK-HNF-4 site and enhances expression. Identification of the role of HNF-4 and other transcription factors important for GK expression will permit us to examine possible interindividual variations in their response elements in the GK 5' UTR. These investigations will allow us to test the hypothesis that influences on transcriptional activity may mediate phenotypic variability in isolated GKD. Since mutations in GK and HNF-4 are associated with type 2 diabetes mellitus, then the involvement of HNF-4 in GK expression is particularly intriguing.

A YY1 Binding Site Functions as a Downstream Promoter Element (DPE) to Direct Accurate Transcriptional Initiation of the Human LINE-1 Retrotransposon. *J.N. Athanikar, J.V. Moran.* Departments of Human Genetics and Internal Medicine, University of Michigan, Ann Arbor, MI.

Long Interspersed Nuclear Elements (LINEs or L1s) are a family of non-Long Terminal Repeat (non-LTR) retrotransposons that can move from one genomic location to another via reverse transcription of an RNA intermediate. They comprise nearly 17% of the human genome sequences and though the vast majority (>99.8%) are retrotransposition-defective, it is estimated that 60-100 remain retrotransposition-competent (RC-L1s). RC-L1 retrotransposition is ongoing, and deleterious insertions have resulted in a number of genetic disorders, including cancer. The initial step in L1 retrotransposition is the transcription of L1 RNA from an internal promoter located within its 5'-untranslated region (5'UTR). Earlier studies had identified a YY1 (Yin Yang 1) binding site near the 5' end of L1 (+13 - +20) as a key *cis*-acting sequence required for transcription from a heterologous reporter, but little else is known about how L1 transcription is regulated. Here, we have employed a genetic assay to detect L1 retrotransposition in cultured cells in conjunction with a luciferase reporter system to test whether the YY1 binding site also is required for L1 retrotransposition. Unexpectedly, mutations in this site neither affected the activation potential of the L1 5'UTR, nor affected the ability of L1 to retrotranspose. Instead, RNase protection analysis demonstrated that these mutations abolish proper transcriptional initiation at the +1 start site. Thus, our data suggest that the YY1 binding site acts as a downstream promoter element (DPE) to direct proper L1 transcriptional initiation, thereby enabling L1 to undergo exponential amplification in subsequent generations.

Functional characterization of possible candidate genes deleted in Wolf-Hirschhorn syndrome. *S.U. Endeke¹, S. Schlickum¹, C. Steglich², N. Pfarr³, F.O. Fackelmayer⁴, A. Winterpacht¹.* 1) Institute of Human Genetics, University Erlangen-Nuremberg, Erlangen, Germany; 2) Institute of Human Genetics, University of Hamburg, Hamburg, Germany; 3) Children's Hospital, University of Mainz, Mainz, Germany; 4) Heinrich-Pette-Institute, Hamburg, Germany.

The Wolf-Hirschhorn syndrome (WHS, MIM194190) is caused by deletions in chromosome region 4p16.3 and is thought to be a contiguous gene syndrome with a yet unknown number of genes contributing to the phenotype. Recently, we and others identified several candidate genes in (and flanking to) a previously defined 165 kb WHS critical region. We have now focused our attention on the neurological and neuromuscular features of this syndrome and started with a detailed functional characterization of three putative candidate genes for this aspect of the phenotype. The first gene, *LETM1*, flanks the WHSCR and is deleted in almost all WHS patients. *LETM1* shows significant homology to proteins from different species which exhibit a characteristic domain structure including a transmembrane domain, 1-2 EF-hand motifs and a novel SAF/SAP related domain. We could show that in contrast to a standard SAF/SAP domain the SAF/SAP related domain possesses no conventional SAR/MAR-binding properties. The function of the novel domain remains unknown and will be analyzed further. To determine the subcellular localization of human *LETM1* we transfected COS7 cells with EGFP-cDNA-fusion constructs. Our results demonstrate that the fusion protein is located in the mitochondria, indicating that *LETM1* plays a role in mitochondrial function. Since mitochondrial dysfunction has gained considerable interest as a potential cause of epileptic seizures and neuromuscular disorders, it is tempting to speculate that *LETM1* represents a suitable candidate for these clinical features characteristic for WHS patients with a full phenotype. In addition, two other novel putative genes from the WHSCR are currently investigated. The genes, which we designated *WHSC3* and *WHSC5*, show a strong expression in developing and adult brain. RNA-in situ hybridizations revealed a cell type specific expression pattern for *WHSC3* suggesting a role in the neurological phenotype of WHS.

Evolutionary Conservation of the Myotonic Dystrophy Type 2 (DM2) Repeat Tract. *C.L. Liquori, J.W. Day, L.P.W. Ranum.* Institute of Human Genetics, University of Minnesota, Minneapolis, MN.

Myotonic dystrophy (DM), the most common form of muscular dystrophy in adults, can be caused by mutations on either chromosome 19 (DM1) or 3 (DM2). We recently demonstrated that a CCTG expansion in intron 1 of the *zinc finger protein 9 (ZNF9)* gene causes DM2. The DM2 repeat contains the complex repeat motif (TG)_n (TCTG)_n (CCTG)_n. The CCTG portion of the repeat tract is interrupted on normal alleles and expands on affected alleles. The *ZNF9* cDNA is highly conserved throughout evolution, with homologs in mouse, chicken, and yeast. To gain insight into possible functions of the DM2 repeat, located in an intron, we looked for evolutionary conservation in chimpanzee, gorilla, mouse, and rat. PCR was performed on genomic DNA from chimpanzee and gorilla using primers within intron 1 flanking the repeat. The 1.3 Kb region was highly conserved (chimpanzee: 98%; gorilla: 97%) and included similar but not identical complex repeat motifs. Chimpanzee has a (TG)_n TCTG (CCTG)_n, with interruptions in the TG but not the CCTG tract. Gorilla has a more complex (TG)_n (CCTG)_n TCTG CCTG (TCTG)_n and (TCTG)_n (CCTG)_n TCTG CCTG TCTG, separated by a 38 nucleotide stretch with homology to an Alu repeat. We also compared the entire intron 1 sequence of mouse, rat, and human. Intron 1 in both mouse (5.1 Kb) and rat (5.8 Kb) is much smaller than in the human gene (>20 Kb) and is conserved throughout its length between mouse and rat (85%). The mouse has a complex repeat motif, (TG)₅ TCTG TG (TCTG)₂, similar to that found in human but without a CCTG tract, whereas the rat only contains the (TG)_n portion of the repeat tract. A small region of intron 1 downstream from the repeat tract is conserved with human (mouse: 51%; rat: 48%). The evolutionary conservation of the DM2 repeat motif suggests a biological function. Given that both TG and tetranucleotide (UCAY) repeats have been shown to be involved in regulating alternative splicing, the normal role of the DM2 repeat tract may be to regulate alternative splicing of *ZNF9*.

Characterization of functional elements in the neurofibromatosis (NF1) promoter. *D.I. Rodenhiser, M.X. Zou, D.T. Butcher, T.C. Groves, S.P. Yee.* Cancer Research Labs, London Regional Cancer Centre, and The University of Western Ontario, London, ON, Canada.

Neurofibromatosis is a familial cancer syndrome attributable to mutations in the NF1 gene. Although considerable insight has been gained on the function of the neurofibromin protein, surprisingly little information is available related to NF1 transcriptional regulation. Previous work from our lab has identified an unmethylated CpG-rich island containing the putative NF1 promoter which is flanked by methylated sequences. In the present study, we have begun identifying and functionally characterizing the NF1 regulatory region, as well as evaluating the molecular mechanisms that regulate NF1 transcription during normal cellular differentiation and the events leading to NF1-related neoplasia. Overlapping regions of the NF1 proximal promoter have been cloned using a series of DNA fragments created by PCR and characterized for use as luciferase reporter constructs. Luciferase reporter assays have identified a 425 bp region displaying activities up to 80 fold higher than baseline reporter levels. Gel mobility shift assays confirm binding of SP1 and CRE to their putative recognition sequences and provide the first evidence identifying functional sites likely involved in regulating NF1 transcription. Mutations at the CRE and SP1 binding sites immediately upstream of the transcription start site have dramatic effects that lead to a 70-90 percent decrease in reporter activity. Our assays have also revealed a putative repressor region within the NF1 promoter region corresponding to CCCTC rich sequences between the transcription and translation start sites. As well, in vitro methylation of the NF1 reporter constructs supports a model where aberrant NF1 promoter methylation could repress transcription in a manner similar to other tumour suppressor genes. This study is providing a clearer understanding of the functional sites within the NF1 regulatory region that are responsible for regulation of NF1 gene expression and the critical elements that may be targeted for inactivation. (This research funded by the US Army / Department of Defense Neurofibromatosis Research Program.).

Functional characterization of protein domains in NYX (nyctalopin on chromosome X). *C. Zeitz*^{1,2,3}, *S. Schweiger*², *H. Scherthan*², *S. Freier*², *W. Berger*^{1,2}. 1) Dept. Med. Molecular Genetics, University of Zurich, Schwerzenbach, Switzerland; 2) Max Plank Institute of Molecular Genetics, Berlin, Germany; 3) Free University, Berlin, Germany.

CSNB1, the complete type of X-linked congenital stationary night blindness, is a nonprogressive retinal disorder characterized by impaired night vision, myopia, nystagmus and reduced visual acuity. The disease is caused by mutations in the CSNB1 gene (NYX). The predicted protein contains an N-terminal signal peptide, a C-terminal glycosylphosphatidylinositol (GPI) membrane anchor and 11 LRRs, flanked by cysteine-rich LRRs. Two previously identified GPI-anchored LRR proteins (chaoptin and connectin) have a pivotal role in photoreceptor cell adhesion as well as axon guidance processes. We isolated the mouse orthologue, mNyx, and compared the amino acid sequence to the human protein. Amino acid sequence identity is much higher in the LRR-core (>90%) than in the signal sequence and GPI anchor (62% and 52%, respectively). Protein localization and the functional relevance of predicted domains (signal sequence and GPI-anchor) were studied by expression of V5-tagged human and mouse constructs in COS7 and HeLa cells by fluorescence immunochemistry. Different protocols were established to localize the protein. When cells were permeabilized and extracted, NYX is confined to the ER and Golgi apparatus, which was proven by colocalization experiments. Using live cell staining against V5 we observed NYX in a punctuate pattern on the surface of the cell. Similar results were obtained with expression constructs containing the mouse cDNA sequence. Deletion of the GPI anchor resulted in a time dependent release of NYX from the cell surface but part of it remained in the ER and Golgi apparatus. Constructs lacking the signal sequence showed a diffuse pattern of NYX in the cytosol as do constructs with neither signal sequence nor GPI anchor. Thus, our data provide evidence that NYX is transported and attached to the cell membrane in both species, human and mouse. Adhesion studies using mutant variants will reveal whether NYX plays indeed an important role for protein interaction and axon guidance processes. >>.

Functional analysis of single-minded 2 (SIM2) gene located on human chromosome 21q22.2:promoter and nuclear localization signal. *Y. Shimizu¹, A. Yamaki¹, J. Kudoh², S. Minoshima², N. Shimizu²*. 1) Department of Medical Genetics, Kyorin Univ Sch Health Sci, Tokyo, Japan; 2) Department of Molecular Biology, Keio Univ School of Medicine,.

Human SIM2 gene encodes a PAS family transcription factor and it has been postulated to be a candidate gene for the pathogenesis of mental retardation in Down syndrome. To understand the molecular mechanism of SIM2 gene expression, we have analyzed the promoter region using a series of deletion constructs and point mutants fused with luciferase reporter gene and gel retardation assay. We found that the 60bp-sequence between nt-1385 and -1325 upstream of the translation initiation site has a significant promoter activity and that c-myb like transcription factor appears to regulate the transcription of human SIM2 gene in T98G cells. Furthermore, we analyzed more downstream region and found that a CAAT cis-element located between nt-1015 and -1004 appears to be important for SIM2 gene expression. To determine the nuclear localization signal of SIM2 protein, we have generated fusion genes of full-length cDNA and deletion mutants of SIM2 with green fluorescent protein (EGFP). Transient expression analysis in HeLa cells revealed that SIM2 protein exists in nuclei without any stimuli. The bHLH-PAS1-PAS2 and HST domains are not necessary for the nuclear localization of SIM2 protein and the region of codon 367 to 389 are sufficient. We made a series of point mutants between codon 367 and 382 where eight basic amino acids exist and found that the important amino acid residues for nuclear localization are arginine of codon 367 and lysine of codon 373.

Alternative Splicing of the Novel HMG Box Transcription Factor BBX (HBP2, MHS4R3). *M. Kiehntopf¹, C. Beetz¹, M. Brodhun², J. Schickel¹, T. Deufel¹.* 1) Institut fuer Klinische Chemie, Universitaetsklinikum Jena, Jena, Germany; 2) Institut fuer Pathologie, Universitaetsklinikum Jena, Jena, Germany.

The human homolog of the drosophila bobby sox gene, BBX, was first designated HBP2 and identified by functional complementation of cells unable to undergo DNA replication in fission yeast. BBX contains a high mobility group domain (HMG) with homology to the SRY-box, which was originally identified in the product of the Sex-determining Region on the Y chromosome (SRY) gene. Thus, BBX is considered a member of the SOX family of transcription factors. A role of sox genes has been implied in several genetic disorders such as XY sex reversal, campomelic dysplasia, and Waardenburg-Hirschsprung disease.

By analyzing the chromosomal region 3q13.1, we have identified a gene which we initially designated as MHS4R3. Only later, comparison with database sequences revealed that MHS4R3 and HBP2 are identical genes; we also found that BBX and BBXa are in fact alternatively spliced transcripts of the same gene, differing from MHS4R3/HBP2 in one exon of the coding region.

In our present study, we found that extensive alternative splicing occurs in transcripts of the BBX gene, resulting in a variety of different putative protein sequences. We show that these splice alternatives are differentially expressed in various tissues. The predicted alternative proteins are identical to BBX at the HMG Box-containing N-terminus, but differ at their C-terminus. This is due to a frame shift caused by loss of one exon, and to the combinatorial use of some of the following exons. Interestingly, the predicted number of NLS and NES domains is unique for every splice variant, indicating that it is the C-terminus that determines sub-cellular localisation of the protein variants. Accordingly, transfection of GFP-fusion constructs revealed that splice variants containing certain NLS were localised in the nucleus. Studies are under way to further elucidate the functional role of the different BBX splice variants.

Program Nr: 901 from 2002 ASHG Annual Meeting

KLHL1, the gene expressed from the SCA8 locus, and KLHL4 evolved from the same orthologous gene in fish.
Y.M. Kim, M.D. Koob. Inst Human Genetics, University of Minnesota, Minneapolis, MN.

Spinocerebellar ataxia type 8 (SCA8) is caused by a CTG expansion in an untranslated, endogenous antisense RNA that overlaps the Kelch-like 1 (KLHL1) gene. The normal functions of this antisense transcript and of the protein encoded by the sense transcript are currently unknown. We have performed extensive sequence analysis of human genes homologous to KLHL1 and have determined that KLHL1 is one of a family of paralogous human genes that also include KLHL4 and KLHL5. Mice have genes that are orthologous to each of these three genes, and we recently reported that the mouse *Klh1* gene has a *Klh1*-antisense transcript as well. Our analysis of the *Fugu rubripes* (pufferfish) and zebrafish genomes indicate that these fish species have only two members of this gene family, one of which is orthologous to human KLHL5 and one of which appears to have been derived from a gene that is ancestral to both KLHL1 and KLHL4. We are currently using morpholino (antisense) oligos to knock down the gene products of these orthologous genes in zebrafish embryos in order to determine their normal function, and are determining if natural antisense transcripts are present for either of the zebrafish KLHL orthologs.

Program Nr: 902 from 2002 ASHG Annual Meeting

One Step In Situ PCR: An Improved Method of In Situ PCR to Detect Gene Expression on Paraffin Embedding Tissues. X. Chang, R. Yamada, A. Suzuki, S. Tokuhira, K. Yamamoto. SNP research center, The Physical and Chemical Research(Riken),Japan. Yokohama, Shinakawa, Japan.

One Step In Situ PCR: An Improved Method of In Situ PCR to Detect Gene Expression on Paraffin Embedding Tissues X. Chang, R. Yamada, A. Suzuki, S. Tokuhira, K. Yamamoto The Institute of Physical and Chemical Research (Riken), Yokohama, Japan. In situ PCR is becoming a common tool to trace gene expression because of its unique ability to identify rare genes on paraffin-embedding tissue sections. In individual cells, low copy mRNAs are observable with microscopy after they are reverse-transcribed into cDNA (RT) and in situ amplified by PCR. However, this powerful method remains relatively imprecise and its reproducibility is not high. The separation of RT and PCR, the critical steps of the procedure, is mainly responsible for the weak points of the technique, because preparation and handling between RT and PCR steps takes long time and make risks of transcripts to be lost, damaged and/or exposed to the RNase, more likely. Recently, we improved the procedure of in situ PCR by merging RT and PCR into one-step and conducting reaction on PCR oven simultaneously in accordance with methodological principle of one-tube RT-PCR. In our report, we applied the modified method to investigate mRNA expression of aromatase, a critical enzyme for estrogen production using bone marrow tissues. Results showed that aromatase could be detected in bone marrow cells and the signals of aromatase mRNAs are more sensitive and well defined than the regular two step in situ PCR. It is suggested that improved in situ PCR method is exceedingly trustable, practicable and timesaving.

Expression of a splice variant of *TRPM6*, the gene causing Hypomagnesemia with Secondary Hypocalcemia, in mouse testis. *R.Y. Walder, R.E. Swiderski, V.C. Sheffield.* Dept Pediatrics, and Howard Hughes Medical Institute, Univ Iowa, Iowa City, IA.

We recently used positional cloning to identify *TRPM6*, the largest member of the TRP channel protein family, as the gene which causes familial hypomagnesemia with secondary hypocalcemia (HSH)(OMIM 602014). The complete cDNA sequence of *TRPM6* contains 8429 nucleotides, including an open reading frame of 6069 nucleotides. The predicted *TRPM6* protein contains 2022 amino acids and has a calculated molecular mass of 234 kD. The genomic sequence contains 39 exons within 166 kb. *TRPM6* is highly homologous to *TRPM7*, a bifunctional protein which can act as non-selective cation channel and as a serine/threonine protein kinase. Individuals with HSH and mutations in *TRPM6* have defects in the renal and intestinal transport of magnesium. These findings indicate that *TRPM6* plays an important role in magnesium homeostasis in the kidney and in the intestine. Expression data from Northern and RT-PCR analyses of human tissues showed that the full-length transcript, 8.5 kb, is abundantly expressed in kidney and colon, two critical sites of magnesium transport. In mouse tissues, the full-length transcript for *TRPM6*, 8.5 kb, was detected in kidney, and weakly in lung. A smaller transcript, 4.0 kb, was detected with a *TRPM6* probe in mouse testis RNA. We report here the DNA sequence and characterization of the 4.0 kb splice variant of *TRPM6*. Preliminary data suggests that this transcript contains the sequence for the protein kinase, and not the TRP channel domain. Further localization studies of the *TRPM6* transcript have been done by in situ hybridization of testis tissues. These data suggest an independent role for the protein kinase domain in testicular tissue.

Dose-Dependent Shift from Repressor to Activator in a DAX-1 Variant from a Female with Adrenal Hypoplasia Congenita. *B.D. Bowling¹, J.J. Wilson¹, P. Bernard¹, M-B. Dinulos², J. Phelan³, E.R.B. McCabe^{1,3}, E. Vilain^{1,3}.* 1) Human Genetics, UCLA, Los Angeles, CA; 2) Pediatrics, Dartmouth, Hanover, NH; 3) Pediatrics, UCLA, Los Angeles, CA.

The nuclear hormone receptor DAX-1 is responsible, when mutated, for the X-linked disease adrenal hypoplasia congenita (AHC). All known missense mutations impair DAX-1 repression of Steroidogenic Factor-1 (SF-1) transactivation and have been limited to the C-terminal putative ligand binding domain (LBD). An asymptomatic father and an AHC daughter were both discovered to share a DAX-1 sequence variation (C200W). C200W is the first missense mutation found in the N-terminal half of DAX-1 and represents the relatively rare presentation of AHC in a female heterozygous carrier. Co-transfection of equimolar concentrations of C200W DAX-1 with SF-1 into embryonic kidney cells (293T) generated wild-type repression of SF-1 transactivation. However, as the C200W concentration increased, a concomitant loss of functional silencing became apparent. High concentrations of C200W synergistically enhanced SF-1 transactivation to levels exceeding those seen with SF-1 activation alone. We conclude that the unique C200W variant, associated with a normal and an AHC phenotype, has the capacity to convert DAX-1 activity from antagonist to agonist in a dosage-sensitive manner. The clinical variability in this family suggests that additional modifier genes and epigenetic factors are involved. Our studies reveal a multifaceted role for DAX-1 in a complex network critical for the developing reproductive axis.

A T-box containing transcription factor on human chromosome 15q14 identified through a retinoic acid-induction gene trap approach in mouse ES-cells. A. Voigt¹, W. Wurst², M. Weickert¹, D. Schlote¹, I. Hansmann¹, M. Schlicker¹. 1) Institut fuer Humangenetik & Medizinische Biologie, Halle (Saale); 2) Max-Planck Institut, Muenchen, Germany.

Prenatal exposure to retinoic acid (RA) and retinoids (RX) is related with specific congenital anomalies. The molecular mechanism for RA/RX teratogenesis and the genes involved are not well known. To identify RA/RX downstream genes we set up an RA-induced gene trap approach based on mouse ES clones (Forrester et al. 1996). From a sample of trapped ES clones with RA-induced reporter-gene repression 5-RACE-PCR identified a fusion transcript of 1.135 kb in clone EScD1. Screening of cDNA libraries and in silico analysis revealed an approx. 9 kb mouse cDNA. This gene represents a transcription factor containing a T-box and a bHLH Zip-domain. Northern analysis revealed tissue specific expression of this single locus gene with transcripts of varying size. A prominent 9.5 kb transcript is present in spleen, kidney, stomach, lung, brain, testis, ovary, placenta, heart and skeletal muscle. Weaker and smaller transcripts of 7.2 kb were observed in placenta and testis and of approx. 4 kb in testis indicating alternative splicing. A genomic P1 clone isolated contains the complete cDNA. Screening of human cDNA libraries and in silico analysis identified the corresponding human gene with sequence homology >82% to mouse cDNA. BACs were isolated for establishing genomic structure and mapping. The gene contains 24 exons, the same domains as the mouse gene and maps o 15q14, according to FISH. The gene was found to be triplicated in a young proband with mental as well as growth retardation and malformations due to partial trisomy 15q14-q15.

Analysis of the characteristics of nucleotide substitutions at the substrate recognizing regions of Cytochrome P450 2C subfamily enzymes. *S. Kuno, N. Kamatani.* Division of Genomic Medicine, Department of Advanced Biomedical Engineering and Science, Tokyo Women's Medical University, Tokyo, Japan.

Cytochrome P450 (CYP) superfamily, the oxidate-reduction enzymes, are widely preserved in the biological world. 265 Families of CYP superfamily are known and 69 families have been identified in animals. In 69 families of animals, the members of CYP 1-3 families mainly play the phase I reaction of the metabolism of outer matters to make those harmless. CYP 2C subfamily enzymes metabolize numerous drugs in liver. The genes for four enzymes (2C8, 2C9, 2C18 and 2C19) that are members of this subfamily have been localized in chromosome 10 q24 in human. These enzymes catabolize various toxic compounds. Since the chemical structures of these compounds have varieties, it is reasonable to assume that the substrate recognizing regions of these enzymes undergo diversity-enhancing evolution just as the antigen-binding regions of major histocompatibility complex. To test for the diversity-enhancing evolution, the comparison of the number of synonymous nucleotide substitution (ds) versus that of nonsynonymous nucleotide substitution (dn) between the sequences of CYP 2C enzyme was performed. If dn is more than that of ds, then we suspect that diversity-enhancing evolution might have occurred. CYP 2C subfamily enzymes have six substrate recognizing regions. It was found that dn were enhanced near the substrate recognizing regions by the window analysis with 30 codons. In the comparison between ds and dn in CYP 2C subfamily enzymes, the diversity-enhancing substitutions were observed in the substrate recognizing regions. However, dominance of dn than ds in the short sequence's range may be generated by chance. Therefore, that should be tested for significance. We performed test with the Monte Carlo simulation experiments and it was supported in most cases with significance. Similar results were obtained in rabbit, rat and golden hamster. These results suggest that the substrate recognizing regions of CYP 2C subfamily enzymes have undergone diversity-enhancing evolution due to the selection pressure favoring the diversity opposing against the attack by various toxic compounds.

Monitoring the TP53 gene to detect genetic damage in tissue-engineered skin. *P.E. McAndrew¹, H. Rodriquez², C. O'Connell², M.A. Marino¹.* 1) Applied Genomics, Transgenomic, Inc, Gaithersburg, MD; 2) DNA Technologies Group, Biotechnology Division, NIST.

The purpose of this study was to assess the safety and performance of tissue-engineered materials by monitoring the TP53 gene as a biological safety checkpoint during the manufacturing process. Samples of tissue-engineered skin (TE; TestSkin II) were obtained and included total TE skin (fibroblasts and keratinocytes combined), TE skin (fibroblasts), TE skin (keratinocytes), adult fibroblasts (55 years old), and adult fibroblasts (96 years old). Neonatal fibroblasts and neonatal keratinocytes were included as controls for this study. Denaturing high performance liquid chromatography (dHPLC) was used to scan the TP53 gene for putative mutations. The TP53 gene was chosen as a biomarker for tissue engineered samples because alterations in this gene occur in almost 50% of all human cancers. DHPLC did not detect any putative mutations in the TP53 gene in these tissue-engineered skin samples. Analysis of exons 2 through 11 was performed using nine PCR amplicons and was completed in less than three hours. Three of the samples contain the previously reported 16bp polymorphic insertion in intron 3 (IVS3+40). Heteroduplex peaks were detected in the exon 10 PCR products of the skin keratinocyte and neonatal keratinocyte samples. Sequence analysis confirmed the presence of base changes indicated by DHPLC analysis, both of which are polymorphic changes due to their location. The WAVE® System provides a highly sensitive and rapid technique to screen for genetic alterations in the TP53 gene, and can be used as an effective method to monitor the integrity of tissue engineered samples.

Genomic structure, promoter activity and developmental expression of the mouse homologue of the Machado-Joseph disease gene. *M.C. Costa*¹, *C. Miranda*², *M. Tessaro*², *J. Sequeiros*^{1,3}, *M.M. Santos*^{1,2}, *P. Maciel*^{1,3}. 1) UnIGENE, IBMC, Univ. Porto, Portugal; 2) Dept. Medicine, CHUM, Hôpital Notre-Dame, Montreal, Canada; 3) Dept. Est. Pop., ICBAS, Univ. Porto, Portugal.

Machado-Joseph disease (MJD) is an autosomal dominant neurodegenerative disorder, caused by the expansion of the (CAG)_n tract in the *MJD1* gene. This encodes the protein ataxin-3, of unknown function. We determined the genomic organization of the *MJD1* mouse homologue (*mMJD*), characterized its promoter and studied its expression pattern during embryonic development and in adult mouse tissues. The mouse gene has a similar structure to its human counterpart, with the same number of exons (11), intron and exon sizes comparable to the human, and a TATA-less promoter. To assess the activity of the *mMJD* gene promoter, we constructed CAT reporter plasmids containing different lengths of its upstream region and performed transient transfections into undifferentiated mouse embryonic carcinoma P19 cells. The largest fragment (extending to -1173 bp), showed a significant promoter activity. Minimal activity was observed with the -237 bp construct and maximal activity with the -928 bp construct. Our results also suggest that transcription repressor sequences exist in the regions -559 to -358 and -1173 to -928 bp. Analysis of differentiated P19 cells (neurons and cardiac/skeletal myocytes) showed a stronger activity of the promoter in myocytes, consistent with the bioinformatic identification of myoblast-specific transcription factor binding regions. Immunohistochemical tissue analysis showed that the *mMJD* gene is expressed throughout all developmental stages (embryonic days 11.5-16.5) and in the adult mouse, with a higher expression in brain, heart and skeletal muscle. A muscle-specific 38KDa isoform of the protein was detected by Western blot, whereas an isoform of larger size was apparent in brain. These isoforms were also observed in human tissues, suggesting that they may be of functional relevance. Further characterization of these isoforms and of the regulation of the *mMJD* gene will help to clarify the normal function of ataxin-3 and its physiological role in muscle and brain.

Tissue specific splice variants of the human A-C1 Ha-Ras suppressor gene (HRASLS). *C. Alexander*¹, *S.S. Bhattacharya*², *B. Wissinger*³. 1) Neurodegeneration, Max-Delbrück-Center, Berlin, Germany; 2) Dept. of Molecular Genetics, Inst. of Ophthalmology, London, UK; 3) Molecular Genetics Lab, University Eye Hospital, Tübingen, Germany.

Purpose: A high fidelity physical map consisting of more than 100 PAC clones on chromosome 3q28-q29 had been created as genomic resource. In order to identify novel disease gene candidates, we sequenced this genomic area of ~1MB on chromosome 3q28-q29 flanked by satellite markers D3S3669 and D3S3562. **Methods:** The raw data were edited and reassembled using the Staden Software Package and our own BLAST-able PAC database was established at the HGMP-UK web site. Open reading frames were predicted through NIX analysis and confirmed by BLAST searches of EST databases at the NCBI server. The intron-exon structure of EST clusters was examined by computational alignments of the cDNA and genomic sequence. We performed northern blot hybridization in order to determine tissue specificity of the identified cDNAs. **Results:** Several open reading frames matched with the sequence of Unigene cluster Hs.36761. The underlying gene was recently identified as the A-C1 Ha-Ras suppressor gene (Ito et al., 2001). Northern blot analysis revealed specific expression of this cluster in skeletal muscle (testis material was not included in our blot). One cDNA sequence belonging to the Unigene cluster had been isolated from testis. In this clone, the first non-coding exon of the A-C1-cDNA was replaced by 235 bp of completely unrelated sequence. This 5UTR stretch was found to be divided into three small exons, which were not present in cDNAs derived from other tissues in this Unigene cluster. **Conclusion:** Tissue specific splice variants of the A-C1 Ha-Ras suppressor gene exist. Whereas the coding sequence is the same for all transcripts in all tissues, the 5UTR of a testis specific transcript differs from that of cDNAs in other organs. This finding might hint towards a testis specific control of translation of this particular gene.

Genetic Analysis of Two Sodium Dependent Vitamin C Transporters, *SLC23A1* and *SLC23A2*. H.C. Erichsen¹, P. Eck², J.G. Taylor¹, M. Yeager¹, A. Hughes³, M.A. Levine², S.J. Chanock¹. 1) NCI Advanced Technology Center, Gaithersburg, MD 20877; 2) NIDDK, NIH, Bethesda, MD 20892; 3) Department of Biological Sciences, University of South Carolina, Columbia, SC 29208.

Vitamin C (L-ascorbic acid) is a critical co-factor for at least eight enzymatic reactions and functions as a scavenger of free oxygen radicals. Due to its role as an antioxidant, vitamin C could be involved in the pathogenesis of cancer, cardiovascular disease, diabetes, and stroke. We have previously characterized the human *SLC23A2* gene and now report the characterization of *SLC23A1*. Their tissue expression patterns differ despite a high degree of similarity in amino acid sequence (65%); *SLC23A1* is ubiquitously expressed, *SLC23A2* is restricted to epithelial surfaces involved in bulk transport, such as the intestines and kidney. They share common intron/exon borders but differ in size by ten fold (*SLC23A1* > *SLC23A2*) and in the 5 and 3 UTR regions. Re-sequencing analysis with coding bias was performed in 48 anonymous controls (Caucasians and African Americans) in both (*SLC23A1*, 14 SNPs with no nonsynonymous changes and 2 intronic deletions; *SLC23A2*, 15 SNPs, including 4 nonsynonymous). Genetic variants were identified and haplotypes estimated. Nucleotide diversity for each gene was estimated; they differ between *SLC23A1* (Tajimas $D=2.14$, $P<0.05$) and *SLC23A2* ($D=-1.26$, P , NS), specifically for nonsynonymous SNPs. The ubiquitously expressed gene, *SLC23A1* could be under more constraint than *SLC23A2*. Comparison of genomic organizations for the mouse ortholog *slc23a1* and *slc23a2* shows comparable structure. Human-mouse orthologs demonstrate conservation of size and organization of the genes. Human- mouse and mouse-rat orthologous comparisons show different rates of nonsynonymous substitutions. These data together with an analysis of SNPs suggest that these genes are under different selective pressures. These studies provide the foundation for investigation of the regulation of sodium-dependent ascorbate transport, a mechanism in which differences in activity could bear pleiotropic effects in health and disease, including recommendations for nutritional supplementation.

Transcriptional and genetic re-analyses of CCK promoter repeat suggest that the frequency of the low activity haplotype is decreased in panic disorder. *M. Ebihara, H. Ohba, E. Hattori, T. Yoshikawa.* Lab Molec Psychiatry, Brain Sci Inst, Riken, Saitama, Japan.

Cholecystokinin (CCK), prototypical brain-gut peptide, is a neurotransmitter in brain. It is known that CCK-4, the carboxyl terminal tetrapeptide of CCK has ability to precipitate panic attacks experimentally, suggesting that the possibility CCK could have an important role in the development of panic disorder. To study transcriptional regulation mechanism of the CCK could reveal the possible pathogenesis of panic disorder. We have already reported that a polymorphic short tandem repeat (STR) in the 5' upstream region of CCK promoter. We also classified the STRs into four groups (S, and L) according to their length and -188A/G. The L class allele with -188G was significantly less frequent in panic disorder ($P = 0.0032$, odds ratio = 0.06). To understand the function of STRs and their role in transcription of CCK gene, we subcloned the CCK promoter including STRs into firefly luciferase assay vector, pGL3-basic and transfected into NB1, neuroblastoma cell line. It is suggested that each STR has transcriptional repressor activity. Surprisingly, L class STR and -188G showed decreased promoter activity less than the others. These results suggest that the L - (-188G) haplotype acts as a protective factor against panic by reducing the expression of anxiogenic CCK.

Identification and characterization of a novel member of the bHLH-PAS transcription factor family. D.

Kamnasaran, D.W. Cox. Medical Genetics, University of Alberta, Edmonton, Alberta, Canada.

The proximal region of human chromosome 14 has many diseases associated with brain malformations and dysfunctions. In order to identify genes involved in brain development and function, a panel of predicted genes and ESTs mapping to human chromosome 14q13 were screened by LeapFrog PCR analyses to determine whether they were expressed in human fetal brain (21-30 wks). We obtained the cDNA sequence encoding the entire open reading frames of one gene expressed in fetal brain by assembling the cDNA sequences obtained from cDNA library screenings, LeapFrog PCR analyses and database searches. The gene, a novel member of the bHLH-PAS family of transcription factors has 12 exons that span about 867 kb of genomic DNA. The sizes of the exons vary from 77 bp to 1.9 kb and the introns vary from 2.1 kb to 275 kb in size. Two pseudogenes with unknown identity, reside within the second and third introns. The gene encodes two alternative transcripts, which are 1 kb and 3.7 kb in size. There are two possible promoters, one upstream of the first exon and one in the first intron. The smaller transcript encodes a 153 amino acid protein containing the PAS domain. This protein is identical to a 901 amino acid protein encoded by the larger transcript. Northern analyses with probes specific to each transcript showed only the larger transcript was expressed in various parts of the adult brain. Both small and large transcripts are expressed in human fetal brain. The *in silico* expression analyses showed the 1 kb transcript is expressed in the placenta and ovarian tumor, while the 3.7 kb transcript is expressed in the placenta, adult uterus, adult hypothalamus, and several cancer cell lines. Cellular localization studies with the 901 amino acid protein tagged in the C terminus with enhanced green fluorescent protein demonstrated the protein is localized in the nucleus of both COS1 and skin fibroblast cell lines. Members of the bHLH-PAS family of transcription factors have many functions, including neurogenesis and neural function. Our gene is an excellent candidate for central nervous system diseases, such as idiopathic basal ganglia calcification that map to chromosome 14q13.

Functional Role for a Dinucleotide Repeat in *CFTR*. *T. Hefferon, G.R. Cutting.* Inst Genetic Medicine, Johns Hopkins Univ, Baltimore, MD.

Dinucleotide repeats are common in the human genome and are useful as genetic markers in positional cloning studies. It has also been reported that variation in these repeats can modify gene expression and thereby disease. A variable TG tract occurs adjacent to the splice acceptor site of exon 9 of the cystic fibrosis transmembrane conductance regulator gene (*CFTR*). Patient and *in vitro* studies suggest that exon 9 skipping, associated with the common IVS8 5T allele, is affected by variations in the TG tract. Since U and G can basepair in RNA, we speculated that the TG repeat may interfere with splice site recognition by forming a stem-loop structure. To test this, we utilized a minigene comprised of *CFTR* exons 8, 9, and 10 in which the TG tract of 12 repeats was replaced with tracts of equal length which would be more or less likely to form stem-loop structures. Exon 9 skipping occurred in $34.2 \pm 1.0\%$ of transcripts derived from the TG₁₂ minigene (n=11). A CG₁₂ tract, predicted to form a strong stem-loop, resulted in increased exon skipping ($70.6 \pm 1.1\%$ 9- transcripts, n=6). However, TA₁₂ and CA₁₂ tracts, which were *not* expected to form stem-loops, also resulted in increased skipping ($68.1 \pm 1.4\%$ and 100% 9- transcripts, respectively, n=6 each). Furthermore, a randomized tract of equal length produced complete exon 9 skipping (100% 9-, n=6). Thus splicing of exon 9 was not corellated with the likelihood that the dinucleotide tract formed a stem-loop. To test the relationship between the length of the TG tract and exon skipping, constructs were generated with TG tracts of varying lengths. We observed that increasing the length of the TG tract from 12 to 16 TG repeats had no effect on splicing ($34.8 \pm 1.0\%$ 9-, n=6). Interestingly, a reduction in the number of repeats to TG₈ completely abolished exon skipping (0% 9-, n=6). Together, these results indicate that both the nature and length of dinucleotide tracts located near RNA processing signals can influence splicing efficiency.

Identification of two keratin-associated protein (KAP) gene clusters on human chromosome 21. *K. Shibuya, I. Obayashi, S. Asakawa, S. Minoshima, J. Kudoh, N. Shimizu.* Department of Molecular Biology, Keio University School of Medicine, Tokyo, Japan.

We have previously determined the entire genomic sequence of the euchromatic region of human chromosome 21, in which we identified unique repetitive elements on 21q22.3 region and presumed it as a cluster of keratin-associated protein (KAP) genes. KAP is one of major components of human hair fibers. This cluster spans approximately 165 kb and consists of 21 putative genes. Detailed computer analysis of these clustered genes revealed 16 active genes, 2 pseudogenes and 3 relics which were further divided into two sub-families. All the 16 active KAP genes harbor several intragenic repetitive elements and belong to the high sulfur KAP gene family. Transcripts were detected for all the 16 active KAP genes by RT-PCR analysis and their expression was solely in the hair root cells (radix pill cells) and not in any other human tissues examined including skin. Among these 16 active KAP genes, two genes produced a spliced minor transcript as well as the unspliced major transcript, whereas the other 14 genes produced only unspliced transcript, indicating all are intronless genes. Moreover, one of 2 pseudogenes was transcribed, indicating the conservation of active promoter region. Besides the KAP gene cluster on 21q22.3, we also identified another KAP gene cluster on 21q22.11 region. Detailed computer analysis and RT-PCR analysis revealed that this novel cluster spans approximately 800 kb and consists of 30 active genes and 22 pseudogenes. These 30 active KAP genes are classified into three sub-families, however, none of them belongs to high sulfur or ultra-high sulfur KAP genes. Thus, chromosome 21 contains 46 KAP genes in addition to the previously identified 225 genes.

Identify KCNQ1 mutations in patients with family history of lethal cardiac arrhythmia and sudden death. S.

Chen^{1,2}, L. Zhang³, R.M. Bryant⁴, G.M. Vincent³, M. Flippin⁵, J.C. Lee^{1,2}, E. Brown^{1,2}, F. Zimmerman⁵, R. Rozich², P. Szafranski⁶, C. Oberti⁷, R. Sterba², P. Tchou², D. Marangi⁴, A. Strauss⁵, M. Chung², Q. Wang^{1,2}. 1) Center for Molecular Genetics, Department of Molecular Cardiology, Lerner Research Institute; 2) Department of Cardiovascular Medicine, The Cleveland Clinic Foundation, Cleveland, OH; 3) Department of Internal Medicine, LDS Hospital, Salt Lake City, UT; 4) Pediatric Cardiology, University of Florida Health Science Center, Jacksonville, FL; 5) Department of Pediatrics (Cardiology), Washington University School of Medicine, St. Louis, MO; 6) Baylor College of Medicine, Houston, TX; 7) Instituto de Cardiologia Infantil, Hospital Italiano, Ospedale Italiano Umberto 15, Montevideo, Uruguay.

The long QT syndrome (LQTS) is a cardiac rhythm disorder characterized by prolongation of QT interval on electrocardiograms (ECGs). LQTS patients have higher risk to develop syncope and sudden death, especially under trigger factors. We screened *KCNQ1* gene by SSCP and DNA sequence analyses in 102 families with clinical suspicion of LQTS, Brugada syndrome, idiopathic ventricular tachycardia/fibrillation or aborted cardiac arrest (ACA) or sudden cardiac death (SCD) with unknown causes. *KCNQ1* mutations were identified in 10 families; G269S in transmembrane domain S5, W305X, G314C, Y315C, and D317N in the pore region, A341E and Q357R in transmembrane domain S6, and 1338insC, G568A and T587M in the C-terminus. Five mutations, W305X, G314C, Q357R, 1338insC, and G568A, are novel. A total of 61 gene carriers were identified: 41% showed QTc 460 ms on their resting ECGs. The incidence of syncope/ACA/SCD is 12/2/5, respectively. Of five SCD, three appeared as the first symptom. Compared to affected family members, probands (n=10) had more severe clinical outcome: QTc 493±42 ms with syncope/ACA/SCD as 5/2/4. Stresses were the trigger for 60% of life-threatening arrhythmias, syncope and sudden death. In conclusions, LQT1 phenotype is hidden in some of the gene carriers and sudden death can be the first/last symptom, therefore, genetic testing is important to identify gene carriers in the family members to prevent lethal cardiac arrhythmias and sudden death.

A novel mutation (A227C) of the *SOX9* gene in a patient with campomelic dysplasia without sex reversal. S. Liu, P. Dewing, P. Bernard, B.K. Jordan, E. Vilain. Human Genetics, UCLA, Los Angeles, CA.

Mutations in the human *SOX9* gene leading to haploinsufficiency cause campomelic dysplasia (CD) and autosomal sex reversal in approximately 75% of affected XY individuals. CD is a severe skeletal and cartilage malformation syndrome characterized by bowing of the long bones, hypoplastic scapulae, cleft palate, flat nasal passages, high forehead and low set ears. The incidence varies from .05 to 2 per 10,000 births and most patients with severe CD die neonatally due to respiratory failure. In this study, a 3 year old XY patient born to healthy non-consanguineous parents was presented with CD with normal male genitalia. DNA sequence analysis revealed a C to A mutation in one allele at position 227 (A227C) resulting in an A to E change at amino acid 76 (E76A). DNA sequencing showed that neither of the parents of the affected patient carried the E76A mutation, showing that this was a *de novo*, disease-causing mutation. This novel *SOX9* E76A mutation is the first identified in the 5' region upstream of the HMG binding domain. Remarkably, the mutation in question only caused CD and not sex reversal. The *SOX9* E76A mutant was produced by site-directed mutagenesis and expressed *in vitro*. Electromobility shift assay showed that the E76A mutation did not affect protein binding to a consensus sequence of the *SRY* HMG box, a known binding site for wild-type *SOX9*. The effects of the E76A mutation on DNA bending and transactivation are currently being examined and will add to the understanding of the *SOX9* protein function. The novel and unusual E76A mutation in *SOX9* associated with CD, highlights the importance of the N-terminal region of *SOX9* as a critical area involved in proper bone formation and not in sex reversal.

The human FGF2 level as an important cardiovascular risk factor is strongly influenced by the FGF2 genotype.

S. Schulz¹, P. Greiser¹, U. Schagdarsurengin¹, T. Suess¹, U. Mueller-Werdan², K. Werdan², C. Glaeser¹. 1) Inst of Human Genet., MLU, Halle, Germany; 2) Dep. of Intern. Med., MLU, Halle, Germany.

Among the important risk factors for coronary atherosclerosis FGF2 as a potent cytokine is standing out by its function in the proliferative response to vascular injury. Methods: 99 clinically, biochemically and by clinical history well examined patients with angiographically confirmed severe CAD were included (49.9y, SD 8.7, 85 males). The individual FGF2 protein- (ELISA, serum level) and mRNA-expression (competitive RT-PCR, cellular expression of native monocytes from venous blood) were related to the genotype constellation of the exon1-polymorphism C223T of FGF2 located in the 5-UTR in the functionally important ribosome entry site. Results: The patient group was characterized by a protein expression of 13.23 ag/cell and a FGF2-gene expression of 49.19 pg/ml. An association study resulted in a positive correlation of FGF2 mRNA and protein expression ($p < 0.001$). The genotype distribution of the C223T-polymorphism identified 84% of CC carriers, 14% heterozygous individuals (CT) and 2% homozygous mutation carriers (TT). The analyses of the genotype/expression relation revealed significant correlations on transcriptional ($p < 0.01$) as well as on translational level ($p < 0.001$). The highest values of both mRNA- and protein-expression were determined among CC-carriers (14.3ag/cell; 54.4pg/ml serum), whereas CT-carriers showed intermediate values (8.3ag/cell; 23.2pg/ml serum). The lowest values were found among TT-carriers: 3.3ag/cell; 14.5pg/ml serum. Conclusions: The FGF2- serum level can not be used itself as a risk marker in the atherosclerosis development. Apart from pathological processes it is strictly determined by the genetic constellation of the FGF gene, an association which must be considered in the interpretation of the individual coronary risk profile.

Functional analysis of DNA variants in ATM gene by mutagenesis. Z. Yang¹, M. Mitui¹, X. Sun¹, H.H. Chun¹, S. Nahas¹, S.P. Scott², M.F. Lavin², R.A. Gatti¹. 1) Department of Pathology, UCLA School of Medicine, Los Angeles, CA 90095-1732; 2) Queensland Institute of Medical Research, PO Royal Brisbane Hospital, Herston, Brisbane 4029, Australia.

Ataxia-telangiectasia (A-T) is an autosomal recessive disorder involving neurodegeneration, immunodeficiency, chromosomal instability, radiosensitivity, and cancer predisposition. The gene mutated in A-T is called ATM (A-T, mutated). Most ATM mutations found in A-T patients are truncation mutations. However, it has been difficult to determine whether certain missense variants in the ATM gene are mutations or polymorphisms. We have used site-directed mutagenesis to distinguish between functional and non-functional ATM variants, introducing missense substitutions identified in A-T patients into full-length ATM cDNA. We stably transfected the variant expression constructs, P1054R and S707P, into two A-T lymphoblastoid cell lines (AT1ABR and AT7LA) to determine the effect of the DNA change on ATM protein expression and kinase function, as well as on radiosensitivity (measured by the colony survival assay, CSA). Immunoblot results showed that both DNA variants induced ATM protein expression and this protein phosphorylated p53 serine 15 in the A-T LCLs; 'empty' constructs did not. Thus, both S707P and P1054R are polymorphisms, not mutations. CSA results are in progress. Other constructs are being evaluated. Mutagenesis represents an effective approach to distinguishing ATM mutations from polymorphisms.

Cellular dysfunction of mutant SCN5A proteins causing long QT syndrome and Brugada syndrome. *S. You, L. Wu, S. Chen, Q. Wang.* Department of Molecular Cardiology, Cleveland Clinic Foundation, Cleveland, OH.

Mutations in the SCN5A gene encoding the cardiac voltage-gated Na⁺ channel cause long QT syndrome (LQT3) and Brugada syndrome. LQT3 is characterized by a prolonged QT interval on electrocardiograms (ECGs), whereas Brugada syndrome is characterized by right bundle branch block and ST-segment elevation on ECGs. Clinically, both disorders cause ventricular arrhythmias and sudden cardiac death. SCN5A mutations causing LQT3 act by a gain-of-function mechanism, whereas those causing Brugada syndrome are functionally distinct from LQT3 mutations, and act by a loss-of-function mechanism. In this study we investigated the cellular localization of SCN5A mutants causing LQT3 syndrome and/or Brugada syndrome. Expression constructs for five LQT3 mutants, four Brugada syndrome mutants and one Brugada/LQT3 mutant were generated by mutagenesis and each mutant construct was transfected into HEK 293 cells. Immunofluorescent staining and fluorescence microscopy showed that the wild-type SCN5A subunit expressed in HEK 293 cells was localized onto the cell surface. However, SCN5A mutants causing LQT3 including DKPQ, N1325S, R1644H, D1790G and E1784K were localized to both cytoplasm and membrane, with predominant immunofluorescent staining in the cytoplasm. Brugada syndrome mutants including T1620M/R1232W, A1924T, L567Q and 4340delA were also localized onto the cytoplasm and membrane, with predominant immunofluorescent staining in the cytoplasm. Similar results were obtained for 1795insD that causes both LQT3 and Brugada syndrome. Our results suggest that defective surface localization of SCN5A mutants can account for the loss of SCN5A function in Brugada syndrome, and may explain why some LQT3 patients also present with the typical ECG pattern of Brugada syndrome.

Promoter polymorphisms within the IL-1 beta gene correlate positively with extracellular IL-1 beta protein

levels. *A.B. Seymour*¹, *D.G. Perregaux*², *C.A. Gabel*², *L.K. Durham*³, *S.K. Hall*¹. 1) Pharmacogenomics, Pfizer Global Research and Development, Groton, CT; 2) Antibacterials, Inflammation, and Immunology, Pfizer Global Research and Development, Groton, CT; 3) Non-Clinical Statistics, Pfizer Global Research and Development, Groton, CT.

The cytokine Interleukin (IL)-1 is a primary mediator in the pathogenesis of inflammatory diseases such as rheumatoid arthritis (RA), asthma and inflammatory bowel disease (IBD). Previous studies have associated a C3953T variant in exon 5 of the IL-1 gene with increased LPS-stimulated IL-1 protein secretion as well as linking two promoter variants to an increased risk of *H. pylori* induced hypochloridia and gastric cancer (Pociot et al., El-Omar et al.; Hamajima, et. al). We have investigated these polymorphisms within the IL-1 beta gene to test for a genetic contribution to interpatient variance observed with a blood-borne, two-step cytokine production assay that measures extracellular IL-1 levels generated in response to LPS and the combination of LPS/ATP; the nucleotide triphosphate enhances posttranslational processing. Genotypes were determined at three polymorphic loci throughout the IL-1 gene: C-511T, T-31C, and C3953T in each of the 31 subjects to test for association with secreted IL-1 protein levels. Individuals homozygous for the haplotype comprised of T-511, C-31 and C3953 (T-C-C) had a significantly higher mean level of LPS-induced IL-1 secretion compared to individuals with zero or one copy of this haplotype (3.3 ng/ml vs. 1.6 ng/ml, $p=.0028$). Further analysis of these data revealed that the association was driven by the T allele at position -511. This finding was replicated in a subsequent study of 30 subjects with rheumatoid arthritis where we observed -511 TT subjects had a significantly increased amount of extracellular IL-1 beta protein ($p=0.0017$) These data provide evidence that genetic variation within regulatory elements of the IL-1 gene may be associated with altered posttranslational processing efficiency. Finally, the T allele at -511 was observed to be significantly associated with hip osteoarthritis in females. (See Meulenbelt et. al, ASHG 2002).

Pseudoxanthoma Elasticum: Molecular investigations in a consanguineous family further supports the existence of pseudogenes (psABCC6) homologous to the ABCC6 gene. *V. Nau, D.P. Germain.* Department of Genetics, European Hospital Georges Pompidou, Paris, France.

Pseudoxanthoma elasticum (PXE) is an inherited systemic disorder of connective tissue, affecting the skin, the eyes, and the vascular system, with highly variable phenotypic expression. The PXE locus has been mapped to chromosome 16p13.1, and mutations in the ABCC6 gene (previously known as MRP6 or eMOAT), encoding a 1503-aminoacids putative membrane transporter of unknown function, have recently been disclosed as the genetic defect responsible for PXE (Bergen et al., Nat Genet 2000; Germain et al., BBRC 2000; Le Saux et al., Nat Genet 2000; Ringpfeil et al., PNAS 2000; Struk et al., J Mol Med 2000). We have identified a heterozygous missense mutation (G226R) in exon 7 of the ABCC6 gene in a PXE female patient, born from parents who were second cousins. Despite complete scanning of the gene, no further mutation was evidenced. A heterozygous profile was also found in the probands unaffected children, the mutant peak being of much lower amplitude. However, haplotype homozygosity was confirmed at locus 16p13.1, using both extragenic microsatellites (D16S3017 and D16S3060), and intragenic polymorphisms located 3' from mutation G226R (V614A in exon 14, and R1268Q in exon 27), in agreement with the known consanguinity in the family. Taken together, our data indicate that PCR products of exon 7 of the ABCC6 gene were amplified from more than 2 genomic copies. This further supports the existence of ABCC6 pseudogene(s) (psABCC6) highly homologous to the 5' end of the human ABCC6 gene (Germain, J Med Genet 2001). These results will prove invaluable when genotyping patients affected with PXE.

E-box mutation in *RAPSN* promoter region causes endplate (EP) acetylcholine receptor (AChR) deficiency. K. Ohno, J.M. Brengman, A.G. Engel. Dept Neurology, Mayo Clinic, Rochester, MN.

EP AChR deficiency is mostly caused by defects in AChR subunit genes, and, in some cases, in *RAPSN*. *RAPSN* encodes a 43-kDa postsynaptic protein rapsyn that plays an essential role in clustering AChR at the EP. The transcriptional control of *RAPSN* has not been studied to date. The E-box has the consensus sequence of CANNTG and binds to basic helix-loop-helix transcription factors. For muscle-specific genes, the E-box is essential for binding to myogenic determination factors MyoD, myogenin, Myf5, Myf6. Here we report a patient with EP AChR deficiency who is heteroallelic for two *RAPSN* mutations, N88K and an E-box mutation, -27C®G.

We previously reported that N88K has no effect on rapsyn self-association but compromises recruitment of AChR to rapsyn clusters (*AJHG* 70: 875-885, 2002). -27C®G is 27 nucleotides upstream of the major transcriptional start site and mutates the E-box sequence of CAGCTG to GAGCTG. -27C®G is not detected in 400 control alleles. RT-PCR analysis of muscle mRNA indicates that the allele harboring -27C®G is not transcribed.

Luciferase reporter assays reveal that the wild-type *RAPSN* promoter region spanning -586 to +172 drives C2C12-myotube-specific gene expression. Introduction of -27C®G reduces reporter expression 15-fold. Four copies of the wild-type *RAPSN* E-box fused to an SV40 promoter enhance reporter expression 53-fold in C2C12 myotubes, but introduction of -27C®G abolishes this effect.

Electrophoretic mobility shift assays indicate that a nuclear extract of C2C12 myotubes binds more efficiently to the wild-type than to the mutant *RAPSN* E-box. Similarly, in vitro synthesized MyoD and myogenin bind to the wild-type E-box more efficiently than to the mutant E-box.

Decreased association of AChR with rapsyn by N88K and reduced *RAPSN* expression in muscle by -27C®G account for the EP AChR deficiency in our patient. To our knowledge, this is the first report of a human E-box mutation.

A POSSIBLE ASSOCIATION BETWEEN THE T-287C POLYMORPHISM IN THE 5' REGULATORY REGION OF THE TISSUE FACTOR PATHWAY INHIBITOR GENE AND VENOUS THROMBOSIS. A.A.

NEKOO^{1,2}, *T.S. FUTERS*², *R.S.A ARIENS*², *P.J. GRANT*², *D.E. ILES*¹. 1) HUMAN GENETICS, THE UNIVERSITY OF LEEDS, LEEDS, YORKSHIRE, UK; 2) Molecular Vascular Medicine, School of Medicine, The University of Leeds, Leeds, UK.

Tissue factor pathway inhibitor (TFPI) is the principal regulator of tissue factor induced blood coagulation pathway. It inhibits FXa directly and inhibits TF-FVIIa indirectly by formation of the FXa/TFPI/TF/FVIIa quaternary complex. We have previously shown that low levels of total TFPI may be associated with deep venous thrombosis (DVT). DNA samples from 96 blood donors were screened for polymorphisms in the 5' flanking region of the TFPI gene by denaturing high performance liquid chromatography (DHPLC) using the Transgenomic WaveTM Analysis System. Samples showing different chromatogram patterns were selected for sequencing. A CT transition at -399, and a TC at -287 were identified. T-287C polymorphism was genotyped in 134 DVT patients who had low levels of TFPI and 120 sex-age matched as a control group. The 287C allele was found to be present at a significant higher frequency in the DVT patients with low total TFPI levels than control samples ($p=0.023$). Since we have previously shown that low total serum TFPI levels are associated with DVT in the same group of patients, we are currently investigating the effects of the promoter polymorphisms on TFPI gene expression using a luciferase reporter gene expression assay.

Transcriptional activity of variants of the Z-DNA forming NRAMP1 promoter repeat polymorphism. *M.G.*

Zaahl^{1,2}, *A.V. Peeters*², *L. Warnich*², *M.J. Kotze*^{2,3}, *K.J.H. Robson*⁴. 1) Division of Human Genetics, Faculty of Health Sciences, University of Stellenbosch, Tygerberg, South Africa; 2) Department of Genetics, University of Stellenbosch, Stellenbosch, South Africa; 3) Genecare Molecular Genetics, Christiaan Barnard Annexe, Cape Town, South Africa; 4) MRC Molecular Haematology Unit, Weatherall Institute of Molecular Medicine, John Radcliffe Hospital, Oxford, United Kingdom.

Background: NRAMP1 is thought to be involved in iron homeostasis. Previous studies indicated that allele 2 [t(gt)5(gt)5(gt)10] of a Z-DNA forming repeat polymorphism in the promoter region is associated with infectious disease susceptibility and allele 3 [t(gt)5(gt)5(gt)9] with autoimmune disease susceptibility. Aim: To determine the effect of the various repeat polymorphism alleles on NRAMP1 expression. Materials and methods: The variants were cloned in a luciferase-reporter vector (pGL2) and transfected into U937 and THP-1 cell lines using FUGENE 6. Cells were incubated in the absence and presence of exogenous stimuli, including interferon-g, bacterial lipopolysaccharide, bacterial lipopolysaccharide plus interferon-g, and ferric ammonium citrate. Luciferase activity in harvested cells was determined luminometrically. Results and Discussion: Six promoter variants were studied, including four previously described variants [alleles 2 and 3, allele 4 (t(gt)5(gt)5(gt)4) and allele 5 (t(gt)4(gt)5(gt)10)] and two novel variants [allele 6 (t(gt)5(gt)5(gt)6) and allele 7 (t(gt)5(gt)5(gt)8)], and one previously described base pair substitution (-237C/T). Ferric ammonium citrate caused a five-fold enhancement of luciferase reporter gene expression for allele 3 with U937 cells. Interferon-g and bacterial lipopolysaccharide caused a ten-fold enhancement of gene expression for allele 5 and a five fold-enhancement for the addition of interferon-g for the -237C/T polymorphism in THP-1 cells. Conclusion The alleles differ in their ability to drive gene expression between constructs and cell lines. These results support the hypothesis that this functional repeat polymorphism could contribute directly to the association of variants with infectious or autoimmune disease.

CTCF binding sites upstream of *GTL2/MEG3* form a methylation sensitive putative insulator in the imprinted domain of 14q32. *L.G. Shaffer*¹, *B. Kwabi-Addo*¹, *K.J. Coveler*¹, *Y.Q. Wu*², *V.R. Sutton*¹. 1) Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Clinical Cancer Prevention, M.D. Anderson Cancer Center, University of Texas, Houston, TX.

Genomic imprinting is an epigenetic phenomenon in which the activity of a gene is reversibly modified depending upon the parent of origin. This leads to unequal expression from the maternal and paternal alleles of a diploid locus. Regulation of one imprinted region, *IGF2/H19* on 11p15, is mediated through 7 CTCF binding sites located upstream of *H19*. At least two imprinted genes have been identified within the region containing *GTL2/MEG3* and *DLK1* on 14q32. Methylation of DNA sequences is one mechanism of regulating gene expression. Although it has been demonstrated that *GTL2/MEG3* is expressed exclusively from the maternal allele, the regulatory elements that modulate its allele-specific transcription are poorly understood. We identified six putative CTCF binding sites within the region immediately upstream of *GTL2/MEG3*. Using an electrophoretic mobility shift assay, we demonstrated CTCF binding to each of these six sites. Mutated or methylated CTCF binding sites showed reduced CTCF binding affinity compared to the wildtype sites. We demonstrated CTCF binding to our putative sites using a chromatin immunoprecipitation (ChIP) assay. One of these CTCF binding sites contains a CpG dinucleotide within a *SacII* restriction endonuclease site. Further analysis of this site using restriction enzyme digestion followed by Southern hybridization in seven individuals with uniparental disomy 14 (UPD14) showed differential methylation patterns between maternal and paternal homologues. This site was unmethylated on the maternally inherited chromosomes 14 and methylated on the paternally inherited chromosomes 14. Thus, we have demonstrated parent-specific methylation of sequences 5' of *GTL2/MEG3*. Based on our observations, we speculate that this CTCF-binding region may provide a mechanism for the transcriptional regulation of the imprinted genes *GTL2/MEG3* and *DLK1*, in a manner similar to the regulation of the *IGF2/H19* domain on 11p15.

Fabry Disease: Identification/Characterization of Novel Double Mutations in the α -Galactosidase A Gene. M.

Yasuda^{1,2}, *J. Shabbeer*¹, *S.D. Benson*³, *R.J. Desnick*¹. 1) Human Genetics, Mount Sinai School of Medicine, New York, NY; 2) Department of Pediatrics, Tokyo Women's Medical University, Tokyo, Japan; 3) Wistar Institute, Philadelphia, PA.

Fabry disease, an X-linked inborn error of glycosphingolipid catabolism, results from the deficient activity of the lysosomal exoglycohydrolase, α -galactosidase A (α -Gal A). To date, over 300 mutations have been identified in the α -Gal A genes of affected males with the classical or cardiac variant phenotypes. Here, we report three unrelated classically affected males who had two missense mutations in their α -Gal A alleles: C172G/D313Y, A143T/Q312H, and D264Y/V269M. Screening of 300 normal X-chromosomes indicated that only D313Y was a polymorphism, with a frequency of 3%. In retrospect, two other classical Fabry families also had the D313Y. To determine the disease causing mutations in the probands, the single and double mutated constructs were expressed in COS-7 cells, and their subcellular localization was determined by immunofluorescence. Compared to that of the wild type, the A143T, D313Y, and V269M constructs had ~40%, ~60%, and ~10% residual enzymatic activity, respectively. The D313Y and V269M mutant enzymes were sorted to the lysosomes, while A143T was detected in the ER and lysosomes. In contrast, Q312H, C172G, D264Y, and the double mutated proteins, which had no or <5% enzymatic activity, were retained in the ER. The relative proportions of the 55k Da precursor and 46k Da mature subunits for each mutant observed by Western blot analysis were consistent with the immunofluorescence results. Molecular modeling revealed that A143T, D313Y, and V269M did not alter the active site, whereas C172G and D264Y did. Q312H, opposite the active site, caused misfolding, while D313Y was active. These are the first structure-function correlations for human α -Gal A, and provide further understanding of the disease causing lesions. Furthermore, these studies highlight the importance of expression analysis of each base substitution for the accurate distinction of mutations and polymorphisms.

Comprehensive expression profile of a newly cloned RNA binding protein gene. *Y. Wang*¹, *G. Lu*³, *GL. GL. Wilson*¹, *L. Tan*¹, *J. Gu*², *T.-J. Chen*¹. 1) Medical Genetics, University of South Alabama, Mobile, AL; 2) Biomedical Sciences, University of South Alabama, Mobile, AL; 3) Genzyme genetics, NY.

Newly cloned human CPEB gene encodes an RNA binding protein, which can specifically recognize the cytoplasmic polyadenylation element (CPE) on mRNA. In mouse, and *C. elegans*, CPEB has been shown to play roles in both polyadenylation-dependent translational activation and CPE-directed translational repression. In mouse brain, CPEB is highly expressed in neuronal cell bodies and synapto-dendritic compartments. Its translational regulation function in response to synaptic stimulation has been shown to be a very important step in synaptic plasticity, which is the basis for the learning and long-term memory storage. We attempted to explore the functions of CPEB in human, since defects in this gene may lead to mental retardation. The cloned cDNA of hCPEB is about 2000 bp. It encodes a 486 amino acid protein with a predicted molecular weight of 54 KD. Its amino acid sequence has an overall 95% identity to mouse CPEB with particularly high homology on the two RNA recognition motifs and the zinc finger domain. The hCPEB comprehensive expression profiles from 22 tissue types were determined by RT-PCR. The first-strand cDNAs from each tissue were first tested and normalized using b-actin cDNA as an internal standard. Human CPEB cDNA and the b-actin cDNA were co-amplified in the same tube. Results from this RT-PCR assay revealed that hCPEB has high-level expression in brain, ovary and testis. However, very low expression in liver, stomach, and skin. Heart, kidney, skeletal muscle, thyroid, adrenal gland, and pancreas have moderate levels of expression. Its expression in the fetal brain is much lower than in the adult brain. In situ hybridization revealed that hCPEB expression is limited to neurons in the human brain. Specific labeling of hCPEB was detected in the cytoplasm of the neurons in the cortex but absent from the nuclei and the extracellular space. Most of the neurons were positive. Our results suggest that hCPEB has a similar expression profile to mouse CPEB and may have similar functions in translational regulation in human brain.

INFLUENCE OF THE APOLIPOPROTEIN POLYMORPHISMS ON PLASMA LIPID LEVELS IN

BRAZILIAN CHILDREN. *E. FRANCA*¹, *J.G.B. ALVES*², *A.S. ARAUJO*³, *M.H. HUTZ*¹. 1) Universidade Federal do Rio Grande do Sul, Porto Alegre, Rio Grande do Sul, Brazil; 2) Instituto Materno Infantil de Pernambuco, Recife, Pernambuco, Brazil; 3) Hemocentro de Pernambuco, Recife, Pernambuco, Brazil.

Genetic studies in adults have shown that common polymorphisms in gene coding for apolipoproteins are significant determinants of plasma lipid levels variation. The influence of the allelic variation at the APOE gene locus (E*2, E*3 and E*4) on plasma lipoprotein parameters have been well evaluated. This influence have not been clearly established for others apolipoproteins. We have studied five apolipoprotein polymorphisms, including APOE/HhaI, APOA-I/MspI-75bp, APOA-I/MspI+83bp, APOA-IV/HinfI and APOA-IV/PvuII in 414 (221 boys and 193 girls) unrelated children aged 5 to 15 years from Pernambuco, a Brazilian Northeast state. The frequencies of the APOE alleles (E*3, E*4 and E*2) were 0.77, 0.17 and 0.06, respectively. The rare allele(A) frequency for the polymorphism APOAI/MspI was 0.18 at -75bp and 0.11 at +83bp. The frequencies of the 347Ser and 360His alleles of the APOA-IV were 0.14 and 0.03, respectively. The influence of the alleles on lipid traits was evaluated by ANOVA test or Kruskal-Wallis test. The allele E*2 is associated with lower levels of Total ($p<0.001$), LDL-C ($p<0.001$) and Total/HDL-C ratio ($p<0.001$). Conversely, the E*4 allele is associated with higher levels of these lipids. No significant association was observed between plasma lipids and the APOA-I/MspI -75bp polymorphism. However, girls heterozigous(+/-) for loss of the site APOA-I/MspI+83bp had higher ($p<0.026$) HDL-C levels than girls homozigous(++). The polymorphism APOA-IV/360PvuII was not associated with lipid concentrations. In the APOA-IV/347HinfI polymorphism the Ser allele was significantly associated in girls ($p<0.016$) with increased HDL-C when compared to Thr allele. These data indicate that the effect of the apolipoprotein polymorphisms on plasma cholesterol levels also can be observed in children.

Human Glycerol Kinase (GK): Tissue-Specific Expression Patterns of Two Alternatively Spliced mRNAs from the Xp21 GK gene. *R.H. Ohira*¹, *K.M. Dipple*², *E.R.B. McCabe*^{1, 2, 3}. 1) Departments of Human Genetics, and; 2) Pediatrics, David Geffen School of Medicine at UCLA; 3) UCLA Molecular Biology Institute, Los Angeles, CA 90095.

Glycerol kinase (GK) phosphorylates glycerol to glycerol 3-phosphate, an intermediate in the formation of glycerolipids. Mutation of GK causes GK deficiency (GKD), an X-linked inborn error of metabolism. There are two alternatively spliced forms of GK: with exon 18 (GK+EX18) in human fetal brain and testes (Sargent et al, Hum Molec Genet 3:1317, 1994) or without exon 18 (GK-EX18) found in liver (Guo et al, Nature Genet 4:367, 1993). Our purpose was to determine the expression profiles of the GK mRNAs in different tissues. Reverse transcriptase-polymerase chain reaction (RT-PCR) using primers to the human Xp21 GK sequence within exon 16 and the 3'-untranslated region (3'UTR) resulted in a 280 bp product for GK+EX18 or 193 bp product for GK-EX18. RT-PCR was conducted on human fetal brain, adult brain, liver, kidney and testis poly-A RNA, as well as on total RNA extracted from cell lines including HepG2 (human liver), WRL-68 (human fetal liver), A-549 (human lung), Cos-7 (monkey kidney), H-4-II-E (rat liver), McA-RH7777 (rat liver), NMuLi (mouse liver), a lymphoblastoid cell line (LBL) derived from a GK-deleted patient (131509-1), and two LBLs from normal individuals. Human liver and kidney only expressed the GK-EX18 transcript. However, human fetal brain, adult brain, testis, the two normal LBLs and the WRL-68 cell line expressed both transcripts, with the GK+EX18 transcript being more prevalent. HepG2 expressed both transcripts with equal intensity. The non-human cell lines (A-549, Cos7, H-4-II-E, McA-RH7777 and NMuLi) and the GK-deleted LBL did not have either PCR product, indicating that the RT-PCR was human-specific and Xp21 GK-specific. We conclude that the two alternatively spliced human GK mRNAs are differentially expressed and speculate that these differences in expression patterns suggest specific and possibly divergent functions for the GK+EX18 and GK-EX18 proteins.

Methylation analysis of the promoter region in fragile X males with hypermethylated, full mutation alleles. *F. Tassone*¹, *P. Sahota*¹, *N. Pleasant*², *C. Laird*², *P. Hagerman*¹. 1) Dept Biological Chemistry, Univ California, Davis, Davis, CA; 2) Department of Zoology, University of Washington, Seattle, Washington.

Methylation of the CpG islands in housekeeping genes has been shown to cause their transcriptional silencing. Expansion of the trinucleotide repeat CGG, located within the 5'UTR of the Fragile X mental retardation 1 gene (FMR1) leads to hypermethylation of -CpG dinucleotides within and upstream of the repeat element. As a consequence the gene becomes silenced and no FMR1 protein is produced. Although methylation of the FMR1 gene is generally accompanied by the absence of FMR1 transcript, we have recently reported a group of male carriers of hypermethylated full mutation alleles who escape the silencing process to varying degrees. Thus, hypermethylation, normally defined as resistance to enzyme cleavage, does not always lead to gene silencing. In order to determine if the absence of specific CpG methylation events within the CpG island region is associated with continued gene activity for hypermethylated full mutation alleles, we have used bisulfite-coupled sequencing to map the positions of methylated/unmethylated CpG dinucleotides in the genomic DNA from twelve males with hypermethylated FMR1 alleles. The region analyzed is, upstream of the CGG repeat element, about 450 bp in length, and contains 52 CpGs. Here, we report progress in our analysis of all methylation pattern variants in this region of the FMR1 promoter. Based on a total of over 400 clones from twelve males (about 35 cloned alleles/male), our results to date indicate that even within heavily methylated alleles, there exist distributed positions that remain at least partially unmethylated; that is, methylation patterns are not all-or-none.

Ferroxidase Activity of Frataxin, the Protein Deficient in Friedreich Ataxia. *O. Gakh*¹, *S. Park*¹, *S.M. Mooney*¹, *H.A. O'Neill*¹, *H.K. Nichol*², *I.J. Pickering*², *G.N. George*², *A. Mangravita*³, *G.C. Ferreira*³, *G. Isaya*¹. 1) Dept. of Pediatric & Adolescent Medicine and Biochemistry & Molecular Biology, Mayo Clinic, Rochester, MN; 2) Stanford Synchrotron Radiation Laboratory, SLAC, Stanford, CA; 3) Dept. of Biochemistry & Molecular Biology, University of South Florida, Tampa, FL.

The mitochondrial protein frataxin is required for cellular iron homeostasis but its mechanism of action is not yet known. We showed previously that in the presence of Fe(II) recombinant yeast frataxin (mYfh1p) assembles into a 840 kDa complex that accumulates iron in soluble form (*Adamec et al. 2001; Gakh et al. 2002*). Iron cores of 2-4 nm are detected by STEM-EDS, and high-resolution EXAFS to $18 \text{ K } \text{\AA}^{-1}$ demonstrates that they resemble 6-line ferrihydrite, the principal biomineral found in ferritin. The mechanism of iron incorporation into the mYfh1p complex has been investigated. The protein binds Fe(II) and regulates its oxidation to Fe(III) in two phases. The first phase corresponds to the assembly of an oligomeric species that catalyzes iron oxidation with a Fe(II)/O₂ stoichiometry of ~2 consistent with ferroxidase activity. The second phase is characterized by Fe(II)/O₂ stoichiometry of ~4 consistent with autoxidation. During stepwise assembly of the complex, ferroxidation is rapidly overcome by a slow autoxidation phase during which the remaining Fe(II) is loosely bound to the protein and can be readily donated to a chelator or the mitochondrial enzyme ferrochelatase to synthesize heme. Assembly is completely inhibited under anaerobic conditions indicating that mYfh1p senses the presence of both Fe(II) and O₂. Frataxin may therefore represent a mechanism to limit participation of Fe(II) in radical-generating reactions and at the same time promote mitochondrial iron metabolism. Supported by NIH/NIA AG15709.

Identification and characterization of human MNMA gene related to mitochondrial tRNA modification. *Q.F. Yan, R.H. Li, X.M. Li, M.X. Guan.* Dept Human Genetics, Children's Hosp Medical Ctr, Cincinnati, OH.

The nucleotide modification in tRNA plays a pivotal role in the fidelity of translational process. The defects in nucleotide modification have often been observed in the mutated mitochondrial tRNAs associated with human diseases. Recently, bacterial *mnmA* encodes the 5-methylaminomethyl-2-thiouridylate methyltransferase, which has been shown to be a component of tRNA modification pathway. Here we report the identification and characterization of human MNMA homolog. Based on the available human EST sequence homologous to bacterial *mnmA*, we have isolated and characterized the human MNMA cDNA and elucidated the genomic structure of this gene. This gene encodes a predicted protein of 47,714 daltons with a typical mitochondrial targeting sequence. The amino acid alignments of the human MNMA with other identified homologs from different species revealed an extensive evolutionary conservation in amino acids and size. This gene, localized in chromosome 21, is composed of 11 exons, ranging from 54 bp to 498 bp and 10 introns varying from 89 bp to 5,317 bp. MNMA is ubiquitously expressed in various tissues, but with markedly elevated expression in tissues of high metabolic rates. We also showed that Gtpbp3 localizes in the mitochondrion by immune-staining with specific antibodies and analyzing with a confocal microscopy. These observations imply that human MNMA is a structural and functional homolog of bacterial *mnmA*, thereby playing a role in the mitochondrial tRNA modification and protein synthesis.

Mice deficient in pyrin, the FMF protein, show increased sensitivity to endotoxin through a new pathway regulating IL-1 activation and apoptosis. *J.J. Chae*¹, *J. Cheng*², *H. Komarow*¹, *G. Wood*¹, *N. Raben*³, *P.P. Liu*², *D.L. Kastner*¹. 1) Genetics and Genomics Branch, NIAMS, NIH, Bethesda, MD; 2) Genetics and Molecular Biology Branch, NHGRI, NIH, Bethesda, MD; 3) Arthritis and Rheumatism Branch, NIAMS, NIH, Bethesda, MD.

Familial Mediterranean fever (FMF) is a recessive disorder of inflammation characterized by episodes of fever with serositis or synovitis. To facilitate studies of pyrin's function, we have used gene targeting to produce mice with a disruption of *Mefv*. These mice exhibit exaggerated body temperature responses to endotoxin (LPS) relative to wild-type littermates. To explore the mechanism of endotoxin sensitivity in pyrin-deficient mice, we studied protein expression by Western blotting in peritoneal macrophages. In peritoneal macrophages from normal animals, mouse pyrin (mpyrin) was induced by LPS and by the anti-inflammatory cytokines IL-4 and IL-10. Induction of mpyrin inhibits IL-1 processing, as evidenced by the fact that peritoneal macrophages from pyrin-deficient mice, but not their wild-type littermates, produced large amounts of mature (cleaved) IL-1a and IL-1b when treated with IL-4 and LPS. Moreover, when the RAW264.7 mouse monocytic cell line was transfected with full length *Mefv*, LPS-induced mature IL-1b was markedly diminished. We found that this effect is likely to be mediated through mASC, an adaptor protein containing an N-terminal pyrin domain (PYD) and a C terminal CARD. As has recently been shown in the human, we found that mpyrin binds mASC through homotypic PYD interactions. We further observed that mASC binds procaspase-1 (interleukin 1 converting enzyme), and, when transfected into RAW264.7 cells, mASC mediated processing of procaspase-1 into active subunits capable of cleaving IL-1b. Pyrin appears to inhibit this pathway, since, in pyrin-deficient mice, LPS induced caspase-1 activation was much greater than in wild-type littermates. We also found evidence for defective apoptosis in the peritoneal macrophages of pyrin-deficient mice. Taken together, these results suggest that pyrin acts as an anti-inflammatory molecule by inhibiting IL-1 production and by permitting monocyte apoptosis.

Analysis of the survival of motor neuron (SMN1) gene mutations in Spinal Muscular Atrophy through models. *N. Owen*¹, *U. Monani*², *S. Squire*¹, *M. Sendtner*³, *A. Burghes*², *K.E. Davies*¹. 1) Dept Human Anatomy/Genetics, University of Oxford, Oxford, UK; 2) Dept. of Molecular Genetics, Ohio State University, Columbus, Ohio; 3) Dept. of Neurology, University of Würzburg, Würzburg, Germany.

Childhood onset Spinal Muscular Atrophy (SMA) is a common autosomal recessive disorder characterised by the loss of a motor neurons and proximal muscle weakness. The Survival Motor Neuron (SMN1) gene is mutated/deleted in the majority of SMA patients and undergoes little alternative splicing. However expression of the copy gene SMN2 results in predominately alternatively spliced transcripts lacking exon 7 or 5. Therefore, in patients the amount of full length SMN protein is markedly reduced. The SMN protein has been demonstrated to be involved in an increasing number of cellular processes, including; RNA processing, snRNP biogenesis, and transcriptional activation, although these functions do not elucidate why this disease has such a specific target tissue.

To further understand the effect of patient mutations and the alternative splicing of SMN2 we have characterised mutant SMN proteins in a number of different cell lines. To specifically characterise the loss of exon 5 of SMN2 transcripts, the second most frequently alternatively spliced exon, we have generated transgenic mice expressing human SMN25. A second transgenic line utilises the E134K patient mutation, a mutation known to alter the interaction of SMN with Sm core proteins. The function of these transgenes was analysed by crossing onto the *Smn* null background..

Analysis of our model system in the yeast has lead to the identification of a important missense mutation in a highly conserved region of the SMN peptide. This domain is analogous to a sequence in human exon 5, spliced in some SMN2 transcripts. To date, the only proteins known to interact with this region of SMN are the profilins (PFNI and PFNII). In vitro binding assays have been carried out to investigate the effect of mutation of SMN on binding to profilins.

Generation of a mouse model of Willams-Beuren Syndrome. *T. Onay*¹, *L. Osborne*², *L-C. Tsui*^{1,3}. 1) The Department of Genetics, the Hospital for Sick Children; 2) the Department of Medicine, University of Toronto; 3) and the Department of Molecular and Medical Genetics, University of Toronto, Toronto, Ontario, Canada.

Willams-Beuren Syndrome (WBS) is an autosomal dominant multisystem developmental disorder caused by haploinsufficiency for genes in a 1.5Mb region of human chromosome 7q11.23. The commonly deleted region encompasses about 18 genes, which include the elastin gene (ELN) that is known to be responsible for the cardiovascular lesions; however, the genes contributing to the other symptoms remain undetermined. Recent studies have narrowed the critical region spanning eight genes including ELN, but further refinement has been difficult due to the paucity of additional deletions. It is therefore unclear whether the complex phenotype is the result of deletion of contiguous genes or a subset of them. We aim to study the effects of multiple gene deletions and to use gene complementation to rescue aspects of the resulting phenotype. A mouse model of WBS is being created with a large deletion spanning seven genes from the critical region with the exclusion of ELN. Our approach is based on the Cre/loxP site specific recombination system. To enable this work, a detailed physical map for the telomeric region of mouse chr. 5, homologous to the human 7q11.23 region, has been constructed. There is remarkable conservation of gene content and order between human and mouse for the region. Accordingly, a proximal 5Hprt-loxP cassette was targeted into the *Gtf2i* gene in mouse ES cells, with the replacement of a 1073bp fragment containing part of exon30 and exon31. 42 of correctly targeted ES cell clones have been identified at a targeting frequency of 25% and two of these lines are being used to insert a second loxP cassette into the *Limk1* gene, which is located about 500Kb telomeric to *Gtf2i*. Cell lines with properly juxtapositioned cassettes will be used to generate the intended, large deletion. Correctly rearranged ES cells will be used to generate hemizygotously and homozygotously deleted mutant mice to help understand the pathogenic basis of the WBS phenotype. This mouse model should provide insight into the mechanisms leading to growth and developmental disturbances observed in the WBS patients.

Palmitoyl-protein thioesterase 1 (PPT1) function in *Drosophila*: Towards a molecular understanding of infantile neuronal ceroid lipofuscinosis. *C.A. Korey, M.E. MacDonald.* Molecular Neurogenetics Unit, Massachusetts General Hospital, Bldg 149, 13th Street, Charlestown, MA 02129.

The most common pediatric neurodegenerative diseases (1 in 12,500 births) are a set of primarily recessive disorders termed Neuronal Ceroid Lipofuscinoses (NCLs). The individual NCLs are classified by their characteristic membrane/protein inclusion pathology and age of onset. The symptoms of the disorders include loss of vision, motor dysfunction, intellectual decline, and seizures. Genetic analysis of the NCLs has identified 8 loci, CLN1-8, that are associated with the differing ages of onset of the disorders. CLN1 was identified as the defective gene in infant onset NCL (INCL) and it encodes the enzyme palmitoyl-protein thioesterase 1 (PPT1). PPT1 is one of the enzymes that catalyze the de-palmitoylation of protein substrates at specific cysteine residues. Its biochemical function suggests that the loss of PPT1 may cause defects in signaling pathways and membrane/protein trafficking through the misregulation of the palmitoylation state of specific proteins, such as PSD95, Ras, SNAP 25, and the neuronal protein GAP-43. This palmitoylation event is dynamic and may play a role in correct membrane trafficking, protein localization and protein-protein interaction. Consistent with this and the fact that neurons are preferentially affected, recent work suggests that CLN1/PPT-1 is associated with synaptic vesicles and synaptosomes in neuronal cell culture. A search of the *Drosophila* genome sequence has found that only the infant onset (CLN1) and the juvenile onset (CLN3) proteins have homologs in the fruit fly. The use of over-expression in *Drosophila* has proven to be a powerful method of understanding gene function and identifying companion signaling components. For example, components of both the dRac1 and dRas signaling pathways were identified through their over-expression in the developing adult visual system. We have developed an over-expression assay, using the GAL4-UAS system, to begin to elucidate the normal cellular functions of *Drosophila* CLN1, thus shedding light on the INCL disease mechanism.

Gene expression in spinal cords of Spinal Muscular Atrophy mouse models. *C.M. Armour^{1,2}, S. Balabanian¹, S. Hayward-McClelland¹, N.H. Gendron¹, A.E. MacKenzie^{1,3,4}*. 1) Molecular Genetics Laboratory, Research Institute, Children's Hospital of Eastern, Ottawa, Ontario, Canada; 2) Department of Clinical Genetics, Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada; 3) Department of Pediatrics, Faculty of Medicine, University of Ottawa, Ottawa, Ontario, Canada; 4) Department of Biochemistry, Microbiology and Immunology, Faculty of Medicine, University of Ottawa, Ottawa, Ontario, Canada.

Spinal Muscular Atrophy (SMA), an autosomal recessive disorder characterized by symmetrical muscle wasting due to motor neuron death, is caused by deletions of the SMN1 gene (survival of motor neuron). A number of SMN interacting partners have been identified and SMN functions proposed, chiefly associated with the machinery which processes hnRNA to mRNA. However, the mechanism causing the strikingly specific motor neuron degeneration remains unknown. In an effort to answer this question, we are establishing a detailed profile of mRNA changes caused by SMN depletion in spinal cords of mice with mild SMA (Schrank et al., 1997). Mice that are *Smn* haploinsufficient (*Smn* +/-), lose 50% of their motor neurons by 6 months and are used as a model for human type III SMA. RNA from spinal cords of 5 week old (*Smn* +/- and *Smn* +/+) mice have been used for representational difference analysis (RDA) and DNA microarray hybridization (Affymetrix). RDA (subtractive hybridization combined with selective PCR amplification) has identified approximately 250 transcripts which are either enriched or depleted in *Smn*+/- spinal cords when compared with *Smn* +/+ wild type siblings. We have identified approximately 100 significant changes in the Affymetrix arrays. We have further confirmed these changes in expression by semi-quantitative RT-PCR. Clones obtained by both these methods can be classified into major groups including cell cycle regulation, cell differentiation and proteolytic degradation.

SUBCELLULAR LOCALISATION OF PYRIN PROTEINS CARRYING DIFFERENT FMF MUTATIONS, EXPRESSED IN HELA CELLS. *S. Papin, C. Cazeneuve, P. Duquesnoy, I. Jeru, S. Amselem.* Genetics, INSERM U468, Creteil, France.

Mutations in MEFV, a gene encoding the pyrin, are associated with familial Mediterranean fever, a genetic condition characterised by febrile episodes of serosal inflammation. The function of pyrin is still unclear, although recently, the ASC (Apoptosis Speck protein containing a CARD) protein has been shown to interact with the pyrin domain of pyrin, both proteins being colocalized in specks, suggesting that pyrin may play a role in regulation of apoptosis. To study the influence of MEFV mutations on the subcellular localisation of pyrin, we transiently expressed in HeLa cells wild type pyrin-GFP (pyrin fused to GFP protein) or pyrin-GFP harbouring either the M694V, M694I, V726A, M680I or E148Q mutation; we also co-expressed the different forms of pyrin-GFP (wild type and mutated forms) together with ASC (fused to a V5 tag). The ASC protein was revealed using a mouse anti-V5 antibody and secondary anti-mouse antibody coupled with the red fluorescent molecule Cy3. In cells transfected with pyrin, we found that all the mutated pyrin-GFP proteins localised exclusively in the cytoplasm, with a pattern similar to the one observed with the wild type pyrin-GFP. Cells expressing a low level of recombinant pyrin exhibited a labelling homogeneously distributed over the entire cytoplasm, whereas cells expressing high levels of pyrin presented often with highly fluorescent bodies over a faint and homogeneous cytoplasmic labelling. In cells co-expressing ASC and pyrin-GFP, the green fluorescence due to pyrin-GFP and the red fluorescence corresponding to ASC were concentrated in specks, whatever the pyrin-GFP construct (wild type or mutated forms). These results suggest that these MEFV mutations do not affect the subcellular localisation of pyrin. In addition, whatever the consequences of the mutant pyrin protein in the regulation of apoptosis, it is tempting to speculate that these consequences do not result from an absence of ASC/pyrin colocalisation.

Program Nr: 939 from 2002 ASHG Annual Meeting

Association of syncoilin and desmin: linking intermediate filament proteins to the dystrophin-associated protein complex. *E. Poon, E.V. Howman, J.E. Britton, S.E. Newey, A.C. Potter, K.E. Davies.* Department of Human Anatomy and Genetics, Oxford University, Oxford, Oxfordshire, UK.

Duchenne muscular dystrophy is an X-linked muscle-wasting disease that affects 1 in 3500 boys and is caused by mutations in the dystrophin gene. In skeletal muscle, dystrophin associates with a number of proteins to form the dystrophin-associated protein complex (DAPC). We recently identified a novel protein, syncoilin, through its interaction with alpha-dystrobrevin, a member of the DAPC. Syncoilin is a putative intermediate filament (IF) protein and has been shown to interact with desmin, the main IF protein in muscle. Syncoilin is upregulated in human and mouse myopathies, suggesting a role in maintaining muscle fibre integrity. Through its interaction with alpha-dystrobrevin and desmin, syncoilin provides a link between the DAPC to the cytoskeleton. Syncoilin is therefore an ideal candidate gene for muscular dystrophies and desmin-related myopathies. To further our understanding of syncoilin function in skeletal muscle, we have a) analysed syncoilin expression in various mouse mutants, b) investigated post-translational modification and c) utilized several cell-lines to analyse filament formation.

The Assembly of Muscle Sarcoglycans in Cell Cultures. *W. Shi¹, J. Shottenfeld¹, L.M. Kunkel², Y. Chan¹.* 1) The Henry Hood Research Program, Sigfried and Janet Weis Center for Research, The Geisinger Clinic, Danville, PA; 2) Howard Hughes Medical Institute and Division of Genetics, Children's Hospital and Harvard Medical School, Boston, MA.

Sarcoglycans (SGs) are a group of four transmembrane proteins that form a complex on the muscle membrane. Mutations in SGs have been shown to cause the autosomal recessive form of Muscular Dystrophy known as Limb-Girdle Muscular Dystrophy. Mutation in one sarcoglycan often results in the loss of other sarcoglycans on the membrane. Using a heterologous expression system, we study the assembly and transport of the sarcoglycans in mammalian cell culture. Expression of all four sarcoglycans showed they are localized to the cell membrane. However, expression of the a-SG alone produced a Golgi-like immunofluorescent staining while b-SG, g-SG or d-SG each generated an ER-like pattern of staining. In addition, the staining pattern of b-SG revealed a uniform distribution in the ER by confocal microscopy while d-SG and g-SG often formed distinctive aggregates. Co-transfection of b-SG with other sarcoglycans demonstrated that 1) b-SG co-localized with either g-SG or d-SG to produce a uniform staining in the ER, 2) b-SG did not co-localize with a-SG in the absence of the other two sarcoglycans, 3) expression of both b-SG and d-SG is sufficient to cause their localization to the cell membrane. Finally, by mutagenesis, we have mapped the glycosylation and intra-molecular di-sulfide bond sites in the sarcoglycans. The results suggest that b-SG and d-SG / g-SG form a critical core for the assembly of the sarcoglycan complex during the early stage of their biosynthesis and they do not interact with g-SG until reaching the Golgi. Thus, there is a hierarchy in the assembly of sarcoglycans and their transport to the membrane is tightly controlled at each stage.

3D structure Modeling for human iduronate and Prediction of Effects by the mutation which was found in Korean patients with Hunter syndrome. *K.B. Moon¹, C.H. Kim², H.Z. Hwang², K.H. Paik¹, J.H. Yoon³, C.K. Han³, D. Jin^{1,2}.* 1) Pediatrics, Samsung Medical Center, Seoul, Seoul, South Korea; 2) Samsung Biomedical Research Center Dept. Medical Genetics; 3) IDR Tech Inc.

Hunter syndrome is a rare, X-linked, recessively inherited disease affecting multi-organ systems. The disease is caused by the inability to degrade dermatan sulphate and heparan sulphate, which is due to mutations in the iduronate-2-sulphatase gene (IDS). The mutations causing the disorder are heterogeneous, ranging from small micro-lesions to gross deletions and inversions. As the first attempt to examine the molecular changes of IDS gene in the Korean Hunter patients, we have screened DNA samples from 35 Korean families with Hunter syndrome using the polymerase chain reaction and single-strand conformation polymorphism analysis. As a result, we have identified and characterized 21 mutations (Table 1). Also 3D modeling structure of iduronate 2 sulfatase was constructed from the known X-ray structures of several sulfatases. We depicted the mutation data at the 3D structure of the enzyme to understand the importance of the mutation in term of functional significance. Our findings indicate that most of the mutation points of IDS gene is located at peripheral areas, but structurally critical points that can cause problem during refolding of protein, although the the mutations of IDS gene in the Korean Hunter syndrome patients are likely to be heterogeneous. Our findings consequently aid to understand the underlying mechanisms associated with this disease.

Modeling splice site and transcription factor binding site variation by information theory. *P.K. Rogan¹, S.R. Svojanovsky¹, I. Hurwitz¹, T.D. Schneider², J.S. Leeder¹*. 1) Children's Mercy Hosp, Kansas City, MO; 2) National Cancer Institute, Frederick, MD.

We have validated information theory-based models for human acceptor and donor splice sites and NF- κ B heterodimer binding sites. The average information describes the range of variation in sites having a common function, whereas the information content of a single site (R_i) measures its conservation within a family of binding sites. The strengths of different sites can be directly compared based on their respective R_i values, since R_i is related to the free energy of binding. The splice site models comprise a set of automatically curated donor ($n=111,772$) and acceptor ($n=108,079$) sites from all known genes in the human genome draft sequence. These comprehensive models accurately predict the effects of mutations, polymorphisms and cryptic splicing, including variants which partially abolish splicing and often produce milder clinical phenotypes. The NF- κ B model was derived initially from previously known strong sites and then iteratively refined by incorporating binding sites predicted from the initial model and validated by EMSA studies. The NF- κ B model accurately rank orders the strengths of known binding sites in competitor EMSA assays, and distinguishes promoters of genes regulated by NF- κ B from those in which transcription is not known to be induced. The model was validated by detecting known (and previously unrecognized) sites in promoters of each of 13 genes regulated by NF- κ B that were excluded from the initial model. The most sensitive and specific information theory-based models are based on sites spanning a wide range of binding affinities. A CCAAT-box protein binding site model ($n=175$) based on the TRANSFAC database accurately predicted a ³1.4 fold increase in binding strength due to a G>A substitution in the promoter of the A_γ -globin gene that results in HPFH. Many other transcription factor binding sites collated in TRANSFAC are biased towards strong binding sites. More representative models will be required to detect weaker binding sites and to reliably assess the effects of mutations. Supported by PHS R01 ES10885-02 and the Merck Genome Research Foundation.

Identification of a novel deletion mutation in the 3' untranslated region (3'UTR) of the lipoprotein lipase gene in Hispanics and its association with the components of glucose homeostasis. *H. Razzaghi*¹, *R.M. Hamman*², *M.I. Kamboh*¹. 1) Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA; 2) Dept Preventive Medicine and Biometrics, Univ Colorado, Denver, CO.

The enzyme lipoprotein lipase (LPL) plays a central role in lipid metabolism and many diseases, including atherosclerosis, obesity, and insulin resistant syndrome, appear to be directly or indirectly related to abnormalities in LPL function. Numerous studies have shown that the LPL gene is sensitive to hormonal regulation of insulin. However, the part of the gene that is insulin sensitive (insulin response element, IRE) has yet to be identified. Using bioinformatic techniques, we identified a 19 bp sequence as a putative IRE in the LPL 3'UTR (exon 10). We then targeted this region for mutational screening using SSCP in three population groups, including Hispanics (N=406), Whites (N=614), and Blacks (N=100). In the putative IRE, a novel five-base deletion mutation (5D2014) was identified only in Hispanics with a carrier frequency of 4.2%. Genotype-phenotype association studies of this ethnic-specific mutation with components of lipid and glucose homeostasis revealed its significant association with elevated insulin, C-peptide, and decreased fasting glucose. Analysis of the mRNA secondary structure of this mutation suggests that mutant RNA is less stable than the wild type. DNA-protein interaction studies using electrophoretic mobility shift assay (EMSA) of the putative IRE revealed binding sites for regulatory factor(s) from muscle cell nuclear extracts. Expression studies are in progress to test the involvement of the 5D2014 mutation in the LPL mRNA stability. In summary, we have identified a novel 5 bp deletion mutation in the putative IRE of LPL that alters the secondary structure of LPL mRNA and is associated with components of glucose homeostasis.

Analysis of the RNA component of human telomerase and its associated activity. *M. Dickman*¹, *J.P. Rose*², *M.A. Marino*³, *D.P. Hornby*². 1) Transgenomic Research Lab, Univ Sheffield, Sheffield, UK; 2) Department of Molecular Biology and Biotechnology, Krebs Institute, Univ Sheffield, Sheffield, UK; 3) Transgenomic, Inc., Gaithersburg, MD.

Functional RNA molecules possess a high degree of secondary and tertiary structure and often adopt complex conformations. Analysis of RNA *in vitro*, involves transcription, traditionally followed by purification and analysis by denaturing gel electrophoresis. The RNA generated in this way often appears as multiple species following electrophoresis. Here we report the use of ion pair reverse phase liquid chromatography under denaturing conditions using the WAVE® DNA Fragment Analysis System (Transgenomic, Inc.) to analyse the RNA component of human telomerase RNA. Furthermore, the chromatography separation process has been extended to analyse folded (or multimeric) RNA species by the incorporation of Mg²⁺ ions into the chromatography buffers. Conformational influences on the separation of human telomerase RNA in the presence of Mg²⁺ by chromatography is compared to gel electrophoresis of the same species. This novel chromatographic procedure permits analysis of the temperature dependent formation of folded (or multimeric) RNA species. We also demonstrate the ability to detect telomerase activity in a high throughput manner using a fluorescent based TRAP assay.

Identification of Cell Senescence Genes at 6q22-q23 and 6q26-q27 by Functional Analysis. *J. Liu^{1,2}, A.K. Sandhu², N. Rane^{1,2}, H.S. Sekhon³, G.P. Kaur², R.S. Athwal^{1,2}.* 1) Dept. of Pathology, School of Medicine, Temple University, Philadelphia, PA 19140, U.S.A; 2) Fels Institute for Cancer Research and Molecular Biology, School of Medicine, Temple University, Philadelphia, PA 19140, U.S.A; 3) Dept. of Biology, University of District of Columbia, Washington D.C.2008, U.S.A.

Applying a functional approach, we have identified two loci for replicative senescence on human chromosome 6q. The introduction of chromosome 6 or 6q restores normal cell growth and senescence in SV40 immortalized mouse and human cells (Sandhu, et al.1994 PNAS 91, 5498). Independent immortal revertant clones, originating from senescent microcell hybrid clones, containing human chromosome 6 or 6q, were analyzed for the presence or loss of chromosome 6 specific DNA markers. These data identified deletions of markers located at 6q22-23 and 6q26-27, suggesting the presence of two candidate growth suppressor loci on 6q. YAC and BAC clones, identified by the markers located in the candidate regions, were assembled to construct a high resolution physical and genetic map of the region. Computer analysis of the draft DNA sequence has identified several ESTs and cDNA mapped at 6q22-23 and 6q26-27. RT-PCR and Northern blot analysis of immortal cell lines, derived from SV40 transformed cells and tumors, for the expression of candidate cDNAs, revealed loss of expression for two cDNAs in 7 cell lines. Full-length cDNAs corresponding to candidate partial cDNAs have been cloned into an inducible mammalian cell expression vector. These cDNAs are currently being tested for the restoration of senescence and growth suppression in immortal cell lines, High incidence of LOH at 6q22-23 and 6q26-27, in multiple studies, suggest a role for these region in the etiology cell transformation and tumorigenesis..

Downstream of an RNA regulatory protein causing a common human disease: Expression profiling human SMN-deficient muscle. *C. Brandoli*¹, *S. Servadei*², *E. Hoffman*¹. 1) Res Ctr Genetic Medicine, Children's Natl Medical Ctr, Washington, DC; 2) Department of Neurology , Catholic University, Rome, Italy.

Spinal Muscular Atrophy (SMA type 1) is an autosomal recessive neuromuscular disease occurring 1 in 10,000 newborns. While the primary pathological feature of SMA has long been considered to be the loss of the cell bodies of alpha-motor neurons in the anterior horns of the spinal cord, increasing evidence points to important defects of the end target of the motor neurons, namely skeletal muscle. SMA is caused by reduction of the expression of the survival of motor neuron (SMN) gene, which is thought to regulate a series of downstream mRNAs, and the protein is highly concentrated at the neuromuscular junction. Downstream targets have not yet been defined. We describe the use of gene expression profiling of muscle biopsies from human SMA type I infants and age/sex-matched controls to identify genes that were potential downstream targets of SMN mRNA regulation. We found specific transcription factors to be highly down-regulated relative to normal age-matched controls, and disease controls (neonatal Duchenne muscular dystrophy patients). Most striking was a 24-fold under expression of a specific Zinc finger transcription factor of otherwise unknown function. These genes become potential down-stream targets of SMN regulation in muscle.

The genetic variation of the small mucin gene MUC7. *K. Rousseau¹, L. Vinal¹, J.A. Holloway², D.M. Swallow¹.* 1) The Galton laboratory, Biology, University College London, London, UK; 2) Human Genetics Division, University of Southampton, Southampton General Hospital, Southampton, UK.

Background: The mucins are a large heterogeneous group of glycoproteins, which share the common feature of having a central domain of tandemly repeated sequence (TR). This domain often shows VNTR type polymorphism and carries most of the glycosylation. MUC7 is a small mucin (377 amino acid residues) which is an important component of the saliva, a major defence barrier against the environment. This mucin has been shown to have anti-fungal activity and interacts with bacteria. Previous studies in our laboratory have indicated that MUC7 plays a role in predisposition to asthma and possibly other chest diseases. There are two common MUC7 TR alleles, one with 5 repeats and the other with 6. The 5 repeat allele is under-represented in patients with asthma. Although the size difference, 23 amino acids, would also alter the number of carbohydrate side groups, this small relative reduction in size seems unlikely to be responsible for the protective effect. Thus it is our hypothesis that other associated single nucleotide polymorphisms (SNPs) are responsible for the association. **Aims:** The aim of this project is to screen MUC7 for polymorphism in non-TR regions to define haplotypes in order to study patterns of association with chest diseases. **Methods:** A combination of bioinformatics and experimental tools were used. Published sequences and those available from the human genome sequencing project were aligned. SNP data were collected and the regions likely to play a role in regulation of expression were then screened using denaturing High Performance Liquid Chromatography (dHPLC) and sequencing. **Results and Conclusions:** The SNP information in the databases was relatively poor with no meaningful allele frequencies being given. However some were confirmed and we have also identified SNPs that had not been reported before. Some, particularly those in the promoter region and the first intron, could be functionally significant and are being investigated further. The haplotypes and allele frequencies are now being studied in patients suffering from chest diseases.

Characterization of regulatory networks controlling Ectodysplasin-A expression: progress toward identification of enhancer-binding proteins. *M.C. Durmowicz, C.-Y. Cui, D. Schlessinger.* Laboratory of Genetics, National Institute on Aging, Baltimore, MD.

When mutated, the *EDA* gene causes the X-linked recessive disorder anhidrotic ectodermal dysplasia, which is characterized by the defective development of skin appendages such as hair follicles, teeth, and sweat glands. We have begun to characterize the function of the *EDA* gene in ectodermal development by studying the regulatory networks controlling *EDA* gene expression. Our previous work has identified multiple regulatory regions within the *EDA* promoter, each of which is responsible for successively more specific levels of control. Here, we focus on the 123-bp enhancer region identified by transfection studies and electrophoretic mobility shift assays. Within this area, two 40-bp regions were shown to be necessary for enhancer function by transfection of deletion constructs of the *EDA* promoter region. Computer analysis identified three potential binding sites for transcription factors; one each for members of the GATA and Nkx families of transcription factors, involved in cardiac development, and one for an unknown binding protein that is found in an *EGFR* enhancer. In this work, two of the enhancer-binding sites, which include the computer identified Nkx and EGFR-related sites, have been experimentally confirmed by gel shift assays. Southwestern blotting of nuclear extract from HeLa cells shows at least two major species, of approximately 125 kD and 60 kD, that bind to both critical enhancer regions. In an effort to isolate and identify these species, HeLa nuclear extract was fractionated with salt gradient elution on a Heparin column. One fraction has been identified that exhibits binding to the region containing the putative GATA and Nkx sites in both gel shift assays and Southwestern blotting. Several fractions also exhibit binding to the EGFR-related site in gel shift assays. Identification of these enhancer-binding species by mass spectrometry is currently underway.

Generation of a genome-wide library of regulatory sequences through the use of a novel DNase hypersensitive site cloning procedure. *G.E. Crawford, I. Holt, C.M. Robbins, T. Moses, T.G. Wolfsberg, F.S. Collins.* NHGRI, NIH, Bethesda, MD.

Initial sequence analysis of the human genome has identified approximately 30,000-40,000 genes, but relatively little is known about how most of these genes are regulated. DNA binding proteins such as transcription factors, repressors, and insulators typically displace histones, making their presence detectable by DNase hypersensitivity (HS) and footprinting assays. Many *in vivo* DNA binding sites for specific genes have been identified to date, but current experimental procedures are limited by size constraints (<20 kb) and the number of genes that can be studied at one time. We have designed a protocol to generate a genome-wide library of regulatory sequences by cloning DNase hypersensitive sites from human K562 erythroleukemia cells, a line in which the DNase hypersensitivity of the globin loci has been extensively characterized. Genomic DNA from intact nuclei was digested with DNase at concentrations optimized for the beta-globin locus control region, polished to generate blunt ends, digested to completion with common restriction enzymes, cloned, and sequenced. The DNase treated library contained approximately 400,000 clones, a number ten fold higher than that of the no DNase control, indicating that very few clones resulted from random shearing. Initial analysis of several hundred clones revealed that approximately 30% of these clones mapped to within 10 kb of a known gene. Of the sequences contained within genes, >50% mapped within the first or second intron, consistent with what is currently known about the location of intergenic regulatory sites. These preliminary data indicate that our library appears to be enriched for regulatory elements involved in the control of gene expression. Deeper library sequencing should identify valid regulatory elements by repeated observation of the same sequence. This procedure, which can be applied to any cell line or tissue, will be useful in identifying regulatory elements controlling global expression differences that delineate tissue types, stages of development, and disease susceptibility.

Tissue specific expression of the branched-chain a-ketoacid dehydrogenase kinase. *E.A. Muller¹, D.J. Danner²*. 1) Genetics and Molecular Biology, Graduate Division of Biological and Biomedical Sciences, Emory University, Atlanta, GA; 2) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA.

The branched-chain a-ketoacids from leucine, isoleucine and valine are oxidatively decarboxylated by the branched-chain a-ketoacid dehydrogenase complex (BCKD). BCKD is present in the mitochondria of every tissue, and its catabolic activity is regulated primarily through changes in the phosphorylation state of the complex. A specific kinase (BCKD kinase) is differentially expressed in tissues, and functions to add the inactivating phosphate. The mechanism for tissue specific expression of BCKD kinase is not known. Northern blot analysis indicates that murine BCKD kinase mRNA is present at a low level in the liver, and in contrast, is highly expressed in skeletal muscle. This pattern is paralleled for the mouse BCKD kinase protein. To address whether mRNA differences among tissues are a result of transcriptional or post-transcriptional regulation, we performed transient transfection studies with luciferase reporter constructs bearing the entire 5' UTR of the mouse BCKD kinase gene and increasing amounts of 5' DNA sequence. BNL Cl.2 liver cells and differentiated C2C12 myotube cell lines modeled mouse liver and skeletal muscle, respectively. Reporter gene expression was higher in the myotubes than in the hepatocytes, depending on the amount of putative promoter sequence used. DNase I protection experiments and gel mobility shift assays are being used in conjunction with chromatin structure assessments to further define the regions in DNA responsible for the tissue specific differences in expression levels of BCKD kinase.

Gene expression profiling endometriosis in Finland. *M. Mahadevappa¹, C. Liu¹, S. Oksjoki², M. Setälä², L. Anttila², E. Vuorio², J.A. Warrington¹.* 1) Health Management Research, Affymetrix, Santa Clara, CA; 2) Dept. of Medical Biochemistry and Molecular Biology, Kiinamyllynkatu, University of Turku, Kiinamyllynkatu 10, Turku, Finland 20520.

Ten to fifteen percent of all women in their reproductive years are diagnosed with endometriosis. The pain caused by endometriosis can be debilitating and the disease often results in infertility. In endometriosis, abnormal endometrial lesions grow within the uterus as well as outside of the uterus including the ovaries, bowel, colon and rectum. Like normal endometrial tissue, these endometrial lesions and endometriomas respond to hormonal changes occurring during the menstrual cycle by proliferating and secreting. Currently the molecular mechanism of endometriosis is not well understood and there is no cure. In an attempt to understand the etiology of endometriosis, gene expression profiling was carried out on samples from patients in Finland. Finland has a well-organized medical system. Many endometriosis patients have a laproscopic exam prior to hormonal or medical intervention. In our study, all patients were diagnosed by the same clinical staff and all samples were freshly collected during laproscopic exam at diagnosis prior to hormonal treatment. Gene expression monitoring was carried out on 18 normal uterine samples, 12 peritoneal lesions of the uterus and 15 ovarian endometriomas. Targets were hybridized to high density oligonucleotide arrays containing probes for approximately 22,000 genes. Candidate genes are identified by multiple methods including both non-parametric, Mann-Whitney, and parametric, Students T, tests. Hierarchical clustering using candidate genes accurately segregates different tissue types. A subset of tens of candidates were selected for confirmation by QRT-PCR and those results will be presented. All candidate genes are annotated with locus and functional category information. Genes in pathways of particular interest will be discussed.

Sp1 CAN INCREASE *CFTR* PROMOTER ACTIVITY. *P.J. Mogayzel Jr, T.L. Wagner, P.L. Zeitlin.* Department of Pediatrics, The Johns Hopkins School of Medicine, Baltimore, MD.

Cystic fibrosis (CF) is an autosomal recessive disease caused by mutations in the cystic fibrosis transmembrane conductance regulator gene (*CFTR*). *CFTR* is expressed at low levels in specialized epithelial cells in several tissues. The *cis*-acting elements that regulate *CFTR* expression are not well characterized in part because of this low level expression. Only a few DNA elements within the minimal promoter have been confirmed to influence *CFTR* expression. Although there is no TATA box the *CFTR* promoter has several consensus sequences for transcription factor binding, including 3 Sp-1 sites located at -1022, -405 and -326 bp upstream from the translational start site. We investigated if binding of Sp1 to these sites could influence *CFTR* promoter activity. The function of these Sp1 consensus regions was assayed by co-transfecting *CFTR* promoter-containing plasmids with an Sp1 expression vector. We constructed plasmids in which 95, 118, 262, 354 or 1993 bp of *CFTR* 5'-flanking DNA were inserted upstream of the luciferase reporter gene in pGL3-basic (Promega, Madison, WI). These *CFTR* promoter-containing plasmids were then transfected into an immortalized fetal human tracheal epithelial (FHTE) cells or human bronchial epithelial cells derived from a CF patient (IB3) cell in the presence or absence of a plasmid that expressed Sp1 driven by the CMV promoter. Transfection efficiency was assessed by co-transfection of a *Renilla reniformis* luciferase-containing plasmid (pRL-TK, Promega). The presence of Sp1 increased *CFTR* promoter activity of the 354 and 1993 bp fragments by 2-4 fold in both cell lines. Sp1 increased *CFTR* promoter activity of the 262 bp fragment by 0.5-1 fold. These data suggest that Sp1 can increase *CFTR* promoter activity and may play a role in the regulation of *CFTR* expression. This work was supported by the Cystic Fibrosis Foundation.

Analysis of the *RUNX2/CBFA1* promoter in cleidocranial dysplasia identifies cis elements that regulate the *CBFA1* transcriptional network. *D. Napierala, R. Mendoza, Q. Zheng, G. Zhou, E. Munivez, Y. Chen, B. Lee.*
Molecular and Human Genetics, Baylor College Medicine, Houston, TX.

Cbfa1 is one of three mammalian orthologs of the *Drosophila runt* gene and encodes a transcription factor essential for osteoblasts differentiation. We and others have shown that *CBFA1* mutations cause cleidocranial dysplasia (CCD), a dominantly inherited skeletal dysplasia characterized by delayed endochondral and intramembranous ossification. The majority of mutations are missense and abolish *CBFA1* binding to a target OSE2 sequence. These and additional nonsense, splicing and frame shift mutations are detectable in approximately 60% of CCD patients. Based on transfection and DNA binding studies, the CCD phenotype arises from haploinsufficiency. To identify additional determinants of the *CBFA1* transcriptional network, we performed sequence analysis of the 1.4 kb proximal *CBFA1* promoter and of the *CBFB* gene in 27 CCD patients without mutations in the *CBFA1* coding region. Mouse studies have shown that the corresponding mouse *Cbfa1* promoter is sufficient for high level expression in osteoblast cell lines and that *CBFB* is an interacting protein critical for RUNT domain function. While no pathogenic mutations of *CBFB* were found in our cohort, a total of 4 sequence variants in the *CBFA1* promoter was detected. DHPLC analysis in 180 control chromosomes showed that an A>C substitution found in two CCD patients, and a G>T substitution found in four CCD patients have allele frequencies of 10% and 15%, respectively, in the general population. We did not observe an increased frequency of these SNPs in a cohort of women with premenopausal osteoporosis. Two other sequence variants were found unique to the CCD group. Both occur within zinc finger transcription factors binding sites. Electrophoretic mobility shift assay (EMSA) using nuclear extracts from ROS17, 10T1/2 and MCT cells showed a specific protein-DNA complex corresponding to each cis element. The analyzed *CBFA1* promoter variants exhibited different DNA-protein binding specificity. Thus, the allelic spectrum of CCD may help us identify important cis-elements that bind trans-acting factors that regulate the *CBFA1* expression.

Activation of the human hepatic lipase gene promoter in vitro by a combination of HNF4 and Coup-TFII/ARP-1 and in vivo by 9-cis retinoic acid. *B. Kurdi-Haidar, S.S. Deeb.* Departments of Medicine and Genome Sciences, Univ Washington, Seattle, WA.

High levels of plasma hepatic lipase (HL) activity are correlated with an atherogenic lipoprotein profile characterized by decreased high-density lipoprotein and prevalence of small, dense low-density lipoprotein. Therefore, modulation of its activity may alter the risk for development of atherosclerosis. The proximal promoter of the HL gene contains 2 direct repeats (DR) of the core motif 5-PuG[G/T][T/A]CA-3, a DR1 and a DR4, that typically bind retinoic acid, vitamin D, and steroid/thyroid hormone nuclear receptors. We investigated the transcription factors that modulate activity of the HL promoter through interaction with these two DRs. First, we conducted functional analysis of the wild type and mutant HL proximal promoters driving expression of the luciferase reporter gene by transient transfection of COS7 cells. Cotransfection with the wild type HL promoter and plasmids expressing the hepatocyte nuclear factor 4 (HNF4) and the chicken ovalbumin upstream promoter transcription factor II (Coup-TFII)/apolipoprotein regulatory protein 1 (ARP-1) resulted in five-fold activation. Analysis using reporter constructs with mutations at the DR1 or DR4 sites indicated that the DR1 element is necessary for activation by the HNF4-Coup-TFII/ARP-1 combination. Second, we determined the effect of treatment with ligands for the nuclear receptors RXR and LXR on endogenous HL mRNA levels in the human hepatoma cell line HuH7 by quantitative real-time RT-PCR. While the ligand of the nuclear receptor RXR, 9-cis retinoic acid resulted in 2-fold increase in HL mRNA, the LXR agonist T0901317 had no effect. In conclusion, the HL promoter is activated by the HNF4-Coup-TFII/ARP-1 combination using the DR1 site, and RXR but not LXR may be involved in its in vivo activation.

Program Nr: 955 from 2002 ASHG Annual Meeting

Isolation, characterization and analysis of the ALX4 promotor region. *W. Wuyts, P. Verdyck, W. Van Hul.* Medical Genetics, University of Antwerp, Antwerp, Belgium.

The Alx4 gene is a homeodomain transcription factor related to the *Drosophila aristaless* gene which plays an important role in craniofacial and limb development. This is demonstrated by Alx4 KO mouse showing preaxial polydactyly, ventral body wall defects and a delay in the formation of the parietal bone of the skull. Previously, we isolated the human ALX4 located on chromosome 11 in a region which is deleted in patients suffering from the Proximal 11p Deletion Syndrome (P11pDS) and we showed that in humans inactivating mutations in ALX4 cause skull ossification defects (Foramina Parietalia Per magna; FPP). Starting from BAC and PAC clones the 5' region flanking the ALX4 gene of both human and rat was isolated and characterized. Reverse transcriptase and RACE experiments were performed and enabled us to map the ALX4 transcription start site (TSS) approximately 700 bp preceding the ATG startcodon. Alignment of human and rat promotor sequences and computeranalysis identified several potential regulatory regions. Deletion constructs surrounding the TSS were generated by PCR and exonuclease/S1 treatment and analyzed by a dual Luciferase reporter assay for their promotor activity in osteoblastic cell lines. Regions associated with a significant increase or decrease in promotoractivity were further characterized to identify and verify potentially binding sites for known transcriptionfactors. This enabled us to identify several potential regulators of ALX4 expression which are currently being investigated.

PITX2 and MEF2A synergistically activate the ANF promoter. *I. Saadi*¹, *A. Kuburas*², *A.F. Russo*^{1,2}. 1) Genetics Program,; 2) Department of Physiology and Biophysics, University of Iowa, Iowa City, IA.

PITX2 is a bicoid-type homeodomain protein that is mutated in patients with Axenfeld-Rieger syndrome (ARS), and is required for development of the heart. PITX2 knock-out mice show defects in cardiac positioning and atrial septation. In order to determine the role of PITX2 in the heart, we looked at atrial natriuretic factor (ANF) and myocyte enhancing factors (MEF2) which are known regulators of cardiac development. ANF is one of the atrial natriuretic polypeptides that are involved in electrolyte homeostasis in the cardiovascular system. MEF2A is highly expressed in skeletal muscle, cardiac muscle and the brain. In addition, MEF2C knockout mice show a complete abolition of ANF expression. Our studies showed that PITX2 can activate the ANF promoter in LS8 (dental epithelium) and CHO (chinese hamster ovary) cell lines. Interestingly, cotransfection of MEF2A and PITX2 synergistically activated the ANF promoter in LS8 and CHO cells. This synergism was not observed with the synthetic TK-Bicoid reporter or the GAD1 promoter. The synergism requires the homeodomain of PITX2. At least two of the ARS mutations that abolish DNA binding of PITX2 could not synergize with MEF2A. We also did transfections in the presence of MKK6, a p38 kinase activating kinase known to activate MEF2A. MKK6 cotransfection with either PITX2 isoform a or c significantly increased the fold activation of the ANF promoter in LS8 cells. This increase was also seen in the presence of MEF2A. However, the synergism of MEF2A with PITX2c was significantly greater than that with PITX2a. Yeast two-hybrid analysis shows that PITX2a does interact with MEF2A. The interaction requires the N-terminus and homeodomain of PITX2a. We are in the process of determining whether PITX2c and MEF2A show a stronger physical interaction. These studies indicate that the PITX2-MEF2A synergism may coordinate ANF peptide expression during cardiac development.

Study of ABCG5 and ABCG8 Genes Regulation. *S. Shulenin, T. Annilo, M. Dean.* LGD, NCI-Frederick, Frederick, MD.

Two new human ATP-binding cassette transporter (ABC transporter) genes (ABCG5 and ABCG8) were found and characterized. The primary structure of these genes shows high homology to the ABCG (White) subfamily of ABC transporters, that includes half-transporter proteins. Previously we have shown that ABCG5 and ABCG8 are involved in cholesterol and sterol transport and cause the rare human disease sitosterolemia. That transport processes that regulate sterol homeostasis in the human body are poorly understood and the study of the regulation of these genes could help to better understand this process.

An initial study of the expression of these genes in different tissues and cells shows independent regulation of these genes. The genes are located on chromosome 2p21 head-to-head to each other and the promoter area between the ATG codons is about 300 base pairs. To understand mechanism of ABCG5 and ABCG8 regulation and identification of the factors that are involved in gene regulation we analyzed DNA the sequence of these genes from different species and applied a gel-shift analysis in order to identify regulatory factors. Comparative analysis of homologous genes from different species revealed few conservative sequences in the promoter area and introns that could serve as binding areas for regulatory elements. Synthetic oligonucleotides that correspond to these sequences were used for gel-shift experiments. These experiments have shown that two proteins bind in the promoter and intronic regions of these genes. DNA fragments that were positive in gel-shift experiments were used for the purification of binding proteins. Identification of proteins that bind to DNA will help to understand their involvement in ABCG5 and ABCG8 genes regulation and mechanism of sterol homeostasis.

Heterogeneous Allele Expression Of Pulmonary Surfactant Protein (SP)-D Gene In Rat Large Intestine And Other Tissues. *Z. Lin¹, J. Floros^{1, 2}*. 1) Dept Cell Mol Physiol, Penn State Univ college Med , Hershey, PA; 2) Dept Pediatrics, Penn State Univ college Med , Hershey, PA.

Epigenetic regulation plays important roles in gene expression. Random allele expression has recently been observed for several genes including interleukins and genes of the lymphoid system. We studied the hypothesis that pulmonary surfactant protein (SP)-D, an innate host defense molecule, exhibits random allele expression in a tissue-specific manner. SP-D gene expression is tissue specific in the 14 tissues studied. SP-D is expressed in lung, large and small intestine, stomach, ear, eye, liver, vagina, and penis, but it is not expressed in tongue, heart, brain, kidney, and spleen as assessed by either Northern or RT-PCR. Study of SP-D allelic expression in several tissues revealed a balanced biallelic (BB) in lung, and, in several extrapulmonary tissues, a heterogeneous pattern: BB, imbalanced biallelic (IB), and monoallelic (MO). The results from 103 heterozygous rats showed an expression profile in large intestine of BB (22%), IB (60%), and MO (18%). Among 8 families, the percent of BB in siblings varied from 0 to 38%, and MO from 0 to 38% and approximately half of the siblings had IB. Allele T is more frequently found in monoallelic expression than allele C (MOT (16%) and MOC (2%)). The parent-of-origin does not play a role in SP-D allele specific expression. However, acquired epigenetic factors, family background or other may contribute to the overall pattern of expression. Allele expression differences point to yet another level of genetic variability where deranged allele expression may contribute to disease susceptibility through phenotypic differences in the expression level and/or the loss of the biallelic expression advantage. The significance of the monoallelic and/or the heterogeneous allele expression of SP-D under normal or adverse conditions is unknown and subject to speculation. This work is supported by NIH R37HL34788 and AHA198312P.

Identification of different elements within exonic splicing enhancer sequence of the dystrophin gene. A. Surono¹, Y. Takeshima², M. Matsuo¹. 1) Div of Molecular Medicine, Kobe University Graduate School of Medicine, Kobe, Japan; 2) Dept. of Pediatrics, Kobe University Graduate School of Medicine, Kobe, Japan.

Exonic splicing enhancers (ESEs) are RNA sequences required for accurate splice site recognition and the control of alternative splicing by recruitment general splicing factors. Previously, we demonstrated that a 31-nt element of exon 19 of the dystrophin gene (named as element A) functions as a *cis*-acting element for the correct maturation of dystrophin mRNA. In order to characterize element A, we separated element A into three overlapped fragments, the 5' region (element A1), the middle region (element A2) and the 3' region (element A3). Each fragment was analyzed for nuclear protein binding ability and enhancer activity by *in vitro* and *in vivo* splicing assay.

RNA binding protein was analyzed by UV crosslinking and mobility shift assay using fluorescence labeled RNA probes of each element and HeLa nuclear extract (HNE). We demonstrated that element A1 bound specifically to nuclear protein of 130-kDa. However, neither element A2 nor A3 has protein-binding site. *In vitro* splicing assay using *chimeric dsx* pre-mRNA revealed that element A1 was able to enhance splicing of the upstream intron as equal as element A, but not for elements A2 and A3. In addition, mutational analysis using dystrophin minigene expressed in HeLa cells demonstrated that when either element A1 or A2 was deleted, exon 19 was skipped during maturation of dystrophin mRNA. In contrast, deleted element A3 did not affect exon 19 splicing. These data indicate that elements A1 and A2 activate exon 19 incorporation into mRNA in different manner.

This is the first evidence demonstrating different character within ESE.

Identification of alternative splicing variants of human biotinidase and their possible role in the intracellular localization of the enzyme. *C.M. Stanley¹, A.J. Hymes¹, G.C. VanTuyle¹, J.W. Bigbee¹, B.T. Webb¹, B. Wolf².* 1) Medical College of Virginia of Virginia Commonwealth University, Richmond; 2) Connecticut Children's Medical Center and the University of Connecticut School of Medicine, Hartford.

Biotinidase is essential for recycling the vitamin biotin. Biotinidase deficiency is an inherited disorder characterized by neurological and cutaneous symptoms that can be successfully treated or prevented with biotin. Biotinidase has at least two enzymatic functions that may require it to be localized to various cellular and/or extracellular sites. RACE-PCR was used to extend the 5' sequence of exon 1 by 90 bases and identify three novel, alternatively spliced variants of biotinidase, 1a, 1b and 1c, in multiple human tissues. Exon 1c was present only in testes and includes sequence originally designated as intron 1. Intron 1 sequence was identified in GenBank (AC027129) and completes the 5' structure of the gene. The 5' splice variants, 1a and 1b, contain sequence motifs that suggest biotinidase localizes to the mitochondria/nucleus and endoplasmic reticulum, respectively. Immunohistochemical and organelle isolation studies were used to determine the intracellular localization of biotinidase. Immunohistochemical studies demonstrate that biotinidase localizes to the cytoplasm, but not the nucleus, of human fibroblasts and Hep G2 cells. Organelle separation by isopycnic gradient centrifugation of rat liver identified an 85 kDa biotinidase protein that had both biotinyl-hydrolase and transferase activities in fractions enriched for a microsomal marker enzyme. These results confirm earlier studies localizing biotinidase to microsomes. A 48 kDa protein that immunoreacted with anti-biotinidase was found in fractions enriched with a mitochondrial marker enzyme. The 48 kDa protein is biotinylated, is localized to the inner mitochondrial matrix, but has neither biotinyl-hydrolase nor transferase activities. The 5' splice variants and organelle fractionation studies suggest that biotinidase is directed to the secretory pathway and to mitochondria, but the function of the protein in mitochondria remains to be determined.

The splice of height: dual enhancers function in GH1 splicing. *R.C.C. Ryther¹, L. McGuinness², J.A. Phillips III³, C.T. Moseley³, C.B. Magoulas², I. Robinson², J.G. Patton¹.* 1) Biological Sciences, Vanderbilt University, Nashville, TN; 2) Molecular Endocrinology, Nat. Inst. for Medical Research, London, England; 3) Pediatrics, Vanderbilt University School of Medicine, Nashville, TN.

Isolated growth hormone deficiency type II (IGHD II) is characterized by short stature due to GH deficiency caused by dominant negative mutations in the GH1 gene. GH1 has five exons and four introns that are alternatively spliced to produce five known isoforms. These isoforms include all five exons (22 kDa), deletion of 15 codons of exon 3 (20 kDa), skipping of exon 3 (17.5 kDa), and deletions of exons 3-4 (11.3 kDa) or exons 2-4 (7.4 kDa). IGHD II mutations misregulate splicing of GH1 transcripts, leading to increases in the 17.5 kD isoform, which for unknown reasons has a dominant negative effect. To determine how GH1 splicing is regulated and why its perturbation causes IGHD II, we studied the role of exonic and intronic splicing enhancers (ESE and ISE, respectively) as well as a transgenic model of IGHD II. We focused on mutations that disrupt an ESE in exon 3 and an ISE in intron 3, causing aberrant splicing of exon 3 and abnormal increases in the 17.5 kDa isoform. The dual enhancers exhibit differential effects on the weak splice sites surrounding exon 3 but combine to ensure exon 3 definition. To determine the mechanism by which the 17.5 kDa isoform causes IGHD II, transgenic mice expressing the human 17.5 kDa isoform were created. Interestingly, these mice exhibit the dominant dwarfism phenotype of IGHD II with anterior pituitary hypoplasia, massive loss of somatotrophs, and gross secretory abnormalities in the few remaining somatotrophs. Our data show that IGHD II results from splicing mutations that disrupt recognition of exon 3, increasing the 17.5 kDa isoform which prevents maturation of GH dense secretory vesicles and causes subsequent cell death *in vivo*. Our results suggest that multiple exonic missense and silent mutations, as well as intronic variations, can perturb splicing enhancers leading to aberrant splicing and disease.

Alternative splicing: a key to dystrophin function. *M.M. Ferguson*^{1,2}, *P. Demacio*^{1,2}, *F. Cisternas*^{1,2}, *P.N. Ray*^{1,2}. 1) Department of Genetics, Hospital for Sick Children, Toronto, ON, Canada; 2) Department of Molecular and Medical Genetics, University of Toronto.

Duchenne muscular dystrophy (DMD) is a severe X-linked recessive disorder that is caused by mutations in the large and complex dystrophin gene. Although DMD is characterized primarily by progressive muscle wasting, patients commonly present with cardiac and respiratory complications. There are also several non-muscle phenotypes, including abnormal retinal neurotransmission.

Dystrophin is expressed as a family of structurally diverse protein isoforms that have different localizations and functions. Part of this diversity is due to alternative splicing at the 3' end of the transcript. The most common splicing event involves exon 78 and changes the C-terminus of the resultant protein from a hydrophilic C-terminus (DCT) to a hydrophobic C-terminus (ACT). In comparison to the DCT, the ACT is highly conserved across species and displays differential tissue expression and localization patterns. This suggests a unique functional role for this spliced region.

Immunofluorescent analysis was used to determine if the two different C-termini of dystrophin have different localization patterns in the heart and in the retina. In the heart, isoforms with the DCT are restricted at the plasma membrane surrounding the cardiomyocytes while isoforms with the ACT display an expression pattern along the transverse tubular system. In the retina, isoforms with the DCT show predominant staining at the outer plexiform layer while isoforms with the ACT show predominant staining at the inner limiting membrane and surrounding the microvasculature.

The high degree of sequence conservation and differing localization patterns suggest a unique function for the two C-termini of dystrophin. We hypothesize that these functional differences arise through differential protein interactions. To elucidate the functional significance of the splicing event involving exon 78 we have used library-based screening methods to identify proteins that interact specifically with the ACT.

Characterization of *Rai1* as a candidate gene for Smith-Magenis syndrome. *R.E. Lucas¹, C.N. Vlangos¹, S.H. Elsea^{1,2,3}.* 1) Genetics Graduate Program, Michigan State University, East Lansing, MI; 2) Department of Zoology, Michigan State University, East Lansing, MI; 3) Department of Pediatrics and Human Development, Michigan State University, East Lansing, MI.

Smith-Magenis syndrome (SMS) is a multiple congenital anomalies/mental retardation syndrome and possible contiguous gene deletion syndrome associated with an interstitial deletion of human chromosome 17p11.2. SMS has a recognizable behavioral and physical phenotype and occurs in approximately 1 in 25,000 births. We are interested in determining the molecular basis of SMS and have recently created a large-insert genomic clone contig of the SMS critical deletion region. Human *retinoic acid-induced 1 (RAI1)* is novel gene which codes for 1863 amino acids and maps to the central region of the SMS critical interval, adjacent to *SREBF1*. In order to assess *RAI1* as a candidate gene for SMS, we are currently analyzing the mouse homolog, *Rai1*, which maps to mouse chromosome 11 BACs RPCI-23 326M22 and 456O18 in a region of the mouse genome which is syntenic to the SMS critical interval. *Rai1* is 1840 amino acids and has approximately 77% overall identity to the human protein. *Rai1* is an attractive candidate gene for SMS because northern analysis demonstrates abundant mRNA expression in brain and database sequence analysis reveals regions of sequence homology with the transcription factor *TCF20*. In addition, based on the phenotypic analysis of patients who harbor deletions within the critical interval, *RAI1* maps to a genomic region which may contain a gene that has an effect on craniofacial development. Our laboratory is especially interested in transcription factors which may be dosage sensitive as well as the potent effects of retinoic acid on embryonic development. In order to determine a more precise expression pattern for *Rai1*, we are performing *in situ* hybridization on sectioned mouse embryos as well as constructing a knockout vector to assess the role of *Rai1 in vivo*.

Generation of Reporter Constructs for High Throughput Functional Analysis of Gene Variants. *R.H. Lipsky, F.-L. Lu, A.S. Card, A.J. Marko.* Dept Neurogenetics, NIAAA/NIH, Rockville, MD.

Single nucleotide polymorphisms (SNPs) in gene coding regions are rare but are likely to contribute significantly to changes in cell signaling pathways, resulting in long-term gene responses. To gain further understanding of variant protein function, it will be necessary to develop high throughput approaches for evaluating SNPs. We developed a qualitative and quantitative method for large-scale high throughput analysis of functional receptor variants. Two reporter gene fusion constructs were made. The first (pdsRed2.1GFP-1XCRE) contained a single copy of a human-derived cyclic AMP response element (CRE). The second (pdsRed2.1 GFP-1XNFkB) incorporated a human-derived NFkB binding site. Each sequence was fused to red-shifted Green Fluorescent Protein (Red GFP) using the plasmid pdsRed2.1. To validate functional activity of the NFkB reporter, we exposed NR2A cells transfected with pdsRed2.1 GFP-1XNFkB to Tumor Necrosis Factor- α (TNF- α), a known NFkB activator. Activation of the CRE reporter plasmid was confirmed by exposing NR2A cells carrying the pdsRed2.1GFP-1XCRE to forskolin, a known activator of CREB. Transfection efficiency was controlled by a reference plasmid that expressed GFP. Because Red GFP and GFP have distinct excitation and emission spectra, ratios of relative fluorescence (Red GFP/GFP) can provide quantitative gene expression data in response to different stimuli. Prior to quantitative analysis, we determined if TNF- α would activate the NFkB reporter construct. TNF- α (100 U/mL) activated NFkB-mediated gene expression, as shown by the presence of Red GFP in the transfected cells. The control cells, which did not receive TNF- α , did not exhibit Red GFP expression, showing that the NFkB reporter construct was not activated. Both control and experimental cells exhibited GFP, as expected. Similar results were obtained for the CRE reporter in the presence of forskolin (1-5 M). Our results show that our approach is sensitive and specific, and support the idea that dual fluorescent markers in real-time can be used to study responses to different stimuli, and to evaluate the role of functional SNPs in components of signal transduction pathways.

Structural analysis of a human nectin-like gene, fifth member of the nectin / PRR family of adhesion molecules.

S.A. Keryanov, K.L. Gardner. Dept. of Neurology, Univ. of Pittsburgh, Pittsburgh, PA.

Objective: Identify, characterize, and perform mutational analysis on brain expressed genes in the 1q23 critical region of linkage for a large previously described hemiplegic migraine family. Background: Among the superfamily of immunoglobulin-like adhesion molecules there are four members of the nectin / poliovirus receptor related (PRR) genes coding for receptors of alpha herpes simplex family viruses expressed at intercellular junctions. Nectin 1 is thought to be involved in synapse formation, is found at high levels in sensory neurons of rat, and binds HSV glycoprotein D for virus entry into cells. We cloned and characterized a fifth member of the nectin/PRR family, most closely related to nectin 1 and nectin-2, between D1S2355 and D1S2635 at 1q23. Methods: Insilico database searches, analysis with programs such as BLOCKS, Compel, MatInspector, standard cloning, RT-PCR, and 5', 3' RACE were used. SSCP of 8 affected individuals selected from all family branches and 4 control individuals were used for mutational analysis of the gene including intron-exon boundaries. Results: The nectin-like gene codes for a transmembrane protein with three extracellular Ig-like domains (V and two C type) that share ~31% and 25.4% amino acid identity with Nectin 1 and 2, respectively. We found two alternative splice sites in the untranslated portion of an extended last exon in the human nectin-like gene. Analysis of the putative promoter region suggests predominantly brain expression, as confirmed by RT-PCR. The nectin like gene was found to be widely expressed, with alternatively spliced isoforms in brain, muscle, placenta, lung and lymphocytes. Only the brain specific isoform appears to skip exon 2, which encodes a unique region similar to the immediate early protein for herpes simplex virus (HSV). Nine single nucleotide polymorphisms were identified, none with complete segregation in hemiplegic migraine individuals. Conclusion: The brain specific isoform of this new member of the nectin / PRR family may have a role in cell-to-cell spread of HSV or other related viruses that should be further explored.

Genotype phenotype relation of TNF α as a risk marker for coronary atherosclerosis. *U. Schagdarsurengin¹, S. Schulz¹, T. Suess¹, U. Mueller-Werdan², K. Werdan², C. Glaeser¹.* 1) Inst. of Human Genet., MLU, Halle, Germany; 2) Dep. of Intern. Med., MLU, Halle, Germany.

The TNF α is an important cytokine in the complex signalling pathway involved in the development of atherosclerosis. We studied the interaction of the TNF α mRNA expression in monocytes of human peripheral blood (competitive RT-PCR), a promoter polymorphism (PM) of TNF α (G-238A; SSCP) and their association with coronary atherosclerosis. In this study 256 patients with angiographically confirmed diagnosis were involved: 128 patients with severe coronary atherosclerosis (CAD; 81 males, average age: 50.3y) and 128 patients without any coronary symptoms (WAS; 83 males, average age: 50.4y) as controls. As proposed by recent studies the mRNA expression of TNF α was shown to be elevated in the CAD compared to the WAS group (7.4 vs. 6.7ag/cell; n.s.). In order to prove the role of the genetic background we examined the dependence of the mRNA expression on the G-238A PM: Whereas the mRNA expression in WAS patients was only slightly increased in dependence on the genotype (AG+AA: 7.4 vs. GG: 6.6ag/cell) the mutation carriers among the CAD patients showed significantly higher expression than wildtype carriers (AG+AA: 12.6 vs. GG: 6.9ag/cell, $p < 0.012$). An analysis of the genotype distribution of the G-238A PM revealed no significant differences in the frequency of AG+AA-carriers (CAD: 0.09 vs. WAS: 0.12). However the evaluation of the importance of this PM for the early development of severe CAD described by an early age of onset (<45y) revealed significant changes in genotype distribution. The CAD patients with an early age of onset were significantly more often mutation carriers than CAD patients who exhibit coronary symptoms at higher age (<45y vs. >45y: 0.18 vs. 0.02; $p < 0.012$). This result underlines the importance of the mutant genotypes AG+AA of the G-238A PM for having a more pronounced mRNA expression and also for the development of coronary symptoms at younger age (<45y). Investigating the role of the message expression of TNF α in the development of coronary atherosclerosis the importance of the genetic background on message level should always be taking into consideration.

Bioinformatic screening of xenobiotic responsive elements in search of downstream targets of aryl hydrocarbon receptor: Identification of DMRT1 as a candidate. H. Fujita¹, R. Kosaki², T. Suzuki¹, T. Takahashi¹, K. Kosaki¹. 1) Dept of Pediatrics, Keio Univ Sch Med, Tokyo, Japan; 2) Dept of Genetics, Saitama Children's Medical Center, Saitama, Japan.

In utero exposure to dioxins affects male external genital development in rodents. The effects of dioxins are mediated via the aryl hydrocarbon receptor and is negatively regulated by the aryl hydrocarbon receptor repressor. The dioxin-aryl hydrocarbon receptor complex binds to the cognate xenobiotic responsive elements in the promoter regions of the target genes. We recently demonstrated weak but significant association between micropenis and the Pro185Ala polymorphism of the aryl hydrocarbon receptor repressor (Fujita et al, Teratology 2002). In order to delineate downstream target genes of the dioxin receptor, we systematically surveyed the promoter sequences of various genes (*DMRT1*, *SOX3*, *SOX9*, *SF-1*, *GATA4*, *WT1* and *FGF9*) implicated in genital development, searching for the core pentamer consensus sequence GCGTG of the xenobiotic responsive element. Two elements were present upstream of the major transcription start site of *DMRT1*, a recently described gene that is specifically expressed in the gonads and is required for postnatal testis differentiation, whereas no more than one element existed adjacently in the upstream of the putative transcription start sites of the remaining genes. The density of the elements was significantly higher than that expected by chance. Comparative genome analysis of the *DMRT1* sequences revealed that these putative xenobiotic responsive elements were conserved in the rat genome. Furthermore, the two putative xenobiotic responsive elements coincide with the activating segment of the promoter documented by other group using site-directed mutagenesis (Lei et al, Biol Reprod 2002). We suggest that the putative xenobiotic responsive elements of the *DMRT1* gene may be functionally relevant and that *DMRT1* may be the downstream target of the aryl hydrocarbon receptor.

Human LINE-1 retrotransposons are translated by an unconventional mechanism. *R.S. Alisch, J.V. Moran.* Dept Human Gen & Internal Med, Univ Michigan, Ann Arbor, MI.

Long Interspersed Elements (L1s) are abundant retrotransposons and comprise ~17% of human DNA. Retrotransposition-competent L1s are 6.0 kb and contain a 5' untranslated region (UTR), two non-overlapping open reading frames (ORF1 and ORF2), and a 3' UTR that ends in a poly (A) tail. ORF1 encodes a RNA binding protein (ORF1p), whereas ORF2 encodes a protein (ORF2p) with both endonuclease (EN) and reverse transcriptase (RT) activities. Previous studies demonstrated that both proteins are required for efficient retrotransposition in cultured human cells. The L1 transcript is unusual because it contains two distinct ORFs. Thus, an understanding of how ORF2 is translated will provide fundamental insight about unconventional translation mechanisms that exist in human cells. To identify cis-acting sites important for ORF2 translation, we created a deletion series of the 66 nucleotide intervening sequence (IS) that lies between ORF1 and ORF2. Partial or complete deletion of the IS had little or no effect on retrotransposition. Similarly, frameshift mutations positioned upstream of the putative ORF2 initiation codon also had no effect on retrotransposition. By contrast, the introduction of a stop codon (L11X) near the presumptive amino terminus of ORF2p completely abolished retrotransposition. These data suggest that the translation of ORF2p does not rely on the IS, that ORF2p is not made an ORF1/ORF2 fusion protein, and that ORF2p initiates prior to codon 11. To further elucidate how ORF2p translation is initiated, we mutated the putative AUG initiation codon to AUA or CCC. Remarkably, these mutations only slightly reduced retrotransposition (~45% of wild-type). Subsequently, we proved that retrotransposition of the mutant constructs was not promoted by endogenous sources of RT. Finally, all of the above constructs demonstrated similar abilities to retrotranspose in Chinese Hamster Ovary cells. Thus, because there is no evidence for splicing of L1 mRNA, and there are no other candidate initiation codons (AUG, GUG, CUG) near the presumptive amino terminus of L1 ORF2, our data strongly suggest that ORF2 may initiate translation in an AUG independent manner.

The LZ Domain of ORF1p is Required for Human L1 Retrotransposition. *A.E. Hulme, J.N. Athanikar, J.V. Moran.*
Department of Human Genetics, University of Michigan, Ann Arbor, MI.

Retrotransposition-competent L1s (RC-L1s) are composed of a 5' UTR, two non-overlapping open reading frames (ORF1 and ORF2), and a 3' UTR that ends in a poly (A) tail. The ORF1 encoded protein (ORF1p) co-localizes with L1 RNA in cytoplasmic ribonucleoprotein particles, which are proposed retrotransposition intermediates, yet its exact function remains unknown. The carboxyl terminus of ORF1p is highly basic and contains a number of amino acids that are conserved among mammals, some of which may function in RNA binding. In contrast, although the sequence of the amino terminus of ORF1p is poorly conserved, a predicted coiled coil domain is conserved among mammalian L1s. Human ORF1p contains a putative leucine zipper (LZ) in this domain, but the LZ is absent from rat and mouse L1s. Therefore, it is uncertain whether the LZ domain is required for retrotransposition.

Here, we show that pairwise missense mutations (Leu to Val) of the four leucine residues constituting the LZ abolish L1 retrotransposition in cultured human cells. We hypothesized that this defect was due to the inability of the LZ mutants to form homomultimers. To investigate this possibility, we expressed either wild type or LZ mutant ORF1p containing a T7 gene 10 epitope tag on their respective carboxyl termini in HeLa cells. Whole cell extracts then were treated with increasing amounts of glutaraldehyde to cross-link tightly associated proteins, and the ability of ORF1p to form homomultimers was examined on SDS-PAGE gels by Western blotting. Unexpectedly, our data demonstrated that the LZ mutants could form homomultimeric complexes under the same conditions as wild type ORF1p. We next conducted GST pulldown assays to investigate ORF1p heteromultimeric complex formation. Our data revealed that wild type and LZ mutant ORF1p could interact either as homodimers or heterodimers. Thus, we conclude that mutations in the LZ domain eliminate retrotransposition, but still allow ORF1p-ORF1p interaction. These paradoxical findings show that multimer formation of ORF-1p is not sufficient for retrotransposition, and suggest that the LZ domain has another role in retrotransposition.

Identification and characterization of an active HERV-E gene (ERVE1) that is expressed in the pancreas and thyroid. *J. Sugimoto*¹, *T. Shiroma*², *G. Okahara*², *T. Oda*¹, *F. Kanaya*², *Y. Jinno*¹. 1) Mol Biol/Okinawa-Asia Res Ctr, Univ Ryukyus Sch Medicine, Nakagami, Okina, Japan; 2) Department of Orthopedic Surgery, University of the Ryukyus, Okinawa, Japan.

To elucidate possible physiological functions of human endogenous retroviruses (HERVs) and their role in the pathogenesis of human diseases, we have developed a strategy to identify transcriptionally active HERV genes. By this approach, we have identified and isolated an active HERV-E gene (ERVE1) that was mapped to 17q11. Northern blot analysis revealed in the pancreas (and thyroid) two major transcripts, 3.3 and 4.1kb in size, associated with 500- to 600-nucleotide-longer minor bands. The 3.3kb cDNA clone, identified by cDNA library screening and RACE, contained an open reading frame of 660 nucleotides, translating into a protein of 219 amino acids. In vitro translational analysis of the cDNA revealed a 25kDa protein, consistent with the predicted molecular weight of the gene. Although the deduced amino acid, from ERVE1 was unique and did not possess a high degree of homology to sequence in the non-redundant protein and nucleotide databases, preferential expression in pancreas and thyroid gland tissues may suggest a role for this gene in physiological functions common to these tissues. In addition, while the activity of these retrotransposons is usually suppressed by DNA methylation and/or other mechanisms, this active ERVE1 may serve as an appropriate material for investigating of gene regulation.

FMR1 mRNA derived from premutation alleles is translated with reduced efficiency. *C. Bagni*¹, *F. Tassone*², *B. Primerano*¹, *A. Ludwig*², *C. Mamay*², *R. Hagerman*³, *P. Hagerman*². 1) Department of Biology, Università di Roma, Tor Vergata, Rome, Italy; 2) Department of Biological Chemistry, University of California at Davis, Davis, California; 3) M.I.N.D. Institute, University of California Davis Medical Center, Sacramento, California.

Reduced levels of the FMR1 protein (FMRP) have been observed in some male carriers of the fragile X premutation despite the presence of elevated FMR1 message levels. In order to determine whether translational efficiency is reduced for FMR1 mRNA derived from premutation alleles, we have determined the polysome profiles for FMR1 mRNA in twelve lymphoblastoid cell lines derived from individuals carrying unmethylated alleles that range from 60 to 500 CGG repeats. FMR1 message and FMRP expression levels were determined in each cell line by quantitative (fluorescence) RT-PCR and Western Blot, respectively. The percent of the mRNA on the polysomal fraction (PMP) was also calculated. Preliminary results demonstrate reduced polysomal loading of the FMR1 mRNA within the premutation range, indicative of decreased translational efficiency. The decrement in polysome loading is more pronounced with increasing CGG repeat number, consistent with both lowered FMRP levels and the tendency to more significant clinical involvement in the upper portion of the premutation range.

Program Nr: 972 from 2002 ASHG Annual Meeting

Expression of the Human and Murine 5'-(CGG)_n-3'-binding proteins CGGBP1. *F. Naumann, B. Schmitz, W. Doerfler.* Institute of Genetics, University of Cologne, Cologne, Germany.

The fragile X syndrome, a frequent cause of mental retardation in humans, is commonly associated with an unstable CGG repeat within and hypermethylation of the promoter of the FMR1 gene. Expansions in trinucleotide repeat sequences in the human genome have been linked to a number of diseases in humans. We have isolated a 20 kDa protein (CGGBP1) which binds specifically to CGG repeats, either in synthetic oligodeoxyribonucleotides or in the 5'-upstream region of the human and the murine FMR1 gene. CGGBP1 does not bind to completely methylated repeats. When overexpressed after transfection into HeLa cells, CGGBP1 can inhibit the activity of the FMR1 promoter. Until June 2002, screening of protein databases with the sequence of CGGBP1 has not revealed a related sequence. We have cloned and determined the sequences of the human and murine genes. Sequence comparisons with available EST clones revealed that both translated and a high proportion of the long 5'- and 3'-untranslated regions are highly conserved in mammals. Furthermore, the promoter of the murine CGGBP1 gene is highly conserved over 450 bp upstream of exon 1. Due to alternative polyadenylations, messages of 1.2 and 4.4 kilobases are expressed at different ratios in human and murine embryonic, fetal and adult tissues. We inserted fragments of varying lengths from the 5'-flanking region of the human CGGBP1 gene upstream of the firefly luciferase gene and assayed for luciferase activity after transfection of these constructs into HeLa cells. Luciferase activity decreased strongly when constructs with less than 200 bp upstream of exon 1 were used. Although sequence analyses of the highly conserved 5-UTR had suggested a role in posttranscriptional control, no difference in luciferase activity could be observed in transfection experiments using HeLa cells with constructs carrying the 5-UTR. The detailed structural analyses described here were performed to obtain a solid base for further work on the biological function of the CGGBP1 gene which is still unknown. [This research was supported by the Center for Molecular Medicine Koeln TV13].

Genomic structure and splice variants of PPP2R2B, the gene associated with spinocerebellar ataxia type 12 (SCA12). *S.E. Holmes¹, H. Hwang¹, E. O'Hearn², S.E. Antonarakis⁵, S. Chip⁶, S. Strack⁶, C.A. Ross^{1,3,4}, R.L. Margolis^{1,4}.* 1) Dept of Psychiatry,; 2) Dept of Neurology,; 3) Dept of Neuroscience,; 4) Program in Cellular and Molecular Medicine, Johns Hopkins Univ Sch Med, Baltimore, MD; 5) Div of Medical Genetics, Univ of Geneva,CMU, Switzerland; 6) Department of Pharmacology, University of Iowa.

SCA12 is associated with an expansion mutation of a CAG repeat located within the gene encoding PPP2R2B, a regulatory subunit of the trimeric phosphatase PP2A. The repeat was in the 5' flanking region of the originally published PPP2R2B cDNA. Using a combination of RT-PCR, ESTs in GenBank, and sequence analysis algorithms, we have now identified additional exons and multiple splice variants of PPP2R2B. The gene contains nineteen known exons, with exons 12-19 contained in all splice variants, and exons 1-11 included in various combinations. The repeat is located in exon 10, and depending on the transcript variant, is therefore alternatively in an intron, in 5'UTR, and potentially within an open reading frame. Our cell model results suggest that the region around the repeat can function as a promoter; but the presence of splice variants containing additional upstream exons suggests that other promoters probably also exist. Translation of the variants indicates that there are at least 6 different potential N-termini of the protein, potentially affecting the subcellular localization of the PP2A enzyme (Strack et al., 2002). While we have shown that an increase in repeat length leads to increased expression of PPP2R2B in cell culture, it is possible that the expansion could lead to pathogenesis through alternate mechanisms, including altered splicing, a toxic effect of mRNA, or a protein with an expanded serine repeat. Strack, S. et al., *J. Biol. Chem.* 2002, 277: 20750-20755.

Microarray analysis of gene expression in SCA1 transgenic mice. *H.G. Serra¹, C.E. Byam¹, J.D. Lande¹, S.K. Tousey¹, H.Y. Zoghbi², H.T. Orr¹.* 1) Lab Medicine & Pathology, Institute of Human Genetics, Univ Minnesota, Minneapolis, MN; 2) Howard Hughes Medical Institute, Dept Molecular and Human Genetics, Baylor College of Medicine.

Spinocerebellar ataxia type 1 (SCA1) is a neurodegenerative disease caused by the expansion of a glutamine repeat within the SCA1-encoded protein, ataxin 1. Although ataxin 1 is ubiquitously expressed, the disease affects a specific subset of neurons including the Purkinje cells of the cerebellar cortex and neurons within the brainstem. We used genome-wide oligonucleotide microarrays to characterize gene expression patterns in the cerebellum of three different SCA1 transgenic mouse lines at 5 weeks of age; that is, before the onset of the neurological disease phenotype. We used an ataxic transgenic line expressing one expanded allele with 82 CAG repeats (B05 line); a non-ataxic transgenic line expressing wild type SCA1 allele with 30 repeats (A02 line) and a non-ataxic line that expresses ataxin 1 with 82 CAG repeats only in Purkinje cell cytoplasm (K772T line). We reasoned that we could perform a genetic analysis by comparing the ataxic line (B05) with the two non-ataxic lines (A02 and K772T) followed by a comparison between the two non-ataxic lines (A02 and K772T). The set of genes obtained in the last comparison (A02 and K772T) is not likely to play an important role in the disease process; therefore, we subtracted these genes from those obtained in the first two comparisons (B05 vs A02, and B05 vs K772T). We were able to identify a set of eleven genes (5 novel and 6 known genes) highly expressed in cerebellar Purkinje cells, the most affected site in SCA1. The set of known genes includes Purkinje cell protein 1 (PCP1), Glutamate transporter (EAAT4), Inositol 1,4,5-triphosphate receptor 1 (IP3R1), Homer-3, G-Substrate and Carbonic anhydrase related sequence (CARP). Of the six known genes, four (Homer-3, G-Substrate, EAAT4, IP3R1) can be placed within the glutamate-signalling pathway. In summary, this work provides a broad-based information on the molecular mechanism involving SCA1 pathogenesis and permits a further insight on the complexity of SCA1 disease.

Systematic identification and characterization of eye-expressed transcripts: novel candidate genes for eye diseases. *S. Banfi*¹, *I. Conte*^{1, 2}, *M. Lestingi*¹, *C. Ziviello*¹, *C. Vitiello*¹, *D. Circolo*¹, *M. Pugliese*¹, *M.G. Miano*², *A. den Hollander*³, *F. Cremers*³, *A. Ballabio*¹, *A. Ciccodicola*². 1) Telethon Institute of Genetics and Medicine (TIGEM), Naples, Italy; 2) Institute of Genetics and Biophysics "Adriano Buzzati-Traverso" (IGB) CNR, Naples, Italy; 3) University Hospital of Nijmegen, The Netherlands.

Inherited eye diseases are a common cause of visual impairment in children and young adults. The molecular causes of the majority of the more than 200 eye disorders recognized thus far have not been elucidated yet. We propose to identify and characterize, in a systematic manner, a number of human genes which are specifically or predominantly expressed in the eye and can therefore represent candidates for inherited eye disorders. We selected these cDNAs both by using bioinformatic tools (in silico differential expression screening using the public EST databases) and by using subtractive human cDNA libraries enriched for retina- and retinal pigment epithelium (RPE)/choroid-specific cDNAs. We are currently carrying out a more detailed characterization of these cDNAs including mapping assignment in the human genome, identification of the full-length human transcripts, and detailed analysis of the expression patterns by RNA in situ hybridization on mouse tissues. So far, we have selected 100 putative eye-specific that have been analyzed by semiquantitative RT-PCR PCR to verify their expression level in retina. Forty of these cDNAs turned out to be specifically or predominantly expressed in retina and/or RPE. Furthermore, for many of them, we have characterized the genomic structure and we have isolated the full-length cDNA. We are analyzing the possible involvement of these candidate genes in eye inherited disorders by carrying out extensive mutation analysis, by DHPLC approach, in a large collection of retinal degeneration patients, including both familial and sporadic cases.

DNA-protein and protein-protein interactions by DNA affinity capture-LC/MS/MS. *T.K. Bane¹, J.M. LeBon¹, T.D. Lee², A.D. Riggs¹.* 1) Division of Biology, City of Hope Nat. Med. Ctr, Duarte, CA; 2) Division of Immunology, City of Hope Nat. Med. Ctr, Duarte, CA.

DNA-protein interactions are at the foundation of gene regulation and epigenetic phenomena such as X Chromosome Inactivation (XCI). Epigenetic regulation is the mechanism for the selective activation or inactivation of genes within cells. Disruptions of epigenetic states represent human disease phenotypes, especially developmental defects and tumorigenesis. Numerous studies have shown that 5-methyl-cytosine strongly affects DNA-protein interactions and inhibits transcription when present in promoters. XCI, which results in the heritable inactivation of one X chromosome early in mammalian embryogenesis, is maintained by the enzymatic hypermethylation of cytosine at CpG sites on the inactive X chromosome. A gene called XIST, which is expressed only from the inactive X chromosome, controls the initiation of XCI. This study investigates the effect of cytosine methylation on protein binding to the human XIST minimal promoter in nuclear extracts. We are using DNA affinity capture (DACA) combined with both Surface-Enhanced Laser Desorption/Ionization-Time of Flight Mass Spectrometry (SELDI-TOF MS) and differential isotopic labeling combined with nano-LC/MS/MS to investigate DNA-protein and protein-protein interactions. We have successfully carried out DACA-TOF mass spectrometry using DNA fragments bound to a surface to analyze 1) sequence specific DNA-protein interactions and 2) the DNA-protein, protein-protein interactions specific to methylated versus unmethylated fragments of the human XIST minimal gene promoter. Comparisons between mass spectra indicate that in general, protein complexes that form on the unmethylated capture molecule are strongly repressed on the methylated molecule. Currently, this method does not provide conclusive identification of the bound proteins. Therefore, we have carried out differential isotopic labeling to examine the differences in our two protein samples enriched by DACA. We have found that the ICAT system is capable of providing significant purification, relative quantitation and identification of the proteins involved.

CTCF binding sites and developmental changes in DNA methylation at the 5' end of a gene that escapes X inactivation. *C.M. Disteche¹, G.N. Filippova², J-P. Truong¹, K. Tsuchiya³*. 1) Department of Pathology, University of Washington, Seattle, WA; 2) Fred Hutchinson Cancer Research Center, Seattle WA; 3) Department of Pathology, Vanderbilt University, Nashville, TN.

SMCX/Smcx is a gene that escapes X inactivation in human and mouse. Our previous studies have shown that Smcx can be completely inactivated in cells of early mouse embryos, whereas the gene escapes inactivation in adult cells, indicating that genes that escape X inactivation undergo a process of reactivation during development. In mouse the CpG island of Smcx is located near a gene subject to X inactivation. Our analysis of the CpG island of Smcx by electrophoretic mobility shift assays showed that two binding sites for the CTCF insulator were located in the region, suggesting that these sites might help establishing chromatin domains. We examined the methylation pattern of Smcx CpG island during development, using the bisulfite method. Although no methylation was found in adult tissues, as expected for a gene that escapes X inactivation, partial CpG methylation was found in Smcx CpG island of early female mouse embryos. However, CpG methylation was absent from the CTCF binding sites, suggesting that CTCF might interfere with the establishment of DNA methylation and thus protect Smcx from stable X inactivation.

DNMT1 and DNMT3b are not required for maintenance of XIST repression in human cancer cells. *L.V. Pereira, L.R. Vasques, M. Soukoyan.* Dept Biol, Inst Biociencias, Universidade de Sao Paulo, Sao Paulo, SP, Brazil.

The process of X chromosome inactivation (XCI) in human and mice involves expression of the XIST/Xist gene from the inactive X chromosome (Xi) and repression of the XIST/Xist allele on the active X chromosome (Xa). Repression of the XIST/Xist gene on the Xa upon differentiation has been associated with methylation of its 5' region. In mice, Dnmt1 has been shown to be involved in the methylation and transcriptional repression of Xist on the Xa. In human cancer cells, DNMT1 and DNMT3b cooperate to maintain global DNA methylation and gene silencing. We examined the role of human DNMT1 and DNMT3b in maintaining XIST gene repression on the Xa in the human cancer cell line HCT116. Methylation of the XIST promoter and XIST transcriptional repression is sustained in DNMT1-, DNMT3b- and DNMT1/DNMT3b-deficient cells. In contrast, global DNA demethylation of these cells with 5-aza-2-deoxycytidine leads to XIST expression. We conclude that additional DNA methyltransferases are involved specifically in the process of maintenance of XIST repression in these human cells.

Program Nr: 979 from 2002 ASHG Annual Meeting

Comparison of methods for recruitment from a high-risk cancer clinic. *T.M. Friebe, R.A. Beutler, S. Lee, B. Bernhardt, K. Helzlsouer, C.A. Griffin.* Mid-Atlantic Cancer Genetics Network, Johns Hopkins University, Baltimore, MD.

The Mid-Atlantic Cancer Genetics Network (MACGN) is one site of the nationwide Cancer Genetics Network (CGN). The CGN was established as an infrastructure to facilitate research in clinical cancer genetics. MACGN targets individuals from cancer risk assessment clinics for recruitment into the CGN registry. Two methods of recruitment into the registry were compared over an eight month period. A passive recruitment technique was used during the first four months of recruitment, which involved a brief mention of the MACGN program and distribution of a brochure. An active recruitment method was used during the second four month period, in which MACGN staff approached patients and initiated a brief discussion of the MACGN program, after which patients were given the opportunity to decline participation, to enroll then and there, or to take an enrollment packet home. One hundred fifty-eight patients were seen in the clinic during the first four month period and 142 in the second four month period. The demographics and clinical characteristics of the patients who were approached using the two methods were similar in age, ethnicity, level of education and marital status. The change to the active recruitment method resulted in a four fold increase in enrollment by invitees (from 15.6% to 67.4%). This increase shows the importance of personal contact with potential participants as well as the value of allowing time for research staff to describe the program in detail and answer questions that potential research participants may have. Funded by NCI/NIH grant CA 78148-04.

Attitudes of adolescents on genetic screening and testing. *D.N. Abuelo¹, A. Harel², A. Kazura³*. 1) Pediatrics, Rhode Island Hosp, Providence, RI; 2) Brandeis University; 3) Psychiatry, Hasbro Children's Hospital, Providence, RI.

Purpose: To examine adolescents' attitudes toward screening/testing for hereditary disorders. **Methods:** A survey was distributed to 672 students grades 10 to 12 attending a suburban high school. It included information about three diseases: Tay-Sachs, hypercholesterolemia and familial breast cancer. A questionnaire explored their attitudes toward testing for these diseases. **Results:** 361 questionnaires were returned, a 54% response rate. Mean age of participants was 17 ± 1 years. Most girls (67%) wanted to be tested for familial breast cancer. Girls were significantly more interested than boys in testing for hypercholesterolemia. Individuals in the ethnic risk groups for Tay-Sachs disease were significantly more willing to be tested than those not in the ethnic risk groups, but only 33% would either "definitely" or "probably" wish to be tested. Girls who had a relative with breast cancer were significantly more willing to be tested than other girls. Similarly, individuals with a family history of hypercholesterolemia were significantly more interested in testing than those without a family history. About 81% of students with a positive family history had never been offered cholesterol testing. Only about 25% of participants stated that their attitude about genetic testing might result in discrimination by insurance companies or employers. **Conclusions:** Adolescents are receptive to educational efforts about genetic diseases and many are interested in having testing or screening for genetic diseases. The main motivator is having someone in the family affected by the disease in question.

Program Nr: 981 from 2002 ASHG Annual Meeting

Long-term re-contact for genetics services. *R.R. Lebel, B. Stradling, B. O'Donnell, D. Skipper, C. Yarshen, C. Malik.*
Genetics Risk Assessment Service, Hinsdale Hospital, Hinsdale, IL.

Modern computerized databases allow for storage of numerous details, including family history information that may be encoded in such a way as to be retrieved to assess risk for complex disease. We may know, for example, that the husband of a woman seen for advanced maternal age has three paternal aunts with breast cancer, placing him and other family members at risk. Searching such a database for families with multiple members affected by cancer of the breast, ovary, colon, prostate or uterus, we identified hundreds of people who might benefit from re-contact for consultation to discuss new technology for the assessment of genetic risk factors. We found not only that many people who have not been seen for ten years are difficult to locate, but also that many of those contacted have limited interest in pursuing consultation and testing. We will present a detailed discussion of the results of these efforts, which show that approximately 5% of the charts reviewed were found to have potential for useful cancer genetics consultation. We will explore some of the psychosocial and ethical aspects of this innovative approach to the duty to re-contact.

Breast cancer families; risk estimation for clinical practice. *C.J. Van Asperen¹, M.A. Jonker², J.E. Van Diemen-Homan¹, E. Bakker¹, M.H. Breuning¹, J.C. Van Houwelingen², G.H. De Bock³.* 1) Departments of Human and Clinical Genetics; 2) Medical Statistics; 3) Medical Decision Making, Leiden University Medical Center, The Netherlands.

Background At present, the majority of women from breast cancer families tested for BRCA1 and BRCA2 mutations will receive a negative test result, although they were referred by a family cancer clinic. For this group of women from high-risk families, risk can only be estimated by examining their pedigree on account of which referral to standard protocols for surveillance takes place. Because of the various kind of counselees from breast cancer families (healthy and affected) it is important to choose for a consistent risk estimation in order to be able to compare the amount of risk in families visiting family cancer clinics. We propose a new method for risk estimation in breast cancer families by analyzing pedigrees from one point of view.

Methods Family histories of 200 consecutive counselees were analyzed. Risks were noted for a (fictive) healthy sister of the breast or ovarian cancer patient, most nearest to the counselee. Risks were subsequently correlated with common risk estimates, like the Claus tables.

Results Out of the 200 family histories, 99 (49.5%) did not fit in the Claus tables only. In comparison with original Claus tables this new method demonstrated higher sensitivity (0.83 vs 0.52) and lower specificity (0.24 vs 0.48) for mutation detection. Both models had a low positive predictive value of 0.2.

Conclusion This method provides a new standard in family cancer clinics as more clinical information is used. Only a model with higher specificity for mutation detection in breast cancer families can reduce the high number of uninformative DNA test results.

The utility of subtelomeric and chromosome testing in patients with congenital heart defects. *K.L. Russell, G. Wernovsky, E. Goldmuntz, J.W. Gaynor, I.D. Krantz, J.E. Ming, S. Saitta, D.M. McDonald-McGinn, L. Celle, N.B. Spinner, E.H. Zackai.* The Children's Hospital of Philadelphia (CHOP) and University of Pennsylvania School of Medicine, Philadelphia, PA.

Here we emphasize the importance of subtelomeric testing in addition to chromosomal analysis in infants with CHD as a means to discern underlying diagnoses and utility in prognostication. Over a one year period (2001), we were asked to evaluate 32 infants with congenital heart disease in the Cardiac Intensive Care Unit at CHOP, in whom there was a question of dysmorphism and/or other organ system involvement. In 12/32 patients, the heart defect was determined to part of a known syndrome: 22q11.2 deletion (4); Noonan (3); CHARGE (1); VATER (1); heterotaxy (2); hemifacial microsomia (1). In 6/32 patients the dysmorphism was minor, if present at all. They were felt to have isolated non-syndromic heart disease after normal chromosome and 22q11.2 studies (and normal Williams probe done in 1). Fourteen/thirty-two children were thought to be dysmorphic but their features did not fit a known syndrome. Chromosomal analysis identified an unbalanced translocation in 2 children. A patient with a double outlet right ventricle and interrupted aortic arch had a 4 way maternally derived unbalanced translocation involving chromosomes 5, 6, 10, 18 (p13;q12;q11;q12). A patient with truncus arteriosus had a de novo unbalanced translocation 45,XY,der(5),t(5;22)(p15;q22.2).

Subtelomeric testing was performed on 11/12 of the remaining undiagnosed patients. Four patients were found to have a subtelomeric rearrangement. These included a de novo 9q deletion; a de novo 1p deletion; 11q deletion; a maternally derived 4q deletion. Thus, examination and laboratory testing was successful in detecting the etiology of congenital heart disease in 24/32 (75%) patients. Having a diagnosis is important for recurrence risk counseling as well as for prognostication and one must now factor in the impact of previously cryptic subtelomeric rearrangements on the long term neurologic outcome following cardiac repair.

Phenotype/karyotype correlation in inv dup(15) marker chromosomes: guidelines for evaluation. *S.E. Thompson, M.D. Graf, S. Schwartz.* Center for Human Genetics and Department of Genetics, Case Western Reserve University and University Hospitals of Cleveland, Cleveland, OH.

The inverted duplicated chromosome 15, [inv dup(15)] is the most common extra structurally abnormal chromosome, comprising approximately 57% of all detected marker chromosomes. The inv dup(15) varies both in size and associated phenotype, ranging from normal to mental retardation, to what has been deemed the inv dup(15) syndrome. With the advent of FISH in the early 1990s, the inv dup(15) has been better identified and defined cytogenetically and molecularly. However, even with the advances in technology, there has been continued debate concerning phenotype/karyotype correlation in the inv dup(15). There has not been complete correlation between cytogenetic or molecular characteristics and the resulting phenotypes, though presence or absence of the PWS/AS critical region (PW/ASCR) has provided the most consistent findings. In this study we report on clinical, cytogenetic, and molecular aspects of a total of 206 cases of inv dup(15) to further characterize the phenotype/karyotype correlation of the inv dup(15) syndrome. Factors studied included phenotype, marker size based on FISH analysis, ascertainment, familial inheritance, and presence of mosaicism. The data showed a significant association between the presence of the PW/ASCR and an abnormal phenotype. Based on this data, recommendations regarding genetic counseling of prenatally detected inv dup(15) marker chromosomes have been developed. From these studies we have gained additional insights concerning the implication of the inv dup(15) chromosome and can conclude that: (1) this is the largest and most definitive study correlating the size of the marker chromosome, based on FISH, and phenotypic consequences; (2) the vast majority of patients with large markers could be classified as having the inv dup (15) syndrome demonstrating MR and seizures and/or autism.; (3) the size of the marker could be correlated to phenotype, inheritance and ascertainment, but not to the presence of mosaicism; and (4) we have developed specific guidelines for approaching these marker chromosomes if ascertained prenatally.

TEACH: Development and evaluation of a computer program for collecting family cancer history. *C.A. Griffin, Q. Qu, R.A. Beutler, J. Sollenberger.* Mid-Atlantic Cancer Genetics Network, Johns Hopkins, Baltimore, MD.

Recognition of an individual's increased risk for development of cancer due to his/her personal or family history of cancer requires collection of family history in sufficient detail. A major obstacle to obtaining the family history is time required to ask the individual about relevant members of the family. Additional barriers include time to record the information and to display it in a quickly usable form. We hypothesize that development of a tool that can be used easily by an individual and which immediately displays the data in a pedigree will facilitate collection, recording, and health care provider evaluation of the family history. We have developed a computer program (TEACH) into which an individual enters personal and family history of cancer in four generations. TEACH consists of original software written in Visual Basic with an Access database back-end loaded on a freestanding secure touchscreen computer placed in a doctors office, waiting room, or clinic. The program automatically draws a pedigree from the information and prints a hard copy for immediate use. The first version of the program was tested on 20 volunteers (mostly Hopkins employees and students) and 20 volunteer patients at the Sidney Kimmel Cancer Center. The testing group was highly educated (45% held graduate degrees). Average time required to enter information was 17.9 minutes, and all testers stated that this was an acceptable length of time. The testing group had little concern about using patient ID numbers as identifiers in the program (4.6 on a 5-point Likert scale) but were less comfortable using social security numbers (3.4). Testers were slightly more comfortable entering family members names into the program (3.5), but overall were only moderately concerned (2.6) about the security of information entered into the program. Testers felt generally comfortable (4.1) with having the completed pedigree placed in their charts. We conclude that TEACH can function as a tool to collect family history, and are in the process of evaluating its use in academic, community, and private practices. Supported by NCI/NIH grant CA 78148-04.

Genetic counseling referral and perceived benefit for New Jersey Fetal Abnormalities Registry (NJFAR)

subjects. *K. DePrince¹, A.J. Fisher¹, J.C. Canterino¹, R.L. Fischer¹, R.J. Librizzi², J.C. Smulian¹ and New Jersey Fetal Abnormalities Registry.* 1) University of Medicine and Dentistry of NJ, New Jersey, USA; 2) Jefferson Medical College, Pennsylvania, USA.

NJFAR collects information on pregnancies of NJ residents after 14 6/7 weeks gestation in which a fetal structural abnormality has been identified or suspected by Maternal-Fetal Medicine specialists. In a sub-set of these cases, women provide consent and actively participate in an extensive interview about medical history, family history, pregnancy course and outcome. Subjects are asked about genetic counseling referral and its outcome during the interview. This study was designed to determine 1) the frequency of genetic counseling referral and delivery; 2) the venue for genetic counseling when obtained; 3) potential reasons for not having genetic counseling; and 4) perceived helpfulness of genetic counseling. Responses from 50 consecutively interviewed subjects showed that genetic counseling was not offered in 9 (18%) cases (all with a defect in 1 organ system), was offered but not obtained in 10 (20%) cases (5 with a defect in 1 organ system / 5 with defects in multiple organ systems), and was offered and obtained in-person (n=27) or via telephone only (n=4) in 31 (62%) cases (14 with a defect in 1 organ system / 17 with defects in multiple organ systems). Genetic counseling was perceived as helpful in 27 (87%) of 31 cases when provided. The most common stated reason for not having genetic counseling when offered was having had genetic counseling in a previous pregnancy (3/10; 30%). This study demonstrates that the majority (82%) of NJFAR consented subjects are offered genetic counseling but only 62% actually receive genetic counseling services. Those who have genetic counseling overwhelmingly find the service helpful in dealing with the diagnosis of a fetal structural abnormality. (Supported by the NJ Department of Health & Senior Services and CDC Centers for Birth Defects Research and Prevention).

Prenatal diagnosis for cystic fibrosis: complex counseling and crisis intervention. *R. Babul-Hirji, L. Steele, D. Hinkson, P.N. Ray, D. Chitayat.* The Hosp Sick Children, Toronto, ON, Canada.

Prenatal diagnosis for cystic fibrosis (CF) is usually available either by mutation or linkage analysis. At our centre, patients are tested for 31 of the most common CFTR mutations with a sensitivity of ~87% in Caucasians. Linkage using 1 intragenic STR and 6 extragenic RFLP markers is offered when 2 mutations aren't identified. We present a case of complex counseling where linkage analysis was uninformative. A 36-year-old pregnant female who has a child with CF was seen for prenatal diagnosis (PND) of CF at 16 weeks. Her affected child had antenatal diagnosis of echogenic gut, didn't have postnatal sweat chloride testing and was diagnosed with CF at 16 months. The child had the maternal DF508 mutation while the father's mutation was unidentified. The patient was counseled that PND for CF would be by exclusion testing for DF508. If identified, linkage analysis would be pursued. The patient had amniocentesis and the fetus had the DF508 mutation. Linkage showed the father to be uninformative at all 7 markers. The fetus therefore had a 50% chance of having CF. As well, ultrasound at 20 weeks showed echogenic gut. Factors causing anxiety for this patient included uncertainty of the CF results, u/s finding of echogenic gut, dilemma of terminating a normal pregnancy and deciding to have further testing to refine the risk for CF with possibly terminating outside of Canada due to her gestational age. Counseling aimed at providing her with psychosocial and emotional support, providing accurate information and helping her identify areas for timely decision-making. Such a session presented many challenges: trying not to overwhelm the patient with too much technical information, helping her in her decision-making process by using counselling strategies and crisis intervention and recognizing the need for involvement of other clinical and research labs. Ultimately, further DNA analysis showed the fetus to be a carrier of CF. Follow-up sweat chloride testing at 6 weeks was normal. In light of this case, it is recommended that sweat chloride testing be done at 6 weeks of age on babies with an antenatal diagnosis of echogenic gut or predicted to be unaffected with CF by linkage analysis.

A randomized trial of telephone and in-person breast cancer genetic counseling. *J.O. Culver, A. Helmes, D.J. Bowen.* Fred Hutchinson Cancer Research Center, Seattle, WA.

Telephone genetic counseling may be considered when a patient or relative cannot be counseled in-person. We have conducted a randomized trial to determine whether breast cancer risk counseling in-person and by telephone are equally effective in communicating risk information, increasing breast cancer screening, and decreasing cancer worry. Study participants were recruited through a Seattle network of primary care providers and consisted of 340 women between ages 18 and 64 with no personal history of breast cancer. After completing a baseline survey, participants were randomized to one of three study arms: in-person genetic counseling, telephone genetic counseling, or a control group. Both counseling protocols included a discussion of the participant's Gail model breast cancer risk estimate, genetics concepts, and breast screening recommendations. All participants were asked to complete a 3-month follow-up survey. Forty-five percent of study participants had a relative with breast cancer, including 15% with at least one affected first-degree relative. The average Gail model risk for breast cancer was 9.5% by age 79. Yet, the average reported perceived risk was 30%, roughly 3-fold higher than predicted by the Gail model. At follow-up, the average perceived risk was significantly lower in the counseling arms ($p < .001$), averaging 20% in the in-person arm, 21% in the telephone arm, and 31% in the control group. At follow-up, participants in both counseling arms had decreased levels of cancer worry ($p < .01$) and increased intentions to do breast self-exam ($p = .055$). Most (88%) in the in-person arm and 81% in the telephone arm reported that they liked the counseling. Yet 15% of the participants in the in-person arm and 37% in the telephone arm would have chosen the other method of counseling. Our results show no outcome differences between these two counseling methods except for a slight preference for in-person counseling. Because genetic counseling may often be needed when in-person counseling is impossible or difficult, these results could have implications for clinical and research practice.

Breast cancer: Patients' perception of genetic risk, beliefs, attitudes, and experience within cultural diversity.

G.A. Karbani¹, K. Atkin¹, J. Hewison², C.E. Chu³. 1) CRPC, University of Leeds, Leeds, West Yorkshire, UK; 2) Psychiatry, University of Leeds, West Yorkshire, UK; 3) Yorkshire Regional Genetics Service, St. James' Hospital, Leeds, West Yorkshire, UK.

Background: Breast cancer is the most common cancer in women accounting for 19% of all cancers. While the incidence of breast cancer in the Indian subcontinent is lower than in Europe, migrant studies have shown that the incidence of cancer in migrant populations approaches that of the indigenous population within one or two generations and that it is an increasing issue for the South Asian population living in the UK. There is evidence that this increase particularly affects young women (25-50 years). The number of cases of breast cancer in the South Asian population resident in Britain is likely to rise and appropriate services will need to be available for these women. The increasing incidence of breast cancer in the South Asian community makes it extremely important that professionals understand cultural beliefs regarding breast cancer treatment and screening. This will allow improved culturally appropriate communication and better health provision to this group of women.

Aim: The aim of the study is to examine health care pathways, attitudes, beliefs and genetic perception of risk factors in South Asian women with breast cancer compared with non-Asian women. Generic issues with relevance to international health care will be drawn out.

Method: The study comprised of two groups of women attending breast clinic because of a diagnosis of breast cancer. The study comprised 25 South Asian women diagnosed with breast cancer and one individual (doctor, nurse, carer) who was a key influence during the breast cancer experienced. The control comprised 15 white women matched for age and socio-economic class diagnosed within the same time frame and individuals who were their key influence.

The method used as qualitative content analysis of interviews conduction in the appropriate language.

Comparison of Web based vs. hospital based retrospective recruitment of participants for a craniosynostosis study. *N. Isaac¹, T.H. Beaty², B. Carson³, E.W. Jabs¹, J. Richtsmeier⁴, C. Vander Kolk³, A.F. Scott¹, S.A. Boyadjiev Boyd¹.* 1) Dept. Pediatrics/Gen Med, Johns Hopkins Univ, Baltimore, MD; 2) Dept. of Epidemiology, Johns Hopkins School of Public Health; 3) Dept. of Surgery, Johns Hopkins School of Medicine; 4) Dept. of Anthropology, The Pennsylvania State University.

A novel Web based approach was used to recruit families, for a study of genetic and non-genetic causes of craniosynostosis. Invitation letters were sent to 4 of the 7 Web based craniosynostosis peer support groups contacted. These 4 groups (Craniosynostosis and Positional Plagiocephaly, Inc.; CRANIOSUPPORT; FACES; and Lets Face It USA) agreed to post study information on their Web sites. Over the past 18 months we received a total of 152 responses. Families were considered for enrollment based on CAT scan reports confirming craniosynostosis and/or a history of surgical correction of abnormal head shape. A sample collection kit was mailed to the family after review of an e-mail based initial screening questionnaire. Genetic evaluation and CAT scan reports were requested to confirm the diagnosis. A phone interview collecting medical and family history completed the recruitment process. Thirty-one families (20%) have been recruited and provided medical information, photographs, and blood samples. Of these 31, 4 probands were syndromic, 21 had one sutural synostosis and 6 had multiple sutural synostoses. An additional 104 families (68%) indicated an interest in participating and are in different stages of the recruitment process. Only 17 families (11%) ultimately chose not to participate. In comparison, invitation letters were sent to 233 families identified retrospectively through pediatric neurosurgery and plastic surgery clinics. Only 16 of these families have been successfully recruited and an additional 11 families have agreed to participate (12%). Of the 16, 2 probands were syndromic, 10 had one sutural synostosis and 4 had multiple sutural synostosis. Web based recruitment was more efficient than the retrospective hospital based approach. There were no significant differences in sutural involvement between participants of both groups.

Autosomal form of Alport syndrome, a model between dominant and recessive inheritance: implications for clinical practice and genetic counseling. *I. Longo¹, F. Mari¹, C. Pescucci¹, F. Ariani¹, M. Bruttini¹, I. Meloni¹, M. De Marchi², A. Renieri¹.* 1) Dept Mol Biol, Medical Genet, University of Siena, Siena, Italy; 2) Dept Clin Biol Sciences, University of Torino, Torino, Italy.

A comprehensive mutation screening of *COL4A3* and *COL4A4* genes let us detect 8 novel mutations in 6 out of 36 Italian families with a suspicious of autosomal Alport syndrome (ATS) (Kidney Int, 2002). Four mutations of *COL4A3* were found in compound heterozygotes in typical autosomal recessive form, i.e. rapidly progressive nephritis. Three mutations of *COL4A3* and 1 of *COL4A4* were found in simple heterozygotes. Further studies let us identify an additional family in which an heterozygous glycine substitution (p.G1198S) was present both in a 34 year-old female with thin basement membrane at renal biopsy, microhematuria and normal renal function and in the father with impaired renal function. Overall, clinical presentation of simple heterozygotes, including parents of recessive patients, ranges from healthy carriers, through Benign Familial Hematuria (BFH), to autosomal dominant ATS, i.e. slowly progressive impaired renal function. Very interestingly, we investigated a large family (36 members) in which two males progressed to End Stage Renal Failure by the age of 20-23 years and had glomerular basement membrane lesions typical of ATS. The father and the paternal grandfather had an apparently non progressive chronic renal failure. One paternal uncle, 1 paternal aunt and 1 paternal cousin had microhematuria only. Linkage analysis was compatible with the presence of two mutations (genetic compound) in the two probands and one heterozygous mutation both in patients with non progressive renal damage and in patients with microhematuria. Our results show that there are no clear-cut limits between the diagnoses of autosomal dominant and recessive ATS and BFH, but that these phenotypes rather belong to a continuous spectrum of graded severity. The wide range of clinical presentation of carriers of a mutation in either *COL4A3* or *COL4A4* gene makes diagnosis and most important prognosis unpredictable in these patients. Moreover this ambiguity makes it very difficult to predict inheritance in single small families.

BRCA1/2 genetic testing: womens information seeking behavior complementary to the informed consent

procedure. A. C.M. Julian-Reynier¹, C. Cypowyj^{1, 2}, F. Eisinger^{1, 3}, F. Chabal¹, M. Morin^{1,2}, H. Sobol³. 1) Inst Paoli-Calmettes, BP156, INSERM U379, Marseille CDX 9, France; 2) Universit de Provence, Aix en Prce, FranceÆ; 3) Inst Paoli-Calmettes, INSERM E9939, Marseille France.

No data are available on information seeking behaviour (ISB) of women outside the cancer genetic consultation when BRCA testing is considered. The objective of this study was to describe ISB for genetic testing complementary to the genetic consultation and their related factors. A prospective ongoing cohort study (2000-2002) is including all women who attended at one cancer genetic clinics in France after a BRCA1/2 analysis had been proposed. Closed questionnaires were administered before and after the occurrence of the 2nd cancer genetic consultation. This consultation aims to confirm the decision to be tested. Preliminary results were analysed (N=104 ; mean age 47, SD=11; 70% affected by cancer). Prior to the 2nd consultation, 36% of the women had actively looked for information on BRCA1/2 testing compared to 23% afterwards. After multivariate adjustment by logistic regression, the before consultation information seeking behavior was related to a higher satisfaction with the cancer genetic consultation occurring afterwards ORadj (95% CI): 1.04 (.99-1.08) (scale from 0 to 100), with the certainty to be a gene carrier ORadj: 3 (1-8), and with the fact to have a treatment for anxiety of depression ORadj: 4 (1-16). Those who actively looked for complementary information were also more often attending with a family member ORadj: 5 (2-14). The other tested variables (depression, coping, sociodemographic and medical characteristics) were not significant (p>0.05). Sources of information will be detailed These results highlight the fact that women who actively seek information on breast/ovarian cancer genetic testing differ from those who do not, not only for their a priori beliefs but also for their satisfaction with counseling and for their social support.

Attitudes of Haemophilia Affected Families Towards Genetic Counselling. *G.S. Pandey, I. Panigrahi, S.R. Phadke, B. Mittal.* Medical Genetics, Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, UP, India.

The aims of this study was to evaluate the knowledge of haemophilia in families enrolled in the Lucknow Haemophilia Society and assess their attitudes towards prenatal diagnosis and the possible factors influencing these. Questionnaire comprising of multiple choice and open-ended questions was distributed at the society meetings for assessing knowledge and attitudes. The source of knowledge in most patients was the Hemophilia Society. There was a positive response from majority of the families. Almost all of them had in depth knowledge about the disease and the frequency of its recurrence in their families. There were 28 respondents to the questionnaire assessing knowledge of hemophilia and 17 respondents to questionnaire on prenatal diagnosis (PND) attitudes. The average score was 7.3 out of 15 points. There was a positive correlation between the extent of knowledge and the frequency of attending the monthly hemophilia society meetings. This was evident from the prenatal diagnosis questionnaire, where most of the families showed positive attitude for termination of pregnancies if the fetus is affected. In four families of haemophilia A prenatal diagnosis was carried out on chorionic villous sample using four polymorphic markers in the factor VIII gene. Three families reported for prenatal diagnosis using DNA-based linkage analysis, 2 fetuses were found to be affected while the third one was unaffected. Out of the two affected, one opted for termination while the other family decided to continue with the pregnancy even after intensive counseling. Hemophilia society has an important role in educating hemophilia families and improving uptake of services. Geographic, ethnic, and financial factors may affect PND attitudes and to be kept in mind during genetic counseling. The present study highlights that there is a good understanding of the disease among affected families yet prenatal diagnosis is not readily accepted in our society because of male pro society. Therefore, there should be extensive awareness program, which will bring in more families for prenatal diagnosis.

Parents' use of the Internet as a source of genetic information. *M.I. Roche*¹, *D. Skinner*², *K. Kuczynski*², *R. Schaffer*³. 1) Dept Pediatrics, CB #7220, Univ North Carolina, Chapel Hill, NC; 2) Frank Porter Graham Child Development Institute, Univ North Carolina, Chapel Hill, NC; 3) Dept Anthropology, Univ North Carolina, Chapel Hill, NC.

Clinical experience suggests that parental Internet use to obtain genetic information is widespread but influencing factors have been largely unexplored. Two previous studies, Taylor(2001) and Christian (2001) surveyed families prior to their genetics clinic visit. Over 75% had Internet access but fewer than half had searched prior to their visit. Locating information about their relative's condition in "layperson's terms" ranked as the main goal. Searching occurred more frequently if a child was the proband and if a diagnosis had been made. As part of a longitudinal study to determine how families seek, interpret, and use genetic information, parents were queried about Internet use. The first semi-structured interview, conducted after the initial clinic visit, sought to determine the searching methods used, types of information sought, and families' appraisals of their searches prior to and after their visit to the Pediatric Genetics and Metabolism Clinic at UNC-CH. Sixty-nine interviews were audio-taped, transcribed, and entered into the program, NUD*IST 4.0 for data coding and analysis. The keywords "Internet", "web", and "computer" were searched. The families were representative of the ethnic distribution of the clinic population. Four-fifths of the families searched the Internet both before and after the visit. Preparatory searches using broad terms occurred prior to the visit and enabled families to build a genetic vocabulary, anticipate what to expect during the session, and construct questions. Following a diagnosis, searches focused on potential treatments, services, and support. Parental assessments of their Internet searching were laudatory but guarded and the information's uncertain validity was recognized. Parents' use of the Internet as a source of genetic information was widespread in our population, occurred more often in Caucasian families and augmented traditional methods such as personal contact with health and other service providers. Supported by NHGRI grant #HG02164-03.

Process issues in genetic counseling for hereditary breast and ovarian cancer: Client ratings and session characteristics. *C. Wang, K. Milliron, R. Gonzalez, S.D. Merajver.* University of Michigan, Ann Arbor, MI.

Purpose: Process research in genetic counseling offers a way to assess the effectiveness of genetic counseling and can help identify possible areas for intervention. Our study set out to identify important components of the counseling process and the extent to which they are associated with desired outcomes of genetic counseling. **Methods:** A total of 70 women attending the Breast and Ovarian Cancer Risk Evaluation Program at the University of Michigan completed a mailed questionnaire one week following genetic counseling. Client ratings were obtained on the following: ability to ask questions and extent to which information was explained clearly. Session characteristics examined included complexity of family history (rated by the genetics team) and time spent face-to-face with the client. Outcomes of interest were subjective knowledge, uncertainty reduction, satisfaction with understanding of breast cancer risk, and general psychological distress. **Results:** Client ratings of being able to ask questions was significantly associated with greater subjective knowledge, higher satisfaction, and lower psychological distress. Ratings of the extent to which information was clearly explained was significantly associated with greater subjective knowledge, higher satisfaction, and greater uncertainty reduction. Complexity of family history was negatively associated with uncertainty reduction, such that clients who had family histories that were more complex (i.e., difficult to determine likelihood of a hereditary cancer syndrome) were less likely to feel that counseling reduced uncertainty about their breast cancer risk. Time spent face-to-face with the genetics staff was not found to be associated with any of the genetic counseling outcomes, although it was found to be negatively associated with ratings of how clearly genetic risk information was explained. **Summary:** A greater understanding of processes variables and how they are related to genetic counseling outcomes will enable researchers to identify aspects of the encounter that may be targeted for intervention.

Genetic counseling in a pediatric cancer clinic: results of a pilot program. *K.A. Schneider¹, T. Brown², C. Medeiros Nancarrow¹, C. Recklitis¹, L. Diller¹.* 1) Dana Farber Cancer Inst, Boston, MA; 2) Boston Univ, Boston, MA.

In our pediatric cancer clinic, mothers were invited to participate in a genetic counseling pilot study. All mothers were seen for one visit by the same genetic counselor who collected detailed family histories and categorized families as having low, high or uncertain risk for an inherited predisposition to cancer. Participating mothers completed pre- and post-visit questionnaires about genetics knowledge, cancer worry, emotional well-being, and patient satisfaction. 31 mothers enrolled, submitting 31 pre- and 15 post-visit surveys. Participating mothers had mean age of 40, 90% were married, 84% had more than 1 child, and 65% were college graduates. Family histories had not been discussed with pediatric oncologists in 53% of cases. Childrens diagnoses were: brain tumor (9), lymphoma/non-ALL leukemia (8), Wilms tumor (5), neuroblastoma (5), sarcoma (2), and solid tumors (2). 29/31 (93.5%) cases were low risk, 1 case was high risk (possible Li-Fraumeni syndrome) and 1 case was uncertain risk pending documentation. On a 32-item test, mothers' mean knowledge scores increased significantly after the genetic counseling visit (20.3 to 23.9; $p < .05$). Distress levels measured on the Brief Symptom Inventory (BSI) were above population norms but revealed no negative sequelae from the genetic counseling encounter ($n=13$; pre/post mean global severity index score 68.1 /67.9; $p < .05$). In fact, cancer worry significantly decreased following the genetic counseling visit (8/15 had reduced worry; $p < .05$). Patient satisfaction scores were very high and overall, 14/15 (93%) mothers found the genetic counseling visit to be beneficial. In conclusion, mothers are concerned about the potential genetic implications of their children's cancer diagnoses. One genetic counseling session can identify the rare high risk family, facilitate referrals to specialists, and in most cases, alleviate fears about inherited susceptibility.

Cancer genetic counseling and testing by telemedicine - results of a feasibility study. *J. Permuth-Wey^{1,2}, J.A. Betts², A.B. Cantor^{1,2}, J.P. Krischer^{1,2}, R. Sutphen^{1,2}.* 1) Department of Interdisciplinary Oncology, University of South Florida College of Medicine, Tampa, FL; 2) H.Lee Moffitt Cancer Center and Research Institute, Tampa, FL.

The use of telemedicine for delivery of cancer genetic counseling has the potential to improve accessibility, reduce costs and allow delivery of counseling simultaneously to multiple family members who are geographically distant. We conducted a randomized, crossover study to assess the feasibility and acceptability of delivering cancer genetic counseling services via telemedicine. All individuals presenting for cancer genetic counseling at an NCI-designated Comprehensive Cancer Center were eligible for participation. A brief pre-session questionnaire was used to evaluate previous computer, teleconferencing and research participation experience, in order to examine differences between individuals who agreed to participate in telemedicine versus those who did not. Study participants were randomized into two groups to receive their genetic counseling: 1) face-to-face, or 2) via telemedicine. Participants and counselors were asked to evaluate the experience for each session through a post-session questionnaire which was modified from a previously published instrument. Of 74 eligible subjects, 60 agreed to participate. There were no differences between the 14 who declined participation and the 60 who agreed. Of the 60 participants, 30 received their initial genetic counseling session via telemedicine, and 30 received the session face-to-face. There were no perceived differences between the face-to-face and telemedicine pre-test sessions. Of the 60 participants, 23 proceeded with genetic testing 12 of whom had received the initial session face-to-face and 11 via telemedicine. Based on the crossover design of the study, these 23 individuals received their post-testing genetic counseling session via the opposite method from their initial session. A two-sided test of significance showed no difference in overall satisfaction between telemedicine and face-to-face sessions. This study suggests that telemedicine is perceived as a satisfactory method for the delivery of cancer genetic counseling.

Oral History of Human Genetics Project. *A. Maestrejuan*¹, *M. Meldrum*¹, *E.R.B. McCabe*^{2,3}. 1) Department of History, UCLA; 2) Department of Pediatrics and Human Genetics, David Geffen School of Medicine at UCLA; 3) UCLA Center for Society, the Individual, and Genetics, Los Angeles, CA, 90095.

The second half of the 20th century saw a dramatic growth of human genetics from its very beginnings to the near-completion of the Human Genome Project. The working parameters, scientific assumptions, methodologies and interpersonal networks that were formed just prior to, and during the development of, the field have shaped today's concepts and have prompted the scientific and social questions that drive current research. The Oral History of Human Genetics (OHHG) Project is premised on the assertions that a knowledge of history: will assist today's and tomorrow's practitioners to re-examine the conceptual frameworks and implications of their assumptions and methods; will suggest new directories for research; will inform debate on ethical, legal and social issues critical to genetics; and will inspire students entering the field. The purpose of the OHHG Project is to preserve the documentary record of human genetics beginning with the period from 1950-2000. The OHHG Project is a collaboration of UCLA, the American College of Medical Genetics and the American Society of Human Genetics. We have begun to document the life stories of pioneers and leaders in the field using the formal tools of the oral historian, including digital video recording and printed transcripts. Dr. Victor McKusick assumed responsibility for the Moore Clinic on July 1, 1957, has disciplined information gathering through the compendium, *Mendelian Inheritance in Man*, and was present in the White House for the announcement of the completion of the Human Genome Project. We will use an interview with Dr. Kusick and a discussion of his early work on Peutz-Jeghers syndrome to illustrate how oral history analysis can add to our knowledge of the development of a discipline. The OHHG Project will create a resource that will help illumine the stories of human and medical genetics for geneticists, historians and investigators from all fields.

Phenotypic description of Hereditary Sensory Neuropathy Type 1A (HSN 1A) in two kindreds segregating the same mutation in the gene encoding Serine Palmitoyl Transferase Long Chain Subunit 1 (SPTLC1). M.P.

O'Driscoll¹, P. Ainsworth², D. Bieger¹, Y.P. Goldberg^{3,5}, R.C. Green¹, A.F. Hahn⁴, A. Khani-Hanjani⁵, M.R. Hayden^{3,5}, J. MacFarlane⁵, W. Pryse-Phillips¹, M. Samuels⁵, H.B. Younghusband¹. 1) Discipline of Genetics, Memorial University of Nfld., St. John's, NF., Canada; 2) Dept. of Paediatrics, Children's Hospital of Western Ontario, London, Ont., Canada; 3) Dept. of Medical Genetics University of British Columbia, Vancouver, B.C., Canada; 4) Clinical Neurosciences, London Health Centre, University Campus, London, Ont., Canada; 5) Xenon Genetics Inc., Burnaby, B.C., Canada.

Hereditary Sensory Neuropathies (HSN) are genetically and clinically heterogeneous, with a variable degree of sensory or pain loss. Classification is based on mode of inheritance and clinical features. We report a detailed phenotypic description of HSN 1A in two families segregating the same mutation in the gene encoding the long chain subunit of serine palmitoyl transferase (*SPTLC1*). A point mutation, 399T®G is the most common HSN 1A mutation to date, found in families of English extraction from the UK, Australia and Canada. The two large families described here descend from a small coastline stretch of Newfoundland, Canada. Both families were traced to Southwest England, suggesting a founder effect. Participants agreed to mutation testing and a neurological and electrophysiological examination. Sural nerve biopsies were done in six affected individuals. Clinical findings were consistent, but of variable severity and onset. Most women noticed first symptoms in the second or third decade and pregnancy appeared to exacerbate disease. Examination revealed signs of an age-related and length-dependent small fibre sensory neuropathy with associated pain and trophic skin changes but few signs of autonomic dysfunction. Motor involvement was common, with early wasting of thenar eminence and intrinsic hand muscles, and with accentuated distal leg muscle wasting resulting in *pes cavus* and foot drop. Primary axonal degeneration was confirmed in the electrophysiological and pathological examinations. This study represents an advance in the potential for genetic counselling and disease management.

Consumer organizations serving individuals and families with genetically-related conditions: potential lessons for outreach and education. *R.M. Fineman¹, C.A. Roeber², B.P. Oles³, J.P.N. Massad², C.E. Crain², N. Tashima².* 1) RMF Associates, Seattle, WA; 2) LTG Associates, Inc, Takoma Park, MD; 3) Human Ecology Dept, Rutgers Univ.

It is widely acknowledged that public and private health care and social services professionals, consumers, and policymakers are frequently uninformed about issues related to genetics, health, and health care. As a result, consumers and providers often are unable to make informed decisions about genetic health care issues. Research on consumer organizations that serve individuals and families with genetically-related conditions can provide valuable lessons for the development of strategies used to educate the audiences noted above. Forty-two consumer organizations that provide education and support to individuals and families affected by genetically-related conditions were selected and contacted for this research. The organizations were selected to allow the research team to identify: how the organizations vary in size, locale, structure, and mission; what roles the organizations play within systems of care; the range and direction of organizational activities in light of advances in human genomics research; outreach and education activities determined to be most effective; and barriers and facilitators encountered when conducting outreach and education (with a specific emphasis on ethnic, minority and under-served populations). Our research yielded several important themes related to the nature and scope and the successes and challenges consumer organizations have experienced including: development of message content; determination of communication channels; and audience targeting. We hope that the findings of this study will help inform outreach and education efforts by public and private health care agencies, and consumer organizations, in order to enhance informed decision-making for the individuals and families they serve.

Assessing the value of an expanded clinical genetics curriculum for medical students. *L.A. Demmer¹, M.M. Carlin², S.V. Barrett², U. Purwono², J. Jonassen², M.P. Pugnair².* 1) Pediatrics, Univ. Mass Medical School, Worcester, MA; 2) Office of Medical Education, Univ. Mass Medical School, Worcester, MA.

Purpose: In 1995, an enhanced genetics curriculum with a clinical focus was introduced into a year one medical student genetics course. New components included patient and family interviews, small group discussions, psychosocial and ethical concerns, role play, and letter-writing exercises to families. A complementary program was introduced in spring 2000 as a third year two-day genetics interclerkship, with opportunities to interview families, engage in panel discussions, and attend lectures on genetic technology. This study assessed the value of the interventions by comparing cross-sectional data for four groups of medical students.

Methods: Effect of the interventions was examined using AAMC Graduation Questionnaire data. Ratings of instruction time of four graduating classes were compiled: one with prior curriculum (GY 1998), two with new curriculum (GY 1999, GY 2000), and one with new curriculum plus interclerkship (GY 2001). Proportions of 'appropriate' ratings were compared.

Results: The 'appropriate' ratings of Genetic Counseling instruction time for GY 1998-2001 were 51.9%, 74.7%, 78.8%, and 90.3% respectively (N=395; 100% response rate). Comparison of proportions revealed a significant difference between prior curriculum (GY 1998) and new curriculum (GY 1999, GY 2000) ($p < .05$). The proportion of 'appropriate' ratings of the new curriculum plus interclerkship (GY 2001) was significantly higher than the prior curriculum and significantly higher than the cohorts with the new curriculum but no interclerkship ($p < .05$).

Conclusions: This study provides evidence of the value of clinical emphasis on a genetics curriculum, first implemented in preclinical work and later expanded upon in clinical years. This suggests that such 'longitudinal' curricular interventions can be successful in promoting an enhanced education experience as perceived by students.

The use of standardized patients enhances medical student learning in medical genetics. *A. Greb, A. Trepanier, M. Kavanagh, G. Feldman.* Ctr Molec Medicine & Genetics, Wayne State Univ, Detroit, MI.

To evaluate the effectiveness of utilizing standardized patients (SPs) compared to student role-playing in teaching medical genetics, first year medical students in our genetics course were randomly assigned one of two case studies. The first case (DMD) involved a pregnant woman at risk for carrying a dystrophin mutation. For this case, SPs were trained to present the clinical scenario. The second case (NTD) involved a 43-year old woman with a family history of spina bifida. For this case, students were given appropriate history information and instructed to play the role of the patient. For both cases, students were expected to ascertain the patient's concerns, review laboratory results, collect relevant history information, perform a risk assessment, explain the genetics and natural history of the condition, offer genetic testing and disclose results. The faculty facilitators in each group documented if students attempted each of these tasks. Data was collected from 8 of 11 facilitators. There were no significant differences with regard to tasks completed between the SP and the student role-play cases. Students were asked to complete an evaluation form to assess their perception of the usefulness of SPs compared to student role-playing (n=142). Sixty-eight percent of the students stated that the use of an SP enhanced their learning compared to student role-playing; 67% stated that the utilization of the SP was a beneficial addition to the DMD case; and 61% stated that they would recommend using SPs in the case studies again. Student comfort level when talking with the patient was also assessed. Those who participated in the SP case were more likely to report that they felt uncomfortable when talking to the patient (22%) than students who participated in the other case (13%). Many students commented that they took the encounter more seriously when an SP was the patient. In conclusion, although SPs and student role-playing appear to be effective tools for medical students to gain experience applying basic genetic principles in a clinical manner, we found that students preferred the SP encounter, which enhanced their learning experience.

Longitudinal Evaluation of an Educational Intervention - Prenatal Diagnosis and General Practitioners. S.A. Metcalfe^{1,2}, A. Flouris¹, M. Seipolt³, MA. Aitken¹. 1) Genetics Education Unit, MCRI, Royal Children's Hospital, Parkville, Vic, Australia; 2) Dept Paediatrics, University of Melbourne, Parkville, Vic, Australia; 3) Genetic Health Services Victoria, Royal Melbourne Hospital, Parkville, Vic, Australia.

Increasingly patients present to general practitioners (GPs) with genetics-related issues. Many studies worldwide have revealed that GPs have insufficient knowledge about genetics and genetics resources. Australian GPs believed their knowledge was deficient, recognised the need for further education and identified prenatal diagnosis (PND) as a priority area.¹ A study was designed to assess GPs' knowledge and practice regarding PND, and to evaluate the effectiveness of a case-based workshop. Invitations for the workshop were mailed out to >1000 antenatal shared-care GPs. The workshop was offered at 3 different hospital-based settings. Places were limited and 106 GPs in total attended. GPs completed a pre-questionnaire prior to attending, which included questions covering a range of genetics topics. GPs who attended the workshop were asked to complete a second (post-) questionnaire, which contained some questions identical to the first relating to PND and the workshop itself. GPs who completed both (94) were given knowledge scores for each questionnaire, which were used to evaluate the effectiveness of the workshop. Six-eight months after the workshop, follow-up surveys were again sent out to participants to investigate if they retained the knowledge learnt from the workshop. Immediately following the workshop, mean knowledge scores increased for about 75% of GPs. The main areas that GPs improved in knowledge were (1) distinction between screening vs diagnostic tests, (2) which women should be offered prenatal screening, and (3) the age-related risk of Down syndrome for younger women. The follow-up survey showed that, whilst knowledge levels did decrease over time, they were still significantly higher than prior to the education intervention, indicating long term retention of knowledge. 1. Metcalfe S et al, Needs assessment study of genetics education for general practitioners in Australia. *Genet Med*, 4:71-77, 2002.

Predictors of interest in hereditary cancer risk information among Cancer Genetic Network (CGN) registry participants. *S.J. Olson¹, A. Ziogas², L. Wenzel² and Cancer Genetics Network, Educational Working Group.* 1) School of Nursing, Johns Hopkins University, Baltimore, MD; 2) College of Medicine, Epidemiology Division, University of California, Irvine.

Individuals need a functional understanding of genetics to make informed decisions about participating in genetic counseling and/or testing, as well as adopting behaviors that may reduce cancer risk. While professional societies acknowledge the importance of education for informed decision-making, little is known of informational needs of those participating in cancer genetics registries. Therefore we examined predictors of interest in further information about hereditary cancer risk among participants voluntarily recruited to the CGN. Of 13,004 individuals belonging to 11,447 families who completed the CGN Core Questionnaire, 83% wanted additional genetic information. Significant differences in interest emerged by gender, marital status and age of the respondent. As anticipated, past participants in genetic testing and genetic counseling were significantly more interested in additional information. Multivariate analysis using generalized estimating equations that account for familial correlations, recruitment center, ascertainment mode, genetic testing- and counseling found that the strongest predictors of interest in further information were: gender, (females expressed more interest than males, OR 1.2, 95% CI 1.1-1.3), age of respondent (participants <40 yrs expressed more interest compared to those >70 yrs (OR 2.5; 95% CI 2.1-3.1), marital status, and history of cancer in first degree relatives (FDRs). Information interest increased with strength of family history, with 76%, 84%, 86%, 88% and 89% desiring information among those with 0, 1, 2, 3, or >4 family members with cancer respectively. Males were more likely to be interested when prostate or colorectal but not breast or ovarian cancer was present in their FDRs. However, females wanted more information when breast, colorectal, ovary, or prostate cancer was present in FDRs. Personal history of cancer, education, and race/ethnicity were not significant predictors. This information will guide future educational efforts within the CGN.

Program Nr: 1005 from 2002 ASHG Annual Meeting

Clinical applications of molecular genetics: An on-line course. *T. Namm.* Dept Health & Clinical Sci, Univ Massachusetts Lowell, Lowell, MA.

The June, 2000 announcement of the completed first draft of the human genome project immediately accelerated activity among pharmaceutical companies, genetics research venues, and medical geneticists to streamline molecular genetic protocols for the diagnosis, treatment, management, and cure of human genetic disorders. Because information generated by molecular genetic technology extends to all corners of health and medicine, keeping current with developments in these areas becomes a must, not only for the "traditional" student, but for those already employed in associated professions. For many years, web-based education has been, and will continue to be, the most efficient way for any student to keep current with the latest developments in any field, no matter where they are located, and no matter where the course is offered. I have developed an on-line course entitled "Clinical Applications of Molecular Genetics." Topics include laboratory techniques employed in molecular diagnostics; methodologies for sequencing the human genome; the diagnosis, treatment, and prevention of diseases using gene therapy; current cloning technology and its applications; stem cell research and its implications for medicine; the development of designer drugs based on the genetic basis of disease; cancer cytogenetics; microarray chips and gene expression; and genomics, including physiological genomics, pharmacogenomics, and developmental genomics. Ethical, legal, and social implications generated by these issues are also discussed. The course culminates with a discussion of the human proteome project, including goals and objectives, existing and future sequencing technology, and the storage of data utilizing complex bioinformatic databases. The poster outlines techniques utilized to teach modern molecular genetics in an on-line platform, citing especially those modifications that are necessary for teaching in the absence of the traditional classroom setting. Also included are samples of: "lecture notes", student discussion board postings, graphic integration techniques, chat line histories, and accessibility to related links. Course requirements, test administration procedures, and the student evaluation system are presented.

A pilot study on psychiatric genetic counseling: counselors needs. *H.L. Peay, J.D. McInerney.* National Coalition for Health Professional Education in Genetics (NCHPEG), Lutherville, MD.

NCHPEG is producing a CD-ROM, funded by the U.S. Department of Energy, to educate genetic counselors about psychiatric genetics. To guide development we surveyed two groups of counselors about their perceived needs and comfort. Few such data exist in the literature. While both groups were small and self-selected, and may not reflect NSGC membership as a whole, the results provide insights into counselors' knowledge of, and comfort with, psychiatric genetics. In the first phase, 209 NSGC members completed an on-line survey. Counselors identified a need for information on: schizophrenia and affective disorders; major psychosocial issues; evaluating psychiatric diagnoses; the etiology of psychiatric disorders; risk assessment; evaluating multiplex families and genetic subtypes; managing uncertainty; teratogenicity of psychotropic medications; and counseling for those at risk. During field-testing 41 practicing genetic counselors (PGC) and 28 second-year genetic counseling students (GCS) completed a pre-test survey. When asked how prepared they feel to raise the issue of psychiatric disease with their clients, 32% (PGC) and 67% (GCS) felt either very unprepared or somewhat unprepared; when asked how prepared they feel to answer questions about psychiatric disease from their clients, 44% (PGC) and 96% (GCS) felt either very unprepared or somewhat unprepared; when asked how comfortable they feel providing psychosocial counseling for psychiatric disease, 54% (PGC) and 78% (GCS) felt either very uncomfortable or somewhat uncomfortable. When asked how often they raise issues related to psychiatric disease when they take a family history, 22% (PGC) and 46% (GCS) responded never or seldom. When asked what limits their ability to provide psychiatric genetic counseling, 59% (PGC) and 93% (GCS) chose "My understanding of psychiatric diagnoses," 83% (PGC) and 82% (GCS) chose "My knowledge of research in psychiatric genetics," and 39% (PGC) and 75% (GCS) chose "My lack of knowledge/experience with psychosocial issues involved in psychiatric genetic counseling." These results suggest a need for education on psychiatric genetics within the genetic counseling community.

Crafting a custom cancer genetics web site for primary care physicians. *S.L. Tobin¹, C.D. Jacobs², J.M. Ford², A. Boughton³, K. Ritter², D. Bamber² and Education Task Force.* 1) Ctr Biomedical Ethics, Stanford University, Palo Alto, CA; 2) Cancer Genetics Clinic, Stanford University, Stanford, CA; 3) Twisted Ladder Media, San Francisco, CA.

The use of genetic tests as tools to assess hereditary cancer risk is expanding rapidly. When such tests are used in the context of a clinical program that includes genetic counseling and consideration of a detailed family medical history, the results are often of substantial value in guiding surveillance and interventions. Access to specialized cancer risk assessment programs can be a key factor in quality patient care. Yet because the clinical applications of genetic tests have emerged so recently, a number of studies have documented the fact that many primary care physicians are unaware of or unsure about how to identify individuals or families who could benefit from specialized genetic services. The Stanford Program for Applied Cancer Genetics is funded by the California Department of Health Services, Cancer Research Section and includes a component to accomplish educational outreach to primary care physicians, especially those whose practices include substantial underserved populations. An Education Task Force was formed, and a workable approach to obtain direct feedback about the educational needs of primary care physicians was developed. Two thousand recruitment letters were sent to primary care physicians in the targeted geographic area. The prospective participants were asked whether they would be willing to evaluate the educational initiatives produced by the Applied Cancer Genetics Program, and their current use of educational resources and their preferences were assessed. The results from 131 responses suggested a demand for more computer-based resources. With the further advice of the Education Task Force, an evaluation version of a cancer genetics web site is under development. This web site utilizes a case-based approach and concentrates on the knowledge and skills that are relevant for appropriate identification, intervention, and referral of patients at risk for hereditary non-polyposis colorectal cancer (HNPCC). The prototype version of this site will be demonstrated.

Web-Based Survey of Families with Autism: Reassessing the Need for Genetic Education. *C.M. Wolpert¹, B. Rosen-Sheidly², S.L. Donnelly¹, L.A. Elston¹, C.S. Turner¹, S.E. Folstein², M.A. Pericak-Vance¹.* 1) Duke Univ Medical Ctr, Durham, NC; 2) New England Medical Ctr, Boston, MA.

Previously we reported the results of a pilot survey mailed to families participating in an autism genetic research study. Data indicated that education of the public and health professionals about genetic research findings and their potential clinical application has lagged. ExploringAutism.org, a web site dedicated to helping families with autism stay informed about autism genetics, was developed to provide a credible source of understandable genetic information. Because the population in the pilot study was limited to a small number of families participating in genetics research, we hypothesized that responses would differ in a larger, non-research oriented population. An online version of the survey was included on the web site. Since February 2002, over 9500 people have visited the web site; 433 submitted surveys (a response rate of 6%). Similar to the pilot population, 387 (89%) of respondents have a family member with autism. In contrast to the pilot data, a majority of respondents (93%) indicated that they are not participating in research. When asked about possible causes of autism, 86% cited genetic factors, while 33% cited environmental factors; and 31% cited vaccinations (despite lack of medical evidence for the latter). 24% of respondents correctly identified the recurrence risk for autism, but 39% percent grossly overestimated the risk and 31% were unsure. Most respondents favored both genetic testing to confirm a diagnosis of autism (92%) and prenatal diagnosis of autism (75%). 98% indicated an interest in learning more about the genetic basis of autism; 98% felt that this web site was informative. 70% felt that learning about the genetic basis of autism reduced their anxiety. These results suggest the widespread need and desire for education regarding the genetics of autism are not limited to families participating in genetic research. Additionally, the data indicate that web-based tools are an effective method to reach these families.

Knowledge and attitude towards ethical issues in human stem cell research: a survey among medical staffs in Taiwan. *SJ. Lin^{1, 2}, CH. Chang³, PL. Kuo³, SC. Hu⁴, MC. Huang⁵, YH. Wang⁵.* 1) Department of Pediatrics, National Cheng Kung University Hospital; 2) Bureau of Health Promotion, Department of Health, Taiwan; 3) Department of Obstetrics and Gynecology, Cheng Kung University Hospital; 4) Department of Public Health, Medical College, Cheng Kung University; 5) Department of Nursing, National Cheng Kung University, Tainan, Taiwan.

Human stem cell research has drawn important attention worldwide. The National Medical Ethics Advisory Committee in the Health Department of Taiwan government had proposed their recommendation and regulation after several public audit in February 2002. The regulation permits researchers using materials from abortion and assisted reproduction, but prohibit nuclear transfer on human cells. In order to understand attitudes towards ethical issues in human stem cell research, we conducted a survey among medical students, obstetricians, pediatricians and neurologists. Self-administered structured questionnaire was used. The results analyzed were based on 61 physicians, included 28 pediatricians, 19 obstetricians and 14 neurologists. 53 medical students who finished their clerkships in the above clinical departments were also included. We found that the key question in the ethical debate on human stem cell research lies on the moral status of embryo/fetus. While 49% of physicians considered the minimal requirement for a human being depended upon the survival after delivery, so a embryo was not considered as a human; there were 45% of students considered human life begins at the moment of conception. However, there were no correlation to their religious belief. Above 50% of the respondents agreed to use any materials for stem cell research. Even for the somatic cell transfer that might lead to human cloning, there were 69%; of respondents agreed upon this technique. Among them, obstetricians had the highest acceptance rate (79%). However, above 50% of the respondents did not know any regulation or recommendation from government officials. In conclusion, physicians and medical students generally took optimistic views on human stem cell research. However, there exist significant controversy and confusion about the moral status of fetal/embryo.

Program Nr: 1010 from 2002 ASHG Annual Meeting

Preimplantation Genetic Diagnosis: attitudes and opinions. *E.S. Ramos, C.A. Vicente, M. Floria, A.K. Bartmann, A.R. Zambianchi, L. Martelli.* Dept Genetics, School of Medicine of Ribeirao Preto, University of Sao Paulo, Ribeirao Preto, Sao Paulo, Brazil.

Preimplantation Genetic Diagnosis (PGD) is a procedure derived from in vitro fertilization and prenatal diagnosis techniques that make it possible to detect some genetic disorders in embryos before they are transferred to the uterus. At the moment, there are no legal regulations in Brazil concerning PGD, but many hospitals are prepared for its clinical use and it has been performed in some services. In contrast, Brazilian law forbids the pregnancy termination in the majority of the cases. The objective of this study was to assess the health students/professionals' attitudes and preferences to embryo biopsy and prenatal diagnosis through Chorionic Villus Sampling (CVS)/Amniocentesis (AF). The design involved a structured questionnaire, which includes other related issues as religion, abortion, familial risk for genetic diseases, and the destination of not transferred embryos. The population sample (a total of 357 respondents) included students from the Medical and Nursing Schools of Ribeirao Preto - University of Sao Paulo and physicians/professors, physicians/residents, and other health professionals. Fifty eight percent were in favor of PGD, whereas 30% preferred diagnosis through CVS/AF, and 12% abstained. The main reason for the PGD choice was that it is performed during the earliest stages of development and abortions can be avoided. In this study, there was also the opportunity to promote the discussion, in special between the students, about ethical importance and social acceptability of new techniques. Supported by: CREMESP, FAEPA, FAPESP, CNPq, CAPES.

Mutation detection rates and organ system involvement in tuberous sclerosis complex. *A.J. Williams, M.W. Bishop, K.-S. Au, H. Northrup.* The University of Texas Medical School, Houston, TX.

Introduction: Tuberous sclerosis complex (TSC) is a dominant condition involving hamartoma and hamartia development in varied organ systems. Causative mutations are found in the *TSC1* and *TSC2* genes. Diagnoses are made using published criteria, with no requirement for involvement in >1 organ system. Mutation detection rates range from 68% to 78%. The presence of large gene deletions in *TSC2* or somatic mosaicism for the causative mutation may account for the remaining cases. **Hypothesis:** Mutation detection rates are lower in individuals with TSC and limited organ system involvement. **Methods:** Mutations in *TSC1* and *TSC2* were identified by direct sequencing of coding exons; results were entered into a Microsoft Excel Database and correlated with patient symptoms. Analysis of organ system involvement was conducted 1) by the number of systems affected (skin, brain, heart, eye, other) and 2) by the embryological derivation of the systems affected (ectodermal-skin, eye, brain; mesodermal-kidney, heart). **Results:** To date, 82 samples from persons with sporadic TSC have been sequenced with a detection rate of 77%. Of the 82 samples, 25 came from persons with 2 affected organ systems, while 57 came from those with 3+ affected systems. Among those with 2 systems affected, 16 were mutation positive (64%) compared to a 82% positive rate in the group with greater involvement (47/57). An evaluation of mutation detection rates by embryological derivation of affected organs yields a 62% detection rate (13/21) in those with symptoms from one source, versus 82% (50/61) in those with symptoms from two. **Conclusion:** Mutation detection rates are less in a TSC population with limited organ system involvement, particularly when affected organs arise from one embryonic tissue. In cases where symptoms arose from one source, the derivation was from ectodermal tissue; none had symptoms solely in organs of mesodermal origin. Mesoderm gives rise to hematologic tissues from which DNA is extracted for most genetic testing. Our findings suggest that somatic mosaicism arising from a post-zygotic mutation in ectodermal tissue may play a role in the ability to identify TSC mutations.

Patient acceptance of amniocentesis after a positive serum AFP screen is not influenced by level of risk. *K.M. Borsack¹, A.B. Metzzenberg¹, S.W. Morton², J.D. Greenberg², R. Petrucha², B.J. Huffaker², J. Siegel-Bartel².* 1) California State University Northridge; 2) Southern California Kaiser Permanente, Los Angeles.

Development of rational public health policy depends on understanding and predicting patient utilization. We retrospectively examined self reported anthropologic factors influencing amniocentesis utilization in 132 patients screen positive (XAFP+) for Down syndrome(DS) from an urban clinic with ethnically varied population from 2001. In California, the state XAFP program reports risk level for DS as a numeric ratio with 1/190 as the cutoff. We found **amnio uptake did not vary with magnitude of DS risk**. Patients with DS risk of 1/20 or greater had 50% acceptance; 1/22-1/96 had 49% acceptance; 1/100-1/190 had 55% acceptance. Patients with XAFP+ who are 38+ years at EDC may have a XAFP risk less than their age related risk. Utilization in these older patients also did not depend on numeric level of risk; acceptance of amnio was 38% if the XAFP risk was less than the age-related risk and 25% if the XAFP risk was greater than the age-related risk. Factors which correlated to patient choice for amnio included: 1)no living children 73%, one LC 54%, 2+ LC 36%($p<0.05$); 2)no previous SAB 62%, one previous SAB 52%, 2+ previous SAB 18% ($p<0.05$). There was a trend for correlation 1) if planning to abort for an abnormality or unsure 87%, planning to continue despite an abnormality 12.5% ($p<0.2$); 2)not employed outside the home 70%, all employed women 48% ($p<0.1$); 3)ethnicity Caucasian,non-Latina 68%, Black 61%, Latina 48%, Asian 47% ($p<0.2$). Latina patients using an interpreter were more likely to accept amnio 55%(16A/13D)($p<0.2$). We postulate that presence of the interpreter alters the counseling dynamic; the interpreter may be accepted by the patient as a nonmedical patient advocate. **We are intrigued that the risk level did not influence patient utilization, and postulate that patients view their risk in a binary fashion, rather than as a numeric continuum.** Alternatives to numeric risk presentation (such as graphs) may help patients understand their risk, and should be evaluated.

Communication and Control in Families with a History of Breast and, or Ovarian Cancer

. R.H.

Kenen¹, A. Ardern-Jones², R. Eeles³. 1) Sociology and Anthropology, The College of New Jersey, Ewing, NJ; 2) The Royal Marsden NHS Trust, Sutton, Surrey, UK; 3) Institute of Cancer Research and The Royal Marsden, Sutton, Surrey, UK.

This study explores how family communication patterns and family scripts influence the dissemination of genetic information and the sharing of feelings about genetic inheritance in families of healthy women who have attended a cancer genetics risk clinic because of their family history of breast and, or ovarian cancer. Family scripts are sets of expectations, beliefs, and norms that assign meaning to patterns of interaction, connect generations and provide guidance for action.

We conducted an IRB reviewed exploratory, qualitative study at a major clinical and research cancer center in the United Kingdom from January through June 2000. Twenty-one semi-structured, in depth interviews were conducted using a purposive sample of women coming to the cancer genetics risk clinic for the first times, supplemented by 5 months of participant observation.

We found several communication patterns: open and supportive; directly blocked, indirectly blocked, self-censored and use of third parties. These varied between members of one family and between families. Some family members shared their feelings and discussed ways of trying to avoid developing breast or ovarian cancer; for others disseminating information or just talking about inherited susceptibility for breast and, or ovarian cancer fell into the script violation category; still others tried to renegotiate their family scripts.

As cancer risk genetics is increasingly incorporated into health care delivery, understanding communication and dissemination of genetic information in families with a history of breast and, or ovarian cancer becomes even more essential.

Genetics & Your Practice Online: An Educational Genetic Resource Project. *T.M. Creeden¹, S.J. Durfy², R.M. Fineman³, M. Greenup¹, N. White⁴.* 1) March of Dimes, White Plains, NY; 2) Illuminata, Inc., Seattle, WA; 3) Robert Fineman Associates, Seattle, WA; 4) Full Circle Associates, Seattle, WA.

With funding from the Robert Wood Johnson Foundation, the March of Dimes Birth Defects Foundation is developing an interactive online genetics information resource and continuing education (CE) program. This resource will provide tools and guidance for health care and social service professionals to assist them in further integrating genetics into their patient services. This project provides a practical, resource-oriented web site to serve as a companion to existing March of Dimes genetic education curricula. The web site will be designed for primary care professionals (PCPs) and will be customized for three patient types (preconception/prenatal, infants/children, and adolescents/adults). Online tools specific to these patient types will be provided. The project goals are to help PCPs 1) Obtain and interpret family health and social history information; 2) Promote the use of tools and collateral resource materials; 3) Refer to genetic services as appropriate and necessary; 4) Identify local genetic resources; 5) Enhance their comfort in interacting with patients who have genetic health care issues. Health care professionals will be able to acquire information about locating genetic resources, genetic testing and screening, family health and social histories, communicating with patients on genetic issues, and clinical genetics research. In addition, users will be able to obtain CE credits online, plus information on other March of Dimes genetics education programs such as the Genetics & Your Practice CD-ROM and lecture series. In preparation for this new online genetic education resource, a needs assessment was performed involving online research, recommendations from professional organizations, expert interviews, an extensive literature review, surveys of health professionals, and a review of current genetic education programs. Based on this research, we established the nature and scope of this web site project. Thorough process and outcome evaluations of this project are planned. The web site is anticipated to be available to users by the end of 2002.

Program Nr: 1015 from 2002 ASHG Annual Meeting

Nurse Practitioners' interest in and recommendations for online genetics continuing education (CE): A survey of Southern California (CA) Nurse Practitioners (NPs). *S. Durfy*¹, *T. Creeden*², *B. Izykowski*³, *B. Bendure*², *R. Fineman*⁴. 1) Illuminata, Inc, Seattle, WA; 2) March of Dimes, White Plains, NY; 3) California State University, Long Beach, CA; 4) Robert Fineman Associates, Seattle, WA.

The March of Dimes Birth Defects Foundation, with funding from the Robert Wood Johnson Foundation, is developing an interactive online genetics information resource and CE program, Genetics & Your Practice Online, for primary health care and social services professionals. In developing this new online resource, an extensive needs assessment is being performed. We report here on one aspect of the needs assessment, i.e. a survey of 700 southern CA NPs. Respondents (n=245 certified NPs) practice in varied settings, encompass new and veteran NPs; approximately 3/4 have masters degrees. About 2/3 report no courses in genetics and most do not feel their educational background has prepared them to incorporate genetic advances into their NP practice. About 3/4 report they would find additional genetics education beneficial to their practice; 1/4 would not. In the preceding year, a majority of respondents had not sought information on genetic disorders or tests, and a majority reported they had not referred a patient for genetic services or been asked about genetics by their patients. For NPs the most important features in an online CE genetics course were that the authors be experts in the field, NPs have flexibility in selecting what they learned, the registration procedures not be time consuming, privacy be assured, links to general medical databases are provided, and the CE web site provide information of value to patients. The least important features were the ability to interact online with other professionals using the CE site and download items to personal digital assistants. NPs are an important target audience for genetic education efforts. These survey results underline the importance of understanding the perceptions and characteristics of the target audience and the attributes of their practice(s) when designing CE programs. Also, it is important to consider personal learning styles, customization and administrative issues in the design of online genetics CE programs.

Assessing Coping Strategies in Families with Jarcho-Levin Syndrome. *J. Acevedo¹, N. Ramirez-Lluch², A.S. Cornier³*. 1) Dept of Nursing, University of Puerto Rico at Arecibo, Arecibo, PR; 2) Department of Ortopedics, Mayaguez Medical Center, Mayaguez, P.R; 3) Division of Genetics, Ponce School of Medicine, Ponce, P.R.

Jarcho-Levin syndrome (MIM#277300) also known as Spondylothoracic Dysplasia syndrome(STD)is an autosomal recessive disorder with high prevalence in Puerto Rican population.The phenotype includes multiple anomalies of the ribs and vertebra in a short thorax, rigid and short neck and dwarfism. Familial understanding and subsequent management of this disorder represents a serious challenge to them. Identifion of patients and parents sucessful coping strategies provide the needed tool to improve patient health status and family adaptation to the illness process. This study described parental and patients coping strategies in dealing with JLS. The Coping Health Inventory for Parents and the Impact on Health Status Scale were used as research tools. Parental most useful coping strategies are: understanding the health care situation through communication with other parents and consultation with health care team; family integration, cooperation, and optimistic definition of the situation; and mantaining social support, self esteem and psychological stability. Patients indicated that being treated as a normal child and support of their parents were helpful in the adaptation process. Contradictory findings were obtained on the level of parental interference in their lives. Some degree of social isolation as a manifestation of clinical depression was noted in 11% of patients. The results shown that there is need to consider parental and patient's reactions to the disorder. Successful coping should be assess and teach to family members. Specific attention should be given to patient's interpretation of parental support and its effectiveness. Patients should be encouraged to openly express their feelings especially toward parental interference in their life.

Patient vs. physician as the target of educational outreach about screening for an inherited susceptibility to colorectal cancer: a randomized controlled trial. S. Loader, C. Shields, J.C. Levenkron, P.T. Rowley. Univ Rochester, Rochester, NY.

Will more patients seek genetic services if a tertiary medical center mails them relevant information in layman's terms or sends the same information in professional language to their physicians? We hypothesized that educating the patient directly would result in a larger proportion of patients receiving genetic services because the patient might feel a greater responsibility to alert relatives than would their physician and because the physician might be reluctant to raise genetic issues because of unfamiliarity with cancer genetics. We identified patients with colorectal cancer at <60 y from 1987-1999 in a 5-county area including Rochester. Qualifying patients (those reporting having at least one 1° or 2° relative with colon cancer) were randomized to either the patient-education group or the physician-education group. Patients in the patient-education group received a brochure in lay language describing inherited susceptibility to colorectal cancer, an invitation to come for genetic counseling, and an offer of DNA testing. In the physician-education group, the patient's physician was sent information in professional language and invited to refer the patient for genetic counseling and the offer of DNA testing. Both groups were offered services free of charge. In the patient-education group (51), 21 (41%) came for counseling and 16 (31%) chose testing. In the physician-education group (52), 26 (50%) came for counseling and 20 (38%) chose testing. These two educational approaches did not significantly differ in percentages of patients receiving counseling or choosing DNA testing. We hypothesize that patients receiving a letter from their personal physician about the availability of genetic counseling regarded it as a *recommendation* to seek genetic counseling and this may have counterbalanced the advantage we had hypothesized for educating patients directly. No patient in either group had been referred for genetic counseling by his/her physician spontaneously, suggesting that tertiary centers should consider making efforts at such educational outreach. (CDC UR6/CCU217194).

The Role of Genetics Professionals in Susceptibility Testing: Lessons from Factor V Leiden. *E.A. Hellmann¹, S. Moll², N.D. Leslie³*. 1) College Allied Health Sciences, University of Cincinnati, Cincinnati, OH; 2) Department of Hematology/Oncology, University of North Carolina, Chapel Hill, NC; 3) Department of Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Genetic testing for factor V Leiden, the most common inherited risk factor predisposing to venous thrombosis, was widely incorporated into clinical practice before consensus guidelines regarding the clinical implications were available. This study examines knowledge, satisfaction with information received from health care providers, health perception, and opinions of genetic testing of 110 individuals who tested positive for factor V Leiden between 1995 and 2001 to assess their experience of genetic susceptibility testing at a time of clinical uncertainty. Surprisingly, fourteen individuals (13%) did not recall being informed of test results and 39% did not recall giving informed consent for testing. Reportedly, results were given by a genetics professional in only 4% of cases. The magnitude of thrombosis risk associated with factor V Leiden was incorrectly estimated by 79% of participants. Patients were dissatisfied with the information they received about factor V Leiden; 64% felt they were not given much information and only 47% felt that their health care providers had an understanding of the condition. A majority (88%) were glad to know their genetic status. Most genetic testing for factor V Leiden is offered outside the auspices of a genetics clinic. To optimize patient understanding of the testing process and the implications of test results, strategies and materials need to be developed for use in the primary care setting. It is likely that such strategies will have application to the anticipated expansion of genetic predisposition testing through primary care oriented practices.

Enhancing genetics education in medical school: An approach using a web-based course program. *S. Taylor¹, J. MacKenzie², K. Harrison¹, I. Sumargo¹, M. Fleming³, E. Van Melle⁴.* 1) Dept Pathology, Queen's Univ, Kingston, ON, Canada; 2) Dept Pediatrics, Queen's Univ, Kingston, ON, Canada; 3) Information Technology Services, Queen's Univ, Kingston, ON, Canada; 4) Faculty of Education, Queen's Univ, Kingston, ON, Canada.

The increasing use of genetic information in clinical practice has created challenges for educators to identify effective strategies for undergraduate medical students to learn, retain and apply genetics concepts. Further, future physicians need skills to keep abreast of advances in the field and refer appropriately. Within the condensed medical school curriculum at Queen's University, challenges include the volume of material, and a condensed timeframe. A project was initiated to evaluate the potential of using a web-based course program (Web CT) to organize and improve accessibility to course material and create an opportunity for students to apply these concepts in the evaluation and management of a clinical case. Members of the team provided expertise in genetics, education and information technology. The team adopted the "ICE" Model (Ideas, Connections and Extensions), a theory that defines learning as a multistage process and encourages the development of higher order thinking skills. In addition to the use of the web site to provide access to reorganized course material, students were divided into small groups and required to review a case study posted on the site, and to email the instructors with a request for a genetic test and the rationale. Once requests were received, the test results were posted on Web CT. The groups were required to present an evaluation of their case and the implications of the genetic test results to their peers. 93% of students indicated that the web-based technology was easy, or very easy, to navigate demonstrating enhanced access to course material. 92% of the students reported active or very active participation in discussions around the clinical case studies. These results demonstrate an approach that captures the potential for computer technology to facilitate student learning in the field of medical genetics.

The Frequency and Characterization of Mitochondrial Hearing Loss in a National DNA Repository from Deaf US Probands. *A. Pandya*¹, *A. Massiello*¹, *B. Landa*¹, *X.J. Xia*¹, *K.O. Welch*², *K.S. Arnos*², *S.H. Blanton*¹, *W.E. Nance*¹, *G. VanTuyle*¹. 1) Medical College Virginia at VCU, Richmond, VA; 2) Gallaudet University, Washington DC.

Mitochondrial mutations are now recognized as an important cause of genetic hearing loss. The A1555G substitution in the 12SrRNA gene is often associated with sensitivity to aminoglycosides. Substitutions at positions 7443, 7444, or 7445 located in the cytochrome oxidase I gene (COX I) stop codon, and adjacent to the 3' end of tRNA ser (UCN) are also associated with non syndromic hearing loss (NSHL). Previous studies in deaf probands from Mongolia, China and Spain have revealed a high incidence between 10% and 30% for the A1555G substitution. The mutations at 7445-7443 position are heterogenous and occur with a frequency of 1% in Mongolia. The high frequency of the A1555G mutation and the potential for preventive intervention makes this gene an attractive candidate for newborn screening. To determine the frequency of these mutations in the United States we screened a national DNA repository of 372 deaf probands who were ascertained through a nation-wide survey of educational programs for the deaf, conducted by the Gallaudet Research Institute. The mitochondrial mutations were detected by PCR-RFLP and confirmed with DNA sequencing. The frequency of the 7445-7443 substitutions were about 1% , similar to our finding in Mongolia. The mutations in the US probands, however, included the A7445G and the G7444A substitutions which differs from the spectrum of mutations observed in deaf Mongolians. Surprisingly, we did not find a single proband with the A1555G substitution. We are currently evaluating cell lines from affected individuals to clarify the pathogenic mechanisms involved in the 7444 and 7445 mutations. Further studies to determine the frequency of the A1555G substitution in the general population will be necessary before assessing the potential value of newborn screening for either of the mitochondrial mutations.

ASSOCIATION OF GENETIC POLIMORPHYSM APOB (VNTR) IN PATIENTS WITH ISQUEMIC CARDIOMYOPATHY OF MEXICAN POPULATION. *M.P. Gallegos Sr¹, H. Rangel², M. Zuniga³, L. Arnaud¹, L. Lopez⁴, L.E. Figuera⁵, T.J. Beltran⁶, M.R. Arechavaleta⁶, L. Sandoval⁵, G.M. Zuniga¹ and heart disease.* 1) Medicina Molec, CIBO IMSS, Guadalajara Jalis, Guadalajara, Mexico; 2) Ciencias de la Salud, Universidad de Guadalajara, La Cienega, Ocotlan,Jal. Mexico; 3) Unidad de Terapia, Cardiologia,; 4) Laboratorio de Lipidos,; 5) Genetica, CIBO,; 6) Departamento de Endocrinologia,HE,CMNO,IMSS.

The coronary heart disease to produce high rates of mortality in many countries of world. Epidemiological studies have established a positive relationship of coronary heart disease and low density lipoprotein cholesterol with apoB levels. The 3 flanking region of the apoB gene contains a hypervariable region consisting of variable number of tandemly repeated short AT rich DNA sequences (VNTR). We determinate the association and frequency of apoB VNTR polymorphism in patients with isquemic cardiomyopathy (IC) of Mexican population. Were analyzed the polymorphism VNTR apoB in 50 controls and 131 patients with IC. The analysis statistical of polymorphism apoB VNTR showed a significant association with allele 39, 1% in controls and 35.49% in patients ($p>0.05$). These results showed that individuals with allele 39 VNTR apoB were associated with IC in Mexican populations.

Interleukin-1 polymorphism significantly associated with increased risk for hip osteoarthritis in females. I.

Meulenbelt¹, A. Seymour², M. Nieuwland¹, C. Bijkerk^{1,4}, C.A. Gabel², T. Huizinga³, C.M. van Duijn⁴, P.E. Slagboom¹.

Osteoarthritis (OA) is characterized by degradation of articular cartilage and formation of new bone in which both genetic and mechanical factors play a significant role. Identification of genes that influence disease susceptibility may give insight which pathways may be involved in the onset of OA. The interleukin-1 (IL1) gene cluster on chromosome 2q contains 3 related genes within a 430 kb region, IL-1A, IL-1B and IL1RN. These genes encode the pro-inflammatory cytokines IL-1a and IL-1b and their endogenous receptor antagonist IL-1ra, respectively. Especially IL-1b is involved in modulating the chondrocyte metabolism by stimulating the chondrocyte to produce metalloproteinases (MMPs). MMPs degrade extracellular matrix components in articular cartilage. The rare -511T allele in the promoter of the IL1B gene was found to alter a HC5 promoter element and to be associated with increased secretion of IL-1B after LPS stimulation (1). In this paper the IL1B C-511T polymorphism was studied by association with the occurrence of radiographic OA (ROA) in knees, hips, hands, and spine in a random sample of 55-65 year old subjects from a population-based cohort (The Rotterdam study, N = 744). A dose response association with hip ROA was observed for hetero- and homozygous carriers of the -511T allele (crude OR = 1.67, 95% CI 0.94-2.96 and 2.56, 95% CI 1.15-5.43, respectively). The effect appeared significantly high in female carriers (crude OR = 4.18, 95% CI 1.38-12.64 and 7.62, 95% CI 2.13-17.24, respectively) and not present in males (crude OR = 1.14, 95% CI 0.53-2.45 and 1.29, 95% CI 0.46-3.62, respectively). These data indicate that the C-511T polymorphism in the IL1B gene is associated with increased secretion of IL-1b after LPS stimulation and may contribute to the onset of hip OA in females. 1) Seymour et al. ASHG 2002 abstract.

Does apolipoprotein E genotype influence the progression of multiple sclerosis? *R. Cittadella¹, V. Andreoli¹, I. Manna¹, A. La Russa¹, P. Serra¹, G. Savettieri², G. Salemi², S. Bonavita³, C. Caltagirone⁴, U. Nocentini⁴, M.C. Fazio⁵, P. Girlanda⁵, F. Le Pira⁶, A. Reggio⁶, M. Liguori⁷, G. Logroscino⁸, A. Lugaresi⁹, L. Toma⁹, P. Valentino¹, A. Quattrone¹.* 1) Inst. of Neurological Sciences, National Research Council, Pianolago, Cosenza, Italy; 2) Institute of Neuropsychiatry, University of Palermo, Italy; 3) Department of Neurological Sciences, II University of Napoli, Italy; 4) I.R.C.C.S. Fondazione Santa Lucia, University of Roma Tor Vergata, Italy; 5) Department of Neurosciences, Psychiatry and Anaesthesiology, University of Messina, Italy; 6) Department of Neurological Sciences, University of Catania, Italy; 7) Department of Neurological and Psychiatric Sciences, University of Bari, Italy; 8) Department of Neurology, Ospedale Miulli, Bari, Italy; 9) Department of Oncology and Neuroscience, University of Chieti Gabriele d'Annunzio, Italy.

To investigate the association between apolipoprotein E (APOE) polymorphisms and the progression of multiple sclerosis (MS) we investigated 428 subjects affected by clinically defined MS, with a disease duration of at least three years. We collected data concerning the age at onset of MS, clinical type, disease duration and disability according to the expanded disability status scale (EDSS). We also calculated the progression index (PI) to evaluate disease progression. APOE genotyping and the —491 A/T polymorphisms of the APOE promoter were determined. The PI was associated directly with age at onset and inversely with the relapsing remitting form of MS. Carriers of the e2 allele showed a lower PI, whereas no association was observed between the APOE e4 allele and clinical characteristics of our study population. We also investigated the —491 A/T APOE promoter polymorphisms in 236 MS subjects and did not find any association between the —491 A/T polymorphisms and selected clinical variables. Our findings indicate that in our population the APOE e2 allele is inversely associated with the PI, suggesting a protective role of this allele in MS progression. The APOE e4 allele and the —491 A/T APOE promoter polymorphism were not associated with a more rapid course of MS.

A NOS3 intronic polymorphism as a risk factor in ischemic stroke. *a.c. Dutra*. Neuroscience, JFK Medical Center, Edison, NJ.

Stroke is the leading cause of disability and the third leading cause of death in the western hemisphere. In the United States approximately 80% of all stroke patients suffer from ischemic infarction caused by thrombosis or embolism. The endothelial nitric oxide synthase gene (NOS3) has been the subject of recent research as a candidate gene contributing to the development of ischemic stroke. The product of this gene, the enzyme nitric oxide synthase, is the only generator of the free radical nitric oxide, in the vascular endothelium, which mediates endothelium-dependent vasodilatation and has also antithrombotic action. There are 2 common polymorphisms in intron 4 of NOS3 gene which have been described, consisting of a 27-bp consensus sequence repeated 4 times (allele a) or five times (allele b). A study in a Chinese population implicates the allele a as a risk factor for ischemic stroke. Our study proposes to analyze the association between this 27-bp polymorphism, and ischemic stroke in an ethnically heterogeneous population in central New Jersey, United States. We studied 400 consecutive patients presenting with ischemic stroke or TIA to a stroke unit of the hospital JFK Medical Center in central New Jersey. Clinical data and brain imaging studies (CT and /or MRI) were collected for all patients. A control dataset was also generated of individuals without stroke matched for age and risk factors recruited from the same region as the stroke population. The genotype of the polymorphism was determined by polymerase chain reaction (PCR) using the forward primer: 5' AGGCCCTATGGTAGTGCCTTT 3' and the reverse primer: 5' TCTCTTAGTGCTGTGGTCAG 3'. The alleles a (393-bp PCR product) and b (420-bp PCR product) were separated by gel electrophoresis in a 6% acryl amide gel. We found a significant difference in the frequency of the ab versus bb genotype between stroke patients and controls (74% versus 61%; $P=0.014$). The genotype aa was rare with frequency below 2% in the studied population compared with 6.5% in the Chinese population. Our results support and extend those of a previous study on Chinese patients on the potential role of the allele a of the NOS3 gene as an independent risk factor for ischemic stroke.

Frequency of Fragile X in Multiplex Autism: Testing the AGRE families. *W.T. Brown¹, S.L. NOLIN¹, C.S. DOBKIN¹, G.S. HOUCK¹, A. GLICKSMAN¹, X.D. DING¹, A.D. GARGANO¹, L. CRAWFORD², N. GITCHO², S.J. SPENCE², D.H. GESCHWIND², AGRE^{1,2}.* 1) Dept Human Genetics, NYS Inst Basic Research, Staten Island, NY; 2) Program in Behavior Genetics, Neuropsychiatric Institute and Neurology Dept, UCLA School of Medicine, Los Angeles, CA.

Autism is behaviorally characterized by profound deficits in social interaction, delayed and deviant communication, and unusual patterns of interests. It has high heritability. The biological basis of autism is unknown, but several genetic syndromes have been associated with it, including the fragile X syndrome. The Autism Genetic Resource Exchange (AGRE) is a publicly available resource of well-characterized multiplex families for genetic studies of autism. AGRE families were recruited without regard to prior testing but families with known neurogenetic syndromes were excluded. In order to better characterize this resource and to provide more information on the association with fragile X, we conducted fragile X DNA analysis (Brown 1993) on one proband in each of 480 AGRE families, with follow-up family studies when indicated. Testing revealed six families to be positive for fragile X. Review of a sampling of 29 chart records showed 11 (38%) had had prior negative genetic testing. Thus, the prevalence of fragile X among the approximately 298 previously untested AGRE families was estimated to be 2.0%. Previous prevalence studies of fragile X in autistic samples have reported frequencies ranging from 0 to 16%; with a mean of around 4%; (Feinstein 1998). The variations may be due to sample sizes, ascertainment differences or differing methodologies. Our frequency of 2.0% is similar to a report of 1.6% among 123 unrelated autistic individuals (Bailey 1993), but lower than the 13% we found on an earlier multicenter study of 183 individuals (Brown 1986). We suggest a growing awareness of fragile X syndrome would increase the probability of prior fragile X screening in multiplex autism families which would have excluded their inclusion among the AGRE families. The observed frequency of 2% is similar to the overall mean of 4% observed in other studies and indicates a significant association of fragile X and autism.

Association of the C677T and A1298C polymorphisms in the MTHFR gene with migraine risk. *I. Kara¹, A. Sazci², G. Kaya¹, E. Ergul², G. Kilic¹.* 1) Department of Neurosciences, Istanbul University, DETAE Institute., 34500, Istanbul, Turkey; 2) Department of Medical Biology and Genetics, Faculty of Medicine, University of Kocaeli, Derince, 41900, Kocaeli, Turkey.

The C677T and A1298C mutations in the methylenetetrahydrofolate reductase gene are associated with hyperhomocysteinemia, increased risk for venous thrombosis and atherosclerosis in homozygotes and in the compound heterozygotes. Increased homocysteine levels in serum can act as an excitatory amino acid and may affect the threshold of migraine headache. We studied the frequency of C677T and A1298C mutations and their association with migraine in 102 Turkish patients with migraine and 120 controls. Hundred and two patients with migraine headaches (23 with aura, 70 without aura), 2 with complicated migraine, and 7 with basal migraine, and 120 normal controls participated in the study. The mean age was 37.16 ± 9.66 in cases and 40.68 ± 13.39 in controls (90.7 % female and 9.3 % male). Genotyping of MTHFR C677T and A1298C polymorphisms was performed by PCR-RFLP method. Population frequencies of the MTHFR C677C, C677T and T677T genotypes were 40.2 %, 52% and 7.8 % in the cases and 50.8%, 44.2% and 5 % in the controls, respectively. The allelic frequency of C677T was 33.82 % in the cases and 27.08% in the controls. And also population frequencies of MTHFR A1298A, A1298C and C1298C genotypes were 44.1%, 44.1%, and 11.8% in the cases and 45%, 46.7% and 8.3% in the controls, respectively. The allelic frequency of MTHFR A1298C was 33.82 % in the cases and 31.67% in the controls. The MTHFR C677T/C1298C was higher among 102 patients compared with 120 controls, conferring a 7.88-fold increase in risk for migraine (OR=4.857; 95% CI=0.534-44.168). We also observed a 4.9 and 2-fold increases in risk for migraine in individuals with the MTHFR T677T/A1298A and C677T/A1298C variant alleles, respectively (OR=3.041; 95 % CI=0.577- 16.022, and OR=1.228; 95 % CI= 0.641- 2.352). In conclusion, our data clearly suggest that The C677T and A1298C genotypes of the MTHFR gene is a genetic risk factor for migraine.

Candidate gene analysis in neural tube defects. *R. Klootwijk¹, M. Schijvenaars¹, P. Groenen², F. Hol¹, J. Willemen¹, R. Steegers-Theunissen^{2,3}, E.C.M. Mariman⁴, B. Franke¹.* 1) Dept of Human Genetics, University Medical Centre Nijmegen, Nijmegen, The Netherlands; 2) Dept of Epidemiology & Biostatistics, University Medical Centre Nijmegen, Nijmegen, The Netherlands; 3) Dept of Gynaecology & Obstetrics, University Medical Centre Nijmegen, Nijmegen, The Netherlands; 4) Dept of Human Biology, Faculty of Health Sciences, Maastricht University, The Netherlands.

Neural tube defects (NTD) are congenital malformations which arise through incorrect formation of the neural tube. NTD belong to the group of multifactorial diseases, caused by a combination of unfavorable environmental conditions and genetic factors. In humans up to 70 % of NTD can be prevented by maternal periconceptional folic acid supplementation. In addition, the nutritional factor myo-inositol and the trace element zinc play a role in the etiology of human NTD. At the moment not much is known about the molecular basis of the effects of inositol and zinc on neural tube formation. One approach to study the interaction between inositol or zinc and NTD in man is mutation-analysis of selected inositol- and zinc-related candidate genes in large NTD patient panels. Using this approach we screened the candidates AP-2 and ZIC2 by SSCP analysis. Screening of ZIC2 resulted in the detection of a novel frequent C1062T change (H354H) and the deletion of an alanine residue (A8 variant) in the proximal aminoterminal alanine stretch of ZIC2. The A9 variant is conserved between man and mouse. The A8 variant was not found in a selected set of controls, indicating a possible involvement of this variant in the etiology of human NTD. SSCP analysis of AP-2 resulted in the identification of a novel frequent C16238T change (N5479N). Transmission Disequilibrium Testing (TDT) was performed for the genes AP-2 and ZIC2 using the novel polymorphisms, which resulted in a borderline significant association between human NTD and AP-2 ($\chi^2=2.92$, $df=1$, $p=0.09$), and no significant association between human NTD and ZIC2 ($\chi^2=0$, $df=1$, $p=1$). The TDT results indicate a possible involvement of AP-2 in human NTD.

Program Nr: 1028 from 2002 ASHG Annual Meeting

Tau as a susceptibility gene for Parkinsons disease. *A.A. Pasqua, F. Annesi, P. Spadafora, D. Civitelli, P. Tarantino, I.C. Cirò Candiano, S. Carrideo, P. Serra, E.V. De Marco, G. Annesi.* Inst. of Neurological Sciences, National Research Council, Mangone, CS, Cosenza, Italy.

Parkinsons disease (PD) is primarily an alpha-synucleinopathy, rather than a taupathy, but there is evidence for an indirect association of tau gene with the pathogenic process in PD. The aim of our study was to verify if the GT dinucleotide repeat marker of the tau gene is associated with PD. We designed a case-control study using sporadic and familial PD subjects and not matched healthy control subjects all coming from the same geographical area. We determined the GT repeat polymorphism of the tau gene in 300 PD patients (180 men and 120 women) and 197 controls (92 men and 105 women). The median age at the time of the study was 66.32 years for PD patients and 74.89 years for controls. Both populations were in Hardy-Weinberg equilibrium. Allelic and genotypic distributions of GT repeat were compared between cases and controls, the relative risk was estimated through estimation of odds ratio (OR) with 95% confidence intervals (CI). The allele and genotype distributions of the GT-STR polymorphism of the Tau gene were significantly different between cases and controls. The allele A3 was more frequent in cases than in controls (30% vs.16%, $p < 0.001$). Individuals carrying the A3 allele had an increased risk of developing PD (OR, 2.6; CI, 1.75-3.70). We found an association of the A3 allele of the Tau gene with PD. Others studies reported a significant association of A0 allele and A0/A0 genotype with PD. The discrepancy among results in different studies suggests that the association between a given disease and genomic characteristics must be confirmed by different investigations in different populations.

Performance of different models predicting BRCA-mutation carrier status in 570 Italian families. *F. Marroni¹, P. Aretini², J.E. Bailey-Wilson³, G. Parmigiani⁴, G. Bevilacqua², S. Presciuttini^{1,3} and Italian Consortium for Hereditary Breast/Ovarian Cancer.* 1) Dept. Biomedicine, Univ. of Pisa, Italy; 2) Dept. Oncology, Univ. of Pisa, Italy; 3) NHGRI-NIH, Baltimore, MD, USA; 4) Dept. Biostatistics, JHU, Baltimore, MD, USA.

The Italian Consortium for Hereditary Breast and Ovarian Cancer has recently established a database of pedigrees analyzed for both BRCA1 and BRCA2; it currently includes 570 families (134 with identified pathogenic mutation). Here, we show a comparison of the probabilities predicted by the program BRCAPRO and by a similar genetic model implemented in the program MLINK of the FASTLINK package. Contrasting results of the two programs should help identifying problematic situations, and may provide estimates of the robustness of the calculated values. In our MLINK model, frequencies of the mutated BRCA1 and BRCA2 alleles were 0.0006, and 0.00022, respectively. Age at cancer onset or at last observation was stratified in 7 groups, and 6 possible phenotypes were considered, for a total of 42 liability classes. Cancer incidences within each class were the means of the corresponding incidences used by BRCAPRO. Probabilities of being carriers of BRCA1 or BRCA2 mutations were computed separately in each family by both programs, and the obtained correlation coefficients were 0.917 and 0.878, respectively. The most discrepant families were those including subjects with multiple tumors (the two programs treat these subjects differently). Data were analyzed both in terms of observed/expected number of identified mutations in different family strata, and in terms of total log-likelihood. Sensitivity of the molecular tests was set to 0.7. For BRCA1, the number of identified mutations was close to expectation, though there was compensation between risk over-estimation in HBC families and risk under-estimation in HBOC families; in BRCA2, the total number of identified mutations was remarkably higher than expectations, and this effect was mostly due to HBC families. We intend to estimate genetic parameters of the BRCA genes that would be appropriate for the Italian population by maximizing the likelihood of the genetic test outcome.

Platelet glycoprotein IIb/IIIa PI^{A2}/PI^{A2} homozygosity associated with 5-fold risk of myocardial infarction in young men - The Copenhagen City Heart Study. *S.E. Bojesen¹, K. Juul¹, P. Schnohr², A. Tybjaerg-Hansen^{2,3}, B.G. Nordestgaard^{1,2}.* 1) Clinical Biochemistry, Herlev University Hospital, Herlev, Denmark; 2) Copenhagen City Heart Study, Copenhagen, Bispebjerg University Hospital; 3) Clinical Biochemistry, Rigshospitalet, Copenhagen University Hospital.

Purpose: To explore association between the platelet glycoprotein IIb/IIIa PI^{A1}/PI^{A2} polymorphism and ischemic cardiovascular disease in a large population-based prospective study. **Methods:** Using the Copenhagen City Heart Study (n=9242) with 22 years follow-up, we assessed risk of ischemic cardiovascular disease and myocardial infarction in PI^{A1}/PI^{A2} heterozygotes or PI^{A2}/PI^{A2} homozygotes versus PI^{A1}/PI^{A1} non-carriers, stratified for gender and age.

Results: In this cohort from the Danish general population, 70.0%, 27.3% and 2.7% were non-carrier, heterozygous and homozygous, respectively. Incidence of ischemic cardiovascular disease was 172 and 109 per 10.000 person-years in homozygous and non-carrier men (log rank: $p=0.006$), while this difference was not observed in women ($p=0.33$). Age-adjusted relative risks of ischemic cardiovascular disease in homozygotes versus non-carriers was 1.5 (95% CI: 1.1-2.2) and 0.7 (0.4-1.4) in men and women (genotype-gender interaction: $p=0.03$). In men aged <40 years, 40-50 years and >50 years at entry, age-adjusted relative risks of ischemic cardiovascular disease were 3.5 (1.4-9.0), 2.4 (1.3-4.6) and 1.0 (0.6-1.8), respectively (genotype-age interaction in men: $p=0.03$). Equivalent age-adjusted relative risks of myocardial infarction in men were 5.3 (1.5-18), 3.5 (1.6-7.6) and 0.5 (0.2-1.5), respectively (genotype-age interaction in men: $p=0.002$). Finally, age at first myocardial infarction was 60 ± 2.5 and 65 ± 0.5 years in homozygous and non-carrier men (Mann-Whitney U-test: $p=0.04$). Homozygous and heterozygous women and heterozygous men did not differ from non-carriers in any of the above-mentioned analyses.

Summary: In men <40 years, 22-year risk of ischemic cardiovascular disease and myocardial infarction in platelet glycoprotein IIb/IIIa PI^{A2}/PI^{A2} homozygotes was 3- and 5-fold that of non-carriers.

Genetic variation in the oxidized LDL-receptor-1 (OLR1) gene and the risk of coronary artery disease. *Q. Chen¹, S.E. Reis¹, C. Kammerer¹, E. Luedeking-Zimmer¹, D.M. McNamara¹, D.F. Pauly², B. Sharaf³, R. Holubkov⁴, C.N. Bairey Merz⁵, G. Sopko⁶, M.I. Kamboh¹ and the WISE study.* 1) Univ Pittsburgh, Pittsburgh, PA; 2) Univ Florida, Gainesville, FL; 3) Brown Univ, Providence, RI; 4) Univ Utah, Salt Lake City, UT; 5) Cedars-Sinai Medical Center, Los Angeles, CA; 6) NHLBI, NIH, Bethesda, MD.

Several lines of evidence suggest that oxidized LDL (OxLDL) is a critical factor in the initiation of the atherogenesis process. OxLDL binds to scavenger receptors and subsequently internalized by macrophages, resulting in foam cell formation. A number of scavenger receptors have been identified, including the lectin-like OxLDL receptor-1 (LOX1 or OLR1). In an effort to understand the role of OLR1 genetic variation with coronary artery disease (CAD), we examined the distribution of three novel OLR1 polymorphisms in the Women's Ischemia Syndrome Evaluation (WISE) study population. The WISE cohort was divided into three groups: minimal/normal disease (<20% stenosis), moderate disease (20-49% stenosis) and significant disease (≥50% stenosis). The three OLR1 polymorphisms (intron 4/G@A, intron 5/T@G and 3'UTR/T@C) were in linkage disequilibrium ($p < 0.0001$). All three polymorphisms showed significant associations with CAD. The frequency of the 3' UTR/T allele carriers was higher in the significant stenosis group than the minimal/normal disease group (OR=1.81, $p < 0.0082$). When the data were stratified by APOE*4 and non-APOE*4 carrier status, the significant association was found to be confined among non-APOE*4 carriers (OR=2.02, $p < 0.0084$), suggesting an interaction between the OLR1 and APOE genes. To examine the functional significance of the 3'UTR sequence variation, we performed electrophoretic mobility shift assay (EMSA) using nuclear extract from aorta smooth muscle cells. Our data show that the sequence encompassing the 3'UTR polymorphism is involved in binding with a transcription factor and that there is an allele-specific binding of the 3'UTR sequence variation with a putative regulatory element. In summary, our data suggest that common genetic variation in the OLR1 gene may be associated with the risk of CAD.

Hepatic lipase mutations, elevated HDL cholesterol, and increased risk of ischemic heart disease; The Copenhagen City Heart Study. *R.V. Andersen¹, H.H. Wittrup¹, A. Tybjaerg-Hansen^{2,4}, R. Steffensen³, P. Schnohr⁴, B.G. Nordestgaard^{1,4}.* 1) Dept. Clinical Biochemistry, Copenhagen University Hospital, Herlev, Denmark; 2) Dept. Clinical Biochemistry, Rigshospitalet, Copenhagen University Hospital, Copenhagen, Denmark; 3) Dept. Medicine B, Division of Cardiology, Rigshospitalet, Copenhagen University Hospital, Copenhagen, Denmark; 4) The Copenhagen City Heart Study, Copenhagen University Hospital, Bispebjerg, Copenhagen, Denmark.

Objectives: Hepatic lipase influences metabolism of high density lipoproteins (HDL). We investigated associations between single nucleotide polymorphisms (SNPs) in the hepatic lipase promoter, levels of HDL, and risk of ischemic heart disease (IHD). **Methods:** We genotyped 9121 20-93 year old whites from The Copenhagen City Heart Study, of whom 957 had IHD, and 921 Danish patients with IHD for the -216, -480 and -729 SNPs of the hepatic lipase promoter. **Results:** Frequencies of wild type, triple heterozygotes and triple mutation homozygotes in the general population were 61%, 33% and 5%, respectively. Compared with wild type, HDL cholesterol levels were 4% (0.06 mmol/L) and 10% (0.15 mmol/L) higher in heterozygotes and mutation homozygotes; the equivalent values for apolipoprotein AI were 3% and 7%. In prospective and case-control studies, mutation homozygotes versus wild type had relative risk and odds ratio for IHD of 1.5 (95% CI: 1.0-2.2) and 1.4 (1.1-1.9) when adjusted for age and 1.7 (1.2-2.4) when adjusted for age, sex and HDL cholesterol. In individuals with the apolipoprotein E 43 genotype, relative risk and odds ratio for IHD in mutation homozygotes versus wild type was 2.9 (1.5-5.6) and 2.0 (1.2-3.2) when adjusted for age, sex and HDL cholesterol. **Conclusions:** Hepatic lipase promoter SNPs are associated with increased HDL cholesterol and paradoxically an increased risk of IHD after adjustment for HDL cholesterol, and particularly in individuals with apolipoprotein E 43 genotype. Thus, in some instances, HDL elevations may mark atherogenic rather than anti-atherogenic states.

Association XBAI (APO B) genetic polymorphism in arterial coronary disease patients in mexican population. *L.*

Arnaud¹, M.P. Gallegos¹, M. Zuñiga², L. López³, H. Rangel⁴, T.J. Beltrán⁵, R. Arechavaleta⁵, J. Arias¹, L.J. Ramírez¹, L.E. Figuera¹, V. Peralta¹, R. Mariaud¹, G.M. Zuñiga¹. 1) Medicina Molecular, CIBO IMSS, Guadalajara, Mexico; 2) Hospital de Especialidades, Guadalajara, Mexico; 3) Servicio de Urgencias, CMNO IMSS, Guadalajara, Mexico; 4) Laboratorio de Ipidos, CMNO IMSS, Guadalajara, Mexico; 5) Servicio de Endocrinologia, CMNO IMSS, Guadalajara, Mexico.

INTRODUCTION: The arterial coronary disease (ACD) is one of the principal causes of death in the world. Between the risk factors most important is find abnormalities in the lipids metabolism whose provide fort correlation with arterial coronary disease. Several studies have described the XbaI polymorphism association between gene Apo B and ACD, even so this association is contradictory in others parts of the world. **OBJECTIVE:** Determine the genotypic and allelic frequency of XbaI polymorphism in the gene Apo B in case-control study of incident Mexican with arterial coronary disease. **MATERIAL AND METHODS:** In this study, genomic DNAs from 89 arterial coronary disease patients and 60 controls in Mexican population were scanned. Analysis of XbaI polymorphism was done by amplification of to segment that included exon 26 (709 bp) of Apo B gene, which thas a site of recognition for the XbaI enzyme. Genotypes were identified like X1 (709 bp), X2(433 y 276 bp), by polyacrylamide gels to 6% staining with silver nitrate. **RESULTS:** The presence of the X1 genotype was identified in 55% of the cases and 50% of the controls whereas 38% of the cases and 45% of the controls were heterozygotes. A statistical difference was not found to compared the previous data (X2=1.1618, p=0.5725). **CONCLUSIONS:** Our data suggest that tendency exists of allele X2 in arterial coronary disease patients in our population.

Prevalence of factor V Leiden G1691A, prothrombin G20210A and methylenetetrahydrofolatreductase C677T mutation in patients with chronic venous insufficiency. *J. Fuchs, M. Podda.* Dept Dermatology, Univ Frankfurt, Aschaffenburg, Germany.

Chronic venous insufficiency (CVI) is a very variable and complex entity including a spectrum of clinical presentations ranging from varicose veins through chronic lower extremity pain and edema to various skin changes and ulceration. CVI affects a large number of people in Western countries, and is responsible for considerable inconvenience, discomfort, suffering, and costs. The pathophysiology of CVI is complex, and involves abnormalities in coagulation, fibrinolysis and proinflammatory cytokines. It is believed that the majority of CVI cases result from primary venous insufficiency involving an alteration in the elasticity of venous walls and the dysfunction of venous valves. Less frequent causes of CVI are primarily acute deep venous thrombosis (DVT), which can occur asymptotically, particularly in the distal part of the lower extremity, and may thus remain undiagnosed. It was recently reported that one of every three patients with deep venous thrombosis of the lower extremities will develop, within 5 years, CVI sequelae that vary from minor signs to severe manifestations. According to our knowledge there are no reports in the literature investigating the thrombophilia status of CVI patients in comparison to their functional venous status. The purpose of this ongoing study is to study the prevalence of factor V Leiden G1691A, prothrombin G20210A and methylenetetrahydrofolatreductase C677T mutation in CVI patients in comparison to a control group and to evaluate the venous function of these patients by color coded duplex scanning and plethysmography. For mutation detection a standardized real-time PCR protocol was used. The preliminary data indicate that factor V Leiden G1691A mutation is more frequent in CVI patients than in the control group and the general population. Thus patients with factor V Leiden mutation have an increased risk of developing CVI. However, the majority of our CVI patients had primary venous valve dysfunction leading to CVI and were not positive for factor V Leiden G1691A, prothrombin G20210A or methylenetetrahydrofolatreductase C677T mutation.

Association of ApoAV haplotypes and triglyceride levels in French Canadians. *J.C. Engert^{1,2}, J. Faith¹, Y. Renaud¹, C. Dore¹, P. Lepage¹, T.J. Hudson^{1,2}, D. Gaudet^{3,4}, M.-C. Vohl^{5,6}*. 1) Montreal Genome Ctr, L3-317, Montreal General Hosp, Montreal, PQ, Canada Montreal Genome Centre, McGill University Health Centre Research Institute, Montreal, Quebec, Canada; 2) Departments of Human Genetics and Medicine, McGill University, Montreal, Canada; 3) Dyslipidemia, Diabetes and Atherosclerosis Group and Community Genetics Research Center, Complexe Hospitalier de la Sagamie, Chicoutimi, Quebec, Canada; 4) Community Genomic Medicine Center and Department of Medicine, University of Montreal, Canada; 5) Lipid Research Center, CHUQ Pavillion CHUL, Quebec, Canada; 6) Department of Food Sciences and Nutrition, Laval University, Quebec, Canada.

ApoAV was recently identified as a member of the apolipoprotein cluster on chromosome 11q23 through comparison with the homologous mouse sequence. A search for sequence variants at the ApoAV locus in a heart disease sample population from the Saguenay-Lac-St-Jean (SLSJ) region of Quebec led to the identification of eight SNPs: two 5' flanking region variants, one in the 5' UTR, one intronic, three in the 3' UTR and one missense mutation. Four of these SNPs are on a previously described haplotype and four haplotypes account for over 97% of all chromosomes observed to date. One haplotype in particular, defined by a single SNP in the 3' UTR, led to significantly lower total plasma tryglyceride levels (TG) in both patients and controls. The affect appears to be specific to TG levels, as no other measured plasma lipid parameters were affected. More than 20 different variants have already been described in the apolipoprotein cluster on chromosome 11q23. Interestingly, the LD is high ($D' > 0.82$) between the previously described haplotype and the SstI variant in the 3' UTR of the ApoCIII gene located just over 40Kb away. This variant has been associated with increased TG levels in several populations, but only inconsistently. In addition, none of the ApoAV allelic variants or haplotypes had any significant association with heart disease frequency in this population. These data will focus future studies and guide analysis of haplotype transmission to characterize the involvement of this apolipoprotein cluster in TG levels and metabolism.

DNA yield as a possible confounder in genetic studies on cardiovascular diseases. *M. Alanne*¹, *V. Salomaa*², *J. Stengård*², *L. Peltonen*^{1, 3}, *M. Perola*^{1, 3}. 1) Molecular Medicine, National Public Health Institute, Helsinki, Finland; 2) Epidemiology and Health Promotion, National Public Health Institute, Helsinki, Finland; 3) Human Genetics, UCLA School of Medicine, Los Angeles, CA.

Most large studies nowadays collect samples for DNA analyses. When the quantity of DNA needed is important, blood leukocytes are preferred because the yield from whole blood is easily much greater than the yield from standard buccal cell procedures. In the FINRISK 97 population-based survey EDTA-blood was collected for the extraction of DNA. The total sample consisted of 7982 participants with DNA. We found, that though treated similarly, the yield from whole blood varies significantly between individuals reflecting most likely different leukocyte levels in the blood. We wanted to see whether this variation in DNA yields would associate with any intermediate or end point cardiovascular phenotypes and thus potentially bias the sampling. DNA yield for females was significantly larger than for males ($p < 0.0001$). The mean yield of extracted DNA was smaller in the cases with myocardial infarction than in healthy controls (211 vs. 236 mg, $p = 0.007$). Age had a small negative trend for the yield of DNA ($p < 0.0001$). From the inflammatory measurements, both fibrinogen and CRP predicted the DNA yield statistically significantly ($p < 0.0001$) in a linear regression analysis. The most important measured predictors of DNA yield were the white blood cell count ($r^2 = 0.05$, $p < 0.0001$), and the time from blood drawing to extraction ($r^2 = 0.08$, $p < 0.0001$). In a linear regression model, myocardial infarction predicted DNA yield at the $p = 0.057$ level of statistical significance, but only if not sex or age were included in the model. The results suggest, that if a study selects its participants by their DNA yield (purposefully or forced to it by the low amounts of DNA), this can bias the study setting from the very beginning. When the role of inflammation in the pathogenesis of many diseases is evidently significant, we suggest that DNA amount should not become a selection factor for any kind of genetic study.

Genetic and environmental correlations between stature growth curve parameters and age at BMI rebound. *S.A. Czerwinski, B. Towne, E.W. Demerath, W.C. Chumlea, S.S. Guo, R.M. Siervogel.* Lifespan Health Research Center, Community Health, Wright State University School of Medicine, Dayton, OH.

Epidemiological studies have shown that children who mature earlier have an increased risk of being overweight in adulthood. In addition, several studies have also shown that children who experience the BMI rebound earlier in life are more likely to be overweight in adulthood. Acknowledging that measures of adiposity and patterns of human growth are under moderate to strong genetic control, we examined the nature of these association using a bivariate variance components approach to estimate the genetic and environmental correlations between stature growth curve parameters during adolescence and age at BMI rebound.

Serial weight and stature data from 428 participants in the Fels Longitudinal Study were used to model two sets of growth curves. Stature data for each individual were fit using the triple logistic model. From this, three adolescent growth curve parameters were derived: peak height velocity (PHV), age at PHV, and height at PHV. Weight and stature were used to calculate BMI (kg/m^2). Serial BMI data for each individual were fit using a third degree polynomial function. From this, age at BMI rebound was derived. Heritability estimates (h^2) for the adolescent growth parameters are $h^2=0.57$ for PHV, $h^2=0.79$ for age at PHV, and $h^2=0.92$ for height at PHV. The heritability estimate for age at BMI rebound is $h^2=0.71$. Although all of the traits examined are highly heritable, preliminary analyses reveal little effect of shared genes between the adolescent growth curve parameters and age at BMI rebound; the genetic correlations are low and insignificant. There are, however, statistically significant environmental correlations between age at PHV and age at BMI rebound ($r_E=0.61$) and between height at PHV and age at BMI rebound ($r_E=-0.81$). These results suggest that shared environmental factors may be more influential than shared genetic factors in any demonstrated associations between the age at BMI rebound and aspects of the adolescent growth spurt.

Polymorphisms in the genes of renin-angiotensin system in Mexicans with Ischemic cardiomyopathy. *T.J. BELTRAN¹, R. ARECHAVALETA², M.P. GALLEGOS¹, J. ARIAS¹, R. CELIS³, J. SANCHEZ¹*. 1) Medicina Molecular, CIBO-IMSS, Guadalajara, Jalisco, Mexico; 2) Servicio de Endocrinología; 3) Departamento de Epidemiología, H.E., CMNO, IMSS.

Ischemic cardiomyopathy (IC) is a multifactorial disease which is evoked by multiple environmental and genetic factors. Recent progress in molecular biology enable us a comprehensive understanding of the molecular pathogenesis of this disease. The genes of renin-angiotensin system has been reported as a positive linkage to IC in other part of world. In Mexico unknown this association. In 93 controls and 115 patients with IC was evaluated by coronariography. The ACE insertion (I)/deletion (D), M235T angiotensinogen and A1166C angiotensin II receptor type 1 polymorphisms were analyzed. No significant association was found when were analyzed the M235T and A1166C polymorphisms in patients with IC. However, a significant association with IC was observed in the patients group (n=111) with ACE D allele ($p < 0.05$). The subjects with the ACE D allele genotype are associated with IC in Mexican population.

A Novel Missense Variation in the Catalytic Domain of Rho-kinase May Genetically Impact on Coronary Vasospastic Ischemic Heart Disease in the Japanese. *H. Kamiunten, G. Koike, H. Shimokawa, A. Takeshita.*
Department of Cardiovascular Medicine, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan.

Background—Coronary vasospasm is one of the major causes of ischemic heart disease (IHD) and its prevalence is higher in the Japanese than in the western population. We have recently shown that Rho-kinase (also known as ROCK2) plays a crucial role in the pathogenesis of coronary vasospasm in humans, however, the genetic impact of Rho-kinase gene variation on coronary vasospasm remains to be examined. *Methods and Results*—Among healthy Japanese subjects, we have identified a novel single nucleotide polymorphism (SNP), G930T, in the catalytic domain of Rho-kinase, which results in an amino acid substitution, Lys310Asn. Then, we genotyped our Japanese patients with IHD (n=125) and Caucasian patients with IHD from ENCORE I study (n=318) to elucidate whether it is associated with coronary vasospasm. We also examined additional 4 SNPs of interest, including angiotensin converting enzyme I/D polymorphism, angiotensinogen C704T, angiotensin II type 1 receptor A1166C, and endothelial nitric oxide synthase C-786T in each population. We tested the effects of intracoronary acetylcholine in 357 consecutive patients and classified them into 3 categories ; large epicardial coronary artery spasm group (LAS), microvascular spasm group (MVS), and normal group (N). The frequency of T930 allele had higher tendency in the LAS+MVS group (3/57 for the LAS group and 2/42 for the MVS group) than in the N group (0/26) in the Japanese ($p=0.0479$). Interestingly, no Caucasian patient had the T930 allele, suggesting this Rho-kinase SNP may explain in part the ethnic difference in the prevalence of coronary vasospasm. There was no remarkable association between coronary vasospasm and other 4 SNPs in both populations. *Conclusion*—The G930T SNP of Rho-kinase may have a genetic impact on IHD in the Japanese, resulting in a higher morbidity due to coronary vasospasm. Further studies with a larger population aiming to elucidate whether this novel SNP alters Rho-kinase function are ongoing.

Association of the Common ABCA1 Variant, R219K with Plasma Lipid Levels and Coronary Artery Disease in Korean Population. *Y. Ko, E. Cho, H. Park, Y. Jang, S. Kim, J.E. Lee.* Cardiovascular Genome Center, Cardiovascular Research Institute, Division of Cardiology, Yonsei University, Seoul, Korea.

Background : ABCA1 is known to play a key role in the reverse cholesterol transport. Recently, a coding single nucleotide polymorphism (SNP) of the ABCA1 gene, the R219K variant, was found commonly in European population and reported to be associated with increased HDL-C, decreased TG, and a reduced progression of atherosclerosis. The purpose of this study was to investigate the frequency of the R219K variant in Korean population and its association with plasma lipid levels and CAD. **Methods :** One hundred ninety six CAD patients (m:f = 148:48, 57.7± 8.3 years) and 935 healthy control subjects (m:f = 402:533, 43.9±11.8 years) were examined. The R219K polymorphism was investigated by using SNP-IT assay. The plasma lipid levels were determined and the findings of coronary angiography in CAD patients were reviewed. **Results :** A homozygous R219K variant genotype KK was found in 21.5% of normal control subjects. The carrier frequency of K allele was 72.0%. The distribution of ABCA1 genotypes in CAD patients did not differ significantly from that of normal control subjects. However, there was a significant association of this ABCA1 genotype variant with HDL-C plasma level, especially in male normal controls; mean HDL level was highest in KK (53.3±11.4) and lowest in RR genotype (49.2±11.7)(P=0.02). Also, in the male CAD patients, KK genotype showed a higher mean HDL level (39.7±9.1) than RR genotype (36.0±7.4), even though the difference was not significant. The female groups showed, however, no association between plasma HDL levels and the genotypes. The severity of CAD was also related to the ABCA1 genotype. Three-vessel diseases were found more commonly in RR genotype (KK vs RR: 15.6% vs 30.2%), whereas one-vessel-disease were present more frequently in KK genotype (KK vs RR: 60.0% vs 35.8%)(p=0.05). **Conclusion :** The R219K variant of ABCA1 gene was found more frequently in Korean population than in Europeans (46%) and was associated with increased HDL plasma levels and a reduced severity of CAD.

Left Ventricular Dilatation in a large Arrhythmogenic Right Ventricular Cardiomyopathy (OMIM# 60440) population: prevalence, incidence and diagnostic utility. *K. Hodgkinson¹, S. Stuckless¹, E. Dicks¹, S. Connors², L. Thierfelder³, J. Drenckhahn³, M. Norman⁴, W. McKenna⁴, P. Parfrey¹.* 1) Patient Research Centre, Health Science Centre, St John's, NF, Canada; 2) Division of Cardiology, Memorial University, St. John's, NF, Canada; 3) Max-Delbruck Centre, Berlin, Germany; 4) St. Georges Hospital Medical School, London, England.

Six large families with Arrhythmogenic Right Ventricular Cardiomyopathy (ARVC) comprise a population with a founder effect, linked to a 2cM haplotype at 3p23-25 in Newfoundland. The families comprise 118 sibships (n=386). 73 sibships (n=263) are well ascertained; i.e. they contain 50% or more individuals of known status as defined by high-risk (sudden death under 50 years, cardiac intervention for manifestations of ARVC, obligate carrier by pedigree or high-risk DNA haplotype) or low risk (low-risk DNA haplotype). Only individuals from well-ascertained sibships are included in the analysis of which, 134 (79 male, 55 female) are high-risk (HR), 70 (30 m, 40 f) are low-risk (LR) and 59 (36 m, 23 f) are unknown. 65 HR (49%) and 47 (67%) LR individuals had at least one echocardiogram (EC). Left ventricular dilatation (LVD) was defined as greater than 117% using the Henry formula (indexing left ventricular dimensions to height, weight and age). At first EC, mean ages for the HR and LR groups respectively were 35(SD 14.4) and 33(SD 11.6). Initial prevalence of LVD in the HR group was 23% (n=15). 34 individuals without LVD at baseline had more than one EC (15 m, 19 f) and a Kaplan Meier analysis showed that 50% developed LVD *de novo* by age 52yrs, with a trend to earlier age of onset for males. At last follow-up EC the mean ages of the HR and LR groups were 38(SD14.2) and 36(SD 10.9) respectively: specificity was 94% (90% m and 96% f) positive predictive value (ppv) was 90% (88% m, 91% f) and sensitivity was 38% (50% m, 28% f). In summary, LVD is common in this population with ARVC, it is age dependant with a trend to a sex-effect and it has a high ppv and specificity.

Heritability of premature coronary artery disease and its related traits based on a study of 428 ascertained multiplex families. *S. Rao*^{1,2}, *G. Shen*^{1,2}, *R. Cannata*¹, *E. Zirzow*¹, *R.C. Elston*³, *X. Li*⁴, *E.F. Plow*², *E.J. Topol*^{1,2}, *Q. Wang*^{1,2}. 1) Center for Cardiovascular Genetics, Department of Cardiovascular Medicine, Cleveland Clinic Foundation, Cleveland, Ohio 44195; 2) Department of Molecular Cardiology, Cleveland Clinic Foundation, Cleveland, Ohio 44195; 3) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, Ohio 44109; 4) Department of Mathematics, Harbin Medical University, China 150086.

Coronary artery disease, the leading cause of death in the developed countries, is a complex disease with a mixed contribution of genetic and environmental factors. Quantitative genetic analysis can be used to distinguish the genetic and environmental components. We estimated genetic and environmental variance components of premature coronary artery disease (PCAD) and its related traits in 2030 participants from 428 multiplex families in the Cleveland Clinic Foundation Gene Quest Study. Mixed linear models were used to decompose their phenotypic variances into additive genetic, common environmental causes, after simultaneously adjusting the effects of measured systematic covariates. In order to confirm the results obtained via mixed linear models, family aggregation analysis was carried out to obtain the correlations between various types of relative pairs. The two types of analyses agreed each other to confirm the existence of genetic cases in the manifestation of PCAD and its related phenotypes. The estimated heritability, a ratio of additive genetic variance over the phenotypic variance, was 0.45 for PCAD, and varied considerably among its related phenotypes. We concluded that premature coronary disease has an important heritable component. However, full elucidation of the genes responsible for this common complex disease must be complemented by lifestyle preventive strategies to deal effectively with a large, non-heritable component.

Sequence variation in hypoxia-inducible factor 1 alpha (*HIF1A*). *S.M. Roth*^{1,2}, *S.J. Prior*², *D.A. Phares*², *M.D. Brown*², *J.M. Hagberg*², *R.E. Ferrell*¹. 1) Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA; 2) Dept Kinesiology, Univ Maryland, College Park, MD.

Hypoxia-inducible factor 1 (HIF-1) is an oxygen sensing transcription factor consisting of two subunits, alpha and beta, with the alpha (HIF-1alpha) subunit unique to HIF-1 and regulated by hypoxia. We pursued polymorphism screening of *HIF1A* (14q21-q24) as a candidate gene contributing to inter-individual variability in maximal oxygen consumption and the response of oxygen consumption to exercise training. To date, we have completed screening of 40% of the exonic, exon/intron boundary, and promoter regions of *HIF1A* and have identified five variants as follows: 2 promoter variants (-2500 and -2209), and three polymorphisms in introns 4, 6, and 9. The two promoter variants appear to influence transcription factor binding sites (CdxA and AhR/Arnt, respectively), with the A-2500T site being more common in our initial screening. We genotyped 136 Caucasians and 59 African Americans for the A-2500T promoter variant and determined that the rare T allele was present only in African Americans ($p = 0.66$, $q = 0.34$). Exercise-induced maximal oxygen consumption ($VO_2\text{max}$) data were available before and after exercise training for 14 African American subjects. Carriers of the T allele ($n = 6$) exhibited lower baseline $VO_2\text{max}$ compared to the A/A group (21.7 ± 0.9 vs 25.1 ± 0.8 ml/kg/min; $P = 0.02$) with no difference between groups for the change in $VO_2\text{max}$ with training (4.4 ± 1.5 vs 5.0 ± 1.2 ml/kg/min; $P = 0.74$). In addition to completing the screening of *HIF1A* for polymorphisms, additional African American subjects are being genotyped for the A-2500T *HIF1A* variant for analysis of oxygen consumption and other exercise training-related phenotypes.

Sponsored by NIH AG15389, AG17474 and AG05893.

Association of the Angiotensinogen (AGT M235T) and Rh Blood Group Polymorphisms with Blood Pressure and Lipids in an African Derived Population in Dominica. *M.Thomas Robinson¹, C.E. Grim²*. 1) Psychiatry, Univ. of Calif. San Diego, La Jolla, CA; 2) Department of Cardiology, Medical College of Wisconsin, Milwaukee, WI.

We investigated the association of two Chromosome 1 polymorphisms (AGT M2235T and the Rh Blood Group) with blood pressure, lipids, and lipoprotein concentrations in a random sample of Afro-Caribbeans age 18-60. In monogenetic analysis, AGT M235T was not associated with blood pressure. However, it was significantly associated with HDL concentrations (MM 4223, MT 4412, TT 5214 ($p=0.002$)). Rh genotype was significantly associated with systolic blood pressure ($p=0.006$) and Apo-A levels ($p=0.003$). These effects were not due to AGT M235T effects on weight or BMI or due to age or gender differences between groups. In the polygenetic analysis AGT M235T and Rh achieved borderline significance in an association with systolic blood pressure ($p=0.0680$; interaction effects, $p=0.037$). The association of the AGT M235T with blood pressure across Rh blood group haplotypes was then tested. Of the five Rh haplotypes available for analysis, the AGT M235T was significantly associated with blood pressure within the D haplotype ($p=0.01$). The Rh blood group and sex were significantly associated with systolic blood pressure and Apo-A levels, ($p=0.005$ and $p=0.012$, respectively). All interactions were independent of age and weight. In conclusion, we demonstrated a significant association of the AGT M235T with blood pressure and cholesterol metabolism in an Afro-Caribbean population in the genetic context of the Rh blood group system. Further investigation of these interactions may help understand the effects of genetic factors on cardiovascular risk in African derived and other populations.

Diagnostic Utility of Premature Ventricular Complexes in a large Arrhythmogenic Right Ventricular Cardiomyopathy (OMIM# 60440) population. *S. Stuckless¹, K. Hodgkinson¹, E. Dicks¹, S. Connors², L. Thierfelder³, J. Drenckhahn³, M. Norman⁴, W. McKenna⁴, P. Parfrey¹.* 1) Patient Research Centre, Health Sciences Centre, St. John's, NF, Canada; 2) Division of Cardiology, Memorial University, St. John's, NF, Canada; 3) Max-Delbrück Centre, Berlin, Germany; 4) St. George's Hospital Medical School, London, England.

A founder effect in a large Newfoundland Arrhythmogenic Right Ventricular Cardiomyopathy (ARVC) population genetically links 6 large families to a 2cM haplotype at 3p23-25. Only individuals from well-ascertained sibships (comprising 50% or more individuals of known status n=263) were included in the analysis. Status was defined as high-risk (sudden death under 50 years, cardiac intervention for manifestations of ARVC, obligate carrier by pedigree or high risk DNA haplotype) or low risk (low-risk DNA haplotype). Of the well-ascertained individuals, 134 (79 male, 55 female) are high-risk (HR), 70 (30 m, 40 f) are low-risk (LR) and 59 (36 m, 23 f) are unknown. 61 (46%) of the HR group (29m, 32f) had at least one 24 hour holter monitor (HM) and 29 (41%) individuals at LR (12m, 17f). Numbers of premature ventricular complexes (PVCs) in a 24-hr period were counted. The mean number of PVCs in the high-risk group was 3324, with a median of 1340 compared with 30 and 1 in the low risk group respectively (p=0.001). To determine the diagnostic utility of HM, 5 PVCs per hour was taken as an upper limit of normal (120 PVCs in 24 hours). Using the last HM obtained specificity was 93% (91% m and 94% f) positive predictive value (ppv) was 96% (96% m and 95% f), and sensitivity was 72% (82% m and 62% f). Prevalence over time for males indicates that all HR males over 30 years were above the cut-off for PVCs. Prevalence in HR females above 30 years was 70% (90% by age 45), with a ppv of 100% over age 30 years. In summary, PVC's occur frequently at an early age in this genetically homogeneous, well-ascertained, geographically stable population, and they are associated with a high positive predictive value.

Increased telomerase activity in older individuals with Down syndrome and dementia. *E.C. Jenkins¹, M.T. Velinov¹, S.-Y. Li¹, L. Ye¹, W.B. Zigman², N. Schupf², S. Sklower Brooks³, W.P. Silverman².* 1) Department of Cytogenetics, New York State Institute for Basic Research in Developmental Disabilities (NYS IBR), Staten Island, NY; 2) Department of Psychology, NSY IBR, Staten Island, NY; 3) Department of Human Genetics, NYS IBR, Staten Island, NY.

Recently, we presented preliminary data indicating reduced mitotic index in short-term whole blood cultures from people with Down Syndrome (DS) and dementia (AJHG 67(4):Abs. 1314). Given that telomeres become shorter with every in vitro cell division, given that individuals with DS have increased vulnerability and earlier onset of dementia, given that individuals with DS have been shown to have shorter telomeres than age- and sex-matched controls with DS (Vaziri, 1993), and given that telomerase, a ribonucleoprotein enzyme, is necessary for the synthesis of highly conserved TTAGGG repeats, we hypothesized that telomerase activity may differ as a function of dementia status in pairs of age- and sex-matched individuals with DS. Dementia status in these individuals was determined based on documented history of progressive memory loss, disorientation, and functional decline over a period of at least one year. In addition, all subjects had received a diagnosis of probable dementia by their personal physicians. Eight pairs of subjects with cytogenetically confirmed trisomy 21, ranging in age from 47 to 64 years, were studied. Using a PCR-based test via the TRAPeze kit (Serological Corp., Norcross, GA), we have found increased telomerase activity in short-term PHA-stimulated lymphocyte cultures from the subject with dementia in six of eight subject pairs (i.e., 75%, $p=.054$ using a one-tailed Wilcoxon signed rank test). We hypothesize that individuals with DS and dementia will exhibit both increased telomerase activity and decreased telomere length on further study. (This work was supported in part by the New York State Office of Mental Retardation and Developmental Disabilities, Alzheimer's Association Grant IIRG-99-1598, and by National Institutes of Health grants PO1 HD3587-15, HD37425-04, and RO1 AG014676-04.).

Variable expressivity of a COL1A2 gly-610-cys mutation in a large Amish pedigree. *D.J. McBride, E.A. Streeten, B.D. Mitchell, A.R. Shuldiner.* Medicine, University of Maryland, Baltimore, MD.

Mutations in the COL1A1 and COL1A2 genes have been associated with osteogenesis imperfecta (OI), a disease characterized by bone fragility and fracture. Phenotypic variation is well recognized among individuals carrying different COL1A1 or COL1A2 mutations. Variation among related subjects carrying the same mutation is also known, but the total number of affected family members is limited. We have identified a COL1A2 mutation in 48 members of a large pedigree of Old Order Amish ancestry. All affected individuals (age 1 month-86 years) can be traced to a single founding couple born ~150 years ago. We assessed fracture history and measured bone mineral density (BMD) at the spine and hip in a subset of 37 affected (age 6-86 years) and 33 unaffected individuals (age 6-80 years) from 20 nuclear families. The average total number of self-reported fractures in individuals with the variant allele is 1.9 (range 0-9) compared to 0.52 (range 0-4) in unaffected relatives. Mean L1-L4 BMD adjusted for standing height in study subjects >18 years of age was significantly reduced in affected family members (5.8 0.5 mg/cm) compared to family controls (4.7 0.6 mg/cm). Variation in height adjusted BMD variation was also observed within nuclear families. Clinical variation in disease severity was observed. For example, one subject presented at age 31 with severe basilar impression. Other clinical features associated with OI such as dentinogenesis imperfecta, stature, scleral hue, and bone deformity have variable presentation both within and between nuclear families. The cause for this phenotypic variation is unclear at this time, but may result from the interaction of genotype with genetic background (modifier genes) and/or environmental factors. Discovery of modifier genes that influence OI phenotype may lead to novel treatment strategies that can impact substantially on mortality and quality of life in terms of fracture history. More importantly, these studies may yield new insights into the molecular and physiological basis of the common forms of osteoporosis, which, in turn, can lead to new prevention and treatment strategies for a broader group of patients.

Association of suicidality in bipolar patients with the T102C polymorphism of the 5-HT receptor 2A gene and coding variants R611H of the Wolfram Syndrome 1 gene. *S. Li¹, J.F. Goldberg⁵, T.A. Sivakumaran², J.H. Kocsis⁵, M.M. Lesperance², M. Burmeister^{1,3,4}.* 1) MHRI, University of Michigan, Ann Arbor, MI; 2) Departments of Otolaryngology Head and Neck Surgery, University of Michigan; 3) Department of Psychiatry, University of Michigan; 4) Department of Human Genetics, University of Michigan; 5) Department of Psychiatry, Cornell University Medical College.

Suicidality is one of the most serious symptoms of bipolar disorder. Several genetic variants have been implicated in suicidality before. Here, we ask whether two such genetic variants, the T102C polymorphism of the serotonin 2A receptor gene and a coding variant, R611H, in the Wolfram syndrome 1 gene, are associated with suicidality within a group of 68 bipolar patients. Suicidality was evaluated at intake and again at 1-year follow-up at Cornell University. Previous studies have shown associations of 5-HT_{2A}-T102C polymorphism with suicidality in patients with major depression. WFS1 was considered as a candidate gene because of an increased risk of psychiatric disorders and suicide has been reported for heterozygote carriers of Wolfram syndrome 1 (WFS1), a rare, autosomal recessive neurodegenerative disorder. Patients with the 102 T/T genotype had a lower mean number of suicide attempts (0.29) than T/C (1.10) and C/C (1.00) genotype patients, consistent with previous findings that the C allele is associated with suicide ideation. However, this finding did not reach statistical significance ($p=0.117$). The major finding of this study was that patients with a 611 R/R genotype of WFS1 had a significantly higher mean number of suicide attempts (2.0) than those with the R/H and H/H genotype patients (0.79, $p=0.038$). There were no significant differences in allele and genotype distributions found between non-suicide attempters and suicide attempters, and no deviation from Hardy Weinberg equilibrium. These preliminary findings suggest that the 5-HT(2A) receptor gene and Wolfram syndrome gene may play a role in suicidality risk of bipolar patients.

Increased frequency of the Apolipoprotein E e4 allele in patients with Down Syndrome. *J. Rodriguez, L. Rengifo, A.H. Alegria, M. Sanchez, P. Osorio, H. Serrano.* Basic Science , Universidad Tecnologica de Per, Pereira, Risaralda, Colombia.

Alzheimers disease (AD) is the most frequent entity in patients with Down syndrome (DS) who live more than 40 years. DS patients develop Alzheimers disease 20-25 years earlier than the normal population with a frequency 4-5 times higher. They all have neuropathology and neurochemical changes corresponding Alzheimers disease but not all develop the clinical symptomatology. It has been established that lipoprotein E e4 allele carriers have a dose dependent risk of developing Alzheimers disease at an earlier age while the e2 allele has a protective effect. On the other hand the e4 allele frequency in patients with Down syndrome has been found statistically similar to that of control populations although in young mothers with a meiosis II error, e4 frequency was 30.0%, significantly higher than in older mother with the same type of error (13% $p=0.03$) Apolipoprotein E genotyping was carried out by PCR amplification of a 244 bp fragment of the apoE gene followed by digestion with HhaI, in 78 patients (37 males, 41 females) with ages between 7 months and 41 years with a clinical and cytogenetic diagnosis of DS. A control group of 525 normal individuals (225 males, 300 females) with ages between 15 and 81 years was similarly analyzed. The e4 allele was found in 17% (95%, CI 15.0-18.3) of DS patients compared with 9% (95%, CI 8.6-9.9) in the normal population. This result is therefore statistically significant and differs from the results found by other mentioned previously. The mothers of the e4 allele carriers DS patients were 34-46 years old, indicating that the patients in the group studied here were conceived by older mothers.

A closer look at human recombination. *J. Barnard*¹, *D.F. Gudbjartsson*², *J. Sainz*², *G.M. Jonsdottir*², *S.A. Gudjonsson*², *B. Richardsson*², *S. Sigurdardottir*², *B. Hallbeck*², *G. Masson*², *A. Shlien*², *S. Palsson*², *M. Frigge*², *Th. Thorgeirsson*², *J. Gulcher*², *A. Kong*², *K. Stefansson*². 1) Statistics Department, DeCODE genetics, Waltham, MA; 2) Statistics Department, deCODE genetics, Reykjavik, Iceland.

Recombination, the mechanism of DNA mixing from one generation to the next, is a major component of the forces that drive human evolution. A recent study of ours (Kong et al 2002) demonstrates a substantially higher correlation between recombination rates and sequence content (e.g. GC content, CpG motifs, and polyA/polyT stretches) than reported before. Most interestingly, we found that not only do mothers have variable recombination rates ('mother effect'), even gametes of the same mother have systematic difference in recombination rates ('gamete effect'). There is a positive correlation of recombination counts across chromosomes suggesting there is some underlying factor that affects recombination rates across the genome. Here we will report results that quantify the substantial contributions of the mother effect and the maternal gamete effect to the total variation of recombination counts. We will also take a close look at whether the underlying factor has an uniform effect on the whole genome or whether the effect is more pronounced on certain chromosomes or certain parts of the chromosomes, and investigate the possibility that the effect is correlated with sequence content. Finally, we will briefly review the novel methodological and computational tools employed in our analysis to handle the issues of incomplete data and crossover interference.

Evidence That UGT A1 gene is a genetic modifiers in adults suffering from hemolytic anemia. *s. pissard*^{1,2}, *A. Jacquette*¹, *F. Roudot-Thoraval*⁴, *D. Bachir*³, *F. galacteros*³, *M. Goossens*^{1,2}. 1) service de biochimie et genetique, hopital Henri Mondor, creteil, France; 2) Inserm U468, creteil, France; 3) Unite de genetic du globule rouge, hopital henri mondor, creteil; 4) service de biostatistique, hopital Henri Mondor, Creteil, France.

Sickle cell disease (SCD : b6 glu>val) is one of the most frequent monogenic disorder and causes an accelerated destruction of red blood cells in peripheral circulation. The chronic hemolysis of SCD results in an hyperbilirubinemia and jaundice with secondary cholelithiasis potentially source of infections, abdominal pains and surgery. Serum bilirubine level is related to Uridine diphosphate Glucuronyl Transfrase 1A (UGT A1) enzyme activity and polymorphisms of the promoter of its gene are known to be strongly associated with UGT A1 activity in Gilbert syndrome. We have screened a cohort of 144 adults patients belonging to five geographic origins (French West Indies (46), western Africa (51), centre Africa (37) and Mediterranean area (7) and suffering either from SCD Hb S/Hb S (n = 115) or HB S/HB C (b6 E>K) (n = 23) and Hb S/b thal (n = 6) to evaluate the role of UGTA 1 as a genetic modifier of SCD and related hemolytic diseases. In these population we screened UGT A1 promoters' "TA" repeats and we found out 4 different alleles characterised respectively by 5, 6, 7 and 8 TA repeats the most frequents being the 6 and 7 repeats' alleles with no significant difference in the frequency of each allele between the populations (chi square = 4.2 df = 9, P = 0,89). Analysed on the 115 S/S patients, the frequency of cholelithiasis and related complications appear to be related to the number of UGT A1 promoters' repeats found in patient with 48.9% (genotype 6/6), 70,2% (genotype 6/7) and 79.3% (genotype 7/7) (p = 0.033). however, allele shorter than 6 repeats or longer than 7 repeats where not associated with decreased or increased severity. These data bring evidence for the role of UGT A1 gene as a genetic modifier of diseases characterized by chronic hemolysis and militate for the determination of UGT A1 genotype in the care of these patients.

Endometriosis in Large Utah Families. *K. Ward*^{1,2}, *D. Hull*². 1) Dept Obstetrics/Gynecology, Univ Utah, Salt Lake City, UT; 2) emerGen, Inc., 2749 E. Parley's Way, SLC, UT.

Our goals were to confirm the familial nature and heritability of endometriosis in Utah and to pursue disease gene identification using large families with common ancestors. Using an IRB approved protocol 784 women were identified as having surgically diagnosed endometriosis from 24 community-based gynecology offices. Three generation family histories were taken. 620 women had a sister of reproductive age with an average of 2.3 sisters. Of the 1404 sisters, 15.2% also had been surgically diagnosed and 22.2% had chronic symptoms consistent with the condition. 8% of the proband's mothers had a surgical diagnosis and 14.4% had suggestive symptoms. The patients were also questioned about their extended family. 35.5% reported at least one extended family member surgically diagnosed. The results are shown in the table below:

	Relatives	Probands	%	%	%
	affected	reporting	Affected	Male side	Female side
Cousin	153	110	14	10.2	3.8
Aunt	133	113	14.4	8.5	5.9
Niece	42	34	4.3	3.7	0.6
Grandmother	22	22	2.8	2.0	0.8
Daughter	40	39	5.0	-----	-----

This study confirms the familial nature of endometriosis and the likelihood of a major gene effect. Affected sibling pair linkage analysis of 210 affected sibling pairs is currently underway.

Trans-species polygenic variation of complement C4 and RCCX modular structures in rhesus macaque (*Macaca mulatta*) and humans. N. Longman-Jacobsen¹, E.K. Chung^{1,2}, Y. Yang^{1,2}, K.R. Clark¹, P. Johnson¹, C.Y. Yu^{1,2}. 1) Children's Research Institute, Columbus, OH; 2) Ohio State University, Columbus, OH.

The evolution of complement C4 in Old World primates appears to have been a complicated process, with humans having complex genetic variations of a four-gene segment containing RP-C4-CYP21-TNX (RCCX module) in the major histocompatibility complex (MHC). Besides humans, little is known regarding the genetic complexity of C4 and RCCX modular variation within each primate species. We have begun an examination of C4 genes and the RCCX complex in a large population of *Macaca mulatta* (Rhesus macaque), a desirable model for studies of C4 and other immune response proteins in infectious and autoimmune diseases. We show that several of the tools for the elucidation of the C4 gene copy number and RCCX modular structures in humans are also informative in macaques. We are able to determine the total number of RCCX modules and thus C4 genes by pulsed field gel electrophoresis of *PmeI* digested genomic DNA, and whether each C4 gene contains the endogenous retrovirus ERV-K(C4) by *TaqI* RFLP. The genotype results reveal that macaques have a similar level of complexity to humans, with mono-, bi- and trimodular RCCX structures that incorporate one, two or three C4 genes on each MHC, respectively. The monomodular short RCCX, which contains one C4 gene without an ERV-K(C4), is relatively common in macaques with a frequency ~31%. In humans, this haplotype has a frequency of 11% in the healthy Caucasian population. Sequencing of the genomic C4d region in macaques reveals a similar level of polymorphism to that seen in humans. One of the nucleotide changes leading to the Cys>Ser 1102 in human C4A and C4B isotypes, respectively, and the isotype definitive *PshAI* RFLP, appears to be invariant in macaques and is identical to human C4A. Sequencing will also allow production of recombinant proteins for the generation of specific antisera against macaque C4, as allotyping using human C4 antisera for immunofixation has not been informative. In summary, we have observed trans-species polymorphism with great genetic diversity in the RCCX modules and polygenic variations of C4 in rhesus macaques and in humans.

Natural Selection as a Curved Plane: Using Mathematic to Model Evolutionary Forces. *C.E. Grim¹, M.T. Robinson², D. Read³, T. Paz⁴, N.J. Schork².* 1) Cardiology, Medical College of Wisconsin, Milwaukee, WI; 2) Department of Psychiatry, University of California, San Diego. La Jolla, CA; 3) Department of Anthropology, University of California, Los Angeles. Los Angeles, CA; 4) Department of Epidemiology, University of Southern California, Los Angeles, CA.

Until recently, many computer systems were capable only of producing graphical display of numeric data in two dimensions. Advances in hardware and software have made the graphical display of numeric data, and its manipulation in three dimensional space possible. In this report we demonstrate the use of Mathematica for modeling the evolutionary force of natural selection and its interface with mutation. Four types of natural selection were examined: no dominance, overdominance, complete dominance with selection against the A2A2 genotype, and complete dominance with selection against the A1 allele. The four equations representing the rate of allele frequency change as a function of selection coefficient and initial allele frequency, derived by D.S. Falconer in *Introduction to Quantitative Genetics*, were used in these models. The change of allele frequency was plotted on the Z axis as a function of gene frequency (X axis) and the selection coefficient (Y axis). In this three dimensional representation, natural selection (the change in gene frequency) is a curved plane. Examination of these three-dimensional plots reveals that the form of natural selection have the largest potential impact on the allele frequency is that of no dominance. Under no dominance, Δq reaches a maximum value of 0.48 when the selection coefficient is 1.0 and the gene frequency is 0.5. Visualization of evolutionary forces in three dimensions, as we have demonstrated, enforces the concept that evolution is dynamic process, and encourages an intuitive understanding of the combination of factors, and their magnitudes, that are needed to produce a desired genetic result in a population.

Program Nr: 1055 from 2002 ASHG Annual Meeting

Detection of Population Structure in Starr County Mexican-Americans. *B.F. Voight, N.J. Cox, J.K. Pritchard.*
Human Genetics, University of Chicago, Chicago, IL.

Population structure is potentially a critical problem in association and in linkage disequilibrium based fine-mapping. Subdivisions that are present and are not appropriately accounted for can give rise to spurious associations between marker and phenotype that are intrinsic to population structure but are not intrinsic to disease. Admixed populations provide a particular challenge for computational approaches to detect subdivision, since the existing substructure may have a continuous distribution, not amenable to classification into discrete units, yet still show differences in marker and/or disease allele frequencies between a patient and a random or control sample. We have examined a population of Mexican-Americans from Starr County, TX with type 2 diabetes as well as a random sample also collected from Starr County using computational approaches developed by Pritchard et al (2000), implemented in the program STRUCTURE, to estimate the number of subpopulations in the sample. We utilized markers from a whole genome screen of 491 microsatellite loci typed in 170 patients (one patient from each of 170 families included in the genome screen) affected with type 2 diabetes. The results show little evidence of population subdivision. In order to maximize our power to detect subdivision within this admixed sample, we are further investigating a subset of the polymorphisms for which allele frequency estimates are available for populations of European, Spanish, and Native American descent.

Association analysis of single nucleotide polymorphisms of serotonin transporter gene and bipolar affective disorder in Taiwan. *H.S. Sun¹, H.C. Wang¹, T.J. Lai²*. 1) Institute Molecular Medicine, National Cheng Kung University Medical College, Tainan, Taiwan; 2) Department of Psychiatry, Chung Shan Medical and Dental University Hospital, Taichung, Taiwan.

Bipolar affective disorder is a chronic, severe mood disorder that is considered as the major mental illness after depression. Little is known about the underlying causes of BPD, which has estimated a lifetime prevalence of 0.5% to 1% in various populations. Current studies using the candidate gene approach have suggested that serotonergic neurotransmission and metabolism were associated with several psychiatric and behavioral traits including BPD, depression, suicidality, alcoholism, and mental control. Genes involved in serotonin transmission and metabolic pathways thus are good candidates for studying the involvement in BPD pathogenesis. Serotonin transporter (SLC6A4) is a member of solute carrier family and responds for re-uptaking serotonin into presynaptic terminal thus fine-tuning brain serotonergic neurotransmission. Serotonin transporter has been the primary target for developing therapeutic medicine for the treatment of depression, panic disorder and other psychiatric disorder. To examine the role of the SLC6A4 gene in etiology of BPD, 10 markers including two variable number of tandem repeat (VNTR) and 8 single nucleotide polymorphisms (SNPs) within 60 kb interval surrounding the SLC6A4 gene were used to study the association with BPD in Taiwan. Two selected SNPs were found not informative in Taiwanese population and eight polymorphic markers have been analyzed by classical chi-square test as well as haplotype analysis. No association can be obtained between all SLC6A4 markers and BPD. In addition, significant linkage disequilibriums were obtained among 8 SNPs but not between markers and a putative disease locus by the use of EH program. This study demonstrates that the SLC6A4 gene may not play an important role in BPD etiology and suggests that other genes in the serotonergic system may be involved.

FREQUENCY OF NON-SYNDROMIC DEAFNESS IN BOGOTA, COLOMBIA: RESULTS OF A SCREENING PROGRAM. *M.L. Tamayo¹, M. Olarte¹, N. Gelvez¹, P. Gonzalez¹, S. Florez², D. Medina².* 1) Instituto de Genetica Humana, Facultad de Medicina, Universidad Javeriana, Bogota, Colombia; 2) Fundacion Oftalmologica Nacional.

Hearing loss is one of the most common human complaints, affecting one in 1000 children. In developed countries, half of the hearing loss is due to a genetic cause. In Bogota, Colombia, we are developing a screening program in order to define the prevalence of Non-syndromic deafness in our City. We applied a special questionnaire to each affected child in all of the institutions for the deaf, asking for possible causes of deafness, presence of some affected relative, parents consanguinity and, other disorders or defects in the propositus. After that, we made a previous selection of some affected families and invited them to participate in our research. All selected individuals were examined by our medical team to define the diagnosis of non-syndromic deafness. We performed a complete clinical exam and a detailed ophthalmologic evaluation with fundoscopy, focus to rule out rubeola prenatal infection and other acquired causes. We classified the families in two groups: hearing loss from possible genetic origin, and hearing loss from unknown cause. Of the total of 731 individuals analyzed, we define a diagnosis of non-syndromic deafness in 299 (40.9%). Among this, 146 (48%) were classified as non-syndromic deafness with possible genetic etiology, and 153 (50.3%) as non-syndromic deafness with unknown cause. Molecular genetic screening for the most common mutations in Cx26, 35delG and 167delT, must be performed to clarify the real basic etiology for the non-syndromic deafness in this population.

Transmission disequilibrium for alleles of MSX1 in a large South American population with cleft lip and palate.

L.A. Ribeiro¹, D. Moretti-Ferreira¹, A. Richieri-Costa¹, M. Cooper², M. Marazyta², J. Murray³. 1) Hospital for Rehabilitation of Craniofacial Anomalies, University of Sao Paulo, Bauru, Sao Paulo, Brazil; 2) Cleft Palate Craniofacial Center, University of Pittsburgh, Pittsburgh, Philadelphia; 3) Department of Pediatrics, University of Iowa, Iowa City, Iowa.

Oral clefts, including cleft palate (CP), cleft lip (CL) and cleft lip with palate (CLP) have been the focus of numerous studies by both epidemiologists and geneticists. Their frequent occurrence as well as their extensive psychological, surgical, speech and dental involvement emphasize the importance of understanding the underlying causes. Previous candidate gene analyses have suggested the involvement of MSX1, TGFA, and TGFB3 in Caucasian population. The purpose of this research was to test the hypothesis that TGFB3 and MSX1 are involved in the etiology of CLP or CP. This was tested by determining, through the use of nuclear family based approach, whether these genes were in linkage disequilibrium as measured by transmission distortion with either form of clefting. The availability of a large sample of complete parent-infant triads (324) on whom DNA is available allowed us to pursue a TDT analysis for genes previously associated with cleft lip and palate. The genes were selected based on previous results, including linkage, linkage disequilibrium, and animal model studies. Markers used to analyse 324 triads were for the MSX1 and TGFB3 genes. MSX1 had positive (p-value 0.05) biallelic TDT results for allele 4 in the overall dataset, and in triads with CP. TGFB3 had a borderline positive result (p-value = 0.06) biallelic TDT result for allele 1 in the CL subset only. For both genes independent confirmation was identified and provides support for the role of these genes in contributing to the genetic influence on cleft lip and palate in a Brazilian population. It may be through the sum of studies like this, we can provide a search for evidence of transmission distortion in candidate genes of high priority for the study of cleft lip and palate. The evidence that MSX1 and TGFB3 contribute to clefting can provide us with more complete understanding of the etiology of human nonsyndromic cleft lip and palate.

The phylogeography of Siberian Y-chromosome lineages. *M. Derenko*¹, *B. Malyarchuk*¹, *G. Denisova*¹, *I. Dambueva*², *Ch. Dorzhui*³, *F. Luzina*⁴, *O. Lotosh*⁴, *I. Zakharov*⁵. 1) Genetics Laboratory, Institute of Biological Problems of the North, Magadan, Russia; 2) Institute of General and Experimental Biology, Ulan-Ude, Russia; 3) Tuva State University, Kyzyl, Russia; 4) Institute of Professional Diseases and Hygiene Problems, Novokuznetsk, Russia; 5) Vavilov Institute of General Genetics, Moscow, Russia.

DNA variation of the non-recombining part of the Y-chromosome was examined in 434 samples representing ten aboriginal Siberian populations (Altai-Kizhi, Teleuts, Tofalars, Khakassians, East Tuvians (Todjins) and Shors from Altai and Sayan region, Buryats and Sojots from Baikal region, Koryaks and Evens from northeast Siberia region). Twelve haplogroups (HGs: 1, 3, 12, 16, 10, 26, 2, 2, 9, 4, 21, 18, according to nomenclature proposed by Jobling et al. (1998) with modifications) were observed by analyses of twelve biallelic polymorphic markers (92R7, SRY1532, Lly22g, RBF5, M9, 12f2, M89, RPS4Y, DYS287, SRY8299, M20, DYS199) and were unevenly distributed among the populations. The most frequent Y-chromosomes in Siberians belonged to HG1 (15.7%), HG3 (30%), HG16 (16.8%) and HG10 (23.3%). Haplogroups 1 and 3 showed the highest frequencies in the Altai and Sayan region populations (up to 80% in Shors). Haplogroup 10 showed regional variation, having the highest frequencies in the Baikal region populations (54.5% in Buryats) and in the northeast populations of Koryaks and Evens (50% and 60%, respectively). The highest frequencies of HG16 were observed in all regional groups of Siberians (25% in Tofalars, 22.1% in Buryats and 28.8% in Koryaks), whereas HG12, which is ancestral to HG16, showed maximum frequency in Tofalars (34.4%). Phylogenetic analysis revealed three monophyletic Siberian clusters, which consisted of northeast/Baikal region populations, Altai-Sayan region populations and Tofalars/ Sojots, respectively. The distribution pattern of Y-chromosome haplogroups as well as the results of phylogenetic analyses testify the considerable inter-population differentiation of Siberian groups studied ($F_{st}=0.157$). AMOVA results show that rather geography and linguistics than anthropology define the degree of genetic differentiation observed.

A high-density SNP allele frequency map reveals genomic signatures of natural selection. *J.M. Akey¹, G. Zhang¹, K. Zhang^{1,2}, L. Jin¹, M. Shriver³*. 1) Dept Environmental Health, Univ Cincinnati, Cincinnati, OH; 2) Human Genetics Center, University of Texas-Houston, Houston, TX; 3) Department of Anthropology, Penn State University, University Park, PA.

Identifying genomic regions that have been targets of natural selection remains one of the most important and challenging areas of research in genetics. To this end, we report the analysis of 26,530 SNPs whose allele frequencies were determined in three populations. Specifically, we calculated a measure of genetic differentiation, F_{ST} , for each locus and examined its distribution at the level of the genome, the chromosome, and individual genes. By comparing the empirical distribution of F_{ST} to that predicted under a model of selective neutrality we observe clear and statistically significant signatures of natural selection at each level of observation. Furthermore, we have identified 174 candidate genes whose distribution of genetic variation suggests that they have been targets of selection. Our work provides a first generation natural selection map of the human genome and provides compelling evidence that selection has shaped extant patterns of human genomic variation.

DNA sequence variation in FOXP2 language gene among humans and great apes. *J.J. Ely^{1,2}, H.H. Khun¹, S.T. Boysen³, J.M. Erwin^{1,2,4}, P.R. Hof^{2,5}, W.I. Frels¹*. 1) Comparative Neurogenomics Laboratory, BIOQUAL, Inc, Rockville, MD; 2) Foundation for Comparative and Conservation Biology; 3) Department of Psychology, Ohio State University; 4) Obesity & Diabetes Research Center, University of Maryland School of Medicine; 5) Kastor Neurobiology of Aging Laboratories, Mount Sinai School of Medicine.

A single G-to-A transition in the FOXP2 gene causes developmental verbal dyspraxia, a severe language disorder involving deficits in the ability to produce fine orofacial movements and in the ability to parse words into constituent phonemes necessary for speech production and comprehension. With appropriate training, great apes have demonstrated the capacity for representational symbol production and comprehension but such capabilities are not seen under natural conditions. We hypothesized that DNA sequence variation in FOXP2 could account for innate differences in language ability among humans and apes. We sequenced 3099bp of genomic DNA including 2066bp in exons and 1933bp in introns, from exons 4-17 in 4 chimpanzees, 2 bonobos, 2 gorillas and 2 orangutans. One noncoding and 2 synonymous transitions, 1 synonymous transversion and 3 intronic SNPs distinguish species but neither the disease-causing R553H mutation nor any other functional differences were observed in the Fox region proper (exons 12-14). However, a 3bp insertion added 1 extra Gly residue in exon 5, while 1 transition and 1 transversion resulted in 2 conservative amino acid changes (N to T and S to N) in exon 7 in chimpanzee and bonobo near the putative zinc finger domain in exon 8. Language is a complex trait involving many different cognitive and motor skills controlled by many independent genes. Although the human neural architecture and motor cortex representation underlying spoken language evolved from phylogenetically ancient brain structures, the cytoarchitecture was probably considerably modified by new cortical circuits subserving the uniquely human motor aspects of language. These changes certainly involved more genes than FOXP2 alone. Thus, the relatively minor genetic changes observed in FOXP2 gene are unlikely to explain species differences in language competence.

Microsatellite and SNP haplotype variability at the SLC11A1 locus in globally diverse human populations.

SLC11A1. A.A. Awomoyi¹, M. Newport², G. Sirugo³, K. McAdam³, S. Tishkoff¹. 1) Dept Biol, Univ Maryland, College Park, MD; 2) CIMR, Wellcome Trust/MRC Building, Addenbrookes's Hospital, Hills Road, Cambridge. CB2 2XY; 3) MRC Laboratories, Fajara, The Gambia.

SLC11A1 Solute carrier 11a1 (formerly called NRAMPI natural resistance associated macrophage protein 1) is a pH dependent divalent cation transporter involved in macrophage function. SLC11A1 is a candidate gene for susceptibility to mycobacterial infections. Studies in humans indicate that polymorphisms at the 5' and 3' end of the gene are associated with increased susceptibility to tuberculosis (TB). Two alleles of a 5' promoter region polymorphism have been shown to have opposing effects on gene expression. Allele 3 results in overexpression and has been functionally linked to autoimmune disease susceptibility, while the decreased level of expression of SLC11A1 caused by allele 2 contributes to infectious disease susceptibility, leading to the hypothesis that polymorphisms at SLC11A1 are maintained in human populations by balancing selection. Hence, alleles that are detrimental in relation to susceptibility to infectious disease may be beneficial for decreased risk of autoimmune disease. In order to reconstruct the evolutionary history of the SLC11A1 gene and to distinguish the role that mutation, migration, drift, and selection have had on shaping the pattern of genetic diversity at this locus in humans, we are studying microsatellite and SNP haplotype diversity at this locus. Eight variable microsatellite repeats, including the promoter polymorphism, spanning a 3 MB region encompassing the SLC11A1 locus as well as 5 SNPs within the SLC11A1 locus have been genotyped in a globally diverse set of human populations (n>450) from Africa (Tanzania, Nigeria, Gambia), the Middle East (Lebanon), China, N. Europe, South America (Peru). Estimation of haplotype frequencies shows that Africans have higher heterozygosity than non-Africans. Analysis of patterns of haplotype variability and linkage disequilibrium have been used to reconstruct the evolutionary history of this locus and provide a clue about which haplotypes play a role in susceptibility to mycobacterial infection and/or autoimmune disorders.

Phylogeographic differentiation of mitochondrial DNA and Y-chromosome in Russian populations. B.

Malyarchuk¹, M. Derenko¹, G. Denisova¹, T. Grzybowski², E. Rogaev³, D. Miscicka-Sliwka², R. Villems⁴. 1) Genetics Laboratory, Institute of Biological Problems of the North, Magadan, Russia; 2) The Ludwik Rydygier Medical University in Bydgoszcz, Poland; 3) National Research Center of Mental Health, Moscow, Russia; 4) Department of Evolution Biology, Tartu University and Estonian Biocentre, Tartu, Estonia.

To characterize the mitochondrial DNA (mtDNA) variation in Russians, sequences of the first hypervariable segment (HVS I) of the control region were obtained from 391 individuals representing six populations of Russians from European part of Russia (Krasnodar, Stavropol, Belgorod, Orel, Saratov, and Nizhnij Novgorod regions). The analysis of HVS I variation in combination with RFLP typing of the coding region haplogroup-diagnostic sites revealed that 98% of mtDNA haplotypes found in Russians fall into major West Eurasian haplogroups. Comparative analysis of the mtDNA variation in Russian populations from different regions of European Russia has shown that despite the high levels of diversity in populations, mtDNA sequences are highly homogeneous across populations. Nevertheless, the low level of differentiation between southern and central-eastern Russian populations ($F_{ST} = 0.4\%$, $p < 0.04$) was found, when the neighboring Finno-Ugric populations are taken into account. In contrast to mtDNA, Y-chromosome analysis performed in southern, central and eastern Russian populations has revealed a high level of between-group differentiation ($F_{ST} = 2.6\%$, $p = 0.03$). It was found that hg9 Y-chromosomes reach the highest frequency of 14% in southern Russian populations. In addition, hg21 (YAP+) chromosomes are also concentrated in the south (7%). The frequency of hg16 varies in Russian populations from 7% to more than 30%, but its pattern of geographic distribution cannot be strongly explained as clinal, suggesting a more complex demographic history. This work was supported by the Russian Fund for Basic Research (grant 00-06-80448) and by the Ludwik Rydygier Medical University in Bydgoszcz (grant BW66/02).

Program Nr: 1064 from 2002 ASHG Annual Meeting

The Pattern of Polymorphism on Human Chromosome 21. *H. Innan, B. Padhukasahasram, M. Nordborg.* Molecular and Computational Biology, University of Southern California, Los Angeles, CA.

Polymorphism data from 20 partially resequenced copies of human chromosome 21 more than 20,000 polymorphic sites are analyzed. The allele-frequency distribution shows no deviation from the simplest population genetic model with a constant population size (although we show that our analysis has no power to detect population growth). The average rate of recombination per site is estimated to be roughly one half of the rate of mutation per site, again in agreement with simple model predictions. However, sliding window analyses of the amount of polymorphism and the extent of linkage disequilibrium (LD) shows significant deviations from standard models. This could be due to the history of selection or demographic change, but it is impossible to draw strong conclusions without much better knowledge of variation in the relationship between genetic and physical distance along the chromosome.

D1S80 variability in different ethnic groups of Russia and Belarus. *D.A. Verbenko¹, T.V. Kekeeva¹, E.K. Khusnutdinova², T.V. Pogoda¹, V.A. Spitsyn³, A.I. Mikulich⁴, N.A. Bebyakova⁵, L.V. Bets⁶, V.P. Ivanov⁷, N.N. Abolmasov⁸, L.A. Tarskaya¹, M.V. Sorensen⁹, S.A. Limborska¹.* 1) Human Molecular Genetics Dept., Institute of Molecular Genetics, Moscow, Russia; 2) Institute of Biochemistry and Genetics, Ufa Scientific Centre of Russian Academy of Sciences, Ufa, Russia; 3) Research Centre of Medical Genetics, Russian Academy of Medical Sciences, Moscow, Russia; 4) Institute of Arts, Ethnography and Folklore, National Academy of Sciences of Belarus, Minsk, Belarus; 5) North State Medical University, Arkhangelsk, Russia; 6) Moscow State University, Moscow, Russia; 7) Kursk Medical University, Kursk, Russia; 8) Smolensk Medical University, Smolensk, Russia; 9) McGaw Medical Center, Northwestern University, Chicago IL, USA.

High individual discrimination power D1S80 (pMCT118) DNA marker was used to learn different ethnic groups from Russia and Belarus. Allele polymorphism for this locus has been explored in Russians (six regions), Belorussians (six regions), Mordvinians-Moksha, Bashkirs, Komi-Zyrjans, Komi-Permjaks, Udmurts, Tatars, Mari, Kalmyks and Yakuts. Eastern Slavonic populations (Russians and Byelorussians) and also Mordovians-Moksha are Caucasoids; Kalmyks and Yakuts are Mongoloids; other populations are considered as admixture populations with different levels of a Mongoloid component. Allele typing was performed using the PCR and subsequent electrophoresis followed by silver staining. Twenty-eight alleles of D1S80 locus were noted in populations studied. The level of observed heterozygosity was appeared to be high and varied from 0.73 to 0.95. Observed allele distributions in Caucasoid populations studied are found to statistically differ from those in Mongoloid populations. D1S80 allele frequencies distribution pattern in Caucasian populations in contrast with others studied were characterized with lowest frequencies of high copy number alleles (more than 31) and allele 16. An analysis of D1S80 variability was made with multidimensional scaling treatment of Nei's genetic distances matrix. The plot obtained let to analyse population relationships and reveal high capability of D1S80 to differ both neighbouring and distant ethnic groups.

Mitochondrial haplogroup structure of Tibeto-Burman populations. *Y. Qian*¹, *J. Chu*², *R. Chakraborty*¹, *L. Jin*¹, *B. Su*¹. 1) 1. Center for Genome Information, Department of Environmental Health, University of Cincinnati, USA; 2) 2. Institute of Medical Biology, the Chinese Academy of Medical Sciences, China.

Using 10 East Asian-specific mitochondrial RFLP polymorphic markers, a total of 570 samples were screened covering nine Tibeto-Burman speaking populations from southwestern China as well as six populations who speak Altaic, Daic, Astro-Asiatic and one Japanese population. Consistent with previous observations in East Asia, the majority of the mtDNAs clustered into two major haplogroups, M (defined by 10394 DdeI+/10397 AluI+) and N (defined 10394 DdeI-/10397 AluI-), indicating a common maternal origin of Tibeto-Burman populations with other East Asians. Furthermore, the presence of the haplotype defined by 10394 DdeI+/10397 AluI- in most of these East Asian populations indicates its antiquity and possibly one of the ancient haplotypes (affiliated to L3 haplogroup) originated from Africa. The principal component (PC) analysis based on mtDNA haplotype frequency distribution revealed a close relationship between Tibetan and Japanese confirming the kin connection of these two populations in the paternal lineage. The Burmese-Lolo populations, a subgroup of Tibeto-Burman, are widely spread in the PC map, implying an extensive female population admixture between Burmese-Lolo and Daic/Astro-Asiatic speaking populations contrasting the relatively monomorphic genetic background in the paternal lineage of Burmese-Lolo.

Population structure and distribution of 100 polymorphic *Alu* insertion polymorphisms. *W.S. Watkins*¹, *C.T. Ostler*¹, *A. Brassington*¹, *M.J. Bamshad*¹, *M.A. Batzer*², *M.L. Carroll*², *S.V. Nguyen*², *L.B. Jorde*¹. 1) Dept. of Human Genetics, University of Utah, Salt Lake City, UT 84112; 2) Dept. of Biological Sciences, Louisiana State University, Baton Rouge, LA 70803.

We have analyzed 100 *Alu* insertion polymorphisms in 155 Africans, 77 Asians, 118 Europeans, and 365 East Indians. *Alu* gene diversity is highest in Africans (0.349) and lowest in Europeans (0.298). The *Alu* insertion frequency is lowest in Africans (0.463) and higher in Indians (0.544), Asians (0.557), and Europeans (0.559). Analysis of genetic distances demonstrates continental clustering with high bootstrap support and large genetic distances between populations within Africa and between African and non-African groups. The pattern we observe is consistent with a bottleneck in non-African populations. Fst analysis indicates that 14.1% of *Alu* diversity occurs between the three continental groups of Africans, Asians, and Europeans. The Fst within each major group is 0.042, 0.021, 0.010, 0.021, and 0.045 for Africans, Asians, Europeans, Indians, and tribal Indians, respectively. Short tandem repeat polymorphisms (STRPs) within 50 kb of 12 different *Alu* loci were also analyzed. The STRP allele size variance ratio is highest in Africans (1.33), intermediate in Europeans (0.91), and lowest in Asians (0.76). STRP heterozygosity is highest in Africans (0.84) and lower in Europeans (0.77) and Asians (0.73). These results indicate a decrease in the number of STRP alleles and STRP diversity with increasing distance from Africa. Haplotypes of *Alu* markers and neighboring STRPs were constructed. This allowed us to date each *Alu* insertion event and to assess ancestral (*Alu* absent) versus derived (*Alu* present) haplotypes. Ancestral haplotypes generally demonstrate high levels of STRP variability, especially in African populations. Derived haplotypes marked by low-frequency *Alu* insertions have low STRP allele variability while older, high-frequency *Alu* haplotypes have higher STRP variability. The results are consistent with an out-of-Africa model of evolution and a genome-wide reduction in haplotype diversity signifying a bottleneck in populations leaving Africa. (Support: NIH grant GM-59290, NSF grant SBR-9818215).

Program Nr: 1068 from 2002 ASHG Annual Meeting

Patterns of DNA Variability in Human Genes. *J.C. Stephens, J.A. Schneider, M. Pungliya, J. Choi, R. Jiang, X. Sun, B.A. Salisbury, R.S. Judson, G.F. Vovis.* Genaisance Pharmaceuticals, New Haven, CT.

We have investigated the DNA-based variation (both SNPS and haplotypes) for nearly 4,000 human genes. In addition, we characterized how this variation is distributed in a number of biologically and clinically important ways. First, we determined: the pattern of how SNPs are distributed within various functional regions of a gene; the frequency with which these SNPs are found in different populations; the pattern of the sequences in which these SNPs occurred; and how these human SNPs compared to the corresponding sequence of a chimpanzee. Second, we determined how these SNPs varied among 82 unrelated individuals: 20 African-Americans, 20 East Asians, 21 European-Americans, 18 Hispanic-Latinos and 3 Native Americans. In particular, we examined patterns of SNP and haplotype sharing among the four larger population samples. Third, we determined the patterns of linkage disequilibrium among these SNPs and, hence, defined the haplotype variability of each gene, which varied substantially among the four populations. An understanding of these patterns of variability within and among genes is a fundamental prerequisite for connecting important clinical variability (e.g., genetic disease or disease susceptibility and variable drug response) to the DNA variability of human genes.

Contrasting patterns of variation in *CCR5* in humans and chimps. *S. Wooding*¹, *S. Mummidi*^{2,3}, *E. Gonzalez*^{2,3}, *S.S. Ahuja*^{2,3}, *D.M. Dunn*^{2,3}, *A.C. Stone*⁴, *L.B. Jorde*¹, *R.B. Weiss*¹, *M.J. Bamshad*¹. 1) Department of Human Genetics, University of Utah, Salt Lake City, UT; 2) Veterans' Administration Research Center, South Texas Health Care System, San Antonio, TX; 3) University of Texas Health Science Center, San Antonio, TX; 4) Department of Anthropology, University of New Mexico, Albuquerque, NM.

CCR5 encodes a cell surface chemokine receptor molecule that serves as a principal coreceptor, with *CD4*, for HIV-1 and SIV. Varied HIV-1 susceptibility has been associated with polymorphisms in the 5' cis-regulatory region of *CCR5*, suggesting that it may have been a target of natural selection. We characterized sequence variation in this region in 400 chromosomes from worldwide human populations and 50 chromosomes from 3 subspecies of chimpanzees. In humans, variation was substantially higher than expected and characterized by an excess of intermediate-frequency alleles. A genealogy of *CCR5* haplotypes had deep branch lengths despite markedly little differentiation among populations. This suggested a deviation from neutrality not accounted for by population structure, and was confirmed by tests for natural selection. This indicates that the pattern of genetic variation in *CCR5* has been shaped by balancing selection. The pattern of variation in chimpanzees was markedly different. For chimpanzees, genetic variation was lower than that observed at other autosomal loci, and in contrast to other loci, it was lower than diversity estimates for human *CCR5*. Moreover, variation in chimpanzees was characterized by a significant excess of rare variants. A genealogy of *CCR5* haplotypes had a star-like pattern, the central node of which represented the only haplotype shared by all 3 subspecies. This indicates that the pattern of genetic variation in *CCR5* in chimpanzees may have been affected by a selective sweep. This pattern may reflect an older adaptive response of chimpanzees to pathogens such as SIV. Analysis of patterns of variation between subspecies of chimpanzees infected with SIV vs. those in which SIV has never been reported should provide further insights.

Association/Linkage and Hardy-Weinberg Equilibrium at the NAT2 locus in Kindreds with Colorectal

Neoplasia. *D. Daley*¹, *R.C. Elston*^{1,4}, *S. Iyengar*¹, *S.D. Markowitz*^{2,4}, *G.L. Wiesner*^{3,4,5}. 1) Departments of Epidemiology and Biostatistics;; 2) Medicine; 3) Genetics: Case Western Reserve University, Cleveland, OH; 4) Ireland Comprehensive Cancer Center; 5) Western Reserve University and University Hospitals of Cleveland.

We recently showed linkage between colon neoplasia and the NAT1/2 locus in 56 severely affected sibships from the Colon Neoplasia Sibling Study (Daley et al, 2002) using the affected sibpair method and Haseman-Elston regression analysis. The sibships were selected on the basis of having at least two sibs affected with an advanced histology and/or early-onset colon neoplasia diagnosed by age 51. Based on our excess allele sharing at NAT2, we hypothesized that specific alleles are associated with disease. If so, associations between these alleles and a departure from HWE would be expected. NAT2 was genotyped at 9 different RFLP sites within the coding region of the gene in the 56 kindreds and parental origin of the alleles could be determined for 12 cases and 36 pseudo-controls. Pseudo-case control conditional logistic regression was performed to examine the relative risks (RR) at each RFLP site. The most significant results were found at the T341C and C481T sites, which code for the NAT2*5A/B/C alleles, previous studies have suggested an association with colon cancer. 11 of 12 cases were heterozygotes at both sites, vs. 13 of 36 pseudo-controls (RR of the T341C and C481T heterozygotes, $p < .00001$). Due to the genotypic dependence of full siblings, standard random sample methods cannot be used to test for HWE in family-based studies. Thus, we developed a sibpair method (SP-HWE) that uses all of the sibpair information in the 56 kindreds to test for HWE at each diallelic RFLP site and overall for the multiallelic NAT2 locus. Significant evidence for departure from HWE was identified for T341C and C481T, supporting an association between these alleles and colon neoplasia. Our method has independently identified a class of colon neoplasia susceptibility alleles and may be used for similar investigations in family-based studies. (Funded by American Cancer Soc PI DD).

Correlation between traits increases the power of linkage detection. *M.d. Andrade*¹, *C. Olswold*¹, *S.L.R. Kardia*², *E. Boerwinkle*³, *S.T. Turner*⁴. 1) Div Biostatistics, Mayo Clinic, Rochester, MN; 2) Dep Human Genetics, University of Michigan, Ann Arbor, MI; 3) Human Genetics, University of Texas Health Science Center, Houston, TX; 4) Div Hypertension, Mayo Clinic, Rochester, MN.

Genome-wide linkage analyses for complex traits such as blood pressure (BP) level and diagnostic category are challenging. Although these traits aggregate in families, they usually do not segregate in a Mendelian fashion, since multiple genes, each of which is polymorphic and has small-to-moderate effects, influence them. Since elevated BP level is the underlying measure of hypertension, several studies have aimed to identify genes that contribute to interindividual variation in BP level. However, none of these studies considered the combined effects on multivariate phenotypes such as systolic blood pressure (SBP) and diastolic blood pressure (DBP) or a measure of blood pressure (e.g., SBP or DBP) and another correlated trait (e.g., body weight). We have performed such multivariate linkage analyses for SBP and DBP using the Rochester Family Heart Study data. Traits that are genetically correlated were included in the analyses. We define polygenic genetic correlation as a measure of correlation between genes simultaneously influencing two traits (the higher the correlation, the more genes the traits share in common). We observed an increase in the bivariate LOD values for SPB and DBP compared to their separate univariate LOD values (an increase varying from 0.5% to 500% throughout the whole genome). These results confirm what we have observed previously in simulated data -- i.e., the power of detecting linkage is greater for multivariate correlated traits than for individual traits analyzed one-at-a-time. Thus, by using multiple traits that are correlated with BP level will provide an enhanced ability to identify responsible genetic factors, which in turn will lead to better understanding the genetic basis of this complex multifactorial phenotype and serve as a basis for the development of more comprehensive prevention and treatment strategies.

Association of an IL-1RN polymorphism with skin prick test positivity in Sheffield asthma families. *G. Ng Man Kwong¹, A.S. Rigby², A.R. Proctor¹, S.P. Ellis¹, R.A. Primhak², M.K.B. Whyte¹.* 1) Respiratory Medicine Unit, Royal Hallamshire Hospital, Sheffield, S Yorkshire, UK; 2) Sheffield Children's Hospital, University of Sheffield, Sheffield, UK.

Background and methods: Skin prick test positivity (SPT+) has been used as an intermediate phenotype for allergic asthma and atopy. In this study, we investigated the relationship between polymorphisms in the interleukin-1 gene cluster and SPT+ to multiple allergens (grass, house dust mite, cat, dog, cockroach, alternaria). Polymorphisms of IL-1 receptor antagonist (IL-1RN) (+2018), IL-1B (-511), IL-1B (-3954), IL-1A (+4845) were studied. Allelic frequencies were determined by 5 nuclease assays (Taqman allelic discrimination test) on DNA obtained from 97 families (421 individuals) recruited with two or more asthmatic siblings. Data was analysed using the transmission disequilibrium test (TDT). Results: A significant association was observed between SPT+ and IL-1RN allele 2.

Genotype		Not Transmitted	Transmitted	TDT Test	p value
	Transmitted	Allele 1	Allele 2		
IL-1RN	Allele 1	128	45	5.83	0.016
	Allele 2	71	22		

When this genotype was examined further we found (1) that the data could be replicated for at least 3 different aeroallergens and (2) there was a dose-response effect for 2 SPT+ ($p=0.035$) and 3 SPT+ ($p=0.014$). Associations with the other polymorphisms were not significant. Conclusions: Our findings suggest that a polymorphism in IL-1RN may be important in determining atopy. Abstract funded by GlaxoSmithKline.

Affected-Relative-Pair Linkage Analysis with Covariates for Hypertension in NHLBI Family Blood Pressure Program (FBPP). *X. Wu¹, B. Thiel², S. Kardiac³, D.C. Rao⁴, M. Province⁴, K. Ranade⁵, X. Zhu¹, A. Luke¹, D. Kan¹, R. Cooper¹.* 1) Dept Preventive Med/Epidemiol, Loyola Univ, Chicago, Maywood, IL; 2) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 3) Department of Epidemiology, University of Michigan, Ann Arbor, MI; 4) Division of Biostatistics, Washington University of School of Medicine, St. Louis, MO; 5) Department of Genetics, Stanford University School of Medicine, Stanford, CA.

An important factor affecting the power to detect linkage in complex diseases studies is locus heterogeneity, which can weaken or even eliminate evidence for linkage that is present only in a subset of families. In a genome scan of adult hypertension in the FBPP study, we used a model-free linkage analysis with covariates developed by Olson (1999) and extended by Goddard et al. (2001). This method is a general conditional-logistic model using affected relative pairs. Discrete or quantitative covariates included in the model increase power to detect linkage when the covariate measures differences, between families, that are important to locus heterogeneity. We performed linkage analyses in four ethnic groups (white, black, Mexican American and Asian) within four networks in FBPP separately, followed by the analyses in pooled white and black samples. Two covariates, age and body mass index (BMI), were selected because they are significantly correlated with hypertension status. Without incorporating covariates, only one region showed suggestive evidence of linkage with $P < 0.001$ ($LOD > 2.08$) in individual genome scans (marker D18S481, $LOD = 2.23$). Two more regions showed suggestive evidence of linkage ($P < 0.001$) when age or BMI was incorporated as covariate in the analysis: 2p21(marker D2S1788, $LOD = 3.09$, covariate = BMI) and 3q22 (marker D3S1744, $LOD = 3.16$, covariate = age). In the pooled black samples, a new region on chromosome 8 (marker D8S1477, $LOD = 2.84$) showed evidence of linkage in an analysis without covariates. Our results suggest that incorporating appropriate covariates may increase the power to detect linkage in complex diseases mapping.

Program Nr: 1074 from 2002 ASHG Annual Meeting

Within haplotype block: which SNPs to choose? *Q. Huang, E. Boerwinkle.* Human Genetics Ctr, Univ Texas, Houston, Houston, TX.

Linkage disequilibrium (LD) between single nucleotide polymorphisms (SNPs) caused reduced number of haplotypes defined by these SNPs. Genomic regions with limited haplotype diversity, so called haplotype blocks, have been characterized in different chromosomes by several recent studies. With the knowledge of underlying haplotype structure of the human genome, certain subset of SNPs could be typed to represent the haplotype blocks and haplotype analysis could be carried out to test the association of genomic segments with disease. But which SNPs comprise the best subset of SNPs that capture most of the information of the haplotype blocks remains unclear. Here we test the association between haplotypes derived from different subset of SNPs and disease endpoint assuming simple case/control sampling design. LD between these SNPs was also characterized. The analysis was carried out on simulated dataset from Genetic Workshop12 (GAW12), where MG6 is one of the seven major genes that contribute to a complex disease, and the location of the casual mutation is already known. Results showed that the causal mutation is not necessarily needed to detect the association. Haplotype analysis could always detect the association, but at least one of the SNPs should be in strong LD with the causal mutation. This suggests that haplotypes comprised by SNPs with low pair-wise LD capture more information than haplotypes comprised by SNPs with high pair-wise LD. Detailed LD information within haplotype blocks could help us determine which subset of SNPs should be chosen to be typed to represent the haplotype blocks.

The transcriptional factor LBP-1c/CP2/LSF gene in chromosome 12q13 is not associated with asthma in two independent populations. *A. Zambelli-Weiner¹, D.H. Farkas², V. Chan³, R.A. Mathias¹, V. Casolaro¹, K.C. Barnes¹.*
1) Johns Hopkins Asthma & Allergy Center, Baltimore, MD; 2) Baylor College of Medicine, Houston, TX; 3) Stanford University Medical Center, Stanford, CA.

CP2, also known as leader-binding protein (LBP)-1c or late SV40 factor (LSF), is a 502-aa nuclear protein shown to regulate transcription of a number of viral and cellular genes including HIV-1 and IL-4. Recent studies showed increased CP2 expression in atopic subjects and in a subgroup of Alzheimer patients. This has been shown to be concomitant to a non-coding polymorphism (GA) in the CP2 3' untranslated region (UTR) at position #2236, a region possibly regulating RNA stability. Because we have previously observed evidence for linkage to markers flanking CP2, and because of the potential role of CP2 in the allergic diathesis, we investigated whether the presence of the 3' single nucleotide polymorphism [SNP] (G2236A) and a promoter SNP (G-310T) was associated with asthma or atopy in both an Afro-Caribbean population (N=571) enriched for atopic asthma and Tangier Island, a complete Caucasian isolate (N=295). An electronic detection platform using DNA chip technology (eSensorTM; Motorola Life Sciences) has been developed for detection of specific DNA sequences for use in molecular diagnosis. In this study we applied this arrayed electrochemical detection platform for simultaneous detection of the two CP2 SNPs. There were no significant associations with asthma for either of the two CP2 SNPs in both populations. Interestingly, the A allele in the 3' SNP, which was reported to have a protective effect for Alzheimers disease in three independent Caucasian populations, was rare in both the Barbados (GA genotype=2.28%; AA genotype=0%) and Tangier Island (GA genotype=10.51%; AA genotype=0%) populations. The GG genotype conferred slightly higher total serum IgE concentrations in the Barbados parent-offspring trios (GG genotype=549.5 ng/mL vs. GA genotype=407.4 ng/mL) but was not significant. In summary, our results do not support CP2 as a candidate gene/risk factor for asthma, although its potential role in the allergic diathesis is still unclear.

Fetal and infant growth rate: genetic and environmental correlations. *E.W. Demerath, S.A. Czerwinski, B. Towne, S.S. Guo, W.C. Chumlea, R.M. Siervogel.* Lifespan Health Research Center, Wright State Univ Sch Med, Dayton, OH.

It has been recently shown that children who grow slowly in utero, but grow rapidly during infancy, appear to be at elevated risk of a number of chronic diseases in adulthood, including diabetes and coronary heart disease. The association between fetal growth retardation and postnatal "catch-up" is usually assumed to be due to the cessation (at birth) of a restrictive intrauterine environment, but the genetic associations amongst these traits are still unknown. In this study, we sought to estimate the degree to which fetal growth and subsequent infant growth rate are influenced by a common set of genetic and environmental factors. The study sample included 537 infants in the Fels Longitudinal Study (N=276 males/261 females) who were followed for two years. Weight and length were measured at birth, and length was measured at 3 months, 6 months, 9 months, 12 months, 18 months and 24 months. We modeled the serial data using a 3rd degree polynomial model, and estimated the growth rate and acceleration for length. Using a maximum likelihood variance components approach, we estimated the heritability (\pm stderr) of the traits of interest as follows: Birth Weight: $h^2=0.79\pm0.09$; Birth Length: $h^2=0.78\pm0.10$; Inf. Length Rate: $h^2=0.34\pm0.10$; and Inf. Length Acceleration: $h^2=0.34\pm0.11$ (all significant $p<0.001$). We then tested the genetic and environmental correlations among these traits. As expected we found evidence for substantial shared genetic effects influencing Birth Weight and Birth Length ($r_G=0.74\pm0.12$). Interestingly, we found no genetic correlation, but rather a moderate environmental correlation between Birth Length and Infant Length Rate ($r_G=-0.54\pm0.18$). The latter finding indicates that the environmental factor/s involved in fetal growth retardation are also involved in rapid infant growth rate. These findings demonstrate the large effect of genes on fetal and infant growth rate and bring into question the notion that "catch-up" growth is recovery from intrauterine restriction. Rather, they suggest that other environmental factors common to the pre- and post-natal environment may explain the association of low birth weight and high infant growth rate.

Effects of heredity and helminthic infections on the growth of children in rural Nepal. *B. Towne¹, S.A.*

Czerwinski¹, E.W. Demerath¹, J. Subedi², B. Jha³, J. Blangero⁴, S. Williams-Blangero⁴. 1) Wright State University School of Medicine, Dayton, OH; 2) Miami University, Oxford, OH; 3) Tribhuvan University Institute of Medicine, Kathmandu, Nepal; 4) Southwest Foundation for Biomedical Research, San Antonio, TX.

Growth is influenced by both genetic and environmental factors, but quantifying their respective contributions is not possible without measures of growth from related children and measures of specific environmental factors known to impact growth. The Jiri Growth Study was recently initiated in collaboration with the Jiri Helminth Project to examine the growth and development of children from the Jirel ethnic group in eastern Nepal where parasitic gastrointestinal infections are endemic. Because helminthic infections negatively impact child health, the goal of the Jiri Growth Study is to elucidate genetic influences on the growth and development of Jirel children taking into account helminthic infection status. In these analyses we used a maximum likelihood method for pedigree data to estimate the heritability of the stature of Jirel boys and girls, while simultaneously modeling the effects of prior history of infection with roundworms, hookworms, or whipworms on stature. Analyses were conducted on data from 1,046 children (517 boys and 529 girls) aged 3 to 18 years, most of whom are from one very large extended pedigree. The heritability of stature in this study sample was highly significant at 0.87, and significant negative effects of roundworm and hookworm infection histories on stature also were found. For example, after taking into account genetic sources of variation in stature, Jirel children with histories of roundworm or hookworm infections are some 1 - 2 cm shorter than children with no prior history of infection. These findings show stature during childhood to be highly heritable, even in this heavily parasitized population, and that in the Jirel population a significant portion of the residual phenotypic variance in childhood stature can be attributed to specific helminthic infections.

Reduced haplotype diversity at the gene encoding Hepatocyte Nuclear Factor 1 alpha. *T. Frayling, K. Thomson, K. Colclough, S. Ellard, A.T. Hattersley.* Dept Diabetes & Vascular Med., Exeter Univ, Exeter, Devon, England.

The gene encoding Hepatocyte Nuclear Factor 1 alpha (TCF1) is an important diabetes gene. Mutations cause the single gene disorder Maturity onset diabetes of the young (MODY) and in one isolated population a common variant predisposes to type 2 diabetes. It also lies in a region of chromosome 12 linked to type 2 diabetes in some genome wide scans. It is not known whether common variants in TCF1 predispose to type 2 diabetes in other populations. Recent studies indicate that due to linkage disequilibrium (LD) there is greatly reduced haplotype diversity across genes when assessing all common (minor allele frequencies (MAF) > 5%) variation. This will potentially facilitate a more robust assessment of the role of gene variation in disease association studies than previously used. We aimed to assess the variation across TCF1 and the resulting haplotype diversity. Sequencing the coding region and intron-exon boundaries in 71 unrelated diabetic (including 14 with a MODY mutation) subjects identified 13 single nucleotide polymorphisms (SNPs) (6 coding) with MAFs ranging from 3 to 37 %, 12 of which had MAFs > 5%. The 2 outermost SNPs are ~22 kbp apart and occur in the first exon and intron/exon boundary of the last exon. A pseudo-Bayesian algorithm, as implemented in the program PHASE was used to estimate haplotype frequencies. Five haplotypes were present at frequencies > 5% and accounted for 82% of all haplotypes ($p < 0.00001$ vs expected). These estimates may be biased towards haplotypes more frequent in diabetes/MODY subjects. There was no evidence that TCF1 mutations occur on certain haplotypes ($p = 0.13$) but analysis of additional subjects with TCF1 mutations and their family members is needed to assess this more accurately. Three SNPs can be used to capture all common haplotype information across the TCF1 gene in association studies. In conclusion we have shown for the first time that the diabetes gene TCF1 exhibits greatly reduced haplotype diversity. This provides further support for the hypothesis that common variation across genes occurs on a limited number of common haplotypes.

Y-Chromosomal Microsatellite Haplotypes in Populations from the Venezuelan North Western Region. *L. Borjas-Fajardo, L. Pineda Bernal, M.A. Sánchez, E. Fernández, W. Zabala, C. Castillo, L.A. Socca, A. Rojas.* Molecular Genetic Laboratory. Medical Genetic Unit. University of Zulia. Venezuela.

The first inhabitants of Zulia State, North Western region of Venezuela, were Arawaco, Caribe and Chibcha natives. Currently this region is a combination of diverse populations, which are the result of a mixture process between the native populations and immigrants, for which reason it is relevant to know and clarify the genetic structure of them. 160 genetically unrelated males were analyzed for four Y-STRs: DYS19, DYS390, DYS391 and DYS393. The samples were obtained from three populations: Maracaibo (100), Wayuu (30) and Island of Toas (30). DNA samples were extracted by conventional techniques, Y-STRs were obtained individually through PCR and samples were characterized on electrophoresis polyacrylamide gels and visualized using silver staining. Allele designation for all loci was ensured using loci-specific allelic ladders, and results were processed employing the Arlequin program. Allele frequencies of each system were compared with the mean frequencies reported in the literature for Europeans, Asians, Africans and Amerindians. It was observed that there were higher levels of gene diversity in Island of Toas and Maracaibo than in Wayuu, except for the locus DYS393 and very markedly for the locus DYS390. Fst values showed significant differences only between Maracaibo and Wayuu. Haplotype diversity was similar across the three populations. The most frequent haplotypes in Wayuu included allele markers typical of Amerindians, whilst the most frequent in Maracaibo and Island of Toas included alleles typical of Europeans. The three populations shared only three haplotypes. The most frequent haplotype found in Maracaibo and Island of Toas is present only once in Wayuu. The two most frequent haplotypes in Wayuu are absent in Island of Toas and one of them is present once in Maracaibo. The exclusive haplotypes of each population showed low levels of frequency except in Wayuu, where the haplotype 13-23-11-14 is the most frequent. It is necessary to increase the number of Y-STR markers and include some SNP, in order to study the origins of these populations in more depth.

Haplotype frequencies in the beta fibrinogen gene. *Y. Berthier-Schaad*^{1,2}, *Y. Liu*¹, *N. Fink*¹, *M.J. Klag*¹, *J. Coresh*¹, *M.W. Smith*³. 1) Johns Hopkins Med. Insts., Baltimore, MD; 2) Laboratory of Genomic Diversity, NCI, Frederick, MD; 3) Basic Research Program, SAIC, NCI, Frederick, MD.

Fibrinogen levels have been implicated as an important risk factor for cardiovascular diseases (CVD). In some studies, several nucleotide polymorphisms (SNPs) located in the promoter and the coding regions of the beta fibrinogen gene have been associated with increased fibrinogen levels and CVD. The difficulty in associating genotype and phenotype has led to the recognition that haplotype-based methods represent a promising approach to a better understanding of the genetic basis of common diseases and led to the human haplotype map project. As a step in the direction of understanding haplotypes at the beta fibrinogen gene, seven SNPs, five in the promoter region (-1420G/A, -854G/A, -455G/A, -249C/T, -148C/T) and two in the coding regions (345C/T in exon 7, 448G/A in exon 8), were analyzed. We obtained 1186 haplotypes from a population of 784 incident dialysis patients of the CHOICE cohort. Haplotypes and their frequencies were estimated using the PHASE program. Six major haplotypes were observed: GGGCCCG (47%, 67%); GAGCCCG (13%, 9%); GGGTCCG (21%, 7%); AGACTTA (16%, 5%) in European Americans and African Americans respectively. Two haplotypes GGGCCCA and AGGCTCG were present in African Americans only with a frequency of 5% each. The fibrinogen haplotypes can be separated into three natural groups where each group only differs stepwise from the others by one nucleotide, a C to T mutation on one of the DNA strands. A haplotype tree can be generated using GGGCCCG as the ancestral haplotype. These findings are consistent with recent analyses of haplotype blocks showing that 6 to 8 common SNPs suffice to identify common haplotypes in a region inherited without significant historic recombination. A greater diversity of haplotypes was also found in African Americans. Determination of these haplotypes will facilitate their evaluation relative to CVD and fibrinogen levels in patient cohorts. Program Nr: 1081 from 2002 ASHG Annual Meeting

Investigation of MtDNA haplogroups and mitochondrial disorders(Report from Iran). *M. Houshmand, F. Sharifpanah, A. AleMohamad, M. Rahmani, F. Babrzadeh, M. Vakilian, S. Joughehdoust, M.H. Sanati.* Medical Genetics Unit, National Research Center for Genetic Engineering and Biotechnology Tehran, Iran.

Analysis of the mtDNA haplogroups is, however, not only restricted to the studies of human origin and evolution. It is also very important for studies of human pathologies. Indeed, recent studies have shown that mtDNA haplogroups can play an important role in modulating disease/phenotype expression. Such as Multiple Sclerosis (MS) (haplotype K and J); Leber Hereditary Optic Neuropathy (LHON) (haplogroup J). The early history of man in Iran goes back well beyond the Neolithic period, it begins to more interesting around 6000 BC, when people began to domesticate animals and plant wheat and barley. The number of settled communities increased particularly in the eastern Zagros mountains. For analysis of MtDNA haplogroup in Iranian population we started with 11778, 3460, 14484, 14459 mutations in 24 LHON and 50 MS affected patients. We detect 11778 mutation from 5 LHON patients and no association found between MS and these mutations. Haplogroup J is only about 9% of general European population but it was found in 37% of LHON patients harboring the LHON mutation. *HinfI* restriction site at np 16065 (haplogroup J) analyzed in our 5 screened LHON patients (positive for 11778) and 20 MS patients. Haplogroup B defined by the 9np COXII-tRNA Lys deletion that is common throughout central and southern Asia and is prominent in coastal Asian population but was absent from all 152 Iranian that we analysed. (Arab, Turk, Kurd, Lor, Baluchi groups) Other prominent Asian haplogroup G and also found in the European populations was detected in one Friedreich Ataxia patient. More investigation is needed to identify that there is any relation between Friedreich Ataxia and haplogroup G or not.

Endothelial constitutive nitric oxide synthase gene polymorphism in Korean population. *S. Han, Y. Jung, J. Oh, M. Oh.* Biology, Cheju National University, Cheju, Cheju, Republic of Korea.

Endothelium-dependent vasodilatation is mediated by nitric oxide formed by constitutively expressed endothelial nitric oxide synthase (eNOS). Recently, three point mutations, variable numbers of tandem repeats (VNTR), microsatellite (CA)_n polymorphism, and Glu298Asp in the endothelial constitutive nitric oxide synthase gene have been reported. In addition, the significant associations of the *eNOS4b/a* polymorphism in intron 4 VNTR and Glu298Asp (G1917T) with coronary artery disease, essential hypertension, renal diseases and Alzheimer's disease have been reported in some populations. We analyzed the VNTR of *eNOS* intron 4 using polymerase chain reaction, polyacrylamide gel electrophoresis, and DNA sequencing. We inspected the polymorphism of the *eNOS* intron 4 in 228 healthy individuals of Korean population. The detected alleles were *b* and *a*, keeping four or five tandem 27-bp repeats, respectively. The genotype frequencies of *eNOS4b/b*, *eNOS4b/a*, and *eNOS4a/a* were 79.82%, 18.86%, and 1.32%, respectively. VNTR of intron 4 showed also polymorphism in Korean population, but allele *c* containing six tandem repeats was not found. On the basis of these results, we will investigate the associations between the polymorphisms of *eNOS* gene and related diseases.

Aldehyde dehydrogenase 2 (ALDH2): Strong LD around the world. H. OOTA, A.J. PAKSTIS, J.R. KIDD, K.K. KIDD. Dept Genetics, Yale U, New Haven, CT.

Aldehyde dehydrogenase 2 (*ALDH2*) is a major enzyme in acetaldehyde oxidation related to alcohol metabolism. The catalytic deficiency of human *ALDH2* has been well known to be present only in East Asia, which is caused by a substitution (G to A) inducing Glu to Lys amino acid change in exon12 (Ex12c). We have typed five SNPs and one STRP for 2006 individuals from 38 worldwide populations. The five SNPs have been selected to cover the *ALDH2* locus uniformly. Four non-coding SNPs are located approximately 40, 30, 20 and 10kb upstream of Ex12c, whereas the STRP site, D12S1344 (CA)_n, is 83kb downstream of this functional variant. Analyses are complete for 33 of the 38 populations.

The polymorphism in intron1 (30kb from Ex12c) is found in Ethiopian Jews and most non-African populations at moderate to high heterozygosities, but was not seen in many west African and central African populations and only rarely in other Africans. Thus, not considering the functional Ex12c variant, only four of 16 possible haplotypes account for almost all chromosomes in all populations. Only three of those haplotypes are common in African populations. The functional variant, Ex12c, occurs on one of those to define a fifth common haplotype in East Asians. The frequencies of those common haplotypes are quite similar within regions of the world but differ considerably from region to region. The STRP shows LD in Africa with different allelic distributions on the three common *ALDH2* haplotypes. The LD is even stronger in non-African populations with more reduced distributions of STRP alleles associated with the four common haplotypes. Thus, LD is strong and highly significant in all parts of the world extending across 120kb.

The *F_{st}* values in 32 populations for the most upstream SNP and Ex12c were .30, and .26, respectively, about two SD above the average of 94 reference sites on other chromosomes (.14). These results suggest that the *ALDH2* locus might have experienced selection as modern human populations evolved. [Supported in part by NIH grant AA09379].

Mitochondrial DNA Diversity Among the Five Civilized Tribes of Oklahoma. *C.A. Jantzen, S. Stevens.* Latta High School, Ada, OK.

To show the feasibility of assessing mtDNA diversity in close Native American tribes, hair follicle DNA was extracted from 20 individuals of each of 5 tribes, after gaining science fair IRB approval, chiefs' permission, and individual informed consent. We only took individuals of strict maternal descent from a full blooded woman of one of the Five Civilized Tribes, who were forced to migrate from the southeast US in the 1820s. 440 nucleotides in the HVI region were amplified; Cold Spring Harbor Laboratories sequenced the fragments. The numbers of single nucleotide differences between all possible pairs of subjects within a tribe were averaged ("intratribal differences"); the intertribal difference was similar mean for all possible pairs of subjects, taken one from each tribe. The smallest differences within single tribes was in the Chickasaw; the most, in the Cherokee; findings consistent with other linguistic and historical evidence. Intertribal differences were least between Creeks and Choctaws and greatest between Creeks and Cherokees; these differences are unexplained.

Chickasaws	Choctaws	Muscogee	Seminoles	Cherokees
Intratribal 4.4	Intratribal 5.5	Intratribal 6.1	Intratribal 11.0	Intratribal 13.6
Intertribal 9.4	Intertribal 8.8	Intertribal 10.6	Intertribal 10.1	Intertribal 13.2
Choctaw 7.8	Chickasaw 7.8	Chickasaw 8.7	Chickasaw 8.3	Chickasaw 12.7
Muscogee 8.7	Muscogee 6.9	Choctaw 6.9	Choctaw 7.6	Choctaw 11.8
Seminole 8.3	Seminole 7.6	Seminole 10.9	Muscogee 10.9	Muscogee 14.7
Cherokee 12.7	Cherokee 11.9	Cherokee 14.7	Cherokee 13.5	Seminole 13.5

Ethnic differences in polymorphisms in GCLC, the gene that encodes the catalytic subunit of glutamate cysteine ligase. A.S. Willis¹, M.L. Freeman², S.R. Summar³, S.M. Williams⁴, E. Dawson⁵, F. Barr⁶, M.L. Summar³. 1) Molecular Physiology and Biophysics, Vanderbilt University Medical Center, Nashville, TN; 2) Radiation Oncology, Vanderbilt University Medical Center, Nashville, TN; 3) Pediatrics/Genetics, Vanderbilt University Medical Center, Nashville, TN; 4) Meharry Medical College, Nashville, TN; 5) BioVentures, Inc., Murfreesboro, TN; 6) Pediatric Cardiology, Vanderbilt University Medical Center, Nashville, TN.

GCLC is the gene that encodes the catalytic subunit of glutamate cysteine ligase, a heterodimeric enzyme that catalyzes the first step in *de novo* synthesis of glutathione, an abundant biomolecule. Glutathione plays roles in many cellular processes including the scavenging of free radicals to neutralize oxidative stress. The pathophysiology of several diseases, including neurodegenerative diseases, and progression of HIV infection, is thought to involve glutathione and oxidative stress. We have identified 11 polymorphisms in GCLC and determined allele frequencies in Caucasians and African Americans. Allele frequencies for 4 polymorphisms, C1384T, IVS12+83G/A, IVS12-21G/A, and 1974-1975insCAGC, differ between Caucasians and African Americans ($p < 0.05$). The allele frequencies for IVS12+83G/A and 1974-1975ins CAGC, vary widely between the two groups ($p < 0.001$). One polymorphism, the nonsynonymous C1384T, has been found only in individuals of African descent; the rare allele (T) has an allele frequency of 2% in African Americans and 5% in Africans from Ghana in western Africa. Proline 462, which is changed to a serine by the T allele, is conserved in a number of eukaryotic species, suggesting that this polymorphism may have functional significance.

Derivation of immortal cell lines from monospermic complete hydatidiform moles: A new resource for haplotype discovery. *V.P. Stanton Jr¹, W.C. Hahn², W. Wojcicki¹, J. Olson¹, S. Jasani³, P.-Y. Kwok⁴, U. Surti³.* 1) Variagenics, Cambridge, MA; 2) Dana-Farber Cancer Institute, Boston, MA; 3) Department of Pathology, University of Pittsburgh, Pittsburgh, PA and Magee-Womens Research Institute, Pittsburgh PA; 4) University of California, San Francisco, CA.

Haplotypes are expected to provide a more powerful system for allele classification than genotypes, and to lead to improved methods for genetic association studies. The only robust methods for haplotype discovery are pedigree analysis and sequencing cloned DNA. Both approaches are inefficient for determining the haplotypes of specific genes in large numbers of subjects. Monospermic complete hydatidiform mole (MCHM) is a rare human tumor formed by the fertilization of an anuclear ovum by a single sperm with subsequent duplication of the paternal chromosomes, yielding a diploid cell which is completely homozygous. DNA sequencing or genotyping of MCHMs yields haplotypes. Exploitation of MCHMs for haplotype identification has been constrained by the difficulty of obtaining material, and by the limited amount of DNA that can be obtained from each specimen. We report that high efficiency introduction of the telomerase catalytic subunit, hTERT, immortalizes human MCHMs.. DNA from eight immortalized MCHMs was proven to be homozygous by DNA sequencing and genotyping. One of us (US) had the foresight to collect primary cultures of MCHMs for the last 20 years. Application of the TERT immortalization method will lead to the production of large numbers of completely homozygous cell lines, suitable for efficient identification of both common and rare haplotypes in genes of interest.

A coalescent estimate of ancestry informative markers in the genome. *C.L. Pfaff, J.C. Long.* University of Michigan Medical School, Ann Arbor, MI.

Admixture between genetically distinct populations can create non-random allelic associations (linkage disequilibrium) that can be used to map genes (Admixture Mapping). In order to effectively perform an admixture mapping study, it is important to identify a panel of Ancestry Informative Markers (AIMs), for which the allele frequencies in the founding populations are very different. The prevalence of AIMs in the genome is unknown. We have developed a coalescent program to simulate population divergence and microsatellite evolution using a stepwise mutation model in order to estimate the proportion of ancestry informative microsatellite loci in the genome. For each set of simulations, the effective population sizes and mutation rates were set according to the observed variance in allele size. Results show that, with a divergence time of 4000 generations ago and simulated founding populations with effective sizes of 10,000 and 5000 (approximating African and European effective sizes), a relatively large proportion of microsatellite loci demonstrate ancestry informative differences in allele frequency. The difference in allele frequency between populations is measured as d_c , which is calculated as the sum of the absolute values of the allele frequency differences for each allele size, divided by 2. On average, 43% of simulated microsatellite loci (out of 10,000 replications) exhibit a $d_c \geq 0.5$ when the mutation rate equals 0.0005 (mutations per generation) and 20% exhibit a $d_c \geq 0.5$ when the mutation rate equals 0.00005 (sample size = 50 observations from each population). For effective population sizes of 5000 and 2000 (approximating European and Native American effective sizes), an average of 70% of simulated loci exhibit a $d_c \geq 0.5$ when the mutation rate equals 0.0005 and 39% exhibit a $d_c \geq 0.5$ when the mutation rate equals 0.00005. These results are consistent with observational data for African American, Native American, and European American population samples and suggest that the abundance of AIMs in the human genome will make it possible to perform effective genome-wide admixture mapping studies. Efforts, therefore, should be made to identify AIMs throughout the genome and assemble a genome-wide admixture mapping panel.

Mannose-binding lectin and mtDNA Genotypes in Peruvian islanders (Quechua and Aymara) of the Lake

Titicaca. *J. Sandoval*¹, *H.O. Madsen*², *P. Garred*², *R. Fujita*¹. 1) Instituto de Genetica y Biologia Molecular, Facultad de Medicina, Universidad de San Martin de Porres, Alameda del Corregidor Cdra. 15, La Molina, Lima, PERU. rfujita@amauta.rcp.net.pe; 2) Dpt. of Clinical Immunology, National University Hospital, Copenhagen, Denmark.

Mannose-binding lectin (MBL) is a serum protein important for immunity, its defective alleles are associated with increased risk of infections and autoimmunity. The defective allele B (codon 54) was found in high frequency in one Amerindian population. We are interested in characterizing native Peruvian populations; thus, we analysed MBL genotypes (n=103) and mtDNA subtypes (n=144) in school children from islands on the Peruvian side of the Lake Titicaca: Taquile (T) and Amantani (Am) who speak Quechua; and Anapia (An) and Los Uros (U) who speak Aymara. We report the highest overall frequency (64%) of the allele B seen in any population so far. However, the distribution of the MBL genotypes differed highly significantly between Quechuas and Aymaras ($P < 0.0001$). Regarding mtDNA we found the highest scores of subtype B1 so far described (T = 100%, Am = 88.6%, An = 87.5%, and U = 75%). Other subtypes exist but in Los Uros it is noticeable the presence of A2 (17%), that is absent in the other islands. Our results indicate genetic differences between Quechua and Aymara populations. Due to the homogeneity of the genetic markers Taquile and Amantani seem to have been populated by a reduced founder group in agreement to one of the local oral traditions. The ethnical group "Uru" was assumed extinct from Peru; but our results suggest that contemporary Los Uros islanders still may have an "Uru" genetic background. Our preliminary studies in Amazonian populations suggest affinity with Los Uros, proposed decades ago by language and protein comparisons. The high frequency of the defective MBL allele B remains a very important topic to investigate in future epidemiological studies. Rapid purification of archival-quality DNA from large whole blood samples using a new rapid protocol. *J. Long¹, H.-W. Deng¹, Y. Zhang¹, L. Zhao¹, E. Hofer², C. Seemann², D. O'Brien².* 1) Creighton University, Omaha, NE; 2) Genra Systems, Minneapolis, MN.

Statement of Purpose: The efficient and effective purification of high quality DNA from large whole blood samples to support clinical studies has become increasingly important as laboratories around the world initiate studies designed to identify the underlying genetic contributions to the most common human diseases. The purification process has traditionally involved hazardous reagents and tedious protocols that compromise both the yield and quality of DNA. The purpose of this study was to identify a more rapid purification method that would provide high quality DNA suitable for archiving. We describe a new protocol, called PUREGENE EP(Enhanced Productivity), for use with the commercially available PUREGENE DNA Purification Kit, (Genra Systems, Inc.). This protocol dramatically reduces the total purification time without compromising yield or quality.

Methods: DNA was purified from replicate 10 mL human whole blood samples using the PUREGENE kit and either the standard PUREGENE protocol or the new PUREGENE EP protocol. The yield of DNA was determined by UV spectrophotometry. The quality of the purified DNA was assessed by analysis of the A_{260}/A_{280} ratio, gel electrophoresis, and performance in PCR amplifications.

Summary of results: Comparison of DNA from purified replicate human whole blood samples with the standard PUREGENE protocol and the PUREGENE EP protocol showed that the PUREGENE EP protocol was 50% faster while maintaining high DNA yield and quality. Yields were equivalent: ~ 300 g of DNA from 10mL samples from both the standard PUREGENE and the PUREGENE EP protocols. In addition, the quality of DNA isolated with the two methods, as measured by A_{260}/A_{280} ratios, DNA fragment size and performance in downstream assays, including PCR, was equivalent. These results suggest that the PUREGENE EP protocol provides effective and efficient purification of high quality DNA suitable for archiving while reducing the time required for purification.

Haplotype Map Of The Chromosome 17 CC Chemokine Gene Cluster. *W.S. Modi¹, M. Jamba¹, B. Roemer-Binns¹, C. Winkler¹, S. O'Brien².* 1) SAIC, NCI-Frederick Cancer Res, Frederick, MD; 2) Lab Genomic Diversity, NCI-Frederick Cancer Res, Frederick, MD.

Chemotactic cytokines mediate the directed migration of various cell types including monocytes, neutrophils, lymphocytes and megakaryocytes. These proteins are also involved in normal metabolic functions including T-cell development, signal transduction, and neuron differentiation. Further, HIV-1 uses chemokine receptors for cell entry, and several ligands are known to limit in vitro infection. Sixteen CC chemokine genes reside in three segments spanning 2 Mb at 17q21. These include: MCP-1, MCP-3, EOTAXIN, MCP-2, MCP-4, and I-309 in a 200 kb segment; RANTES, LEC, HCC-1, MPIF-1, HCC-2 PARC, MIP-1A and ACT-2 in a 250 kb segment; and LD78B and LAG-1 in a 40 kb segment. We have identified about 125 single nucleotide polymorphisms (SNPs) at varying densities covering each of the three segments. One hundred seventy-five individuals from each of three racial groups: European American, African American, and Chinese are being genotyped in order to determine allele and haplotype frequencies. Preliminary results indicate extensive linkage disequilibrium and reduced haplotype diversity exists within each segment. A complete definition of the haplotype structure in the entire 2 Mb region will enable targeted genotyping using representative SNPs in subsequent disease association studies. Funded in part by NCI, NIH Contract No. NO1-CO-124000.

Linkage Disequilibrium and Haplotype Structure of the Protein Tyrosine Phosphatase 1B (PTPN1) Gene Region on Human Chromosome 20. *M. Olivier, D. Savic, S. Brauer.* Human & Molecular Genetics Center, Department of Physiology, Medical College of Wisconsin, Milwaukee, WI.

Single nucleotide polymorphisms (SNPs) are of major interest for association studies in common human diseases. Factors that determine the usefulness of these markers are the extent of linkage disequilibrium (LD) between them, and the number of observed haplotypes in regions of significant LD.

In this study, we analyzed SNPs and the resulting haplotype patterns on human chromosome 20 surrounding the PTPN1 gene. The protein encoded by this gene, protein tyrosine phosphatase 1B, is associated with and regulates the activity of the insulin receptor. Several SNPs in this gene have been shown to be associated with type 2 diabetes, insulin resistance, and hypertension in humans. The gene PTPN1 is located on 20q13, and consists of ten exons covering 75 kb of genomic sequence.

We have previously identified SNPs in this genomic interval as part of our disease association studies. For the analysis of the LD and haplotype structure of the region, we selected 25 SNPs covering over 150 kb of genomic sequence around PTPN1. SNPs were genotyped on 90 unrelated individuals from different ethnic origin, and on ten Utah CEPH families (80 individuals) to obtain unambiguous haplotypes. SNPs in a region of over 100 kb covering the entire coding sequence of PTPN1 are in significant pairwise LD. Within this region, only four haplotypes with a frequency of greater than 5% can be identified. Alleles of SNPs that were previously identified in disease association studies are represented in these four major haplotypes. Data will be presented on the effects of different haplotypes on mRNA and protein levels of PTPN1 in human cells, and the potential functional relevance of these haplotypes for gene function.

Molecular genotyping and distribution of A¹, A², B, O¹, and O² alleles of the ABO locus in a Kuwaiti population.

*M.M. El-Zawahri*¹, *Y.A. Luqmani*², *K.M. Al-Hurais*¹. 1) Dept Biological Sci, Fac Sci, Kuwait Univ, Safat, Kuwait; 2) Dept Pharmaceutical Chemistry, Fac Pharmacy, Kuwait Univ, Kuwait.

The present study is the first demonstration of an extensive variability linked to A¹, A², B, O¹ and O² alleles of the ABO locus in a Kuwaiti population. Genomic DNA from 200 unrelated healthy Kuwaiti blood donors was amplified using primers A10 and AB2. These primers amplify a 357-bp fragment, spanning nucleotides 385-742 of the ABO cDNA sequence. Diagnostic restriction enzyme digestions were carried out using either PvuII for the detection of the A² allele or BssHII for the detection of the O² allele. To distinguish the A allele from the O² allele, we chose to use nucleotide 526, which is a cytosine in the A (and O¹) alleles, but a guanine in the O² (and B) alleles. The base substitution in the O² and B alleles abolishes a BssHII restriction enzyme site found in the A and O¹ alleles. The typing at position 703 distinguishes the O² allele from the B allele. The base change at nucleotide 467 changes an MspI restriction enzyme site in the A¹ allele to a PvuII site in the A² allele. 13 genotypes arising from the major alleles of the ABO blood group; A¹, A², B, O¹ and O²; were distinguished in the Kuwaiti sample population. The calculated allele frequencies of A¹, A², B, O¹ and O² were 0.1579, 0.0199, 0.1566, 0.6243 and 0.0413, respectively. These frequency data of a Kuwaiti population may provide a useful additional information for forensic, population genetics, phylogenetics and evolution studies.

This work is supported by a grant from Kuwait University (SZ 01/00).

The FKRP L276I change: High allele frequency and common cause of LGMD. *K. Gorni, M. Bakay, J. Devaney, E. Hoffman.* Res Ctr Genetic Medicine, Children's Ntl Medical Center, Washington, DC.

Limb-girdle muscular dystrophy (LGMD) is a disorder where weakness affects mainly the proximal limb-girdle musculature. To date, 15 genetically different types have been identified, which show great clinical and genetic heterogeneity. Autosomal dominant forms are very rare and generally less severe than recessive types. In 2001 Brockington et al used database mining to identify a gene related to the Fukuyama muscular dystrophy gene (FKRP), and showed association of mutations of this gene in both congenital muscular dystrophy and limb-girdle muscular dystrophy. Interestingly, a single C826A mutation (Leu276Ileu) was found homozygous in the large majority of LGMD mutation-positive changes, and this same change was found in 1:100 normal individuals, suggesting a high carrier rate for this change. We undertook a retrospective mutation analysis of 66 potential LGMD2I patients that had a previous inconclusive biopsy study. We choose to include in our sample a group of patients showing clinical features consistent with a limb-girdle muscular dystrophy and with a reduction of all proteins regularly screened in suspected muscular dystrophies. We performed first a restriction enzyme analysis confirming our cases with the sequence analysis, looking in both cases for the most frequently found mutation (the C826A, Leu276Ileu). We found 5 patients (9%) carrying this change, four as homozygotes (1 male and 3 females), and one compound heterozygote (male). This study confirms this single mutation as a relatively common cause of recessive LGMD, and suggests a founder effect and possible heterozygote advantage given the high frequency of this missense change. Antibody results are presented, as well as a non-PCR-based 3rd WAVE assay for rapid genotyping. We suggest that all Caucasians with LGMD should be screened for the FKRP L276I change. In addition, this data has ramifications for genetic counseling, given the relatively high rate of the change in the Caucasian population.

Genetic Variation in Beta Fibrinogen (FGB) and Plasma Fibrinogen Levels in Dialysis Patients: the CHOICE Study. *Y. Liu¹, Y. Berthier-Schaad², N. Fink¹, R.P. Tracy³, M.J. Klag¹, M.W. Smith⁴, J. Coresh¹ and The CHOICE Study.* 1) Johns Hopkins Medical Institutions, Baltimore, MD; 2) Laboratory of Genomic Diversity, NCI, Frederick, MD; 3) University of Vermont, Burlington, VT; 4) Basic Research Program, SAIC, NCI, Frederick, MD.

Hyperfibrinogenemia is common among dialysis patients and may be related to an elevated risk of cardiovascular disease. We tested the hypothesis that genetic variation in FGB, shown to explain 1-5% of fibrinogen level variation in the general population, plays an important role in elevated fibrinogen levels among dialysis patients. Methods: Plasma fibrinogen was measured on 678 dialysis patients a median of 3 months from the start of dialysis using an automated clot-rate assay. Seven polymorphisms of the beta-fibrinogen gene were determined. Haplotype analysis was conducted using the PHASE program to estimate haplotype frequency with stratification for race. Multiple linear regression was used to analyze the association of fibrinogen with the haplotypes assuming an additive model. Results: Mean [SD] fibrinogen concentrations were high and varied by ethnicity (Blacks: 357[120] mg/dl, Whites 382[120], $p=0.006$). Genotype frequencies were in Hardy-Weinberg equilibrium. Four common haplotypes identified were not associated with fibrinogen levels in the whole cohort, or after stratification by race. The A allele at 455, known to alter gene expression in vitro, was positively associated with fibrinogen levels only in non-diabetics (30 mg/dl for +1 copy of A allele, $p=0.034$, $R^2=2\%$). After adjustment for age, gender, race, smoking, baseline dialysis modality, comorbidity, and statin use, this association was only marginally significant (21 mg/dl for +1 copy of A allele, $p=0.07$). Conclusion: In this study, beta fibrinogen gene does not play an important role in determining variation in elevated plasma fibrinogen levels among dialysis patients. Susceptibility to Psoriatic Arthritis: influence of activating Killer Immunoglobulin-like Receptor genes. *M.P. Martin*¹, *G. Nelson*¹, *J-H. Lee*², *F. Pellett*³, *X. Gao*¹, *J. Wade*⁴, *M. Wilson*⁵, *J. Trowsdale*⁶, *M. Carrington*¹. 1) SAIC, NCI at Frederick, Frederick, MD; 2) LGD, NCI at Frederick, Frederick, MD; 3) Toronto Western Research Institute, and Centre for Prognosis Studies in the Rheumatic Diseases, Toronto Western Hospital, Toronto, Canada; 4) Regional HLA Laboratory, University Health Network, Toronto, Canada; 5) GlaxoSmithKline, Stevenage, UK; 6) University of Cambridge, Cambridge, UK.

Natural killer (NK) cell activity is controlled by a complex array of activating and inhibitory signals occurring in part through the interactions between killer immunoglobulin-like receptors (KIR) on the NK cell surface and their respective HLA class I ligands. The independent segregation of *HLA* and *KIR* genes along with specificity of each receptor for particular HLA allotypes raises the possibility that any given individual may express one or more KIR molecules for which no HLA ligand is present. Here we report that individuals who have genes encoding the activating *KIRs* *2DS1* and *2DS2*, are relatively susceptible to developing psoriatic arthritis, but only in the absence of HLA C ligands for the homologous inhibitory receptors *2DL1* and *2DL2/3* respectively. A model is presented in which absence of the ligands for inhibitory KIRs could potentially lower the threshold for NK (and/or T) cell activation mediated through activating receptors, thereby contributing to the pathogenesis of psoriatic arthritis. This project has been funded by DHHS #NO1-CO-12400, the Arthritis Society, and the Canadian Institutes for Health Research.

Interleukin-10 gene polymorphisms are associated with asthma phenotypes. *H. Lyon*^{1,3}, *C. Lange*², *E.K. Silverman*¹, *A. Randolph*^{1,3}, *D. Kwiatkowski*¹, *B.A. Raby*¹, *R. Lazarus*¹, *K. Weiland*¹, *N. Laird*², *S.T. Weiss*¹. 1) Channing Laboratory, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 2) Harvard School of Public Health, Boston, MA; 3) Children's Hospital, Boston, MA.

Introduction: IL-10 is an anti-inflammatory cytokine reported to have lower protein levels in asthmatics. Since reduced IL-10 levels may influence the severity of asthma phenotypes, we examined IL-10 SNPs for association with asthma severity and allergy phenotypes.

Method: Utilizing DNA samples from 518 Caucasian asthmatic children from the Childhood Asthma Management Program (CAMP) and their parents, we genotyped six IL-10 SNPs: 3 in the promoter, 2 in introns and one in the 3' UTR. Using family-based association tests in the FBAT program, each SNP was tested for association with asthma and allergy phenotypes individually and by multilocus analysis. IgE, eosinophil counts, and number of positive antigen skin tests were used as allergy phenotypes. Asthma severity was assessed by measurements of post bronchodilator forced expiratory volume in one second (FEV1) percent predicted and response to methacholine as measured by log PC20. Bronchodilator response phenotypes were also assessed at baseline enrollment in the study. **Results:** One promoter SNP (-1119A>G) and the 3' UTR SNP (c4299T>C) were significantly associated with post bronchodilator FEV1 percent predicted ($p=0.025$ and 0.0002 , respectively). SNP c4299T>C was also associated with the number of positive skin tests ($p=0.003$). SNP -1119A>G was associated with IgE level ($p=0.049$). The multilocus analyses showed a significant association between asthma severity and all six SNPs ($p=0.006$) as well as the four SNPs that defined the most common haplotype in Caucasians ($p=0.005$). **Conclusions:** Polymorphisms in IL-10 are associated with asthma severity and allergy in this cohort. Further studies of variation in the IL-10 gene may help elucidate the mechanism of asthma development in children.

Meta-analysis of the association of peroxisome proliferator-activated receptor (PPAR-gamma) *Pro12Ala* polymorphism with body mass index: a potential marker for diabetic tendency. *L.L. Roberts, J. Coresh, J.B. Hetmanski, T.H. Beaty.* Department of Epidemiology, Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD.

Peroxisome proliferator-activated receptor-g2 (PPAR-g2) is a nuclear receptor that regulates adipocyte differentiation and possibly insulin sensitivity with a common proline-to-alanine substitution (*Pro12Ala*). A number of association studies of this *Pro12Ala* variant with body mass index (BMI) have reached contradictory conclusions. We conducted a meta-analysis to examine rigorously whether the PPAR-g2 *Pro12Ala* variant is associated with higher BMI, document the extent of heterogeneity across studies, and assess whether measured covariates could explain this heterogeneity. A search of the literature revealed 33 subpopulations (17 Caucasian, 9 Asian and 7 Finnish) with relevant data published from 1998 to 2001. In the pooled sample size of 13,414 genotypes (2315 -/A variant, 11,099 P/P wildtype), the overall standardized mean BMI difference between variant -/A and wildtype P/P genotypes in a random effects meta-analysis was 0.11 kg/m² (95% CI [0.03, 0.18], p=0.004). However, heterogeneity of the association with BMI was highly significant ($c^2_{df=32} = 222.97$, $p < 0.0001$). The genotypic difference in mean BMI was significant for Caucasians (0.15 kg/m², 95% CI [0.04, 0.27]) and for the 18 published subpopulations without type 2 diabetes (0.19 kg/m², 95% CI [0.09, 0.29]), but the between study heterogeneity remains significant. In summary, the association of the PPAR-g2 *Pro12Ala* variant with BMI is weak overall and inconsistent across studies suggesting unidentified modifiers or publication bias without causal association.

Rapid Confirmation of Southeast Asian (--^{SEA}) and Filipino (--^{FIL}) α -Thalassemia Genotypes from Newborn Screening Samples. *U. Bhardwaj*¹, *Y.H. Zhang*¹, *L. McCabe*^{1,2}, *W. Blackburn*³, *E.R.B. McCabe*^{1,2,4}. 1) Department of Pediatrics, and; 2) Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA; 3) Hemoglobinopathy Screening Section, Texas Department of Health, Austin, TX; 4) Molecular Biology Institute, UCLA, Los Angeles, CA.

α -Thalassemia, the most prevalent genetic disorder, frequently results from the deletion of one (α^+ : $-a/$) or two (α^0 : $--/$) cis linked α -genes on chromosome 16. Homozygosity for α^0 -thalassemia ($--/--$) is a serious health problem and is responsible for the majority of hydrops fetalis in Southeast Asia. Asian immigration into the United States has impacted the demography of genetic diseases, particularly the hemoglobinopathies. Asians comprise 10% of California births and represent the population at highest risk for α^0 -thalassemia. The purpose of our investigation was to develop a single-tube PCR assay using neonatal dried blood specimens to identify individuals with α^0 -thalassemia due to the Southeast Asian deletion (--^{SEA}) and/or the Filipino deletion (--^{FIL}). A multiplex PCR assay was performed using the gap-PCR strategy. Primers were designed across the --^{SEA} and --^{FIL} deletion breakpoints. The PCR assay generated products for the normal genotype, as well as for the --^{SEA} and the --^{FIL} deletions. This technique was standardized on cell lines with known --^{SEA} and --^{FIL} deletions (NIGMS Human Mutant Cell Repository). We tested this multiplex PCR approach on 21 anonymized blood spots from neonates of Asian descent showing Hb Barts on newborn screening. We found that 12 samples were heterozygous for the --^{SEA} deletion and one for the --^{FIL} deletion. The other eight samples of the presumed α -globin defect may have had mutations other than --^{SEA} and --^{FIL}. We conclude that neonatal dried blood spots can be used to screen for severe α -thalassemia deletions among individuals of Southeast Asian and Philippine descent. We speculate that the implementation of DNA confirmation for α^0 -thalassemia using the original newborn screening sample will not only accelerate accurate diagnosis, but will also facilitate carrier detection, genetic counseling and prenatal diagnosis for future pregnancies in these families.

Investigation of the age dependent genotype frequencies of candidate genes for coronary atherosclerosis in healthy blood donors. A. Kabisch¹, S. Schulz², P. Greiser², U. Mueller-Werdan³, K. Werdan³, C. Glaeser². 1) Bloodbank, MLU, Halle, Germany; 2) Inst. of Human Gen., MLU, Halle, Germany; 3) Dep. of Intern. Med., MLU, Halle, Germany.

Atherosclerosis is a complex disease influenced by a variety of environmental and genetic factors. Among the genetic factors there are a lot of well investigated established risk markers like e.g. polymorphisms (PM) in the ACE-, ApoE-, and E-selectin-gene as well as the Leiden-PM in the factor V-gene. Methods: We investigated the genotype distribution of the above-mentioned PM in a group of 362 long-standing healthy blood donors without any coronary symptoms and coronary risk factors including hypertension, smoking, diabetes mellitus and drug treatment (medical monitoring >3y; mean age: 41.9y; 61.3% male). All blood donors belong to the same Central German Caucasian origin. Results: For evaluation of the genotype distributions the DD- (ACE), the 3/4- (ApoE), the Arg/Arg- (E-selectin) as well as the AA-genotype (factor V) were considered pathologically in terms of coronary atherosclerosis in common consent. We evaluated the score of the pathological genotypes taking the gender as well as the age (18-29y vs. 30-39y vs. 40-49y vs. 50-70y) into consideration. We could not detect any gender specific significant differences in the score within the group of healthy blood donors irrespective of age ($p=0.542$) even though it is known that there is a gender specific preference to the incidence of coronary afflictions. In addition one could imagine that with increasing age the number of these pathological genetic risk markers should be decreased considerably in the group of healthy blood donors because of the supposed cardiovascular susceptibility of persons carrying these genotypes. Surprisingly this expected decrease with age was not found among the healthy blood donors ($p=0.337$). Conclusions: Our results suggest that the investigated genetic markers are not predictors for the incidence of coronary atherosclerosis in general. These findings do not rule out that these PMs could be markers for the progress and therefore for a practicable clinical therapy of the complex atherosclerotic disease.

Genetic Risk Factors for Pediatric Tuberculosis Disease. *S. Malik*^{1,2}, *L. Abel*³, *H. Tooker*⁴, *A. Poon*¹, *L. Simkin*¹, *M. Girard*¹, *G. Adams*⁴, *J.R. Starke*⁴, *K. Connely-Smith*⁴, *E.A. Graviss*⁴, *J.M. Musser*⁵, *E. Schurr*^{1,2,6}. 1) McGill Centre for the Study of Host Resistance; 2) Department of Medicine, McGill University, Montreal, PQ, Canada; 3) INSERM U550, Hopital Necker, Paris, France; 4) Baylor College of Medicine, Houston, TX; 5) Laboratory of Human Bacterial Pathogenesis, NIH, Hamilton, MT; 6) Department of Human Genetics, McGill University.

Tuberculosis, an infectious disease caused by *Mycobacterium tuberculosis* kills an estimated 2 million people per year. There is strong evidence that tuberculosis susceptibility is strongly influenced by genetic factors. We undertook a family based association study between genetic markers in selected candidate genes and pediatric ("primary") tuberculosis. A total of 183 nuclear families with pediatric tuberculosis cases were enrolled from Harris County, Texas where the incidence of pediatric tuberculosis is 3.1/100 000, well above the US national average of 1.6/100 000. The majority of families, 143, comprised only a single tuberculosis case (simplex families) while in 41 families more than one case was diagnosed (multiplex families). With regard to ethnicity and racial background of tuberculosis patients, 136 were of Latino origins, 69 were Blacks, 13 Asian, 7 White, and 9 of mixed racial origin. The disease manifestation was classified as pulmonary in 57.3%, extrapulmonary in 37.5%, and mixed pulmonary and extrapulmonary in 11.2% of all pediatric cases. Finally, 100 pediatric cases were female and 106 were male. Candidate genes (*NRAMP1*, *MBL*, *VDR*) were chosen based on previous genetic findings and immunopathogenic studies of tuberculosis. Alleles of all candidate genes tested were in Hardy-Weinberg equilibrium. Associations between disease phenotype and three allelic variants, *NRAMP1*-N01 ($P= 0.04$), *NRAMP1*-N02 ($P= 0.04$), and *VDR*-VD01 ($P= 0.02$) were found significantly associated with pediatric tuberculosis. The effect of *NRAMP1*-N02 allele transmission distortion was significantly more evident in simplex families ($P= 0.0005$).

Meta-analysis of genetic association studies supports a role for common variants in common disease risk. *J.N. Hirschhorn*^{1,2,3}, *K.E. Lohmueller*³, *C.L. Pearce*⁴, *M. Pike*⁴, *E.S. Lander*^{3,5}. 1) Genetics, Harvard Medical School, Boston, MA; 2) Genetics and Endocrinology, Children's Hospital, Boston, MA; 3) Center for Genome Research, Whitehead Institute, Boston, MA; 4) Norris Comprehensive Cancer Center, USC, Los Angeles, CA; 5) Biology, MIT, Cambridge, MA.

Association studies offer a potentially powerful approach to identify common genetic variants that influence susceptibility to common disease, but are plagued by the impression that they are not consistently reproducible. In principle, the inconsistency may be due to false positive studies, false negative studies, and/or true variability in association between different populations. The critical question is whether false positives overwhelmingly explain the inconsistency.

We analyzed 301 published studies covering 25 different reported associations. There was a large excess of studies replicating the first positive reports, inconsistent with the hypothesis of no true positive associations ($P < 10^{-14}$). This excess of replications could not be reasonably explained by publication bias, and was concentrated among 11 of the 25 associations. For 8 of these 11 associations, a pooled analysis of follow-up studies yielded a statistically significant replication of the first report, with modest estimated genetic effects that would be difficult to detect using small samples. Thus, a sizable fraction (but well under half) of reported associations have strong evidence of replication; for these, false negative, underpowered studies probably contribute to inconsistent replication. We conclude that there are likely many common variants in the human genome with modest but real effects on common disease risk, and that studies utilizing large samples will convincingly identify such variants.

Prediction of hypertensive status by MDR analysis of multilocus genotypes. *S.M. Williams^{1,2,3}, M.D. Ritchie³, J.A. Phillips III^{2,4}, E. Dawson⁵, M. Prince⁴, E. Dzshura⁴, A. Willis^{3,4}, A. While hypertension is recognized as a complex disease with a significant genetic component, most genetic studies of hypertension fail to identify variants that can be replicated across populations. We hypothesize that this is due to differences in underlying genetic architecture that is rarely investigated. We previously demonstrated that multilocus interactions are risk factors for hypertension. To determine the specific multilocus genotypes that underlie hypertension we used a new methodology, multifactor-dimensionality reduction (MDR) analysis, to identify high-risk and low-risk genotypes. We analyzed 13 polymorphisms in 8 genes (angiotensinogen - AGT, angiotensin-I-converting enzyme - ACE, G protein-coupled receptor kinase GRK4, nitric oxide synthase I - NOS1, NOS3, carbamyl phosphate synthase I - CPSI and cyp2C8). The genes play a role in 4 physiological pathways. None of the polymorphisms associate with hypertension individually, but genotypes at four polymorphisms in three unlinked loci, AGT, ACE, and GRK4 predict phenotype correctly in approximately 70% of the individuals in our study. These genes play a role in vasoconstriction (AGT, ACE) or in sodium excretion and fluid volume (GRK4). Our findings support the idea that combinations of genotypes from multiple loci provide more information about hypertension susceptibility than genotypes from any single gene, and that the role of specific candidate genes is dependent on variation at some, but not all, other loci with a proposed role in hypertension.

Association of a novel promoter variation in the peroxisome proliferator-activated receptor-g coactivator-1 (PGC-1/PPARGC1) gene with body mass index (BMI). *T.I. Pollin¹, Z. Fan², M.J. Garant¹, D.G. Lewis¹, B.M. Spiegelman³, B.D. Mitchell¹, E.T. Poehlman⁴, A.R. Shuldiner¹.* 1) University of Maryland, Baltimore, MD; 2) University of Missouri, Columbia, MO; 3) Harvard University, Boston, MA; 4) University of Montreal, Montreal, Canada.

We previously reported association of homozygosity (AA) for a polymorphism in intron-2 (C®A) of the PGC-1 gene with protection against obesity in Caucasians. We also found evidence for interaction of this variant with the b-3 adrenergic receptor (b3AR) Trp64Arg variant, consistent with functional studies showing that stimulation of the b3AR induces PGC-1 expression. We now report the identification and analysis of a novel 8 base pair expansion of a 13 poly-A segment in the promoter region of PGC-1. This variant was genotyped in 829 women and 66 men and was in partial linkage disequilibrium with the intron-2 variant ($D' = 0.46$, $p < 0.0001$). The promoter variant was not by itself associated with BMI, but inspection of the BMI levels for each of the nine possible promoter/intron-2 genotype combinations pointed to a recessive model in which individuals homozygous for the 13A/intron-2A haplotype were leaner than those with other genotypes (age- and sex- adjusted BMI: 29.3 ± 1.0 vs. 32.8 ± 0.3 kg/m², $p = 0.0007$).

Our previous detection of a combined PGC-1/b3AR association with BMI was reinforced by the difference in BMI between those with 13A/intron-2A homozygosity and the b3AR Trp/Trp genotype (28.8 ± 1.1 kg/m²) and those with other PGC-1/b3AR genotype combinations (32.8 ± 0.3 kg/m²) ($p = 0.0005$).

In summary, we observed an association between a novel 8 base pair insertion in the promoter of the PGC-1 gene and BMI when this variant was combined with a single nucleotide polymorphism in the second intron, and a PGC-1/b3AR interaction was supported. These results may reflect a functional relationship whereby the combination of the two PGC-1 variants alters expression of PGC-1 protein, which in turn augments the known functional effect of the Trp64Arg b3AR variant on adrenergic signaling, lipolysis, and fat accretion.

Use of Regression Trees to Detect Linkage of Rheumatoid Arthritis to Chromosome 1. *C.J. Etzel¹, D. Jawaheer², M.F. Seldin³, W.V. Chen¹, P.J. Gregersen², C.I. Amos¹.* 1) Dept of Epidemiology, The University of Texas MD Anderson Cancer Center, Houston, TX; 2) Division of Biology and Human Genetics, North Shore University Hospital, Manhasset, NY; 3) Dept of Biological Chemistry, University of California at Davis, Davis, CA.

Rheumatoid arthritis (RA) is a debilitating chronic, inflammatory disease that affects the synovial membranes of multiple joints in the body. The etiology of the disease remains unknown, but appears to have a complex genetic component. The North American Rheumatoid Arthritis Consortium (NARAC) recently completed a genome scan of multiplex RA families from within the United States. We found significant evidence ($p < 0.01$) for linkages in two separate sets of families to two regions on chromosome 1. Subsequent affected relative pair linkage analysis on all the NARAC sib-pairs allowing for covariates using LODPAL at the marker H18a (136.9 cM) yielded a LOD score of 1.53 including erosive disease and 1.09 without covariates. We constructed classification and regression trees to search for subsets of the data providing the strongest evidence for linkage to this locus on chromosome 1 using 523 affected sib-pairs from NARAC. Our response was the proportion of alleles shared IBD for H18a and we considered the following predictors: ethnicity and numbers of sibs per sib-pair with: one or more DR4 alleles, erosive factor, rheumatoid factor > 100 (RF), male affected, and existence of nodules. We compared the results from the tree analyses to the linkage results. From LODPAL, the covariates male affected, RF, DR4 and erosive factor nonsignificantly increase evidence for linkage to this region of chromosome 1. The results from classification and regression tree analysis identified a subgroup of sib pairs that shared a very high proportion of alleles i.b.d. for H18a. For these pairs, both members had erosive factor, at least one member had a nodule, both sibs were female and at least one pair member had RF > 100 . These results indicate a subgroup that is particularly useful for further fine mapping studies.

Segregation Analysis of Total Serum IgE in a Completely Ascertained Isolated Island Population. *R.A. Mathias¹, T.H. Beaty¹, J. Bailey-Wilson², A. Wilson², K.C. Barnes¹*. 1) Johns Hopkins Univ, Baltimore, MD; 2) NHGRI, NIH, Baltimore, MD.

Total serum Immunoglobulin E (tIgE) is a quantitative trait highly correlated with asthma and plays a major role in its pathophysiology. We performed a segregation analysis of tIgE levels in a genetic isolate under a random ascertainment scheme. Genealogical data dating back to 1722 and spanning 13 generations for 664 individuals living in Tangier Island, Virginia, were available. All individuals belonged to one extended pedigree (N=3,501). Pedigree complexity indicates that current inbreeding ($F = 0.009$) is only due to old lines of consanguinity. Serum samples for tIgE concentrations were collected from 445 (68.2%) of the population. Computation time needed for the segregation analysis using Pedigree Analysis Package was evaluated for several alternate pedigree structures. Only two pedigree reconstructions were feasible: a *reduced* pedigree retaining all phenotyped individuals and their parents (57 pedigrees), and the breakup into *nuclear* components with the duplication of individuals as necessary (922 pedigrees). Age- and gender-adjusted log-transformed tIgE was used. Both the *reduced* and *nuclear* pedigrees indicated that the most parsimonious model for log(tIgE) in these data is a two-distribution Mendelian model. There was ambiguity between dominant and recessive models, and this putative major gene accounted for all the familial correlation in the trait. However, codominant and non-genetic models could not be rejected. Simulations of a quantitative trait were performed to evaluate the reliability of this most parsimonious model. Simulations over 200 replicates for both pedigree structures indicated the results obtained when using the restricted genealogical information for the two-distribution Mendelian model were reliable. In conclusion, it appears that tIgE may have a strong genetic component in this Tangier Island population with two underlying distributions, and a majority of founders falling into the lower phenotypic distribution. Additionally, the results based on either the reduced and nuclear pedigrees appear to be quite reliable for the most parsimonious model.

An SNP Map for Admixture Linkage Disequilibrium Studies in African Americans. *J.A. Lautenberger¹, J.-P. Chretien^{1,2}, J. Coresh², S.J. O'Brien¹, M.W. Smith³*. 1) Laboratory of Genomic Diversity, National Cancer Institute, Frederick, MD; 2) Welch Center for Prevention, Epidemiology, and Clinical Research, Johns Hopkins University, Baltimore, MD; 3) Basic Research Program, SAIC-Frederick, National Cancer Institute at Frederick, Frederick, MD.

Association mapping requires linkage disequilibrium (LD) between a disease susceptibility locus and a marker. In non-admixed human populations, significant LD is limited to several hundred Kb which is equivalent to a few tenths of a cM. A novel method of gene mapping, mapping by admixture linkage disequilibrium (MALD), has been developed to take advantage of the increased LD across 5-25 cM in admixed populations. Many fewer highly differentiating markers must be typed using a MALD screen as compared to the proposed haplotype approach in a non-admixed population. We focus on African Americans (20% average European ancestry) as a suitable population for MALD mapping of disease genes.

We have analyzed a set of 27,054 single nucleotide polymorphisms (SNPs) from the SNP Consortium allele frequency database. Markers having at least 20 subjects typed in both African and European Americans were examined with Var(MAPP*) - a measure of affiliation with parental population that takes centrality and directionality of allele frequencies into account. 61% of the human genome is within 2.5 Mb of an SNP with Var(MAPP*) > 6 and 89% is within 7.5 Mb. Under reasonable assumptions, about 1,200 cases and an equal number of controls would be required to detect an association between a disease locus with a genotypic risk ratio of two or greater and such a marker located within 2.5 cM. After ongoing verification, these informative SNPs constitute the foundation of a suitable set of markers for genomic MALD scans in African Americans. Funded in part by DHHS#NO1-CO-12400.

Association between Viliuisk Encephalomyelitis syndrome in Sakha People of Siberia and the inflammation gene polymorphisms. *T.K. Oleksyk¹, T. Sivtseva², A.P. Danilova², V.L. Osakovskiy², S.J. O'Brien¹, L.G. Goldfarb³, M.W. Smith⁴.* 1) Laboratory of Genomic Diversity, National Cancer Institute, NIH, Frederick, MD; 2) Institute of Health, Sakha Republic, Russia; 3) Clinical Neurogenetics Unit, National Institute of Neurological Disorders and Stroke, NIH, Bethesda, MD; 4) Basic Research Program, SAIC Frederick, National Cancer Institute, NIH, Frederick, MD.

Since the discovery of Viliuisk Encephalomyelitis (VE) in 1887 scientists have tried to understand the etiology and identify the causative agent of this endemic neurological disorder common among the native Sakha population of Central Siberia. Analysis of VE occurrence in affected families indicated a greater than expected by chance aggregation of VE in relatives, suggesting that a genetic component may contribute to VE susceptibility. Our main objective was to analyze the degree of association between VE and genetic markers in several candidate genes that have been implicated in other inflammatory diseases. DNA samples were collected from 83 affected families comprising 89 verified VE cases. DNA of additional 72 unrelated unaffected inhabitants of the same geographical area was obtained. We tested seven inflammation candidate genes: CCR2/5, IFNG, IL4, IL10, MBL, SDF, and RANTES using 24 variable SNPs to perform fluorescent ddNTP length-modified single base extension. Results were analyzed using the Transmission/Disequilibrium Test (TDT) by inferring the genotypes of missing parents. The degree of association between the SNP markers and VE in affected versus the unrelated reference individuals using inferred haplotypes was also examined. None of the seven genes were significantly associated with VE occurrence. However, results of the TDT tests with the SNP markers located in the IL10 region were marginal ($p \sim 0.07$) which suggests that further work around this gene could be fruitful. This collection of individuals and the analytic approach has laid the foundation for discovering the natural human variants may contribute to the identification of the etiology of Viliuisk Encephalomyelitis. Funded in part by DHHS # NO1-CO-12400.

Population subisolate structure approach for complex gene mapping. *J.K. Kere*^{1,2}, *E. Salmela*², *P. Lahermo*², *P. Sistonen*³, *M.-L. Savontaus*⁴. 1) Dept Biosciences at Novum, Karolinska Inst, Huddinge, Sweden; 2) Finnish Genome Center, Univ Helsinki, Finland; 3) FRC Blood Transfusion Service, Helsinki; 4) Dept Med Genet, Univ Turku, Finland.

Finland is a model population for disease gene studies. Much debate has focused on the utility of founder populations for disease gene mapping, and it has been suggested that such populations offer no advantages. In Finland, linkage disequilibrium (LD) levels are similar to other European populations for common alleles. Such data are compatible with a relatively broad (hundreds of founders) bottleneck, whereas examples of rare alleles (<1%) have shown long segments of LD. We aim at obtaining a more comprehensive picture of the substructure of the Finnish population, to aid the design of genetic studies of complex diseases. Distinct substructuring was already suggested by classical blood group studies as well as the uneven geographical spread of rare disease alleles, and was confirmed by our microsatellite studies on >450 individuals from 9 provinces. Allele frequencies for 31 markers deviated by up to 3.5 SD around the national mean in different provinces, suggesting local drift. Principal component (PC) analysis revealed that the 1st and 2nd PCs recovered 47% of total variance, and the geographical interpretation of the 1st PC was along an east-west axis. We have selected additional markers to study LD in different provinces. We propose a novel strategy for the mapping of common disease genes. The steps of the strategy are the following: 1. Look for subpopulations with very different incidence for a common disease, 2. Collect representative population samples, 3. Scan the genome for markers and regions that have very different allele distributions between the subpopulations (most of the allele frequency variations are due to drift, but some may mark disease-associated haplotypes), 4. Perform an association study with that subset of markers between cases and controls to find true disease association, and 5. Replicate the mapping result in independent populations. We conclude that a distinct substructuring verified in Finland may allow the use of novel strategies for mapping common disease genes.

Program Nr: 1109 from 2002 ASHG Annual Meeting

Linkage Disequilibrium across 150 kb region around RET gene on chromosome 10. *N. Mukherjee, A.J. Pakstis, P. Chaudhuri, W. Speed, J.R. Kidd, K.K. Kidd.* Dept.Genetics, Yale U, New Haven, CT.

Because recombination can be a significant factor in reducing LD, regions of low recombination rates per Mb should have LD extending for longer distances than regions of known high recombination rates. One region of known reduced recombination rate relative to the genome average is the centromeric region of 10q around the RET locus. To examine LD in this region we have identified SNPs at approximately 30kb interval across ~300 kb from RET to D10S94 and are typing these markers in over 30 populations from major continental regions. Preliminary analysis of the several markers with sufficiently high heterozygosities demonstrate high levels of pair-wise LD extending across segments of >150kb in this region but with considerable variation among populations. For a 100kb region extending telomeric from RET, most populations in all regions outside of Africa showed strong and highly significant LD with D' generally greater than 0.6 and $p < 0.001$. LD was difficult to assess for many segments in African populations because of low heterozygosity for one or both markers. A permutation test of LD across a segment of 137 kb using 3-site haplotypes at each end shows highly significant LD in most populations, even in some African populations. However, some individual populations showed no suggestion of any LD. We conclude that for most populations in most regions of the world, LD does extend farther in this centromeric region of reduced recombination than seen for the average mid-arm genomic region. Supported in part by GM 57672.

Strong linkage disequilibrium for the frequent 35delG GJB2 mutation in the Greek population. *S. Pomoni*¹, *L. Van Laer*², *M. Grigoriadou*¹, *A. Pampanos*¹, *T. Iliades*³, *N. Voyiatzis*³, *J. Economides*⁴, *P. Leotsakos*⁴, *P. Neou*⁵, *M. Tsakanikos*⁵, *A. Skevas*⁶, *G. Van Camp*², *M.B. Petersen*¹. 1) Inst. of Child Health, Athens, Greece; 2) Univ. of Antwerp, Belgium; 3) Aristotle Univ. of Thessaloniki, Greece; 4) "Aghia Sophia" Children's Hosp., Athens, Greece; 5) "P. & A. Kyriakou" Children's Hosp., Athens, Greece; 6) Univ. of Ioannina, Greece.

Mutations in the GJB2 gene represent the most important cause of nonsyndromic, prelingual deafness. One specific mutation in this gene, the 35delG, has accounted for the majority of GJB2 mutations detected in Caucasian populations and represents one of the most frequent disease mutations identified so far. High carrier frequencies of the 35delG mutation have been detected in southern European countries. Most investigators have assumed that the high frequency of the 35delG mutation reflects the presence of a mutational hot spot, but a recent study including patients from Belgium, U.K., and the U.S.A. reported evidence of a founder effect. In the present study we genotyped 60 Greek deafness patients homozygous for the 35delG mutation for 6 SNPs and one microsatellite marker, mapping within the 3'UTR or flanking the GJB2 gene. The allele distribution in the patients was compared to 60 Greek hearing controls. On the centromeric side of the GJB2 gene, no significant difference in genotypes was detected between patients and controls using SNP5 and SNP6 located at a distance of 76.5 and 62.8 kb from the 35delG mutation, respectively. The two SNPs within the 3'UTR showed a strong association with the 35delG mutation ($p < 0.001$ for SNP1 and $p = 0.013$ for SNP2). On the telomeric side of GJB2, two SNPs showed significant genotype differences between patients and controls (SNP3 at 5.5 kb distance, $p = 0.004$ and SNP4 at 6.0 kb distance, $p < 0.001$). Surprisingly, the microsatellite marker D13S175 located at a distance of about 90 kb telomeric to GJB2 showed a strong association between the 105 bp allele in patients (92.9%) compared to controls (47.3%, $p < 0.0005$). We conclude that the 35delG mutation is in strong linkage disequilibrium with intragenic and flanking markers in the Greek population supporting that this mutation is derived from a common founder.

Positive results in association studies are associated with departure from Hardy-Weinberg Equilibrium: hint for genotyping error? *A.R. Turner, J.L. Little, E.R. Bleecker, D.A. Meyers, J. Xu.* Center for Human Genomics, Wake Forest Univ Sch Medicine, Winston-Salem, NC.

Case-control studies have been widely used in association studies of complex diseases. The premise of genetic association studies is that increased allele or genotype frequencies in cases compared with controls implicates sequence variants that increase risk to a disease, or are in strong linkage disequilibrium (LD) with a disease-causal mutation. However, many other factors can also lead to an observed difference in allele or genotype frequencies between cases and controls. While much attention has been devoted to the potential impact of incomparability between cases and controls in terms of sources of cases and controls, environmental exposures, and genetic background (population stratification), there is a clear lack of comprehension of the impact of genotyping error on the results of association studies. This may be due to the lack of direct measures of this type of error. To indirectly assess the prevalence and magnitude of genotyping error in case-control studies, we systematically reviewed reported association studies from PUBMED and performed Hardy-Weinberg Equilibrium (HWE) tests in control subjects for each reported single nucleotide polymorphism (SNP), as deviation from HWE may indicate genotyping error. We searched for keywords "association genotype genetic case control", and limited to articles in English, with human subjects, and 2000 publication date. The search yielded 157 articles, which we then limited to the 101 available articles. Our analysis revealed significant deviation from HWE among 12» (n=16) of the SNP genotypes ($\chi^2=4.22$, $P=0.04$). Also, we found more deviation from HWE among positive association studies (18.9»; n=10). We offer several suggestions to reduce systematic biases: 1) Blind researchers to case-control status, 2) Include multiple controls and blanks in different positions of each plate, 3) Check allele scoring, 4) Run one plate in duplicate for each gene, 5) Determine an acceptable amount of missing data and rerun assays if there is more missing data, 6) Perform a HWE test for each SNP before testing hypotheses.

Genetic evidence for “The Trail of Tears”: signatures of expansion preceded by a bottleneck in the Choctaw population of Oklahoma. *X. Zhou*¹, *N. Wang*², *F.K. Tan*¹, *M.F. Foster*³, *F.C. Arnett*¹, *R. Chakraborty*². 1) Division of Rheumatology and Clinical Immunogenetics, University of Texas-Houston Medical School, Houston, TX; 2) Center for Genome Information, University of Cincinnati, Cincinnati, OH; 3) Department of Anthropology, University of Oklahoma, Norman, OK.

Previous research has shown that the Choctaw Indians of Oklahoma exhibited considerable linkage disequilibria (LD) in a number of regions of the genome that has allowed genetic fine mapping for potential susceptibility genes for the autoimmune connective tissue disease scleroderma or systemic sclerosis (SSc). In principle, such enhanced background LD in the Choctaw could be caused by the recent expansion of their population size preceded by a population bottleneck. This investigation utilized partial genome-scan data on 54 dinucleotide loci from 76 Choctaw individuals that were used as controls in our previous SSc linkage studies, to seek genetic evidence of the known demographic history of the Choctaw Nation often referred to as The Trail of Tears. According to historical records, the Choctaw Nation was relocated to Oklahoma, from their original homeland in Mississippi in 1830-1850 during which time only 7,000 out of over 20,000 survived. Recent estimates of their current population size are approximately 70,000 suggesting a 10-fold increase in about 8 to 10 generations. The average expected homozygosity for the Choctaws at the 54 di-nucleotide loci (36.2%) was significantly higher than that in European-Americans (24.8%), and when adjusted for sample size differences, the Choctaws also exhibited a smaller number of segregating alleles at these loci. Both these observations are consistent with the trend expected in an isolated population. Comparison of the allele size variance and gene diversity yielded an imbalance index of 1.19 in the Choctaw. Of the 54 loci examined, 53 exhibited an excess of expected homozygosity in comparison to the expectations of a stepwise mutation model in a population of constant size. Taken together, these observations are consistent with a signature of the recent population size expansion of the Choctaws, preceded by a bottleneck event that occurred 8 to 10 generations ago.

Population genetics of the angiotensin-1 converting enzyme (ACE) locus in global populations. *M. Wolujewicz¹, R. Kaushal¹, N. Wang¹, G. Sun¹, E. Lutkenhoff¹, S.T. McGarvey², L. Jin¹, R. Chakraborty¹, R. Deko¹.* 1) Center for Genome Information, Department of Environmental Health, University of Cincinnati, Cincinnati, OH; 2) International Health Institute and Department of Community Health, Brown University, Providence, RI.

We have typed the *Alu* indel (I/D) polymorphism in intron 16 of the *ACE* gene, previously thought to be associated with plasma ACE activity, in 1262 individuals belonging to 26 worldwide populations. We observed a distinct cline of the *Alu**I allele increasing geographically from Africa (.34), extending through Europe (.40), South Asia (.54) and East Asia (.72), with the highest frequency in Oceania (.85). A sample (N = 39) of chimpanzees was surprisingly found to be polymorphic (*I = 0.18), contradicting the earlier assertion that the *ACE-Alu* indel locus is human specific. Sequencing establishes that this polymorphism predates the human-chimpanzee split. To further characterize the population genetic properties of the *ACE* gene, we have analyzed three additional SNPs downstream to the *Alu* locus in Benin from Africa (N = 56), German (N = 59), Chinese (N = 62), Samoan (N = 90), and the chimps (N = 38). One of the SNPs, 22982, earlier shown to be in strong linkage disequilibrium (LD) with ACE determining variants, is in complete LD (D' = 1) with the *Alu* indel locus among the Samoans, an isolated Polynesian population. These two sites are approximately 9 kb apart. A geographic cline of the "IA" haplotype (*Alu**I/22982*A) similar to the *Alu**I is evident in these populations. The two other SNPs (17634 and 20120), located between the above two markers, are monomorphic in the examined populations other than the Benin and the Samoan. At the 4-locus haplotype level, of the possible eight haplotypes, six are found in the combined sample of 305 individuals. Haplotype diversity is the highest in Africa, lowest in Samoa (lower than the chimpanzees) and intermediate in Europe and Asia. Together with the least number of observed haplotypes (4), the Samoans present the strongest evidence of an LD block, which has important implications for disease-gene association mapping in isolated human populations.

GABA_A receptor genes on chromosome 15 associated with alcohol dependence in the Collaborative Study on the Genetics of Alcoholism sample. *D.M. Dick¹, X. Xuei¹, J. Song¹, H.J. Edenberg¹, T. Foroud¹, COGA*

collaborators^{1,2,3,4,5,6,7,8}. 1) Indiana Univ Sch Medicine, Indianapolis, IN; 2) University of Iowa; 3) University of California at San Diego; 4) University of Connecticut; 5) State University of New York, Health Sciences Center at Brooklyn; 6) Washington University in St. Louis; 7) Rutgers University; 8) 8.

Several lines of evidence suggest that GABA is involved in many of the behavioral effects of alcohol, including motor incoordination, anxiolysis, sedation, withdrawal, and ethanol preference. GABA_A receptor agonists tend to potentiate the behavioral effects of alcohol, while GABA_A receptor antagonists attenuate these effects. Chromosome 15 contains a cluster of GABA_A receptor genes: *GABRA5*, *GABRB3*, and *GABRG3*. *GABRA5* and *GABRB3* were reported to be uniparentally expressed from the paternal chromosome, and an earlier analysis of microsatellite markers in those genes showed evidence for association with the paternally transmitted alleles. To follow up this finding and narrow the region, seven SNPs were genotyped in more than 2200 individuals from 262 multiplex alcoholic families ascertained as part of the Collaborative Study on the Genetics of Alcoholism (COGA). Both pedigree disequilibrium tests (PDT) and the classic trio based TDT tests were performed, and the TDTEX program in S.A.G.E. was used to test for paternal transmission. Using the TDT programs there was consistent evidence of association with a SNP in *GABRG3* with three hierarchical models of alcohol dependence. This association was due to excess paternal transmission. There was also some evidence of association with a SNP in *GABRB3* using the PDT. These results suggest that further investigation of the chromosome 15 GABA gene cluster is warranted to elucidate the role of these genes in the development of alcohol dependence. We are currently in the process of testing additional SNPs in this region.

Accounting for heterogeneity in a power analysis exemplified by ovarian ageing. *K.M. Asselt van*^{1,2,3}, *H.S. Kok*^{1,2,3}, *P.L. Pearson*³, *E.R. te Velde*², *D.E. Grobbee*¹, *L.A. Sandkuijt*⁴. 1) Julius Center, UMCU, NL; 2) Infertility Studies, UMCU, NL; 3) Medical Genetics, UMCU, NL; 4) Medical Statistics, LUMC, NL.

Objectives: Age at menopause is under influence of various genes and has been estimated to have a heritability of 60-85% in several studies. The range of normal menopausal age is between 40-60 years with a mean of 50-51 years. ~1% of all women cease menstruating prior to the arbitrarily selected cut-off of 40 years and exhibit Premature Ovarian Failure (POF). Various genetic studies suggest that POF has a different etiology to natural menopause and is caused by single chromosomal or gene mutations. Segregation analysis show that both women with POF as women with early menopause (40-45 years) co-segregate in families suggesting that the natural menopause distribution overlaps with the POF distribution. To successfully perform a genome scan to search for genes responsible for the variation in age of normal menopause, we need to take account of this heterogeneity. **Methods:** We collected sisters with concordant (both <46 or both >54) and discordant ages at menopause. In the lower tail of the distribution a mixture of women with monogenetic POF causes and women with a normal early menopause is possibly collected. To estimate the power of the sib pair analysis we have used a procedure in which both concordant pairs from the upper tail of the distribution and discordant pairs were used. By doing so we hope to minimize mapping putative strong POF genes which might have occurred if pairs from the lower end of the distribution were used. The IBD probabilities were calculated with the method of Risch and Zhang using the known menopausal ages, the mean menopausal age and the corresponding standard deviation of a population based cohort. These IBD probabilities were used with simulated marker data in a Haseman-Elston model. **Results:** The power to find at least one locus in the presence of 6 responsible genes with a heritability of 80% and with allele frequencies of 0.1 and 0.25 varied between 85-99% (p<0.01). **Conclusions:** The dataset (158 sib-pairs) and sib-pair selection procedure appears adequate to perform a linkage study in a genome screen for variation in age at menopause.

Linkage of the *APOE* locus with ApoE plasma levels in adolescent Dutch twins is completely explained by the *APOE* e2/e3/e4 alleles. M. Beekman¹, D. Posthuma², BT. Heijmans¹, N. Lakenberg¹, HED. Suchiman¹, C. Klufft³, GP. Vogler⁴, P. de Knijff⁵, GJB. van Ommen⁵, RR. Frants⁵, PE. Slagboom¹, DI. Boomsma². 1) Section Molecular Epidemiology, LUMC, Leiden, Netherlands; 2) Dept of Biological Psychology, Free University of Amsterdam, Netherlands; 3) Dept of Vascular and Connective Tissue Research, TNO Prevention and Health, Leiden, Netherlands; 4) Center for Developmental and Health Genetics and Dept of Biobehavioral Health, Pennsylvania State University, USA; 5) Dept of Human and Clinical Genetics, LUMC, Leiden, Netherlands.

ApoE plasma level and isoform influence the clearance rate of lipoprotein particles by the liver. *APOE* e2/e3/e4 alleles underlying the isoforms have been indicated to be one of the determinants of ApoE plasma level. The effect of additional genetic variation at the *APOE* locus remains unclear. We determined the contribution of *APOE* e2/e3/e4 alleles to variation in ApoE plasma level and tested for the existence of additional genetic variation within the *APOE* region influencing ApoE levels using a recently developed combined linkage-association approach. We genotyped the *APOE* e2/e3/e4 polymorphism and 16 short tandem repeats on chromosome 19 in 65 monozygotic and 82 dizygotic Dutch twins. A two-step analysis procedure was applied. First, multi-point variance-components linkage analysis was performed. A putative QTL explaining 38% of the variation in ApoE plasma level was found at the *APOE* locus (19q13.2; p=0.08). Next, linkage and association with the *APOE* e2/e3/e4 alleles were modelled simultaneously. Association was implemented as the between and within twin pair effect of the alleles, allowing to separate genuine associations from associations due to population stratification. In the combined analysis, association with e2/e3/e4 alleles explained 41% of the variation in ApoE level (p<0.0005) and neutralized the linkage due to the putative QTL. Thus, the complete linkage of the *APOE* locus with ApoE level can be attributed to the e2/e3/e4 alleles. These findings exclude the presence of other genetic variation at the *APOE* locus with a major independent effect on ApoE plasma level in adolescent Dutch twins.

The segregation distortion of MTHFR haplotypes is not increased in DZ twinning. *G.W. Montgomery¹, D.L. Duffy¹, K.I. Morley¹, Z.Z. Zhao¹, A.J. Marsh¹, D.I. Boomsma², N.G. Martin¹.* 1) Genetic Epidemiology Lab, Qld Inst Medical Res, Brisbane, Australia; 2) Psychology Dept, Free University, Amsterdam, Netherlands.

Folic acid is essential for DNA replication and cellular methylation reactions. Folate deficiency increases the risk of neural tube defects (NTD) and recurrent early pregnancy loss. Supplementation with folate around conception reduces NTD, but may increase twinning rates. A key enzyme in folate metabolism is methylenetetrahydrofolate reductase (MTHFR). Common variants at this locus result in the synthesis of an enzyme with reduced catalytic activity leading to elevated plasma concentrations of homocysteine, especially when dietary folate intake is low. Certain MTHFR haplotypes are present in fetal tissue, but not amongst neonates, suggesting that MTHFR may influence embryo survival. A recent case-control study of the C677T polymorphism found a higher frequency of the 677C allele amongst mothers of dizygotic twins (MODZT) in comparison to women who gave birth to singletons. We therefore investigated inheritance of MTHFR alleles in families of DZ and MZ twins and in families where two sisters have both given birth to spontaneous DZ twins. Allelic transmission of two common MTHFR polymorphisms (C677T and A1298C) were analyzed in 462 families of DZ and MZ twins. Allele frequencies for the 677T and 1298C alleles were 0.35 and 0.29 respectively. We also typed the variants in 454 affected sister pair families with a total of 735 MODZT. Allele frequencies for the 677T and 1298C alleles were similar in this population (0.33 and 0.31 respectively). There was strong linkage disequilibrium between the two variants and the 677T/1298C haplotype was very rare. There was statistically significant evidence of segregation distortion with reduced transmission of the 1298C allele in both groups and consequently reduced transmission of the 677C/1298C haplotype. There was no excess allele sharing among DZ twins that would be expected if MTHFR variants contributed to variation in DZ twinning. Inherited twinning was not associated with segregation of the common variants at MTHFR. The data show no association between MTHFR and DZ twinning, but some variants of MTHFR may affect embryonic survival.

Evolutionary Haplotype Linkage Disequilibrium analysis of a candidate gene for schizophrenia on 22q12-13. *F. Macciardi*^{1,2,3}, *J.R. Kim*¹, *T. Cate*¹, *A. Wong*¹, *T. Klempam*¹, *A. Macedo*⁴, *C. Pato*⁵. 1) Dept Psychiatry, CAMH, Univ Toronto, Toronto, ON, Canada; 2) Dept. of Medical Genetics, Univ of Milan, Italy; 3) GENSET S.A., Paris, France; 4) Dept. of Psychiatry, Univ of Coimbra, Coimbra, Portugal; 5) Center for Neurosciences, SUNY at Syracuse, NY, USA.

The aim of our study was to detect a possible susceptibility gene for schizophrenia on 22q12-13. Given that schizophrenia is a complex genetic trait and that consequently a susceptibility gene only conveys a small portion of the overall genetic risk, we adopted a case-control Linkage Disequilibrium strategy to detect a possible effect of such a locus, if existing. We analyzed 2 separate and independent populations, respectively from the Azores Island and Coimbra (Portugal) and Ontario (Canada): diagnosis of schizophrenia was made according to the DSM IV criteria, following a DIGS (Portugal) or a SCID-R interview. We collected 158 (P) and 189 (C) cases with matched controls. All patients and controls signed an informed consensus. We then typed 11 polymorphisms (5 microsatellites and 7 SNPs) on 22q12-13, covering a quite large area of about 5cM. As expected considering their different evolutionary history, an analysis of the marker to marker LD in both cases and controls, showed different patterns in the 2 populations, requiring an independent haplotype-disease association strategy. To detect the possible effect of an etiologic gene of small effect on schizophrenia and to reduce the high variability of the extant haplotypes, we applied a haplotype analysis by also looking at the founding haplotypes in the 2 populations separately using the program DHSMAP (Mc Peek and Strahs, 1999). Despite the haplotypes in the Portuguese and in the Canadian populations were different, reflecting their different genetic background, in both cases we obtained the same exact and significant location for a putative susceptibility gene for schizophrenia, strongly supporting the hypothesis that a true etiological genetic component for the disease exists in the area. Acknowledgment: This work has been supported by a NARSAD Independent Investigator Award to FM, 2001 Essel Investigator.

A Population Genetic Study of Autism in Andalusia, Spain. *L.A. McInnes¹, J. Hallmayer², E. Manghi³, J. Pritchard⁴, K. Wills⁵, A. Hervas⁶, S. Sanz⁷, J.L. Benitez⁷, T. Guijarro⁷, E. Gay⁷, V. Sanchez⁷, D. Llanes⁸, M. Ruiz-Rubio⁸.* 1) Dept Psychiatry/Human Gen, Mount Sinai Sch of Med, New York, NY; 2) Department of Psychiatry, Stanford University School of Medicine, Stanford CA 94304; 3) Department on Disabilities and Human Development, University of Chicago, Chicago, IL 60637; 4) 4Department of Human Genetics, The University of Chicago, Chicago, IL 60637; 5) Department of Psychology, Children's Hospitals and Clinics Minneapolis, MN 55404,; 6) Department of Child and Adolescent Psychiatry, Hospital Mutua de Terrassa, Barcelona Spain 08022; 7) Unidad de Salud Mental Infantil, Cordoba, Spain 14071; 8) Department of Genetics, University of Cordoba, Cordoba Spain 14071.

We are conducting an epidemiological and genetic study of autism in Andalusia, Spain. Andalusia harbors a population of 7 million in its 8 provinces (approximately 1.5 million are under 18) and offers several excellent advantages for such studies. Healthcare in Andalusia is coordinated by one centralized health system, the Servicio Andaluz de Salud. Medical records are centralized and virtually 100%; of cases diagnosed with autism are evaluated within this system. All children suspected of developmental delay receive Fragile X testing. We anticipate that there are up to 1500 potential cases under the age of 18 in the system. We will also collect an equal number of age and sex matched controls. Additionally, the PI of this project is organizing a genetic study of autism in the isolated population of the Central Valley of Costa Rica (CVCR). The CVCR population was largely derived from persons living in Andalusia in the 16th Century. The demographic history of Andalusia also suggests that the majority of persons now living there are descendants of the population present in the 16th Century. We will trace the genealogy of autistic probands to determine ancestry back to Andalusia at that time. We will then be able to use this subset of probands to follow up autism susceptibility loci isolated in the Costa Rican population. Our collaborators also plan to collect autistic probands from two other isolated populations founded by Andalusian immigrants.

Program Nr: 1120 from 2002 ASHG Annual Meeting

Novel analytical methods applied analysis Type 1 diabetes genome scan data. *F. Pociot, A.E. Karlsen, J. Nerup.*
Steno Diabetes Ctr, Gentofte, Denmark.

Background and Aims: Complex traits as T1DM are under influence of multiple genes that may interact to confer diseases susceptibility. Statistical methods in current use essentially work under single gene models, thus not allowing identification of the genetic basis of a complex trait. We therefore see an urgent need for exploring new strategies for detecting in-teracting sets of marker loci to identify interacting disease genes. **Materials and Methods:** We have chosen a combination of methods using inductive models. The methods employ spatial pattern recognition through statistical and graphical tools, in-cluding neural networks and decision tree construction, known as data-mining. These meth-ods were applied on whole-genome scan data generated on Scandinavian T1DM families (464 affected sib pairs). **Results:** In addition to the 5 regions demonstrating the highest LOD scores in classical analy-sis (HLA, IDDM15, 16p, 5p, and 2p), the present analysis identified regions on chromosomes 7, 8 and 10 to be of major importance. Interaction analysis using data mining identified the following interactions: HLA and D4S403, and HLA and D5S407 as the best predictive for T1DM, whereas the combination IDDM15 and D16S287 was the most protective, i.e. predic-tive for not having T1DM. **Conclusion:** Data-mining based methods can identify observations known from classical analysis, and may provide novel information about related interactions, which is not obtained by established methods. Finally, data mining provides also a tool for identification of protec-tive alleles.

Large variability of the FMR2 gene alleles in a normal population from Risaralda, Colombia, S.A. *L. Rengifo, J. Rodriguez, A.H. Alegria, P. Osorio, D. Gaviria, H. Serrano.* Basic Sci, Fac Med, Favi II, Univ Technologica de Pereira, Pereira, Colombia.

FRAXA and FRAXE syndromes are due to expansion of repetitive triplets. Although related by common mechanisms for expansion and abnormal methylation, they are recognized as different entities. FRAXE is considered the most prevalent cause of non specific X-linked mental retardation (FRAXE-MR) and affects at least 1/ 23.423 males. Gene FMR2 is located distally to the FRAXA region and corresponds to a folate sensitive site. FRAXE affected individuals do not present a characteristic phenotype but have slight to moderate mental retardation and other behaviour alterations. They have the FRAXA cytogenetic marker but are negative for FMR1 mutations. The FMR2 normal allele has between 3-42 CCG repeats non interrupted by AGG triplets. The limit between the normal and premutated alleles is not well defined because FRAXE full mutations are rare. Intermediate alleles have between 31-60 repeats. Affected individuals present more than 200 CCG repeats with absence or diminished synthesis of the FMR2 protein. We analyzed by PCR and Southern blot 1220 FMR2 alleles corresponding to 464 males and 378 females with ages between 18 and 81 years from a normal population in the department of Risaralda, Colombia. A large variability was found for the FMR2 allelic distribution. In the normal range (3-42 CCG repeats) we found the following groups: 2-15 repeats 137 (11.2%), 16-30 repeats 743 (60.9%) The most frequent allele had 26 repeats (203, 16.6%) followed by the one with 21 repeats (129, 15.7%). In the intermediate range (31-60 repeats) there were 340 (27.9%). The most frequent allele had 32 repeats (143, 11.7%) followed by 34 repeats (62, 5.1%). No alleles with more than 57 repeats were found. Homozygotic women were 78.5% and the most frequent genotypes were 21-21 with 55 cases and 26-26 with 46. There was no significant difference by gender.

Influence of b₂ receptor Haplotype on Obesity. *C.D. Crumel¹, J. Wang¹, H. Garg², J. Sylvester¹, J.J. Lima¹.* 1) Nemours Children's Clinic, Jacksonville, FL; 2) University of Florida, Shands Jacksonville, Jacksonville, FL.

Obesity can lead to Type II diabetes, cardiovascular disease and increased mortality. Genetic and environmental factors are known to contribute to obesity. Genes that regulate catecholamine function may be important because of the role catecholamines play in energy expenditure and lipolysis. Associations between single b₂ adrenergic receptor (b₂AR) polymorphisms and obesity have been reported in different genders of various ethnic groups. To our knowledge, there are no studies that explore associations between b₂AR haplotype and obesity. These studies are important because of the tight linkage disequilibrium between b₂AR polymorphisms. The objective of this study was to determine if the b₂AR haplotype is associated with obesity in healthy American adults. Obesity was defined as a body mass index (BMI) > 30kg/m² and a percentage of body fat (PBF) > 20% for males and > 30% for females. Final PBF was determined by averaging PBF according to skinfold thickness and PBF by bioelectrical impedance. The b₂AR polymorphisms at codons 19, Cysteine (C)/Arginine (R), 16 Glycine (G)/Arginine (R) and, 27 Glutamine (Q)/Glutamate (E) and haplotype were determined as described (Wang et al. *Am J Pharmacogenomics* 2001;1:315) in 104 obese and 89 non-obese healthy adults (average age 30 yo). The mean ± SD in BMI, PBF, fasting glucose and insulin concentrations in obese vs. non-obese were: 36±6.5 vs. 24±3.2 kg/m² (p<0.0001); 39±8.1 vs. 27±7.2 (p<0.0001); 77±26.1 vs. 75±26 mg/dl (p=0.532); 12±9.2 vs. 7.5±5.3 mIU/ml (p<0.0001), respectively. The haplotype allele frequencies were RGE 33%; CRQ, 41%; CGQ 26%. The RGE/RGE haplotype frequency was significantly higher in non-obese (20% vs. 9.6%; $\chi^2=4.24$, p=0.037) compared to obese individuals. No other significant association between the frequencies of haplotype pairs and obesity was observed. Stratification by gender and race resulted in insufficient numbers for statistical analysis. Larger numbers are required to determine if the association between RGE haplotype and obesity is dependent on gender and race. Conclusion: The b₂AR RGE haplotype may have a modest protective effect against obesity in healthy American adults.

Heritabilities of Biochemical Urine Components in Families with Nephrolithiasis. *I.P. Kovac¹, A.F. Wilson¹, J. Kinder², B.J. Coe², F.L. Coe³, J.R. Asplin².* 1) Genometrics, NHGRI, Baltimore, MD; 2) Litholink Corporation, Chicago, IL; 3) University of Chicago, Chicago, IL.

Nephrolithiasis is a common disorder with a lifetime prevalence in the United States of 10% in men and 4% in women. Stone formation is familial but also affected by diet and environment. Our objective was to estimate the heritabilities of quantitative measurements associated with kidney stone formation to determine their suitability for further genetic studies. Seventeen biochemical traits were measured in 877 individuals from 242 families. Data were analyzed as averages from two 24h urine collections, except for 68 individuals for which only one urine collection was obtained and included as such. Biochemical measurements included: urine volume, citrate, calcium, oxalate, uric acid, sodium, potassium, phosphorus, magnesium, creatinine, ammonium, sulfate, pH, and urea nitrogen. Estimates of heritabilities and 95% confidence intervals were obtained using age-adjusted regression of offspring on mid-parental biochemical trait values, computed on 181 observations. Excretion rates for all chemistries were adjusted for creatinine excretion to compensate for variability in completeness of collection in duplicate urine collections. Highest heritabilities were for creatinine (0.54, 95% CI = 0.17 - 0.90), uric acid supersaturation (0.45, 95% CI = 0.26 - 0.64), calcium/creatinine ratio (0.43, 95% CI = 0.22 - 0.64), calcium oxalate supersaturation (0.40, 95% CI = 0.15 - 0.65), and urine volume (0.39, 95% CI = 0.18 - 0.60). Moderate heritabilities were also observed for oxalate/creatinine ratio (0.38, 95% CI = 0.12 - 0.64), uric acid/creatinine ratio (0.34, 95% CI = 0.14 - 0.54), phosphorus/creatinine ratio (0.33, 95% CI = 0.07 - 0.59), urine pH (0.29, 95% CI = 0.13 - 0.46), and potassium/creatinine ratio (0.24, 95% CI = 0.03 - 0.44). We conclude that several phenotypes in our data set, particularly those with higher estimated heritabilities, may represent quantitative phenotypes suitable for further studies focusing on the detection and localization of genes influencing the pathogenesis of kidney stones.

Mitochondrial DNA sequence variations of five ethnic populations in northern China. *Q.-P. Kong¹, Y.-G. Yao¹, M. Liu², S.-P. Shen², C. Chen², C.-L. Zhu¹, M.G. Palanichamy¹, Y.-P. Zhang¹.* 1) Kunming Institute of Zoology, Chinese Academy of Sciences, Kunming, Yunnan, 650223 China; 2) Department of Pathology, Baotou Medical College, Baotou, Inner Mongolia, 014010 China.

To study the mitochondrial DNA sequence variations in a total of 232 individuals from five ethnic populations (Ewenki, N=47; Korean, N=48; Mongolian, N=48; Oroqen, N=44; Daur, N=45) in northern China, we analyzed the control region and typed for a number of characteristic mutations in coding regions by direct sequencing or restriction-fragment-length-polymorphism tests. With the exception of several individuals belonged to the European specific haplogroup J, which might reflect a recent gene flow from Europe, most of the individuals considered can be assigned into the east Asia specific haplogroups as reported in the recent studies. The distribution frequencies of haplogroups varied in the five ethnic populations. Haplogroup B had the highest frequency in Daur (17.8%), followed by Korean (16.7%). However, in Oroqen, only one individual belonged to haplogroup B. The frequency of haplogroup D was more than 31% in the four populations except for that of Daur (24.5%). The Daur sample also contained a high amount of M7 types (20.0%), which were either absent or with low frequency in other populations. Haplogroup A had the highest frequency in Korean (14.6%), while in the other populations, the frequency was lower than 8.5%. Haplogroup C constituted a main genetic component of Oroqen (29.5%). Generally, Ewenki and Oroqen, Mongolian and Korean showed closer genetic relationship in the principle component map based on the haplogroup frequency matrix, whereas Daur occupied a relative remote location in the map. The lower genetic diversities observed in Ewenki and Oroqen were also consistent with their small population census sizes.

Specific mitochondrial haplogroups affect risk for late-onset Parkinson disease. *J.M. Van Der Walt^{1,2}, K.K. Nicodemus^{1,2}, E.R. Martin^{1,2}, W.K. Scott^{1,2}, M.A. Nance², J.P. Hubble², J.L. Haines², W.C. Koller², R. Pahwa², M. Stern², B.C. Hiner², J. Jankovic², C.G. Goetz², G.W. Small², F. Mastaglia², R.A. Gibson², L.T. Middleton², A.C. McLaurin^{1,2}, M.A. Pericak-Vance^{1,2}, J.M. Vance^{1,2}.* 1) Ctr Human Genetics, Duke Univ, Durham, NC; 2) Duke CHG/GlaxoSmithKline PD Genetics Collaboration.

Evidence suggests that mitochondrial (mt) impairment contributes to the pathogenesis of Parkinson disease (PD). We tested whether single nucleotide polymorphisms (SNPs) and mt haplogroups confer risk to late-onset PD in a Caucasian sample consisting of 627 cases and 353 controls. Ten stable, ancestral SNPs were genotyped by the allelic discrimination method (Taqman). Combinations of SNPs were used to classify each individual into a European haplogroup (H, I, J, K, T, U, V, W and X). Overall, individuals classified as haplogroup J (OR=0.56; 95% CI, 0.34 to 0.91; p=0.02) or haplogroup K (OR=0.52; 95% CI, 0.31 to 0.86; p=0.01) demonstrated a significant decrease in risk of PD versus individuals carrying the common haplogroup H. Furthermore, a specific SNP that defines these haplogroups, 10389G, strongly contributes to this overall protective effect (OR=0.55; 95% CI, 0.41 to 0.75; p=0.0001). The protective effect of the J haplogroup is interesting given the recently published association between J and longevity. Stratification by gender revealed that males classified as haplogroup U showed an increase in risk of developing PD (OR=2.2; 95% CI, 1.09 to 4.43; p=0.03) when compared to all other males classified as haplogroup H. This result is compelling since haplogroup U is also a risk factor for Alzheimer disease in males (Pericak-Vance et al., ASHG 2002). These findings demonstrate that the closely related K and U haplogroups have markedly different effects on risk of developing late-onset neurological diseases. The difference in risk between these haplogroups can be explained by the presence of the SNP 10398G in K and J and its absence in haplogroup U. We have revealed that mt variability affects risk for late-onset PD and suggest that males of a certain mitochondrial lineage may be at greater risk.

Frequency of deletions in dystrophin gene in Mexican patients with muscular dystrophy Duchenne/Becker and carrier status detection. *G. Garcia-Escalante¹, L. Gonzalez-Herrera¹, I. Castillo-Zapata¹, D. Pinto-Escalante¹, A. Gonzalez-Del Angel².* 1) Lab de Genetica, Univ Autonoma Yucatan, Merida Yucatan, Mexico; 2) Departamento de Investigacion en Genetica Humana INP Mexico, DF:.

Muscular dystrophy Duchenne and Becker are allelic disorders with an X linked recessive pattern of inheritance, caused by mutations on the dystrophin gene (Xp21.2). Most frequent mutations are intragenic deletions of one or more exons 50-70%, intragenic duplications in 6-8% while the remaining are point mutations and others. One third of patients have new mutations. Detection of carrier status is very important for diagnosis and genetic counselling in DMD/DMB to prevent the disorder. We determined the frequency of deletions in dystrophin gene in Mexican DMD/DMB patients and identified the carrier status in familial cases. Detection of deletions was carried out in 11 subjects with a clinical diagnosis of DMD and their families, using Multiplex-PCR of 22 segments included in 4 series. Analysis of intragenic RFLPs markers pERT 87.8/TaqI, intron 13, pERT87.15 /Bam/Hi intron 15, y the VNTR MP1P UTR 3' were used for the determination of carrier status on the basis of segregation analysis. The 81% (9/11) were sporadic familial cases. The 64% of the mutations detected in patients were deletions localized in major hotspot region (44-52 exons). 86% of the mothers were informative for at least one polymorphic marker. Carrier status was identified in 84% (11/13) of the sisters and it was discarded in two of them. The allele frequency of polymorphic markers and heterozygosity index found in the studied population were: 0.61 allele A2 (74+71 pb) 87.8/Taq I and 0.91 allele F2 (166+50 pb) pERT 87.15/BamHI and 0.42 and 0.17 of heterozygosity index for each one. The frequency of deletions in the dystrophin gene obtained in these Mexican patients (64%) correlates with the frequency reported for populations worldwide. Detection of mutation and identification of carrier status will provide DMD families accurate genetic counselling.

Molecular evidence for the paternal age effect in sperm. *R.L. Glaser, R.L. Schulman, E.W. Jabs.* Inst. Genet. Med, Johns Hopkins Univ., Balto., MD.

More than 10 genetic disorders are associated with advanced paternal age; half result from mutations that are exclusively paternal in origin. The paternal age effect could be explained by the copy-error hypothesis. In males, 36 divisions give rise to the spermatogonia stem cells that are present before puberty. After puberty, these cells divide every 16 days or 23 times per year. Because replication of spermatogonia is constant during a man's lifetime, the number of mutations could increase or accumulate with age. To test this hypothesis we collected sperm samples from men who were recruited using a questionnaire designed to exclude unusual exposures. Samples were screened for the two FGFR2 mutations accounting for 99% of all cases of Apert syndrome because they are associated with advanced paternal age, exclusively paternal in origin, recurrent and relatively frequent. The more prevalent mutation, 934C→G, occurs within a CpG dinucleotide while the 937C→G mutation does not. We developed allele-specific peptide nucleic acid mediated PCR-clamp methods with the Roche LightCycler that were robust, specific and sensitive enough to detect one mutant sperm per 20,000. Samples from 59 men ages 20-79 were analyzed (13 had fathered a child with sporadic Apert syndrome). Mosaicism was also assessed by analyzing a second sperm sample and a blood sample from a subset of positive individuals. In 46% (27/59) of the men either one or both mutations were detected in their sperm but were not present in their blood. Among the men who had not fathered a child with Apert syndrome, the percentage with the 937C→G mutation increased with age (17%, ages 20-29 vs 60%, ages 70-79). The frequency of this mutation in sperm also increased with age. The average number of mutant sperm per million in men ages 20-29 was 0.044 ± 2.08 as compared to 10.73 ± 3.83 in men ages 70-79 ($p < 0.01$). The frequency of the 934C→G mutation did not increase with age. However, the fathers of Apert children had 2.09 ± 0.87 more mutant sperm per million with the 934C→G mutation as compared to their age matched cohort ($p < 0.01$). Our data provides molecular evidence in support of the paternal age effect and suggests that different types of mutations may have different frequencies in sperm.

Identification of new mutations within ARS gene in MDM Tunisian patients. *C. Charfeddine¹, S. Abdelhak¹, M. Mokni², S. Boubaker³, S. Ghedamsi², R. Elkares¹, A. Ben Osman², K. Dellagi¹.* 1) Immunology, Institut Pasteur, Tunis, Tunisia; 2) Service de Dermatologie, Hôpital de La Rabta, Tunis, Tunisia; 3) Service Anatomopathologie, Institut Pasteur, Tunis, Tunisia.

Mal de Meleda (MDM) is a rare autosomal recessive genodermatosis with a prevalence in the general population of 1 in 100 000. This skin disorder is characterized by symmetric, transgressive palmoplantar keratoderma (PPK), keratotic skin lesion and hyperhidrosis. It can be associated with brachydactyly and nail abnormalities. The gene responsible for MDM has been mapped on chromosome 8qter by homozygosity mapping in large consanguineous Algerian families and coding a protein named SLURP-1, for secreted Ly-6/uPAR related protein-1. Mutations have been shown to be involved in MDM. The ARS gene extends over 2 Kb and comprises 3 exons. Three different homozygous mutations 82delT, 178G+1A and C286T were detected in families of Algerian and Croatian origin. Genetic analysis revealed three different haplotypes cosegregate with these mutations. Our aim study was the investigation of the molecular basis of MDM in Tunisian patients. Mutation screening of ARS gene within 8 consanguineous Tunisian families from different geographical origins, including 12 affected individuals, lead to the identification of three different ARS alteration. The 82delT mutation, identified within Algerian and Croatian patients was found in 8 patients belonging to 4 families. Two new mutations specific to Tunisian patients were identified, these mutations are missense C99Y and C77A within exon 3.

Mutation in the *PAX9* gene and absence of mutations in *MSX1* gene in Portuguese families with hypodontia.

*P.M.P. Seada*³, *T. Pinho*^{1,2}, *C. Pollman*¹, *J. Sequeiros*^{3,4}, *P. Tavares*¹, *P. Maciel*^{3,4}. 1) Faculty of Dental Medicine, Univ. Porto; 2) ISCS-Norte, Portugal; 3) UnIGENe, IBMC, Univ. Porto, Portugal; 4) ICBAS, Univ. Porto, Portugal.

Hypodontia, the congenital absence of one or several permanent teeth, represents one of the most common forms of dental anomalies. Although the molecular mechanisms involved in tooth development are largely unknown, homeobox genes are known to be related to tooth genesis and orofacial clefting. Two genes, *PAX9* and *MSX1*, have been implicated in the agenesis of the second premolars and third molars and in the lack of most permanent molars, respectively. *MSX1*, however, has been excluded in families with other forms of specific hypodontia, such as the lack of incisors and premolars. We have studied the occurrence of congenitally missing permanent lateral incisors in a sample of 16,771 patients, registered at a university dental clinic, for whom ortopantomographies were available. In 219 patients, congenital absence of maxillary incisor was observed and confirmed by questionnaire/observation, corresponding to a prevalence of 1.3%. Thirty-four of these probands were observed clinically, as well as their direct relatives and from these, 17 (50%) reported a familial history of tooth absence and/or anomalous tooth structure. We performed mutational analysis of the coding region (exons 2 to 4) of *PAX9* and of the coding region of *MSX1* (first and second exons), in probands from twelve Portuguese families, comprising 23 cases of hypodontia and 24 healthy individuals. The direct sequencing of PCR products containing the exons and intron/exon borders of these genes showed two nucleotide changes in exon 3 of *PAX9* gene: a silent change (C717T) in His239 codon in the homozygous state was present in one family, while a missense mutation (G718C), causing an Ala240Pro substitution, was observed in 5 families, both in the homozygous and heterozygous state. This study will proceed with analysis of other members of these families, to determine the correlation between the referred mutation and the observed phenotypes. No nucleotide changes were observed in the *MSX1* gene.

Double Mutations Can Cause False Exclusions in STR Paternity Testing. *G. Sun¹, S. Raskin², J. Sun¹, H. Cheng¹, A. Deka¹, R. Chakraborty¹, R. Deka¹.* 1) Dept Environmental Health, Univ Cincinnati, Cincinnati, OH; 2) Laboratório Genética, Curitiba, Brazil.

PCR-based typing of STR loci is currently the most widely used genetic tool for paternity testing. However, as yet the analytical treatment of mutations at such analyses is not a fully resolved issue. Mutation rate at most tetra-nucleotide loci is low, and consequently, the chance of two paternal mutations is low. Therefore, it is accepted that nonpaternity can be asserted when at least two exclusions are found. In the analysis of 13 CODIS STR loci involving the mother, child, and alleged father, one mismatch between the alleged father and child is a single exclusion. Non-paternity cannot be determined without typing additional loci. Such tests will reveal either: more loci excluding the alleged father; or no further exclusion, indicating that the original single exclusion is a mutational event. In a dataset of 3322 trios with disputed paternity, 77 single exclusionary cases were found to be mutational events. In addition, for the 6 double exclusionary cases, we analyzed nine supplementary STR loci. Only one case was found to be real exclusion, confirmed by six exclusions; the other five double exclusionary cases could not be excluded, establishing these to be double mutational events. The observed probability is 0.15%, indicating that double mutations may be observed three times in two thousand trios. These observations imply that all two-locus exclusionary events are not necessarily due to non-paternity. In our data, the observed average mutation rate is 1.6×10^{-3} , with a 10-fold bias of paternal versus maternal mutations. So, when 13 STR loci are tested, the expected frequencies of one-locus and two-locus paternal mutations would be 3.15%, and 0.099%, respectively, translating in an occurrence of one double mutation event in every one thousand tests. We observed 94% of the mutations are loss or gain one repeat, and only 6% involving two or more repeats. Thus, repeat number differences of discordant alleles at the exclusionary loci should also be considered along with typing a supplementary set of loci to distinguish double mutation events from actual nonpaternity.

An analysis of OPTN gene mutations among Japanese patients with normal tension glaucoma and primary open-angle glaucoma. *S. Tang¹, Y. Toda¹, D.R. Smith¹, F. Mabuchi², Z. Yamagata¹*. 1) Health Sciences, Yamanashi Medical University, Yamanashi, Japan; 2) UCSD Shiley Eye Center, La Jolla, California.

Glaucoma represents one of the most common eye diseases and is characterized by progressive loss of visual acuity. In the more advanced stages, bilateral blindness may result due to optic nerve atrophy and an excavated optic nerve head. Open-angle glaucoma represents one of the main disease subsets, which may be further divided into primary open-angle glaucoma (POAG) and normal tension glaucoma (NTG). The optic neuropathy inducing gene (OPTN) has been previously identified as a causative factor for POAG. To investigate possible racial differences, single-strand conformation polymorphism analysis and subsequent sequence analysis was performed for genotyping the OPTN gene in 148 unrelated Japanese patients with NTG, 165 patients with POAG and 202 controls who were not suffering glaucoma. Although c.412G>A was found in all NTG, POAG and controls, we were unable to detect any c.458G>A mutation among the Japanese patients. Furthermore, there were no significant differences between NTG / POAG and control groups. Interestingly, the novel c.457C>T (T49T) genotype was found in one POAG patient. Our study suggests that there may be certain racial differences between Japanese and Caucasians with respect to OPTN genotypes.

Program Nr: 1132 from 2002 ASHG Annual Meeting

Genetic Polymorphism of N-acetyltransferases 1 in a Korean Population. *S.Y. Kong, J.W. Kim.* Clinical Pathology, Samsung Medical Center, Seoul, Korea.

N-acetyltransferase isozymes, NAT1 is polymorphic and capable of N-acetylation of aromatic and heterocyclic amine carcinogens. Ethnic differences exist in NAT1 genotype frequencies that may be a factor in cancer incidence. But, less work has been done to characterize NAT1* allelic variants in Korean population. A group of 100 unrelated Korean subjects was genotyped using a polymerase chain reaction and direct sequencing. A entire 872 base pair coding region of NAT1 gene was fully sequenced. Of 200 NAT1*alleles assayed, 57% were NAT1*4 wild type. Alleles NAT1*10 and *3 were found at 39.5% and 3.5%, respectively. Major genotypes were NAT1 *4/*10(45%), *4/*4 (31%) and *10/*10(17%). The unusually high frequency of NAT1*10 alleles, which contains a variant polyadenylation signal may be significant for epidemiological studies of the effects of the NAT1 polymorphism in Korean population.

Haplotype analysis of non-response to antihypertensive medication and predicting progression to renal failure in the AASK trial. *M.O. Skidmore¹, M.S. Lipkowitz⁴, B.K. Rana¹, M.G. Robinson¹, P. Mahbouti², G. Zhang¹, D. Smith³, D.T. OConnor², N.J. Schork¹ and The UCSD/Sequenom Autonomic Pharmacodynamic Pharmacogenomics Program Project.* 1) Dept. of Psychiatry, UC San Diego, School of Medicine, La Jolla, CA; 2) Dept. of Medicine, UC San Diego, School of Medicine, La Jolla, CA; 3) Dept. of Biology, UC San Diego, La Jolla, CA; 4) Dept of Medicine, Mount Sinai School of Medicine, New York, NY.

The African American Study of Hypertension and Kidney Disease (AASK) trial¹ conducted from 1995 to 2000 examined 1094 African American patients with hypertensive renal disease and compared metoprolol, ramipril, and amlodipine for efficacy with respect to blood pressure, end stage renal failure (ESRF), and mortality. Patients were followed for three to four years and changes in their blood pressure, urinary protein to creatinine ratio, and glomerular filtration rate were assessed. We have genotyped over 300 trial patients using SNPs in genes in the renin-angiotensin-aldosterone (RAS) system, beta adrenergic receptors and ion channels. SNPs were used to infer phased haplotypes with the program SNP-EM. These SNPs were also used to assess population specific substructure² using the program STRUCTURE. Our results suggest that haplotypes analysis in a heterogeneous cohort can be used to evaluate efficacy in a clinical trial. These results will further refine the development of molecular diagnostic assays for internists and nephrologists managing hypertensive patients with renal disease.

Latent class analysis does not support migraine with aura and migraine without aura as separate entities. *D.R. Nyholt¹, N.G. Gillespie¹, A.C. Heath², K.R. Merikangas³, D.L. Duffy¹, N.G. Martin¹.* 1) Genetic Epidemiology Lab, QIMR, Herston, QLD, Australia; 2) Department of Psychiatry, Washington University School of Medicine, St Louis, Missouri; 3) Yale University School of Medicine, Genetic Epidemiology Research Unit, New Haven, Connecticut.

To examine whether or not migraine without aura (MO) and migraine with aura (MA) are two separate entities, latent class analysis (LCA) was used to investigate the presence and composition of migraine symptom subgroups in a community sample of 6265 Australian twins (55% female) aged 25-36 who had completed an interview based on International Headache Society's (IHS) criteria. Consistent with prevalences in similar populations, 605 (17.5%) female and 212 (7.6%) male twins satisfied the IHS criteria for migraine without aura.

Latent class analysis of IHS symptoms identified three major symptom classes, representing i) a mild form of recurrent, typically pulsating, non-migrainous headache, ii) a moderately severe form of migraine typically, but not always, *without* visual aura (i.e., 41.9% individuals positive for aura), loading on all IHS MO symptoms except "unilateral location" and "nausea, vomiting or diarrhoea", and iii) a severe form of migraine typically *with* visual aura (i.e., 76.3% individuals positive for aura), loading on all IHS symptoms for migraine.

Genetic model fitting indicated a significantly greater genetic contribution to migraine using the LCA classification (heritability, $h^2=0.44$, 95% CI: 0.38-0.51) compared to the IHS classification ($h^2=0.33$, 95% CI: 0.22-0.43). Importantly, factor analysis indicated a single factor best fit the data and therefore does not support the hypothesis of MO and MA as separate subtypes. Rather, our data indicate the existence of a continuum of severity.

In searching for predisposing genes, we should therefore expect to find some trait loci in common to all major classes of migraine, with perhaps additional loci, or more severe alleles associated with more severe types, including MA.

Folic acid fortification decreases the rate of Spina Bifida (SB) in an inner city population by 65%. *R.W. Marion^{1,2}, L. Schendel², E. Hantman^{1,2}*. 1) Children's Hospital at Montefiore, Bronx, NY; 2) Blythedale Children's Hospital, Valhalla, NY.

In 1992, the U.S. Public Health Service recommended that to reduce the risk of neural tube defects, women should take 0.4 mg of folic acid prior to conception. In 1998, by order of the FDA, fortification of staple foods with 140 ug/100 g was begun. In order to assess the effect of these recommendations on the incidence of SB, we analyzed the year of birth of all 204 patients registered for care at the SB Clinic (SBC) at Blythedale Children's Hospital since the clinic's inception in February 1987. The clinic serves an inner city population. Since 1987, no changes have occurred in prenatal diagnostic availability, incidence of elective TOP or referral patterns. All babies with SB discharged from our affiliated hospitals are referred to our clinic. Our data show that from 1987 through 1992, an average of 9.3 new infants per year were enrolled in the SBC. From 1993-1998 (the years following the Public Health Service's recommendation), the average dropped slightly to 8 infants/yr. In 1999-2001, following mandated fortification of staple foods, only 10 new pts were born, an average of 3.3 pts/year. Our data indicate that, although passive recommendations about folic acid use had little effect on the incidence of SB in an inner city population, active fortification of the food supply decreased the number of children entering our SBC by nearly 2/3. This figure correlates well with observations from other populations.

A TNF- α inducible promoter variant of interferon-gamma accelerates AIDS progression. *P. An*¹, *D. Vlahov*², *J.B. Maroglick*², *J. Phair*³, *T.R. OBrien*⁴, *J. Lautenberger*⁵, *S.J. OBrien*⁵, *C.A. Winkler*¹. 1) IRSP, SAIC-Frederick, Inc., NCI Frederick, Frederick, MD; 2) Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 3) Northwestern University Medical School, Comprehensive AIDS Center, Chicago, IL; 4) Viral Epidemiology Branch, DCEG, National Cancer Institute, Bethesda, MD; 5) Laboratory of Genomic Diversity, National Cancer Institute, Frederick, MD.

Polymorphisms in the genes for HIV-1 coreceptors and their natural ligands have been shown to modify HIV-1 transmission and disease progression and have led to important insights into the pathogenesis of HIV-1 infection. Cytokine genes, having a broad role in immune regulation, are candidate genetic factors that may modify HIV-1 pathogenesis. Interferon-gamma (IFN-gamma), is a crucial regulator of cellular immune responses to intracellular pathogens. We recently reported a single nucleotide polymorphism, IFNG -179G/T, in the promoter of IFNG that the variant allele is present in 4% of African Americans and less than 0.2% of European Americans. The IFNG promoter carrying the variant allele -179T was shown to be inducible by TNF- α and to constitutively bind nuclear extracts obtained from T cells, while the promoter with the more frequent -179G allele is non-responsive to TNF- α . We thus investigate the effects of IFNG -179G/T on AIDS progression in HIV-1 infected individuals. In African American HIV-1 seroconverters, the IFNG -179G/T heterozygous genotype was found to be associated with accelerated rate of progression to CD4⁺ T cell < 200 cells/mm³ and AIDS (1993 CDC definition). Our results show that IFNG -179T associated with altered regulation of gene transcription is a risk factor for progression of HIV-1 disease. It is possible that TNF- α induces increased IFN-gamma production when the -179T allele is present, and together these two cytokines act synergistically to induce CD4⁺ T cell depletion by apoptosis. It remains to be determined if the -179T allele is associated with susceptibility to other infectious diseases or immune disorders, particularly those disproportionately affecting people of African origin or descent. (Funded in part by DHHS #NO1-CO-12400.).

Association between the ABCA1/G1051A polymorphism and Alzheimers disease. *P.P. Desai*¹, *S.T. DeKosky*^{1,2,3}, *M.I. Kamboh*^{1,2}. 1) Human Genetics, Univ Pittsburgh, Pittsburgh, PA; 2) Psychiatry, Univ Pittsburgh, Pittsburgh, PA; 3) Neurology, Univ Pittsburgh, Pittsburgh, PA.

Alzheimers disease (AD) is a genetically complex neurodegenerative disorder that results in the impairment of multiple cognitive functions. Increasing evidence suggests a potential role of cholesterol in the pathophysiology of AD, and provides a rationale for examining the role of genes involved in cholesterol metabolism in AD pathogenesis. The ATP-binding cassette transporter 1 (ABCA1) regulates cholesterol efflux from tissues into the reverse cholesterol transport pathway. Thus, ABCA1 activity is crucial for the excretion of cellular cholesterol and for the synthesis of high-density lipoproteins. ABCA1 is also a positional candidate gene as it is located on human chromosome 9q22-q31, which is in close vicinity to the 9q34 region linked to AD in previous studies. Several polymorphisms have been identified in the ABCA1 gene, which have been associated with coronary artery disease or Tangier disease. No genetic association studies have yet been carried out to investigate the role of ABCA1 in AD. In the present study, we examined the role of the ABCA1/G1051A polymorphism in modifying the risk of AD in 693 sporadic, late-onset AD cases (mean age $72.94 \pm \text{SD } 6.82$) and 645 non-demented controls (mean age $75.89 \pm \text{SD } 5.08$). The G1051A variant showed a modest association with AD, with an age, gender and APOE-adjusted OR of 1.30 (95%CI: 1.02-1.66; $p=0.036$). When the data were stratified by gender, significantly higher frequencies of 1051*A allele (0.308 vs. 0.255; $p=0.014$) and 1051*A allele carriers (54.8% vs. 43.7%; $p=0.001$) were observed among female AD cases ($n=469$) compared to female controls ($n=396$), with an adjusted OR of 1.68 (95%CI: 1.24-2.28; $p=0.0009$). When the female data were further stratified by APOE*4 carrier status, the G1051A polymorphism showed a significant association with AD among non-APOE*4 carriers (OR 1.74; 95%CI: 1.20-2.52; $p=0.0036$). Our data confirm the existence of a putative AD risk gene in the chromosome 9q region, and suggest gender differences in that risk.

alpha 2b adrenoceptor polymorphism and Cardiovascular disease in Koreans. *J.R Choi^{1,2}, E.Y Cho^{1,2}, S.J. Bae^{1,3}, H.Y. Park^{1,2}, Y. Ko^{1,2}, Y. Jang^{1,2}.* 1) Cardiovascular Genome Center, Yonsei University, Seoul, Korea; 2) Yonsei Cardiovascular Research Institute, Division of Cardiology, Department of Internal Medicine, Yonsei University, College of Medicine, Seoul, Korea; 3) Department of Food and Nutrition, College of Human Ecology, Yonsei University, Seoul, Korea.

Cardiovascular disease is a complex multigenic disorder, which the significant inheritable element have important roles with environmental factors. Recently significant evidence has been provided for the pathophysiological involvement of the alpha 2 adrenoceptor gene in coronary artery disease. alpha 2-adrenoceptor subtype, in particular the 2b subtype, may also play an important role in the vasoconstrictor responses to the alpha 2-adrenoceptor agonists. The aim of this study was to investigate the relationships between an insertion/deletion(I/D), 9 base size difference polymorphism in the 2b-adrenoceptor gene and cardiovascular diseases and blood pressure in Korean male subjects. We examined alpha-2b adrenoceptor polymorphism which was located in the third intracellular loop of the receptor polypeptide, in 134 patients with myocardial infarction and 94 healthy males who visited the cardiovascular genome center in Yonsei Medical Center. In patient group, 53 men (0.40) had the I/I genotype; 54 men (0.40) had a heterozygous genotype, and 27 (0.20) had the D/D genotype. In control, 30 of 94 men(0.32) had the I/I genotype; 52(0.55) had the I/D genotype and D/D genotype frequency was 0.13. D allele frequency in MI patients was slightly higher than its in controls, but was not significantly different from two groups. alpha-2b adrenoceptor D polymorphism was not affected to systolic and diastolic blood pressure in healthy group. According to the logistic multiple regression test, the alpha 2-adrenoceptor genotype was not significantly associated with coronary artery disease in this study groups(OR=1.724 CI:0.824-3.608). The alpha 2-adrenoceptor gene is not a novel risk factor for coronary artery disease in Koreans and it was a different results in Finnish men.

Guanine nucleotide binding 3 (GNB3) haplotype analysis in the Venecia-Colombia Latin-American blood pressure study. *E.A. Garcia*^{1,2}, *D. Aristizabal*³, *J. McEwen*², *J. Mendez*², *P. Munroe*¹, *M. Caulfield*¹. 1) Clinical Pharmacology, St Bartholomews, London, Central london, England; 2) Corporacion para Investigaciones Biologicas CIB, Seccion de Biologia Molecular. Medellin-Colombia; 3) Department of Preventive Medicine. Clinica Medellin. Medellin-Colombia.

Blood pressure is a continuous variable and the upper extreme of the distribution is an independent risk factor for cardiovascular disease. Polymorphisms in GNB3 have been associated with essential hypertension in some genetic studies. Our aim was to test if GNB3 was associated with hypertension in individuals of Latin-American descent. One thousand and two healthy individuals from Venecia-Colombia were recruited in 1997 to study the genetic component of blood pressure. A diastolic population blood pressure distribution was constructed. Individuals in the upper and lowest quintile were studied: hypertensive (HT) and normotensive (NT) groups. Five SNPs: A-350G in the promoter and 4 in the gene T657A, G814A, C825T, and C1429T were genotyped for both groups using the SNP scoring platform of PyrosequencingTM. One hundred and thirty-two hypertensives and 160 NTs were genotyped for all SNPs. Hardy Weinberg Equilibrium was found for all the SNPs typed. The allele frequencies were not found to differ between HT and NT groups. Twelve haplotypes were found in 584 chromosomes, 4 haplotypes represented 68% of the population. The 4 common haplotypes were (HT frequencies-NT frequencies): hap4 GTGTT 0.28-0.31; hap2 GTGTC 0.16-0.12; hap5 GTGCC 0.30-0.33 and hap1 ATGCC 0.12-0.14, none were associated with hypertension ($P > 0.05$). In summary, no association was found between the variants analyzed in GNB3 and blood pressure. Power calculations with the observed allele frequencies suggest that more individuals are required before GNB3 can be excluded. At present we are genotyping the whole Venecia population to establish if this gene is associated with normal variation in blood pressure levels.

LACK OF ASSOCIATION BETWEEN ANGIOTENSIN I CONVERTING ENZYME GENE POLYMORPHISM AND DIABETIC NEPHROPATHY IN TUNISIAN POPULATION. *I. Arfa¹, C. Amrouch-Rached², A. Abid², S. Blousa-Chabchoub², S. Chakroun¹, K. Dellagi¹, S. Abdelhak¹.* 1) Immunology, Institut Pasteur, Tunis, Tunisia; 2) Institut national de nutrition ,Tunis ,Tunisia.

Diabetic nephropathy is a micro vascular complication of type 1 and type 2 diabetes due to uncontrolled diabetes and genetic susceptibility factors. It can be caused by an increase of glomerular pressure due to diabetes. The glomerular pressure is controlled by the renin-angiotensin system namely angiotensin II and angiotensin I converting enzyme (ACE). The gene encoding ACE has an insertion/deletion(I/D) polymorphism that appears to be associated with diabetic nephropathy. The aim of our study was to investigate the relationship of this polymorphism and diabetic nephropathy in the Tunisian population. A case-control study was conducted among 55 diabetic patients with nephropathy complication ,53 diabetic patients without diabetic nephropathy and 71 healthy controls. Genotyping was performed using a nested PCR amplification in order to identify correctly heterozygotes individuals. Our results indicate that the distribution of DD, ID and II genotypes of the ACE gene did not differ among the three groups. The present study shows that there is no association between ACE I/D polymorphism and diabetic nephropathy in the Tunisian population.

Interaction of C677T and A1298C polymorphisms in the MTHFR gene in association with neural tube defects in the State of Yucatan, Mexico. *L.J. Gonzalez-Herrera¹, M.P. Flores-Machado¹, I.C. Castillo-Zapata¹, M.G. Garcia-Escalante¹, D. Pinto-Escalante¹, A. Gonzalez-Del Angel².* 1) Genetics Lab, CIR, Univ Autonoma de Yucatan, Merida, Yucatan, Mexico; 2) Departamento de Investigacion en Genetica Humana. INP.

Neural tube defects (NTD) are highly prevalent (6.6 in 1 000 births) in the State of Yucatan, Mexico. Several studies have demonstrated that the two common polymorphisms, C677T and A1298C in the MTHFR gene might be associated with NTD in some populations. Compound heterozygosity CT/AC accounts for a proportion of folate related NTDs and might be associated with an increased risk for spina bifida in comparison with the presence of two wild-type alleles. In order to determine the role of these two polymorphisms and their interaction in the aetiology of NTD in the State of Yucatan, we genotyped 74 subjects with NTD and 102 NTD parents to compare with 110 control subjects. Both polymorphisms were determined by PCR-RFLP's. Allelic, genotypic and haplotypic frequencies for both polymorphisms were obtained in each group. Genotypic frequencies in control group for both polymorphisms were according to Hardy-Weinberg expectations ($p > 0.33$). We did not find any statistically significant difference in frequencies for the two polymorphisms between cases and controls ($p > 0.05$). Additionally, we made a comparison on the basis of the gender to distinguish the contribution of mothers and fathers. NTD mothers were compared with control mothers and NTD fathers with control fathers. Interestingly, we found a statistically significant differences in the mothers for allele 1298C ($p = 0.025$; OR 2.91 IC 1.02-8.68), for the heterozygous AC genotype ($p = 0.046$; OR 2.78 IC 0.90-8.88) and for the double heterozygous haplotype CT/AC ($p = 0.054$; OR 4.0 IC 0.68-26.19). Results suggest that the C677T and A1298C variants in MTHFR gene are not associated with NTD neither in the affected subjects nor in the fathers with NTD, whereas for mothers, the A1298C allele, AC genotype and AC/CT are associated with NTD. So, these genetic features are maternal risk factors for having NTD offspring in the studied population of the State of Yucatan, Mexico.

Effects of additive selection and recombination on Homozygosity Test at microsatellite loci under generalized stepwise mutation model. *Y.-X. Fu¹, H. Xu¹, M. Kimmel², A. Renwick², R. Chakraborty³*. 1) Human Genetics Center, Univ. Texas School of Public Health, Houston, TX; 2) Statistics Department, Rice University, Houston, TX; 3) Center for Genome Information, Department of Environmental Health, Univ. Cincinnati, Cincinnati, OH.

The conditional distribution of expected homozygosity in a sample given the number of segregating alleles has been widely used as a test of selective neutrality for protein and immunological markers. The underlying theory is that the allele frequency spectrum observed in a sample for a fixed number of observed alleles is independent of the parameters of the allele frequency distribution. Thus, the critical region of the test procedure can be evaluated from the knowledge of sample size (n) and number of alleles (k). Analytical proof of this theory holds for a population of constant size under mutation-drift equilibrium with the Infinite Allele Model (IAM) of mutations. However, theoretical as well as empirical data demonstrate that microsatellite loci evolve with stepwise mutations (SMM) where the repeat size changes induced by single mutations are restricted (most often increase/decrease of one repeat unit). We have shown that for loci evolving under such mutation models the conditional distribution of allele frequency spectrum, given a number of alleles (k), is no longer independent of q (product of effective population size, N_e , and mutation rate, m). In fact, with increasing value of q , the distribution of sample homozygosity (F) shifts towards left (i.e., smaller values). In this investigation, we show that this is also true for microsatellite loci that are closely linked (no recombination) to a locus under additive directional selection. Compared with the case of neutrality, additive directional selection produces an excess of F for a given k . But when two-locus haplotypes are considered as distinct alleles, given the number of segregating haplotypes in a sample (k), the distribution of sample homozygosity (F) is independent of q and consequently the homozygosity test is robust against recombination. (Research supported by US PHS grants CA 75432 and GM 58545 from the US National Institutes of Health).

Characterization of genetic variants within the 10 kb mannose binding lectin (MBL2) locus. *T. Bernig, C. Foster, M. Yeager, J.G. Taylor, S. Chanock.* Pediatric Oncology Branch, National Cancer Institute-ATC, Gaithersburg, MD.

Mannose-binding lectin, MBL2, constitutes an important component of innate immune response. MBL2 is an opsonin that binds carbohydrate structures on microorganisms and activates the complement pathway. MBL2 variants have been associated with disorders characterized by poor immune complex clearance (e.g., polyarthritis), chronic infections (e.g., filariasis) and complications of immunodeficiency states. Three non-synonymous SNPs in exon1 (known as B, C and D) have been shown to decrease oligomerization and complement activation. B and C have arisen independently (B in Eurasian and Native Americans and C in Sub-Saharan Africa) and the cumulative heterozygosity in populations with substantial admixture is between 20 and 35%. Three low efficiency promoter SNPs, (H/L, X/Y and P/Q at positions 550, -221 and +4 respectively) have been described and are in linkage disequilibrium with the structural SNPs, B, C and D. Haplotypes based upon these 6 SNPs correlate with low circulating levels and decreased function. In an effort to comprehensively characterize variation across this locus, we have re-sequenced the 10 kb gene in 32 subjects (3,004 bp of 5' UTR and 675 3' UTR) representing four separate populations. Sixty-five variants including 2 common intronic deletions and 15 novel promoter SNPs have been validated; an estimate of nucleotide diversity by Tajimas test in MBL2 suggests it is not under positive selection ($p=16.9 \times 10^{-4}$ and $q=13.6 \times 10^{-4}$). The proportion of synonymous substitutions/synonymous site (DS) and non-synonymous substitutions/nonsynonymous site (DN) was determined for human MBL2 and the mouse ortholog, *mb1c*, was calculated for the coding region; the value of DN/DS was 0.386, as predicted for a gene not under positive selection. A high density of common SNPs together with the calculated DN/DS suggests purifying selection for MBL2. Furthermore, based upon the high density of newly validated SNPs, further analysis is required to validate the newly determined haplotypes estimated thus far (by E-M), before these data can be applied to investigate MBL2 variants in disease association studies and the study of population genetics.

CD36 as a candidate gene predisposing to severe malaria: polymorphism screening and association with cerebral malaria. K. Omi¹, J. Ohashi¹, J. Patarapotikul², H. Hananantachai², I. Naka¹, S. Looareesuwan², K. Tokunaga¹. 1) Human Genetics, University of Tokyo, Tokyo, Japan; 2) Tropical Medicine, Mahidol University, Bangkok, Thailand.

Plasmodium falciparum malaria remains a major cause of morbidity and mortality in tropical countries. To date, a large number of association studies have highlighted the potential importance of host genetic polymorphisms in the pathogenesis of severe malaria. The human *CD36* gene represents one of most attractive candidate genes for susceptibility to severe forms of malaria. Therefore we screened the all 15 exons, including parts of the neighboring introns, as well as the promoter region of *CD36* and examined a possible association of identified polymorphisms with the severity of malaria in 475 Thai malaria patients. In the screening, a total of 10 polymorphisms were detected, including one novel non-synonymous substitution (S127L). Among these polymorphisms, the -53G>T promoter polymorphism was associated with the protection from cerebral malaria (OR = 0.67, 95%CI = 0.46-0.98, P = 0.043). To examine the influence of this polymorphism on *CD36* transcription level, *CD36* mRNA in monocytes derived from healthy Japanese was semi-quantitatively analyzed by real-time RT-PCR. Our result showed the tendency for mRNA level of *CD36* to decrease in the -53T allele carriers. Mean mRNA level of *CD36* was decreased in the -53T allele carriers compared to the non-carriers by 0.14-fold, although no statistical significant difference was observed. These findings would contribute to understand the mechanism of transcriptional regulation of *CD36* and the pathogenesis of cerebral malaria.

Association Study of Nonsyndromic Cleft Lip With or Without Cleft Palate with AHR, ARNT, and CYP1A1

Genes. *S. Kayano*^{1,2}, *K. Kanno*^{1,2}, *A. Yamada*¹, *Y. Suzuki*², *S. Kure*², *Y. Matsubara*². 1) Dept of Plast and Reconst Surg, Tohoku Univ School of Med, Sendai, Miyagi, Japan; 2) Dept of Medical Genetics, Tohoku Univ School of Med, Sendai, Miyagi, Japan.

The etiology of nonsyndromic cleft lip with or without cleft palate (NSCL/P) is still controversial, but is considered to involve both genetic and environmental factors. One of the suspected environmental factors is 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) contained in tobacco smoke, because TCDD causes a high percentage of cleft palate in fetuses when administered during organogenesis in mice. Aryl hydrocarbon receptor (AHR), aryl hydrocarbon receptor nuclear translocator (ARNT), and cytochrome P450 1A1 (CYP1A1) are the enzymes involved in TCDD metabolism, thereby candidate genes for NSCL/P. We assessed whether there is any association of NSCL/P and single nucleotide polymorphisms (SNPs) in the AHR (R554L), ARNT (V623V, P706L), CYP1A1 (I462L) genes using transmission disequilibrium test (TDT). Genomic DNA was prepared from blood samples from 100 Japanese families (287 members) with NSCL/P. Genotyping was performed with a unique allele-specific TaqMan polymerase chain reaction method (Fujii et al., Hum. Mutat. 15:189-196,2000). TDT was carried out by GENEHUNTER 2. Significance levels of AHR (R554L), ARNT (V623V), and CYP1A1 (I462L) were, 0.8312 ($c^2=0.05$), 0.3173 ($c^2=1.00$), and 0.9013 ($c^2=0.02$) respectively. Analysis of ARNT (P706L) could not be performed because of low allelic frequencies. In conclusion the SNPs of AHR, ARNT, and CYP1A1 examined in this study were not associated with NSCL/P in Japanese.

Allele frequency distributions of two VNTR markers in North Indian population and Apo B polymorphism in patients with gall stone disease. *M. Mukherjee, A. Srivastava, A. Kesari, M.K. Singh, G. Choudhury, B. Mittal.*
Medical Genetics, Sanjay Gandhi Postgraduate Ins, Lucknow, Uttar Pradesh, INDIA.

Markers like VNTRs at locus D1S80 and Apolipoprotein B 3 HVR are widely used for polymorphic studies in different populations. The polymorphism data in North Indian population at these VNTR loci and association of Apo B polymorphism with gall stone disease is unknown. In this study, we analyzed the polymorphisms of VNTRs D1S80 and ApoB in 86 unrelated normal individuals and carried out the Apo B polymorphism in 36 patients with gall stone disease. Genomic DNA was extracted from blood samples, related regions were PCR amplified and allele sizes were determined. In 86 individuals, 24 and 17 alleles of D1S80 and Apo B respectively determined the presence of 50 and 51 genotypes. By χ^2 analysis, the allele and genotype frequencies for both VNTRs were in Hardy-Weinberg equilibrium. The most frequent allele of D1S80 and Apo B was ~450 bp (28 repeats) and ~600 bp (40 repeats) with frequencies of 0.17 and 0.087 respectively. The Apo B alleles containing 39, 41 and 42 repeats were reported to occur more often in patients in contrast to controls having 40, 42, 43 and 48 repeats. No significant difference ($P > 0.05$) was observed in the allele or genotype frequencies between the patients and controls. The observed heterozygosity for D1S80 was 56 % and Apo B was 53.5 and 50 % in normals and patients respectively. The Apo B polymorphism may not be significantly associated with gall stone disease and therefore cannot be used as the only marker for increased risk of gall stone disease.

Assessment of SNP Haplotype-Block and Estimation of Individual Diplotype in Japanese towards Searching for Disease Susceptibility Gene. *H. Morisaki¹, A. Takashima¹, K. Yamamoto¹, Y. Kitamura², N. Kamatani², T. Morisaki^{1,3}*. 1) Dept. Bioscience, NCVC Research Institute, Suita, Osaka, Japan; 2) Institute of Rheumatology, Tokyo Women's Medical University, Tokyo, Japan; 3) Dept. Molecular Pathophysiology, Osaka University Graduate School of Pharmaceutical Sciences, Osaka, Japan.

Recent studies indicate that patterns of linkage disequilibrium in the human genome are not uniformly distributed. Therefore, the recombination events are thought to have been frequently occurred in the short hot-spots, resulting in formation of low-recombination blocks that separate longer stretches of DNA. Markers within these low-recombination blocks show increased levels of linkage disequilibrium and very low haplotype diversity. This could simplify study of the genetic basis of complex diseases in which causal variants are thought to be common. Here, we have assessed haplotype blocks of several candidate gene loci including APM1, UCP2 and SMTN in Japanese to facilitate to search for the disease-susceptibility gene of the common diseases. We have tried to select marker SNPs to minimize the number of representative single nucleotide polymorphisms (SNPs) required to account for most of the common haplotypes in each block, based on the results of analysis by the LD Support software. By this study, we have defined three haplotype blocks in APM1 locus, one block in UCP2 locus and five blocks in SMTN locus, and estimated individual diplotypes in these loci.

Program Nr: 1148 from 2002 ASHG Annual Meeting

Novel Coding Variation at codon 351 of *ADH1C* Common in Native Americans. *M.V. Osier, A.J. Pakstis, J.R. Kidd, K.K. Kidd.* Dept Genetics, Yale U, New Haven, CT.

A new *ADH1C* coding variant, Pro351Thr, has been identified and is nearly specific to Native American populations. The newly identified *ADH1C*351Thr* allele is found in most Native American populations we have studied with allele frequencies as high as 26%; only two instances of this allele have been seen in several hundred samples of Eurasian populations. This variant is only 6bp away from the commonly studied Ile349Val polymorphism and likely arose on a haplotype with the ancestral *ADH1C*349Ile* allele. Most of the haplotypes that are common globally can be accounted for by a simple tree of mutations starting from the ancestral haplotype, the one with the ancestral alleles at all sites. From that ancestral haplotype two independent haplotype lineages have evolved accumulating different variants. One lineage involves two identified mutations to generate a haplotype now common in Europe and seen in most populations around the world. A subsequent mutation on this haplotype produced the *ADH1C*351Thr* allele observed in the Americas. The *ADH1C*349Val* allele appears to have arisen on a haplotype from a separate lineage involving two different known mutations. Most significantly, we observe all four possible haplotype combinations of alleles at this new site with alleles of the adjacent *ADH1C* Ile349Val site among Native Americans, presumably due to recombination and subsequent drift, that will translate to four different amino acid sequences of ADH1C. The changes in charge, size, and rotational mobility caused by this new amino acid substitution should be significant. Because four different enzyme forms exist in Native Americans, the kinetics of these enzymes should be studied and haplotypes must be considered in studies of the role of this gene in the metabolism of ethanol and protection against alcoholism in Native Americans. It is also crucial that other previously under-examined populations be screened systematically for more functional variants of the ADH genes. [Funded in part by NIAAA grant AA09379].

Program Nr: 1149 from 2002 ASHG Annual Meeting

Non-neutral evolution revealed by comparison of gene-based DNA sequence diversity in humans and chimpanzees. *J.A. Schneider, A.E. Anastasio, Y. Morozov, T.S. Kalbfleisch, C.D. Brain, J.L. Vanden Eng, M.S. Pungliya, R. Jiang, C. Xu, R.S. Judson, J.C. Stephens.* Genaissance Pharmaceuticals, Five Science Park, New Haven, CT 06511.

We discovered 3,899 SNPs in 313 human genes by sequencing specific gene regions including exons, exon-intron boundaries, untranslated regions and 5' and 3' flanking regions. In addition to analyzing a group of 82 unrelated humans comprised of African-Americans, Asians, European-Americans and Hispanic Latinos; we also sequenced a single chimpanzee. For 2,968 of the 3,899 human SNPs discovered, we inferred the ancestral state of these polymorphisms from the chimpanzee sequence. For the majority of human SNPs, the chimpanzee sequence contained the common human allele. However, we observed a significant excess of SNPs with minor allele frequencies <20% in which the minor human allele matched the corresponding chimpanzee allele, suggesting that the major human allele at each of these sites is a derived mutation in humans. While positive directional selection is a likely mechanism to explain this observed excess of high frequency, derived alleles, we did not detect a strong overall signal of positive directional selection in these 313 genes using standard analyses of polymorphism and divergence. These results highlight the difficulty involved in understanding the potentially complicated effects of natural selection throughout human evolution.

Relative heterozygosity contributed by alleles of different frequency class is not invariant at microsatellite loci. A. Renwick¹, H. Xu², Y.-X. Fu², M. Kimmel¹, R. Chakraborty³. 1) Dept Statistics, Rice Univ, Houston, TX; 2) Human Genetics Center, Univ. Texas School of Public Health, Houston, TX; 3) Center for Genome Information, Department of Environmental Health, Univ. Cincinnati, Cincinnati, OH.

Allele frequency distribution has played an important role in characterizing the genetic variation. When alleles are divided into different frequency classes and their relative contributions to sample heterozygosity are computed, previous research showed that the relative heterozygosity contributed by alleles of different gene frequency classes is an invariant for neutral alleles under the infinite allele model. This has been used as a neutrality test and it is claimed to be robust against population substructure. In this investigation, we show that under the infinite allele model, the result is only true when q (the product of effective population size, N_e , and mutation rate, m) is small (say, $q \ll 1.0$). For microsatellite loci evolving via a generalized stepwise mutation model, the relative heterozygosity is invariant only for small q (say, $q \ll 1.0$). Since for most microsatellite loci, the mutation rate is relatively high, and consequently, q is greater than 1.0, the test can not be uncritically used to analyze data on microsatellite loci. Applications of this theory to data on microsatellite loci around the human HLA gene region suggest that either this test of selective neutrality has a low power of detecting signatures of natural selection, or strength of selection applicable to the microsatellite loci linked to the HLA gene region is too small to be detected in random sample of individuals from a population. (Research supported by US PHS grants CA 75432 and GM 58545 from the US National Institutes of Health).

Program Nr: 1151 from 2002 ASHG Annual Meeting

Mitochondrial DNA variation in a Mestizo population from the Southwest Pacific Mexican coasts. *L. Sandoval, C.A. Robles, M.T. Magaña, B. Ibarra, M.P. Gallegos-Arreola, F. Rivas, L.E. Figuera.* Divisiones de Genética, Inmunología y Medicina Molecular, CIBO, IMSS, Guadalajara, Mexico.

Mestizo populations in Mexico have Native American, European (Spanish) and African roots. The admixture took place predominantly through Caucasian and African males with Amerindian females. Genetic markers with blood groups, HLA, and other polymorphisms of nuclear DNA (Lisker et al. 1996, Gorodezky et al. 2001, Cerda Flores et al. 2002) showed that African genetic component varies by geographic region in Mexico. In this report, five mtDNA polymorphisms typed by PCR-RFLP, in 114 Mestizos from the Oaxaca and Guerrero coast communities, are presented. Out of the total samples, 105 (92.1%) Native American and five (4.4%) African haplotypes were found. Besides studies with autosomal polymorphisms (Magaña et al. 2002), present data stress the relevance of African maternal origin in Mexico, with variable marker frequencies from zero (Sandoval et al. 1998) to 4.5% (Green et al. 2000) in both Native and Mestizo populations. This study will contribute to knowledge the African maternal component in Mexican Mestizo populations.

Evidence for genetic susceptibility for Pseudotumor Cerebri in Turkish population. *C.F. Dogulu¹, T. Kansu², V. Baxendale¹, S-M. Wu¹, M. Ozguc², W-Y. Chan¹, O.M. Rennert¹.* 1) Lab of Clinical Genomics, NICHD, NIH, Bethesda, MD; 2) Hacettepe University, Ankara, TURKEY.

Pseudotumor cerebri (PTC) is characterized by symptoms and signs of isolated intracranial hypertension leading to catastrophic effects on the visual system. The clinical picture is caused by raised cerebrospinal fluid (CSF) pressure but the pathogenesis is not clear with the most widely accepted hypothesis being reduced CSF absorption through the arachnoid villi. Although the majority of cases is nonfamilial, there are reports of familial PTC that raise the possibility of some genetic defect that may become clinically manifested after exposure to a precipitating agent. We hypothesized that PTC is a multifactorial disorder with an underlying genetic thrombotic risk factor that predisposes the patients to local thrombus lining arachnoid villi that leads to increased intracranial pressure when the patient is exposed the factors known to precipitate PTC. Exon 10 of factor V was scanned for sequence variation by nucleotide sequencing in 51 PTC patients and 69 controls. Seven patients with PTC were (14%) heterozygous for factor V Leiden (FVL) mutation, versus 11 of 69 control subjects (16%; no significant difference). We also identified a heterozygous single nucleotide substitution (G to A) at nucleotide position 1628 that predicts an amino acid replacement of Arg(R)485Lys(K) in 10 of PTC patients (19.6%), versus 5 of 69 controls (7.2%). Our data revealed: 1) The prevalence of the R485K polymorphism in PTC patients was significantly different compared to the controls by chi-square test ($p < 0.05$) (OR=3.1, 95% CI -0.08 to 24.7%) and might be an important genetic modifier for the development of PTC. Our study is the first to report that a genetic polymorphism is related to an increased risk to PTC. 2) The high frequency of FVL mutation and R485K polymorphism suggests that the present day Turkish population is a perfect admixture of ancient Anatolians and Altaic-speaking, nomadic population originating in Mongolia that migrated to Anatolia. This is in contrast to previous report that ancient Turks contributed little to the gene pool of preexisting Anatolian populations.

Variation in FABP2 5'-Flanking Region Alters Transcriptional Activity and is Associated with Body Composition and Plasma Cholesterol. *C.M. Damcott¹, E. Feingold¹, S.P. Moffett¹, J.A. Marshall², R.H. Hamman², R.E. Ferrell¹.* 1) Human Genetics, Univ of Pittsburgh, Pittsburgh, PA; 2) Univ of Colorado School of Med, Denver, CO.

The fatty acid binding proteins (FABPs) are a family of cytoplasmic proteins involved in intracellular fatty acid transport and metabolism. FABP2, the intestinal-type FABP, is expressed exclusively in enterocytes in the small intestine. Previously, an Ala55Thr substitution was identified in exon 2 of FABP2. *In vitro* studies in Caco-2 cells showed that the Thr-encoding allele is associated with increased binding affinity and transport of long-chain fatty acids and increased secretion of triglycerides. In population studies, the Thr-encoding allele has been associated with increased lipid oxidation, elevated plasma lipids, and impaired insulin sensitivity. We screened roughly 1 kb 5' of the FABP2 initiation codon by direct sequencing and identified three insertion/deletion polymorphisms and three point mutations which were in perfect linkage disequilibrium (FABP2p-ID). We tested the hypothesis that this variation alters gene expression by inserting 5'-flanking sequence of individuals with opposite FABP2p-ID haplotypes into pGL3-basic reporter vector. The constructs were cloned and transfected into Caco-2 cells. Subsequent luciferase assays showed a statistically significant two-fold increase in gene expression of the pGL3-insertion construct over the pGL3-deletion construct ($p < 0.001$). We also tested for association with measures of body composition, plasma lipids, and insulin sensitivity in a sample of non-Hispanic white subjects from the San Luis Valley Diabetes Study ($n=417$). FABP2p-ID was significantly associated with fat mass from DEXA ($p=0.024$), BMI ($p=0.012$), and plasma cholesterol ($p=0.037$) in two-way ANOVAs including sex as a second factor. Plasma free fatty acids ($p=0.602$), plasma triglycerides ($p=0.152$) and HOMA IR ($p=0.165$) were not statistically significant. These results suggest that common genetic variation in the 5' region of the FABP2 gene affects transcriptional activity, presumably leading to alteration in body composition and cholesterol processing.

Dissecting the genetic contribution of a QTL within the DCP1 gene on ACE level. *A. Angius, E. Petretto, I. Persico, M. Fanciulli, D. Bebbere, A. Pernisa, R. Baldinu, G.B. Maestrale, P.M. Melis, M. Pirastu.* Istituto di Genetica delle Popolazioni, CNR, Alghero, SS, Italy.

Circulating ACE level is influenced by a quantitative trait locus (QTL) within the DCP1 gene. In order to clarify the role of this QTL, we carried out haplotype analysis and ACE levels in about 800 individuals (80% of the entire adult population) belonging to a Sardinian genetic isolate (Talana) which exhibits peculiar features such as low number of founders, high inbreeding and 16th generation genealogical records. We determined the serum ACE activity and genotyped 8 SNPs within the DCP1 gene, numbered as follows: (1)A2400T, (2)T2547C, (3)T8128C, (4)13506AluI/D, (5)G14521A, (6)A22982G, (7)23945(CT)3/2, (8)C24599T. These SNPs were chosen based on previous studies which demonstrated their association with ACE level. In addition we studied two new 5' DCP1 gene SNPs: ext1 A/G -37kb, ext2 A/G -75 kb. Linkage disequilibrium (LD) distribution was uneven in the region analysed: two recombination hot spots were detected between ext1 and SNP1 and between SNP2 and 4. The highest LD ($D > 0.9$) was observed between SNPs 4, 5, 6, 7 and between 1, 5. Single SNP association analysis suggest correlation of all the SNPs within the DCP1 gene with ACE mean activity. By haplotype analysis we refine the region of interest from SNP 4 to 7, where we found two common haplotypes DGG2 (50%) and IAA3 (40%), already described in different ethnic groups. ACE levels were normally distributed and showed significant ($P < 0.05$) correlation with age and sex. We detected a mean value of 26.1 U/l for ACE level in homozygotes IAA3, 43.5 U/l in homozygotes DGG2 and 34.1 U/l in heterozygotes IAA3/DGG2. Recombination and gene conversion of these two common haplotypes produce several rare ones differing either for a single or several SNPs included in small LD blocks. ACE phenotype was variously associated with different combination of the SNPs in these haplotypes. Our results suggest that differences in LD blocks arrangements account for the observed variation in ACE activity suggesting that these regions could contain important functional variants.

Analysis of founder effect in *SFTPB* 1549C@GAA (121ins2) mutation. *M. Bahuau*¹, *M. Stuhmann*², *J. Christodoulou*³, *T. Lorant*¹, *C. Houdayer*¹, *J. Elion*¹, *R. Couderc*¹, *M. Griese*⁴, *M. Tredano*¹. 1) Biochimie Biologie Moléculaire, Hôpital Trousseau (MB, TL, CH, RC, MT); Biochimie Génétique, Hôpital Robert-Debré (JE), AP-HP, Paris, France; 2) Institut für Humangenetik, Medizinische Hochschule, Hannover, FRG; 3) Departments of Paediatrics, University of Sydney, Australia; 4) Ludwig-Maximilians Universität, München, FRG.

Surfactant protein B (SP-B) deficiency is an uncommon cause of unexplained respiratory distress in the neonate, *i.e.*, when hyaline membrane disease, pneumonia due to atypical micro-organisms, or congenital heart disease have been ruled out. When complete, SP-B deficiency entails the absence of production of lamellar bodies and tubular myelin (the organized precursors of active surfactant), and eventual storage of protein material within the alveolar space. The onset of disease is congenital and the family pattern is consistent with an autosomal recessive which has been linked to mutations of the SP-B-encoding gene (*SFTPB*). A common mutation (1549C@GAA, or 121ins2) accounts for a sizeable fraction of the mutated chromosomes, although wide allelic heterogeneity has been lately recognized. Since no obvious unstable genetic structure seemed to underlie this lesion (mutation hot spot), we sought to examine the possibility of founder effect. For this purpose, we ascertained the genotype at 8 intragenic SNPs (including 4 novel) in 17 independent 121ins2 chromosomes from 10 probands, parental non-121ins2 chromosomes serving as controls. All subjects were of Caucasian descent (French, Dutch, German, or Australian). One major haplotype was shared by 10/17 121ins2 chromosomes versus 5, or 6/23 control chromosomes (proband and parents from one kindred were heterozygous at one SNP) ($p \gg 0.019$, or $p \gg 0.039$, Fisher's exact test). Overall, these data suggest founder effect with a major haplotype harboring the 121ins2 mutation in the Caucasian population although at least 5 independent haplotypes were elicited. Whether this diversity is due to recurrence of the mutation or intragenic recombination/genetic drift from an ancestral, mutationharboring, haplotype remains to be determined.

MEFV MUTATION SPECTRUM IN FMF PATIENTS FROM KARABAKH. *C. Cazeneuve¹, K. Atayan², D. Genevieve¹, H. Ajrapetyan³, J. Feingold⁴, T. Sarkisian³, S. Amselem¹.* 1) INSERM 468, Hosp Henri Mondor, Creteil Cedex, France; 2) Karabakh; 3) Department of Genetics, Yerevan, Armenia; 4) INSERM 155, Jussieu, Paris, France.

Familial Mediterranean fever (FMF) is an autosomal recessive disorder common in populations of Armenian, Turkish, Arab or Sephardic Jewish ancestry. To delineate the mutation spectrum in another population of Mediterranean extraction, we have investigated a cohort of 50 patients living in Karabakh. As the population from Karabakh has been isolated from the actual frontier of Armenia since the beginning of the XXth century, the spectrum of MEFV gene mutations in this area may differ from that described among Armenian patients. In particular, very rare mutations, absent from the Armenian population samples previously investigated, might be over-represented in this isolated population, due to a founder effect. Screening for mutations of all MEFV coding exons and their intronic boundaries by DGGE revealed a mutation spectrum significantly different from that reported in Armenia. The frequency of non-identified (NI) MEFV alleles is much higher among patients from Karabakh than among those from Armenia (26% vs 7%, $P=5.10^{-5}$). As no particular MEFV haplotype was over represented among the NI alleles, we excluded the existence of a unique and rare MEFV mutation resulting from a founder effect that could have escaped our mutation screening procedure. The spectrum of the identified mutations among Karabakhtsis and Armenian patients is also different: the M694V and R761H mutations were more frequent among Karabakhtsis patients ($P=0.01$ and 0.04 , respectively) and, conversely, the V726A mutation represented only 5% of the identified alleles among Karabakhtsis patients, whereas it accounted for 26% of the characterized FMF alleles in Armenian patients ($P=0.0003$); the M680I mutation was found at a similar frequency in the two populations. No new MEFV mutation was identified among the Karabakhtsis patients. Altogether, these results show that the mutation spectrum differs significantly between the two populations, an observation which may result from the relative independent evolution of each population since the beginning of the XXth century.

Low frequency of Friedreich ataxia in the Mexican Mestizo population. *M. Gomez*¹, *S. Nath*², *S. Bhatti*¹, *A. Rasmussen*³, *S.I. Bidichandani*¹. 1) Biochemistry & Mol Biol, Oklahoma Univ Health Sci Ctr, Oklahoma City, OK; 2) OMRF, Oklahoma Univ Health Sci Ctr, Oklahoma City, OK; 3) National Institute of Neurology, Mexico City, Mexico.

Friedreich ataxia is caused by an expansion of a GAA triplet-repeat sequence in the first intron of the *FRDA* gene. This sequence is polymorphic; short normal (SN) and long normal (LN) alleles have 5-11 and 12-60 triplets, respectively. Disease-causing expanded alleles (E) contain 100-1700 triplets. Most LN and E alleles share the same haplotype at the *FRDA* locus (A-T-C-C at FAD1-ITR4-ITR3-CS2 SNPs) indicating that E alleles arise from LN alleles. LN alleles with >33 triplets have been observed to expand to E alleles upon parental transmission. The allelic frequency of LN alleles predicts the incidence of Friedreich ataxia in most populations. In the Indo-European population 15% of all chromosomes have LN alleles and Friedreich ataxia is the most common inherited ataxia accounting for over 50% of all recessive and sporadic ataxias. Friedreich ataxia is non-existent in South-East Asia and in Native Americans where LN alleles account for <1% of all chromosomes. We have found that the frequency of Friedreich ataxia and LN alleles in the Mexican Mestizo population is intermediate between the Indo-European and Asian populations. Out of 91 recessive and sporadic ataxia patients we found only 9 patients (9.9%) homozygous for E alleles, consistent with the molecular diagnosis of Friedreich ataxia. Only 8 LN alleles were detected among 172 Mexican chromosomes (4.5%). Given the history of the peopling of the Americas we reasoned that the intermediate frequency among the Mestizo population might be due to genetic admixture of European *FRDA* genes in the Native population(s). We have analyzed 344 chromosomes from the Nahua (Aztec) population of Mexico and found that LN alleles account for only 2% of all alleles. In support of our hypothesis, we have found that all E alleles in the Mestizo Friedreich ataxia patients share the same conserved A-T-C-C haplotype of European *FRDA* alleles. These data have important implications for the institution of efficient diagnostic testing in ataxia patients of Mexican origin.

Markers That Discriminate Between European And African Ancestry Show Limited African Diversity. H.E.

*Collins-Schramm*¹, *R.A. Kittles*², *D.J. Operario*¹, *J.L. Weber*³, *L.A. Criswell*⁴, *R.S. Cooper*⁵, *M.F. Seldin*¹. 1) Rowe Program in Hum Genet, UC Davis, Davis, CA 95616; 2) Ntl Hum Genome Center, Howard Univ, Washington DC 20060; 3) Marshfield Med Res Found, Marshfield, WI 54449; 4) Dept of Med, UC San Francisco, San Francisco, CA 94143; 5) Prev Med and Epid, Loyola Univ, Maywood, IL 60153.

Markers informative for ancestry are necessary for admixture mapping and improving case-control association analyses. For studies in African Americans (AA) this will require markers that can be used to determine if a given genomic region is of European or African ancestry. We show that despite studies indicating high intra-African sequence diversity, markers with large inter-ethnic differences have only small variations in allele distribution among divergent African populations. 32 unlinked diallelic insertion/deletion markers with large frequency differences between one African population and European Americans (EA) were individually genotyped in >150 DNA samples each from Africans in Nigeria and Zimbabwe, EAs, and AAs. Allele frequencies in Nigerians were nearly identical to those in Zimbabweans and dramatically different from those in EAs. Perhaps more surprising, there was a strong correlation between allele distributions in the above African groups and a pooled DNA sample from 21 Pygmies. The variation for the intra-African comparisons, Nigerian/Zimbabwe (mean Wahlund variance $f=0.005$) and Nigerian/Pygmy ($f=0.02$), was very small compared to inter-ethnic African/EA comparisons: Nigerian/EA ($f=0.38$) and Zimbabwe/EA ($f=0.37$). We also examined individual admixture using the Structure program. Africans were clearly separated from EAs without prior knowledge of population affiliation, and no distinction was evident between Nigerians and Zimbabweans. AA showed considerable variation in the proportions contributed from the two parental populations. These studies emphasize the importance of controlling for individual admixture ratios in admixture mapping studies, and provide evidence that the African contribution to AA subjects can be accurately analyzed with a set of obtainable markers that distinguish between European and African ancestry.

The V281L mutation in the *CYP21* gene is a founder mutation that is prevalent among individuals of Ashkenazi Jewish and European ancestry. L. Edelman, R. Kornreich, R.J. Desnick, G.A. Diaz. Dept Human Gen, Box 1497, Mt Sinai Sch Medicine, New York, NY.

Congenital Adrenal Hyperplasia (CAH) results from mutations in the *CYP21* gene, which is located in the MHC region on chromosome 6p21. A duplicated but non-functional copy of the gene is present approximately 50 kb distal to the gene, and a number of mutations have arisen as a consequence of recombination or gene conversion between *CYP21* and the pseudogene. One such mutation, V281L, has been reported in individuals of Ashkenazi Jewish (AJ) and European ancestry with the nonclassical form of CAH. To determine the frequency of carriers of this mutation in the AJ population, an ARMS assay was designed to specifically target the *CYP21* gene and avoid confounding amplification of the pseudogene. Approximately 1,000 anonymous AJ and 120 anonymous non-Jewish (NJ) individuals of European ancestry were tested by allele specific oligonucleotide hybridization (ASOH) for the presence of the V281L allele. The carrier frequencies of this mutation were 17% and 5.8%, respectively. Sequence analysis revealed that the mutation arose by gene conversion of ≥ 262 bp to ≤ 372 bp, such that the *CYP21* gene, containing the V281L mutation, also had other changes that were present in the pseudogene. Both AJ and NJ carriers possessed this block of changes that spanned intron 6 through exon 7, suggesting a common origin. This finding was in agreement with reports that HLA-B14/DR1 haplotype was in linkage disequilibrium (LD) with the mutation. To determine the extent of LD present at this locus, microsatellite markers flanking the region were tested on 40 AJ V281L, chromosomes, 50 AJ non-carrier chromosomes and seven NJ V281L carriers. The results were consistent with the presence of a small but conserved haplotype surrounding the locus that is less than a Mb in size in both AJ and NJ carriers. These findings confirm the existence of a founder allele for the V281L mutation and raise some interesting questions about the actual age of the allele, the rate of recombination in the region and the potential source of selective pressure on the locus that has resulted in its high frequency in both populations.

Genetic variation near RXRb is associated with increased cholesterol levels in Hispanic males. *S.P. Moffett¹, C.M. Damcott¹, M. Barmada¹, E. Feingold¹, J.A. Marshall², R.F. Hamman², J.M. Norris², R.E. Ferrell¹.* 1) Human Genetics, Univ of Pittsburgh, Pittsburgh, PA; 2) Univ of Colorado School of Medicine, Denver, CO.

The retinoid X receptors (RXRs) are members of the nuclear receptor superfamily that heterodimerize with a number of the other nuclear receptors including the peroxisome proliferator activated receptors (PPARs) to form transcriptionally active complexes. The PPAR:RXR complex acts as a transcription factor, altering gene expression related to lipid metabolism and adipocyte differentiation. RXRb, one of three RXR genes, is expressed ubiquitously in human tissues. The purpose of this analysis was to determine the effect of variation near RXRb on plasma lipid levels in Hispanic individuals enrolled in the San Luis Valley Diabetes Study. An A to T transition 140bp downstream of the last exon (RXRb140) was typed in 247 individuals of Hispanic descent using an *Mbo*I restriction enzyme site. The frequency of the less common T allele was 0.271 and conformed to the expectations of Hardy Weinberg equilibrium. Analysis of variance showed an association between the T allele of RXRb140 and increased total cholesterol levels (AA=193mg/dL, AT=208mg/dL, TT=202mg/dL; $p=0.007$) that accounted for 4% of the trait variation. Plasma triglycerides and fasting free fatty acids showed no statistically significant associations with RXRb140 in this sample ($p=0.177$ and $p=0.394$, respectively). To further explore the association between RXRb140 and cholesterol, the analysis was repeated separately for males and females. The female subjects showed no statistically significant association between RXRb140 and total cholesterol ($p=0.128$), but the male individuals showed an apparently dominant effect of the T allele on total cholesterol levels that explained over 7% of the variation in the trait ($r^2=0.071$). Presence of the T allele increased total cholesterol levels by 18 to 20mg/dL as compared to the AA homozygotes (AA=186mg/dL, AT=204mg/dL, TT=206mg/dL; $p=0.013$). These results suggest a gender specific role for RXRb in cholesterol metabolism, presumably through interaction with other nuclear receptors.

Population variation at human SNPs associated with HIV resistance, susceptibility and therapy. *J.J. Martinson, A.L. Edge, M. Lewis, P.M.R. Aldred.* Inst. of Genetics, University of Nottingham, Nottingham, England.

Several human genetic loci are now known to influence the severity of HIV disease, and it is likely that many more remain to be discovered. Most aspects of HIV disease progression from initial infection through to end-stage AIDS, and even the response to common antiretroviral drugs, have been shown to be affected by host genetic loci. SNP variation at these loci is likely to become increasingly important, in predicting disease outcome and in influencing the choice of antiretroviral therapy, for individuals and also for populations. The full extent of such variation, however, is not clear at present. Here we integrate data obtained from a global survey of variation at seven SNP and other alleles known or suspected to influence HIV outcome, including three (IL-10 C-592A, eotaxin C-1382A, and MDR1 C3435T) not previously studied at the global level.

Our results show substantial variation between populations in these alleles. Many populations have high frequencies of several resistance-associated SNPs, and so their members may carry more than one resistance allele. The observed variation cannot be easily partitioned along lines of geographical proximity or of ethnic group, regardless of how these groups are defined. With the exception of the well-known cline in frequency of the CCR5-D32 allele in Europe, no strong geographical trends are seen at these loci. For example, the frequency of the MDR1 3435C allele is substantially higher in sub-Saharan Africans than in other populations, but the overall SNP allele frequency distribution does not correlate well with geographic proximity ($r=0.011$). This allele is associated with a higher rate of cellular excretion of antiretroviral drugs, and hence their reduced bioavailability; a knowledge of its prevalence in different populations may affect prescribing practice. Our results show that it is not sufficient to make assumptions of an individual's HIV resistance phenotype based on their membership of a particular ethnic group, however. A thorough determination of each individual's genotypes provides a more reliable means of predicting disease progression and response to treatment.

Evidence for the changing incidence of cystic fibrosis. *V. Scotet¹, M.P. Audrezet¹, M. Roussey², G. Rault³, M. Blayau⁴, M. De Braekeleer^{1,5}, C. Ferec¹.* 1) Dept of Molecular Genetics, INSERM EMI 01-15, Brest, France; 2) CHRU Ponchaillou, Rennes, France; 3) Centre de Perharidy, Roscoff, France; 4) Dept of Molecular Genetics, Rennes, France; 5) Dept of Cytogenetics, Brest, France.

The cloning of the gene responsible for cystic fibrosis (CF) in 1989 and the identification of its mutations have enabled to implement efficient strategies of diagnosis and disease prevention, such as neonatal screening and prenatal diagnosis. Taking into account the situation of Brittany, a region of western France where CF is common and where a neonatal screening program was set up 13 years ago, the aim of this study was to assess the changing incidence of CF and to determine how it was influenced by different programs. From 1992 to 2001, the neonatal screening program identified 123 CF children, leading to an incidence of 1/2838. Over the same period, we collected the prenatal diagnoses realised in Brittany in families related to a CF child, as well as those made following the detection of an echogenic bowel during pregnancy. By considering the 54 CF-affected pregnancies terminated during these 10 years, the corrected CF incidence was 1/1972. Prenatal diagnosis was therefore responsible for a global decrease of 30.5% in CF incidence. Two-thirds of these 54 abortions were chosen by couples related to a CF child (n=36); this led to a change of 22.6% in incidence. The 18 other abortions were made after the detection of an echogenic bowel; this ultrasound examination of pregnancies led to a decrease of 12.8% in CF incidence. Moreover, neonatal screening, through early diagnosis, enables couples to benefit from prenatal diagnosis, even before the first symptoms appeared on their previously screened child. This was the case for 13 couples in our study, which modified the incidence 6.1 percent. Finally, cascade screening, through the detection of 17 new 1-in-4-risk couples in the kin of a CF child, led to a decrease of 3.9% in incidence. This study is the first one able to determine the evolution of CF incidence through both neonatal screening, prenatal diagnosis, ultrasound exams and cascade screening. Awaiting the development of a cure, prevention remains an important aspect in the management of CF.

Effect of consanguinity on the incidence of several autosomal recessive disorders in the Azorean island of São Miguel (Portugal). *A. Simas, P.R. Pacheco, C.C. Branco, B.R. Peixoto, L. Mota-Vieira.* Genet and Molec Pathol Unit, Hospital of Divino Espirito Santo, Azores Islands, Portugal.

São Miguel island is the biggest and the most populated island (131,510 inhabitants, Census 2001) of the Azores. The present-day population is the result of <22 generations and it shows evidences of relative homogeneity. Recently, we demonstrated that »50% of the subscribers listed in the 2001 telephone book are distributed by a very small number of surnames (26 out 1,315) and that 2.2% have surnames that appear only once. Here we investigate the role of consanguinity in 20 unrelated patients affected with one of the following autosomal recessive disorders: cystic fibrosis, CF (6), hereditary hemochromatosis, HH (5), spinal muscular atrophy type I, SMA-I (3), hereditary spastic paraplegia, HSP (2), Gilbert syndrome, GS (1), Hurler syndrome, HS (1), Friedrich ataxia, FA (1) and metachromatic leucodystrophy, ML (1). To that end, we surveyed the patient's ascending genealogy up to the 6th generation. We collected maternal and paternal surnames, and place of birth for each relative. All families were classified according to the degree of parental consanguinity: closely related (second cousins or closer, $F^3=0.0156$), suspected consanguinity (same village origin and sharing common surnames) and non-consanguineous (no relationship). Among these families, 8 were consanguineous, 2 had suspected consanguinity and 10 were non-consanguineous. The mean inbreeding coefficient of the 8 patients whose parents were closely related is very high ($F=0.0596$), if compared to the island population ($a=0.00069$). Moreover, they are affected with different pathologies: CF (2), HH (2), SMA-I (2), HSP (1) and FA (1). The geographic distribution of all 20 families shows that 12 come from different rural communities, which is consistent with the fact that »60% of the population lives in rural area. Although the number of families analyzed here is small, the data indicate that the recessive mutated alleles may not be rare. The characterization of the pattern of all recessive diseases in this island is crucial for future studies of genetic epidemiology. (lmv.hospdelgada@mail.telepac.pt).

Use of multilocus DNA fingerprinting for the studies of human populations from Eastern Europe and North Asia. *E.V. Shabrova*¹, *E.K. Khusnutdinova*², *A.I. Mikulich*³, *L.A. Tarskaia*¹, *S.A. Limborska*¹. 1) Dept. of Human Molecular Genetics, Institute of Molecular Genetics, Moscow, Russian Federation; 2) Bashkir Science Center of Ural Branch of Russian Academy of Sciences, Ufa, Russian Federation; 3) Institute of Arts, Ethnography and Folklore, Minsk, Byelorussia.

We have used the technique of DNA fingerprint analysis with M13 phage DNA as a probe to investigate rather heterogeneous group of 14 human populations from Eastern Europe and Asia. These populations belong to three language families: Indo-European language family (Slavonic branch: Russians, Byelorussians), Uralic language family (Finno-Ugric branch: Mari, Mordvinians, Udmurts, Komi), Altai language family (Turkic branch: Bashkirs, Tatars, Chuvashes, Yakuts). As the result of the analysis of restriction fragments patterns generated by hybridization the size matrix of all the fragments from 10,000 bp to 2,000 bp was constructed. The set of individual patterns was presented as a binary matrix like "Object-Trait". Coefficients of differentiation for the linguistic hierarchical structure were estimated according to Lynch (1990. *Mol. Biol. Evol.* 7(5)). Phylogenetic trees were constructed and multidimensional scaling was carried out on the bases of some types of the genetic distances matrices calculated from the populations profiles of fragments frequencies. Multiple correspondence analyses were applied for the treatment of binary populations matrices. Levels of population subdivision in the groups of closely related populations appeared to be quite different. In our study two territorially separated Byelorussian populations produced no regional differences in contrast to four Bashkir populations. On the whole different methods of statistical analysis have demonstrated that the populations of Slavonic branch form the common group isolated from the populations of Volga-Ural region, Yakuts found to be most close to some of Bashkir populations and Komi to be the most distant from others. In our studies we have not found the absolute correlation between the data of multilocus DNA fingerprinting and the linguistic affinity data.

Polymorphism of the MUC1 gene and haplotype analysis in healthy individuals and in patients with gastric and oesophageal diseases. A. Teixeira¹, J. Fowler¹, L. Vinall¹, L. Lovat², M. Sarnier², D. Swallow¹. 1) The Galton Laboratory, Department of Biology, University College London, London, United Kingdom; 2) Department of Gastroenterology, University College London, London, United Kingdom.

Background: The membrane mucin MUC1, like other epithelial mucins, contains a long and variable length array of tandem repeat units. We and others have previously shown that short tandem repeat alleles are associated with an increased risk of developing *H. pylori* gastritis (Vinall et al, *Gastroenterology*, 2002, 123, in press) (Silva et al, *Eur J Hum Genet*, 2001, 9: 548-52). Despite the high level of allelic variability of MUC1, two polymorphic markers flanking the array, one SNP and one microsatellite, are in tight linkage disequilibrium. **Aims:** The aim of this study is to further characterise the polymorphism and haplotype distribution of MUC1 in the patients with gastritis as well as other patient groups and in healthy people of different ancestry. **Methods:** Southern blot analysis of *HinfI* restriction digests was used to determine TR length. Multiplex PCR, restriction enzyme digestion and analysis on ALF express (Pharmacia Biotech) were used for analysis of the flanking markers. MVR analysis (Minisatellite Variant Repeat) was used to generate maps of the tandem repeats. **Results and Discussion:** The flanking, as well as TR, polymorphisms were examined in cohorts of individuals of northern European ancestry including the previous studied patients with gastritis and 83 new patients with oesophageal carcinoma. Haplotype analysis showed some differences in the patient groups: in particular, in the gastritis group there was an over-representation of small alleles of rare haplotype. MUC1 polymorphism was also examined in a cohort of 94 Nigerians. In this population the flanking markers showed the same alleles as those present in Northern Europe, also in strong linkage disequilibrium. MVR analysis of MUC1 in a selection of patients and controls shows evidence of genetically determined tandem repeat sequence variability and the maps could be classified into classes with respect to TR map and haplotype.

Patterns of genetic variation at interleukin-13 (IL13) in human populations. *E. Tarazona, S. Tishkoff.* Dept. of Biology, Univ. of Maryland, College Park, MD.

IL13 is a pro-inflammatory cytokine that plays a critical role in the induction of Th2 immune response against extracellular parasites. It is also shown to be a susceptibility locus for asthma. We have sequenced 2891bp encompassing the entire gene in 150 individuals from 12 ethnic groups from West Africa (Maasai, Hadza), East Africa (Yoruba, Igbo, Fulani), MiddleEast/Europe (Lebanese, Northern European, Russian), China and South America (Quechua, Cayapa, Ashaninka). The nucleotide diversity is 0.0012, corresponding to 23 SNPs. Only one SNP is a non-synonymous substitution (Arg130Gln) in the fourth exon. Western-African populations show the highest level of genetic variability, followed by East-Africa, Europe and South America. African populations have higher level of intra-genic recombination and lower level of linkage disequilibrium (LD) than non-African populations. While LD decreases with increased distance between SNPs in Eurasian and Amerindian populations, African populations show no correlation between genetic distance and LD. We analyzed the spectrum of allelic diversity across the gene using several neutrality tests in order to test the hypothesis of natural selection acting on the Arg130Gln substitution. Fu and Lis test indicates a significant excess of rare SNPs in both African and Amerindian populations in the same two regions of the gene. The excess of rare alleles in African populations is consistent with evidence from numerous loci indicating past population expansion in Africa. However, because South Amerindian populations do not show any evidence of past population expansion based on nuclear loci, and due to significant LD between the Arg130Gln substitution and the region where an excess of rare alleles are observed, positive selection could have influenced the allelic spectrum of IL13 in these populations. Analysis of additional populations is required to confirm this pattern. Our identification of 16 common SNPs and the haplotype structure is informative for design of haplotype association studies for IL13 and common autoimmune disorders such as asthma. Funded by Burroughs Wellcome and Packard Career Awards and NSF grants to SAT.

Selection and gene conversion produce a unique haplotype structure at X-linked color vision genes. *B.C. Verrelli, S.A. Tishkoff.* Dept Biol, Univ Maryland, College Park, MD.

Trichromatic color vision in humans is made possible by three genes that code for red, green, and blue light-sensitive cone pigments. The red and green pigment genes are the result of a relatively recent tandem duplication on the X chromosome and frequently undergo unequal crossing over and gene conversion events, much of which leads to color blindness. Studies have shown that these two genes share many polymorphisms and that mutations in the red pigment gene can cause shifts in the visual color spectrum. Because much of this variation is not associated with color vision deficiencies, it raises the question whether this variation has an adaptive explanation. In this current study we characterize the nucleotide diversity for a 5.5-kb region of the red and green pigment genes to address the molecular and functional variation associated with color vision. Our random sample of over 160 Africans and 60 non-Africans for exons and introns finds more than 75 SNPs in the red pigment gene that account for over 12 amino acid substitutions and 22 protein haplotypes due to linkage equilibrium between some SNPs only 10 bp apart. We also find that protein haplotypes differ in frequency between African and non-African populations. Although gene conversion homogenizes red and green intron sequences, purifying selection apparently maintains several amino acid residues that are responsible for the spectral properties of the two genes. However, our comparisons with chimpanzee sequences indicate that balancing selection also maintains amino acid variation at these genes. This indicates that protein haplotypes, and not single amino acid variants, should be used to define color vision phenotypes. This study indicates that gene duplication and gene conversion may account for blocks of low linkage disequilibrium (LD) that are often found in genomic regions of high LD. It is also apparent that color vision genes rival the level of polymorphism found at other duplicated genes that show high functional diversity, like the HLA loci. Additional studies of this nature may reveal how gene duplication and selection account for novel patterns of genetic diversity and LD in the genome.

Malarial selection and the Dogon: patterns of DNA sequence variation at the b-globin locus. *E.T. Wood¹, Z. Mobasher¹, B. Strassman², M.F. Hammer¹.* 1) Ecology & Evolutionary Biology, University of Arizona, Tucson, AZ; 2) Anthropology, University of Michigan, Ann Arbor, MI.

To better understand the role of selection in shaping patterns of variation at loci that confer resistance to malaria, we sequenced 6-kb from b-globin and Dmd intron 44 (Dmd44) in 32 individuals from the Dogon, a population who reside in an endemic malarial environment in Mali, West Africa. B-globin contains two mutational sites that are known to confer resistance to malaria while Dmd44 is not subject to malarial selection and likely reflects demographic processes. Patterns of variation at these two loci were also compared in a global panel of 41 humans. Levels of pairwise nucleotide diversity at both b-globin and Dmd44 in the Dogon, as well as in the global sample, were very close to the average for the human genome ($\pi = 0.11-0.15\%$). However, there was a much higher proportion of segregating sites at the b-globin locus in the Dogon compared with the global sample ($\theta = 0.22\%$ and 0.14% , respectively). These patterns contrasted with those found at the Dmd44 locus which showed fewer number of segregating sites in the Dogon relative to that found in the global sample ($\theta = 0.09\%$ and 0.15% , respectively). The contrasting patterns of variation at these two loci in the Dogon are reflected in very different frequency distributions of polymorphisms. B-globin exhibited an excess of rare polymorphic sites in the Dogon (Tajimas $D = -0.73$; $0.10 > P > 0.05$); whereas, patterns of variation at Dmd44 in the Dogon showed a slight excess of intermediate frequency polymorphisms (Tajimas $D = 0.72$, $P > 0.10$). These results are consistent with a model of selection because demographic processes such as population expansion and subdivision are expected to affect all loci in a similar manner. To further support this inference and to clarify the model of selection acting at b-globin, these loci are being sequenced in another sub-Saharan African population from a non-malarial area.

A reference distribution of Fst values for biallelic DNA markers. A.J. Pakstis, J.R. Kidd, K.K. Kidd. Dept Genetics, Yale U., New Haven, CT.

Demographic and evolutionary histories shape the expected allele frequency variation among populations, measured as Fst. Random genetic drift (r.g.d.) will account for much of this variability for unlinked loci and even for tightly linked markers if LD is incomplete. To avoid variability in Fst estimates due to using different sets of populations, we studied 94 biallelic markers (mostly SNPs) on the same set of 32 population samples (avg ~53 persons/pop) distributed across major world regions. A distribution of Fst values for many markers based on a *standard* set of geographically diverse human populations can define the variation expected among sites due to r.g.d. Extremely large or small Fst values support some form of selection at work, at least historically. Most of the markers studied are within the intronic regions of 28 loci or gene clusters--23 widely separated regions on 16 autosomes. None of the markers are known to have been subject to selection. Most were prescreened to avoid monomorphism in a majority of populations. So, the reference distribution does not have as many Fst values close to zero as it would if all low frequency polymorphisms were included. The mean of the Fst distribution for 32 populations is .14 (median .13, std dev .07; range .04 to .37). With 2 to 7 SNPs at each of 21 loci (84 biallelic), it is possible to test for similarity of Fst values at the same locus. The eta correlation ratio is .61 for this large subset but it is not significantly different from zero. A trend may exist for some weak global correlation based on tight linkage ranging from 1 to 120 kb. When Fst is computed for the same 94 polymorphisms within 6 continental regions the avg Fst values are much smaller (Africa .06, Europe/SWAsia .03, E.Asia .04, Pacific .06, N.America .05, S.America .08) than for the world as a whole reflecting the resemblance of populations in the same geographic area. Variation of Fst values is greatest for African pops when both the range (.00 to .42) and std dev (.05) are considered but large std devs do occur for Pacific(.07), N.Amer(.05), S.Amer(.07). Europe/SWAsia and E.Asia have the smallest ranges (.00 to .09; .00 to .16) and std devs(.02,.03). Support: NIH GM57672, MH62495, AA09379, NSF BCS-9912028.

No evidence for heterozygote advantage at MTHFR in patients with lumbosacral myelomeningocele or their relatives. *E. Rampersaud¹, C. Brusata¹, K. Metcalf², E. Melvin¹, M.C. Speer¹ and NTD Collaborative Group.* 1) Center for Human Genetics, Duke University, Durham, NC; 2) North Carolina School of Science and Math, Durham, NC.

Folate supplementation appears to reduce the risk for NTDs. Methylenetetrahydrofolate reductase (MTHFR) is a candidate gene in the folate metabolism pathway that has been associated with mothers and children with NTDs in some populations. The C677T mutation in the 5,10-methylenetetrahydrofolate-reductase gene (MTHFR) yields a common thermolabile variant (T) with a reduction of 30-50% activity compared to the allelic form (C). Previously, Weitkamp et al. reported a heterozygote advantage of the MTHFR gene in patients with neural tube defects and their relatives. We examined our own series of 166 American Caucasian families for evidence of heterozygote advantage. Our sample included 166 probands, 162 mothers, 136 fathers, and 120 unaffected siblings. The allele transmission ratio from C/T heterozygous parents was 85.88C: 86.85T to offspring with NTD ($X^2 = 0.005$, $p = 0.82$) and 55.27C: 63.7T to unaffected offspring ($X^2 = 0.600$, $p = .44$). For the number of offspring of each genotype (C/C, C/T, T/T), expectations among the 286 total offspring ($X^2 = 49.18$, $p = 0.56$), the 166 affected offspring ($X^2 = 16.74$, $p = 0.56$), and the 120 unaffected offspring ($X^2 = 9.58$, $p = 0.70$) did not differ from Mendelian expectations. In addition, the number of offspring of each genotype among the 226 offspring of C/T heterozygous parents did not differ from Mendelian expectations ($X^2 = 1.17$, $p = .56$). There is neither an excess of heterozygotes (107.2 observed, 75.16 expected) nor a deficiency of C/C (75.01 observed, 75.16 expected) or T/T homozygotes (43.46 observed, 37.68 expected). There was no departure from Hardy-Weinberg equilibrium in the mothers (65 C/C, 82 C/T, 20 T/T observed; 67 C/C, 80 C/T, 22 T/T expected; $X^2 = 0.71$, $p = .40$), nor in fathers (64 C/C, 85 C/T, 17 T/T observed; 68 C/C, 76 C/T, 21 T/T expected; $X^2 = 2.0$, $p = .16$). Therefore, our data does not demonstrate the existence of any heterozygote advantage.

Genetic and sequence based analysis of the human *TGFB3* in cleft lip and palate and cross-species homology comparisons. *Y. Watanabe*^{1,2}, *E. Park*¹, *S. O'Brien*¹, *C. Nishimura*¹, *B. Ludwig*¹, *J.C. Murray*¹. 1) Dept Pediatrics, Univ Iowa, Iowa City, IA; 2) Dept Pediatrics and Child Health, Kurume Univ, Fukuoka, JAPAN.

Genetic association studies have been increasingly successful identifying mutations within genes that cause human complex traits. Cleft lip and palate is one such complex trait and is a common birth defect with a frequency ranging from 1/500 to 1/2500 depending on the ethnic or geographic origin of the population under study. Previous studies of genetic linkage and association have supported a role for *TGFA*, *MSX*, and *TGFB3* in non-syndromic clefting in humans. A complimentary approach, involving establishment of a mouse knockout for *TGFB3*, also supports a role for *TGFB3* in craniofacial development. In this report, we described a detailed sequence based comparison of the *TGFB3* genomic locus and its surrounding 5 and 3 flanking regions for single nucleotide polymorphisms. A collection of four such markers were then studied in detail on one Caucasian and one Asian based panel of mother/father/infant nuclear triads for evidence of Transmission Disequilibrium Test (TDT) distortion and haplotype analysis. A subset of individuals totaling approximately 180 were also directly sequenced in all coding regions as well as in regions of homology identified by comparing the human and mouse genomic sequences. Finally, a clone for the *Fugu TGFB3* homolog was identified and sequenced in cross-species homologies between *Fugu*, mouse and human. While no specific mutations that are clearly etiologic could be identified in any of the individuals directly sequenced, the statistical support for a role in *TGFB3* remains, and haplotype analysis suggests that a regulatory element located somewhere within the coding structure is the most likely etiologic event.

Study of genetic diversity by surname analysis of the Azorean population (Portugal). *C.C. Branco, L. Mota-Vieira.*
Genet and Molec Pathol Unit, Hospital of Divino Espirito Santo, Azores Islands, Portugal.

Azores is an archipelago located in the North Atlantic Ocean (parallel 38). It is composed by 9 islands dispersed over three groups: oriental (São Miguel and Santa Maria), central (Terceira, Graciosa, Pico, São Jorge and Faial) and occidental (Flores and Corvo). The present-day population stands at 242,073 inhabitants (Census 2001), being the result of <22 generations. About 75% of the population is concentrated on two islands, São Miguel (50%) and Terceira (25%), whereas the remaining 25% are distributed among the other 7 islands.

In order to investigate the genetic structure of the Azorean population we conducted a survey based on frequencies of surnames listed in the 2001 telephone book. We first calculated the following parameters: isonymy (I), coefficient of inbreeding (F_{st}), coefficient of kinship between islands (R_i), abundance of surnames according to Fisher (a), Karlin-McGregor's migration rate (n) and Nei's distance. As expected, the results show that the migrating phenomenon occurs mainly towards the big islands. The values of migration rate range from 0.247, for the smallest island of Corvo, to 0.0027 for the biggest one, São Miguel. The assessment of the isonymy similarity was performed by calculating Nei's distance using the UPGMA method. The dendrogram obtained reveals three major clusters corresponding to the geographic distribution of the nine islands. On the other hand, Graciosa, the second smallest island, presents the lowest value of abundance of surnames ($a=15.75$), suggesting a greater genetic isolation when compared to other islands. Moreover, the diversity analysis of surnames for all islands demonstrates that 11% of all 57,385 subscribers are distributed by only 3 surnames. Finally, the value of F_{st} obtained for this population (0.0039) indicates a little genetic differentiation (Wright's $F_{st}<0.05$). In conclusion, our data provides evidences that the Azorean population is relatively homogeneous, representing an ideal source for genetic epidemiological studies, as well as, for mapping of alleles underlying complex and autosomal recessive disorders. (claudia.branco@clix.pt).

Linkage Disequilibrium's extension in Corsica. Looking for genetic isolates. *V. Latini¹, D. Poddie², G. Vona¹, L. Varesi³, M. Memm³, G. Sole², S. Doratiotto², A. Cao², M.S. Ristaldi².* 1) Biologia Sperimentale, Cagliari University, Monserrato, CA, Italy; 2) INN-CNR, Selargius, CA, Italy; 3) Corte University, Corte, France.

Genetic isolates represent an exceptional resource for the identification of complex disease susceptibility genes. Recent reports have in fact demonstrated that in isolated and conservative populations the extension of the Linkage Disequilibrium (LD), the non-random association of alleles at closely linked loci, is particularly high. The higher the extension of the LD, the lower is the number of polymorphism markers which have to be examined to find an association with a particular disease. This study has been designed to examine the extension of LD on a region of the X chromosome (Xq13.3) in genetic isolates of the island of Corsica. We have analysed the LD extension in three populations of Corsica: Niolo (n = 39), Bozio (n = 35) and Corte (n = 40), which are genetically isolated and conservative compared to the rest of Corsica. Samples (only unrelated males) have been analysed using seven dinucleotide microsatellite markers on chromosome X: DXS983, DXS986, DXS8092, DXS8082, DXS1225, DXS8037 e DXS995. Microsatellite genotyping was performed using ABI377 sequencer and Gene Scan 3.1 and Genotyper 2.0 software. We measured LD using D' statistic (Lewontin 1964). The significance of non-random allelic association between pairs of microsatellite loci was calculated using Fishers exact test. Our preliminary results show a strong degree of LD in all the three Corsicans isolates. The extent and the strength of the LD is higher than that of the general population of Corsica and comparable to that reported for other isolates such as the village of Gavoi (Sardinia) and Saami (North Europe). This data indicated that the populations investigated in the present study are well suited for associations studies aimed at the mapping of genes involved in the pathogenesis of complex diseases. Nevertheless, since the D' value is influenced by the sample size we are currently expanding our sample to validate these results.

Genetic history of linguistically diverse Tanzanian populations inferred from mtDNA. *H.M. Mortensen¹, M.K. Gonder¹, J.B. Hirbo¹, B.C. Verrelli¹, J.L. Mountain², S.A. Tishkoff¹.* 1) Dept of Biology, Univ Maryland, College Park, MD; 2) Dept. of Anthro. Sciences, Stanford Univ, Stanford, CA.

East Africa is a key region to sample genetic diversity because it is a likely site for the origin of all modern humans and because there are many linguistically diverse ethnic groups living in close proximity to one another. Tanzania is one of the most ethnolinguistically diverse regions of Africa, with populations speaking languages belonging to the four, major linguistic families of Africa: Khoisan, Afro-Asiatic, Nilo-Saharan and Niger-Kordofanian. The genetic history of these populations remains largely unknown. Analysis of genetic variation in Tanzanian populations enables us to estimate long-term effective population sizes, timing and extent of historic population expansions or contractions, levels of exchange between populations, and correlations between genetic and linguistic variation. A linguistically and culturally diverse panel of >400 Tanzanians representing the four major linguistic families of Africa and practicing diverse subsistence methods (pastoralism, agriculture, and hunting/gathering) was analyzed for mitochondrial DNA variation. These include Khoisan-speaking Hadza and Sandawe, Nilotic-speaking Maasai and Datog, Cushitic-speaking Burunge and Iraqw, and Bantu-speaking Gogo and Turu. Control region (CR) sequence encompassing both hyper-variable segment I (HVSI) and II (HVSII) was generated. Phylogenetic and population genetic methods were applied to analyze these data, in comparison to a broad African and global human dataset. Genetic and linguistic affinity did not correspond in all instances. The Tanzanian panel was generally found to exhibit high genetic diversity, which is in concordance with the long and complex demographic history of this geographic region. We observe the genetic signature of a number of recent migration events into northern Tanzania. These data help clarify existing linguistic and archaeological interpretations regarding East African population history as well as early migration of modern humans out of Africa. Funded by BWF and Packard career awards, Wenner Gren, Leakey, and NSF grant BCS-9905396 to ST.

Assessing population structure and its effects on association studies in a genome wide SNP dataset. *J.L. Marchini¹, P. Donnelly¹, M. Boyce-Jacino², L. Cardon³*. 1) Department of Statistics, Oxford University, Oxford, UK; 2) Orchid BioSciences, Inc; 3) Wellcome Trust Centre for Human Genetics, University of Oxford, Roosevelt Drive, Oxford OX3 7BN, UK.

Association studies using genome wide SNP datasets have been suggested as a powerful method to detect the genetic basis of common complex diseases. A potential problem with such studies is the presence of undetected population structure in the sample of cases and controls. This raises two general issues: (i) how much underlying stratification is there in various human populations, and when might this pose problems for association studies, and (ii) are the suggested approaches for correcting for population structure in case-control studies accurate and efficient.

We investigate these question across and within populations in the context of a genome wide dataset in which around 12,000 SNP's have been genotyped in 130 individuals from 3 populations. We assess the ability of model based methods (like STRUCTURE) to detect fine levels of differentiation, such as that between Asian-Americans of Japanese/Chinese origin and the performance of both Structured Association and Genomic Control approaches to association studies in this context.

Genetic Epidemiology of Severe, Early-Onset Chronic Obstructive Pulmonary Disease: Risk to Relatives for Sensitive Spirometric Phenotypes. *D.L. DeMeo^{1,2}, S.T. Weiss^{1,2}, J.M. Drazen², H.A. Chapman², J.J. Reilly², L.C. Ginns³, F.E. Speizer^{1,2}, E.K. Silverman^{1,2}.* 1) Channing Laboratory, Boston, MA; 2) Brigham & Women's Hospital, Boston, MA; 3) Massachusetts General Hospital, Boston, MA.

The Boston Early-Onset COPD study has enrolled family members of probands identified with severe, early-onset COPD before age 53, and forced expiratory volume in one second (FEV1) less than 40 percent predicted in the absence of alpha 1-antitrypsin deficiency. Current or ex-smoking, first degree relatives of early-onset COPD probands previously have been demonstrated to have significantly lower FEV1 and FEV1/FVC values than control subjects, suggesting that genetic risk factors for COPD are expressed in response to cigarette smoking. We hypothesized that first-degree relatives of early-onset COPD probands would also demonstrate alterations in more sensitive indicators of pulmonary function, such as the ratio of forced expiratory flow in the mid-portion of forced vital capacity divided by forced vital capacity (FEF25-75/FVC). This measure has been suggested to represent dysanaptic lung growth, a disproportionate growth between airways and lung parenchyma. Using generalized estimating equations, FEF25-75 and FEF25-75/FVC were analyzed in 348 first-degree relatives of probands and 83 sex and smoking matched controls. A statistically significant risk to first-degree relatives of individuals with early-onset COPD was demonstrated in ever smokers for abnormalities in FEF25-75 ($p=0.013$ women, $P=0.021$ men) and FEF25-75/FVC ($p=0.008$ women, $p=0.002$ men), but not FVC alone ($p=0.185$ women, $p=0.706$ men). No significant differences were found among lifelong never smokers. Because of the cross-sectional nature of these findings we are unable to distinguish if they represent a susceptibility for underlying dysanaptic lung growth in family members of individuals with early-onset COPD, or whether these more sensitive pulmonary function parameters may identify early smoking-related lung damage, to which first-degree relatives of probands with early-onset COPD may be more susceptible. Longitudinal follow-up would be required to determine the underlying pathophysiology. Supported by NIH R01 HL61575, T32 HL07427-22.

Variation in genes of the IL-4/IL-13 pathway: association with early atopic phenotypes in the COAST study. *S. Hoffjan*¹, *D. Nicolae*¹, *J. Gern*², *K. Roberg*², *K. Carlson-Dakes*², *K. Adler*², *C. Tizler*², *S. Sund*², *D. DaSilva*², *R. Hamilton*², *S. White-Gilbertson*², *D. Yoshihara*², *D. Mirel*³, *R. Lemanske Jr*², *C. Ober*¹. 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Pediatrics, University of Wisconsin, Madison, WI; 3) Roche Molecular Systems Inc, Alameda, CA.

Asthma is a heterogeneous and multifactorial disorder with symptoms often developing during the first years of life. To assess the contribution of environmental factors in early childhood as well as genetic factors to the subsequent development of asthma, a cohort of children (n=287) at increased risk for asthma and atopic diseases was recruited in the COAST (Childhood Origin of ASThma) study. We studied variation in genes in the IL-4/IL-13 pathway and the expression of various atopic phenotypes in the first year of life in this cohort. 213 COAST children were genotyped for 12 SNPs in the IL4 (-582C/T), IL13 (-1055C/T, 4045C/T, Arg110Gln), and IL4RA (Ile50Val, Asn142Asn, Arg375Ala, Leu289Leu, Cys406Arg, Ser478Pro, Gln551Arg, Ser761Pro) genes. We examined the relationship between individual SNPs and haplotypes with PHA-induced cord blood mononuclear cell IL-13 and IFN- γ responses, the development of atopic dermatitis (AD) and susceptibility to respiratory syncytial virus (RSV) infection in the first year of life. In the IL13 gene we identified a haplotype composed of the -1055C and +4045C alleles and the arginine at position 110, that was associated with reduced IL-13 responses in cord blood (p=0.006), a phenotype characterized by an increased risk of wheezing in the first year of life in this cohort. Further, the IL13 Arg110 allele and the IL4RA Ile50 allele were each associated with increased susceptibility to RSV infection in the first year (p=0.044 and p=0.040, respectively). Lastly, we found an association between the IL4 -590T allele and increased risk of AD (p=0.013). These data suggest that genetic variation in the IL-4/IL-13 pathway may be uniquely associated with the early expression of phenotypic profiles in the first year of life that are known to increase risk for the subsequent development of childhood asthma.

Estimation of genetic risk for bronchial asthma by multiple SNPs in candidate genes. *Y. Suzuki¹, C. Shao¹, F. Kamada¹, M. Tamari², K. Hasegawa², X. Yang¹, Y. Aoki¹, S. Kure¹, K. Kanno¹, X.-Q. Mao³, J.M. Hopkin⁴, T. Shirakawa^{2,3}, Y. Matsubara¹.* 1) Dept of Medical Genetics, Tohoku Univ School of Medicine, Sendai, Japan; 2) Laboratory for Functional Analysis, SNP Research Center, The Institute of Physical and Chemical Research, Yokohama, Japan; 3) Dept of Health Promotion & Human Behavior, Kyoto Univ School of Public Health, Kyoto, Japan; 4) Experimental Medicine Unit, UWS, UK.

Bronchial asthma is a multi-factorial disease caused by interactions between genetic and environmental factors. Several genetic polymorphisms associated with the disease have already been identified, but none of them accounts for a major part of the disease. It seems essential to take multiple polymorphisms into consideration to evaluate the genetic susceptibility for asthma. Here we show a logistic regression approach to integrate multiple single nucleotide polymorphism (SNP) genotypes for understanding and evaluating genetic risk for asthma. We determined 56 SNP genotypes of the candidate genes in 150 adult asthmatics and 150 controls in the English population, and 25 SNPs in 384 adult, 423 child patients, and 335 controls in the Japanese population. To screen SNP-SNP interactions, we performed "two-gene association study" in which an association of one SNP with the disease was assessed after stratification by another SNP's genotype and all the possible two-SNP combinations were tested. Significant SNPs and SNP-SNP interactions were selected with a backward stepwise elimination method in SPSS program. In the English population, the final regression model showed excellent performance. Improvement of $-2LL$ was 129.6 ($P=9.99 \times 10^{-16}$), Nagelkerke's R^2 was 0.502, and c statistic (area under the ROC curve) was 0.867. In Japanese childhood asthma, the performance of the regression was also good, although it was less than that in English. Improvement of $-2LL$ was 83.1 ($P=9.93 \times 10^{-9}$), Nagelkerke's R^2 was 0.167, and c statistic was 0.693. Our results suggested that the logistic regression model is useful in explaining the genetic predisposition to asthma through a set of SNPs of candidate genes. This approach may be applicable for other complex diseases.

Frequency of Human Cytomegalovirus in patients with kidney transplant from Mexican population. R.M.

Hernandez¹, C. Vivas¹, M.P. Gallegos², R. Campos³, A. Celis de la Rosa⁴, S. Ruelas⁵, A.M. Contreras¹ and CMV virus detection. 1) Diagnostico Molecular, IMSS, Guadalajara, Jalisco, Mexico; 2) Medicina Molecular, CIBO, IMSS; 3) Departamento de Medicina Interna; 4) Departamento de Epidemiologia; 5) Unidad de Transplantes, HE, CMNO, IMSS.

Human cytomegalovirus (HCMV) can cause severe morbidity and mortality in allograft and patients kidney transplant development viremia. In our country the kidney insufficiency to produce high rates of mortality by cytomegalovirus and the incidence is unknown. Until a few years ago, HCMV isolation by culture techniques was the only reliable diagnostic method, with as a major drawback the long isolation period (1-8 weeks). Recently, an in vitro DNA amplification technique has been described: the polymerase chain reaction (PCR) with a much higher sensitivity than conventional analysis. We studied the incidence of HCMV in patients with kidney transplant of our population. In 72 patients with kidney transplant was amplified by HCMV PCR. We detected an incidence of 26%, with a tendency to increase after to kidney transplant.

Phylogeny of Fragile X haplotypes from an English population. *S. Ennis*¹, *G. Brightwell*², *A. Collins*¹, *P. Jacobs*², *N.E. Morton*¹. 1) Human Genetics Division, Southampton General Hosp, Tremona Rd., Southampton, Hampshire, England, SO16 6YD; 2) Wessex Regional Genetics Laboratory, Salisbury District Hosp., Salisbury, Wiltshire, England, SP2 8BJ*cis*.

Dynamic expansion of the FRAXA trinucleotide repeat in the FMR1 gene at Xq27.3 causes methylation and transcriptional silencing of the gene. Absence of the gene product FMRP, leads to manifestation of the fragile X syndrome, the most common form of inherited mental retardation in humans. Many factors that predispose to instability of the repeat tract have been identified, but exact determinants of risk remain unclear. Previous linkage disequilibrium studies suggest that *cis*-acting factors may play a role in germline stability.

A panel of 797 independent male chromosomes that span the range of FRAXA repeat sizes have been additionally typed for one microsatellite, three dinucleotide repeats and 11 single nucleotide polymorphisms (SNPs) across 650 kb of the FRAX region. The dinucleotide repeats, DXS548, FRAXAC1 and FRAXAC2, have been used to assign one of 5 haplogroups to each of these chromosomes as previously described (Ennis *et al*, 2001). As would be expected, significant association exists between many of the SNPs and these haplogroups. Although risk of expansion between these haplogroups is variable, within the haplogroups no single SNP appears to be associated with expanded FRAXA alleles. Applying cluster analysis methodology to these 15-marker haplotypes, we have created a dendrogram that represents each of the most closely related haplotypes within this primarily Caucasian population. Evidence suggests that recurrent mutation and/or gene conversion is common in this region, and that variable rates of expansion among clusters within a major haplogroup reflects FRAXA repeat size in founders. The comparatively high risk D haplogroup is the most homogenous group and preliminary evidence also suggests that this group may represent the ancestral haplotype.

Genetic Predisposition to Nuclear Cataract. *A.P. Klein¹, J.A. O'Neill¹, J.E. Bailey-Wilson¹, R. Klein², K.E. Lee², B.E.K. Klein².* 1) Statistical Genetics Section, NIH/NHGRI/IDRB, Baltimore, MD; 2) Department of Ophthalmology and Visual Sciences, University of Wisconsin-Madison Medical School.

Cataract is the most common cause of blindness worldwide. Nuclear cataract is the most common type of age-related cataract and is a late stage of nuclear sclerosis. We assessed the familial aggregation of nuclear sclerosis within data collected as part of the Beaver Dam Eye Study. Previous analysis of these data supported the involvement of a major gene accounting for some of the variability in age-sex adjusted nuclear sclerosis. However these analyses were based upon 1,247 individuals in 564 sibships and therefore did not allow for direct estimation of regressive familial effects including correlations between spouse and between parents and offspring. Follow-up of this cohort identified additional familial relationships, such that data on 2,101 individuals in 620 extended pedigrees with complete age, sex and examination results are now available for analysis. In order to confirm previous results and further examine the influence of additional shared familial effects, other than those due to a major gene, we examined the familial correlations and performed segregation analyses. We confirmed the results of the previous analysis, which found that the inheritance of a major gene accounted for 35% of the variation in adjusted nuclear sclerosis. However, in addition to the effect of the major gene there was also an additional correlation of .16 between parents and offspring. No significant correlation was found between spouses either before or after inclusion of a major gene in the model. The relative ability of both analyses (sibships only and extended pedigrees) to estimate the model parameters will be discussed. The results of the segregation analysis will provide a model for future linkage studies aimed at identifying the genes involved in nuclear cataract development.

Program Nr: 1183 from 2002 ASHG Annual Meeting

Ethnic prevalence of MTRR A66G polymorphism in NW Louisiana pregnant population. *R. Dhanireddy, K. Yanamandra, J.A. Bocchini Jr, T.F. Thurmon, D. Napper, S. Ursin, H. Chen.* Pediatrics, LSU Med Sch, Shreveport, LA.

Since the cloning of human methionine synthase reductase (MTRR) few years ago by Leclerc et al., (1998), limited publications have appeared in the literature on the polymorphism of MTRR gene. Wilson et al. (1999) have first identified the variant A66G in MTRR gene and correlated the variant with neural tube defects (NTD) especially in the pregnant women with low levels of vitamin B12 (cobalamine). The incidence of MTRR 66G allele in the Caucasian population was reported to be 0.51. However, there were no reports on the large scale studies on the incidence of this gene polymorphism in the African-American (AA) population.

Here, we report the incidence of MTRR A66G polymorphism in this ethnic group from 1000 pregnant women. The 66GG mutant homozygosity and allele frequency were 11% and 0.36 respectively, far lower than the Caucasian population (p value <0.0001, odds ratio 0.19, 95% CI 0.12-0.31). Although we have not correlated this polymorphism with NTD in our AA community, this lower mutant gene frequency might reflect the general low incidence of NTD seen in this population. Data, statistics, and ethnic stratification of genotypes from Louisiana will be presented.

NF1-gene analysis based on Denaturing High-Performance Liquid Chromatography (DHPLC). A. De Luca¹, A. Buccino¹, D. Gianni¹, A.I. Lazzarino^{1,2}, M. Mangino¹, S. Giustini³, A. Richetta³, L. Divona³, S. Calvieri³, R. Mingarelli¹, B. Dallapiccola^{1,2}. 1) Istituto CSS - Mendel, Rome, Italy; 2) Department of Experimental Medicine and Pathology, University of Rome La Sapienza, Rome, Italy; 3) Institute of Clinical Dermatology, University of Rome La Sapienza, Rome, Italy.

Neurofibromatosis type 1 (NF1; MIM# 162200) is a common autosomal dominant disorder, characterized by café-au-lait spots, peripheral neurofibromas, Lisch nodules and freckling. The high mutation rate at the NF1 locus results in a wide range of molecular abnormalities. The majority of these mutations are private and rare, generating elevated allelic diversity with a restricted number of recurrent mutations. In this study, we have assessed the efficacy of Denaturing high-performance liquid chromatography (DHPLC), a fast and highly sensitive technique based on the detection of heteroduplexes in PCR products by ion pair reverse-phase HPLC under partially denaturing conditions, for detecting mutation in the NF1 gene. We established theoretical conditions for DHPLC analysis of all coding exons and splice junctions of the NF1 gene using the WAVEmaker software version 4.1.40 (Transgenomic, Crewe, UK) and screened for mutations a panel of 40 unrelated NF1 patients (25 sporadic and 15 familial), genetically uncharacterized. Disruptive mutations were identified in twenty-nine individuals with an overall mutation detection rate of 72,5%. The mutations included eight deletions (exons 4b, 7, 10a, 14, 26 and 31), one insertion (exon 8), nine nonsense mutations (exons 10a, 13, 23.1, 27a, 29, 31 and 36), six missense mutations (exons 15, 16, 17, 24 and 31), four splice errors (exons 11, 14, 36 and 40) and a complex rearrangement within exon 16. Nineteen (65,5%) of the identified mutations are novel. Eight unclassified and three previously reported polymorphisms were also detected. None of the missense mutations identified in this study were found in a screen of 150 controls. Our results suggest that DHPLC provides an accurate method for the rapid identification of NF1 mutations. This work was supported by the Italian Ministry of Health and Education.

Calculating the frequency of (GJB6-D13S1830) and identifying other non-coding GJB2 deafness-causing mutations. *P.G. Chamberlin¹, H. Azaiez¹, S. Prasad¹, R.A. Cucchi¹, F. Moreno², I. del Castillo², R.J.H. Smith¹.* 1) Molecular Otolaryngology Research Laboratories, Department of Otolaryngology, University of Iowa, Iowa City, IA, USA; 2) Unidad de Genetica Molecular, Hospital Ramon y Cajal, Madrid, Spain.

Statement of Purpose. Most mutations at the DFNB1 locus cause autosomal recessive sensorineural deafness (ARSND) by changing the coding sequence of GJB2, the gene that encodes the gap junction protein Connexin-26. Recently, a large deletion 35kb upstream of GJB2 [(GJB6-D13S1830)] was identified and determined to cause ARSND in homozygotes for this mutation and in compound heterozygotes carrying deafness-causing allele variants of GJB2 on the opposite allele. The carrier frequency of the (GJB6-D13S1830) mutation and its overall contribution to the total GJB2 deafness load in the United States is unknown. **Methods Used.** To determine the frequency of the (GJB6-D13S1830) deletion, we screened 49 deaf persons from our hereditary hearing impairment registry who carry a single GJB2 deafness-causing allele variant. We estimated the (GJB6-D13S1830) carrier rate based on the 35delG carrier rate and the relative frequency of these two mutations. We used the 35delG carrier rate to predict missed mutations by calculating the expected number of 35delG carriers in a panel of 602 non-DFNB1 deaf patients. **Summary of Results.** We identified the (GJB6-D13S1830) deletion in 5 persons, making it the sixth most common deafness-causing mutation at the DFNB1 locus (prevalence of 3.42% in persons with GJB2-related deafness). Our calculated carrier frequency of 0.06% in the US population is consistent with our negative screen of 96 controls. In our panel of 602 non-DFNB1 deaf patients, a difference between the observed number of 35delG carriers (21) and the expected number (15) suggests that there are other non-coding deafness-causing mutations of GJB2. **Conclusion.** Many laboratories offer mutation screening of GJB2 as "state-of-the-art" medicine. Our data illustrate the necessity of including a screen for the (GJB6-D13S1830) deletion. It is likely that other mutations exist outside the coding sequence of GJB2. (Supported by R01-DC02842 to RJHS).

Program Nr: 1186 from 2002 ASHG Annual Meeting

The Contribution of Otoferlin to Autosomal Recessive Non-Syndromic Deafness. *M.R. Avenarius, N.C. Meyer, R.J.H. Smith.* Molecular Otolaryngology Research Laboratories, University of Iowa, Iowa City, IA.

Statement of Purpose. Approximately 50% of the autosomal recessive non-syndromic deafness (ARNSD) is accounted for by mutations at the DFNB1 locus. We hypothesize that mutations at the DFNB9 locus play a moderate role in making up a fraction of the remaining 50% of ARNSD. **Methods Used.** We studied multiplex families segregating ARNSD in whom mutation screening of GJB2 and SLC26A4 was negative. To identify the subset of these families for OTOF mutation screening, we determined haplotype segregation at the DFNB9 locus using tightly linked microsatellite repeat polymorphic markers. Mutation screening of OTOF in selected families was completed by SSCP and bi-directional sequencing. **Summary of Results.** Eighteen multiplex families segregated ARNSD and did not demonstrate mutations in GJB2 or SLC26A4. Of five of these families haplotype segregation in affected persons was consistent with deafness at the DFNB9 locus. In three of these families, mutation screening of OTOF identified allele variants presumed to cause ARNSD. **Conclusion.** We estimate the contribution of OTOF to autosomal recessive non-syndromic genetic deafness at 8%. This contribution is substantial enough to warrant mutation screening of OTOF in children with ARNSD.

GJB2 (Connexin 26) mutations in non-syndromic hearing loss patients from North India. *B. Mittal, M. Mukherjee, R. Puri, S.R. Phadke.* Dept of Genetics, Sanjay Gandhi PostGrad Inst, Lucknow, UP, India.

Non-syndromic hearing loss (NSHL) is the most common form of deafness with a frequency of approximately 1 in 1000 live births. Mutations in the gap junction protein connexin 26 (Cx26) have been established as the basis of autosomal recessive non-syndromic hearing loss (ARNSHL). The Cx26 gene is located at the DFNB1 locus on chromosome 13q12. In caucasian populations a single mutation, 35delG, accounts for most cases of NSHL. We have looked for Cx26 mutations in 55 ARNSHL patients of North India from the local institutions and our genetics out-patient-department. The patients were selected on the basis of their having bilateral, sensorineural, prelingual and non-syndromic hearing loss. Six mutations in the Cx26 gene viz. Gdel 35 bp, G-to-A 71 bp, G-to-A 231 > bp, C-to-T 370 bp, T-to-C 101 bp, 235del C were included in our initial screening programme. Allele-specific primer pairs, normal and mutant were used for PCR amplification of genomic DNA. Out of 55 patients analysed only one patient showed a homozygous mutation of C-to-T, 370 bp. The father of this patient was found to be a carrier for the mutation. Two patients in another family were heterozygous for the mutation G-to-A 71 bp. Based on our present study, we conclude that the common mutation, 35del G is not prevalent in our North Indian population as described in few other ethnic groups in some parts of the world.

A Multiethnic Study of 35delG and 167delT Mutations in the Connexin 26 Gene in Diverse Los Angeles

Population Groups. *P.S. Kim*¹, *G. Manligas*¹, *M. Telatar*², *K.V. Lu*², *R.K. Iyer*², *W.W. Grody*^{1,2}, *L. Schimmenti*¹. 1) Department of Human Genetics, UCLA, Los Angeles, CA 90095; 2) Department of Pathology and Laboratory Medicine, UCLA, School of Medicine, Los Angeles, CA 90095.

Nonsyndromic deafness (DFN) is characterized by mild-to-profound hearing loss with no other associated medical conditions. Over thirty non-syndromic deafness-causing genes have been identified. Among these genes, mutations in *Connexin 26* (*Cx26*) on chromosome 13q11-12 account for approximately 50% of patients with an autosomal recessive form of deafness. Two common mutations, 35delG and 167delT, have been identified in populations with European, Middle Eastern and Ashkenazi ancestry; however, few studies have surveyed an ethnically diverse North American population. Here we report the results of a survey screening for the presence of two common mutant alleles in the *Cx26* gene, 35delG and 167delT, in an anonymized multiethnic cohort of 350 individuals from the Los Angeles area. While we did not detect carriers for these two mutant alleles from Native American (50), Asian American (100), or African American (50) populations; Hispanic Americans (150) exhibited an overall carrier frequency of 2.0%. The mutant 35delG allele was found in 2 of 150 Hispanic American genomic DNA samples analyzed (1.5%), whereas the mutant 167delT allele was detected in one Hispanic American sample (0.5%). Because there are various other highly prevalent mutant alleles commonly found within specific ethnic populations (such as 235delC in Asian populations), and because *Cx26* is a relatively small gene, complete sequencing of the gene could be considered for mutation screening in ethnically diverse populations as technologies become amenable.

Mutation Screening of SLC26A4 by DHPLC. *S.D. Prasad¹, K.A. Kolln¹, R.A. Cucci¹, P. Van Hauwe², P. Coucke², R. Trembath³, G. Van Camp², R.J.H. Smith¹.* 1) Department of Otolaryngology; Interdepartmental PhD Program in Genetics, University of Iowa, Iowa City, IA, USA; 2) Department of Medical Genetics, University of Antwerp, Antwerp, Belgium; 3) Division of Medical Genetics, University of Leicester, Leicester, England.

Pendred's syndrome (PS), an autosomal recessive disease characterized by goiter and congenital sensorineural hearing loss, accounts for approximately 10% of hereditary deafness. Most patients with PS are euthyroid, although they usually have an abnormal perchlorate test reflecting perchlorate-induced inhibition of the sodium/iodide symporter in the thyrocyte and cytoplasmic leakage of iodide back into the bloodstream. The sensorineural deafness is typically associated with inner ear malformations that range in severity from dilation of the vestibular aqueduct to Mondini dysplasia. The PDS gene (SLC26A4) encodes pendrin. Initial predictions of SLC26A4 structure suggested a protein with 11 transmembrane domains and an extracellular carboxy terminus (Everett et al 1997). However, Royaux et al have shown that the carboxy terminus is intracellular implying that an additional alpha helix spans the cell membrane (Royaux et al 2000). Data from 10 transmembrane prediction programs generated results ranging from in 8-13 transmembrane domains, with four programs predicting 12 transmembrane domains. We considered MEMSAT2 results most reasonable based on a recent review ranking this program as one of the most accurate (Jones et al 1994, Simon et al 2001). It predicted 12 transmembrane domains. A wide spectrum of mutations in SLC26A4 has been associated with PS. In this study, we describe our strategy for mutation screening of SLC26A4 using denaturing HPLC. We report the detection of ~42 distinct mutations using DHPLC. In comparison to SSCP, DHPLC is more sensitive. Samples with known mutations were PCR amplified, heteroduplexed, and analyzed under denaturing conditions using the Wave DHPLC system. To achieve a high detection rate, we performed the analysis at multiple temperatures and buffer gradients. Acknowledgements. This research was supported by the Doris Duke Clinical Research Fellowship Program (KAK) and R01-DC02842 (RJHS).

Cytokine gene polymorphism correlates with ischemic cardiomyopathy and rates of rejection episodes in cardiac transplantation. *D.O. McDaniel¹, P. Perrin¹, V. Coleman³, S. Yamout¹, J. Cameron³, C. Moore².* 1) Dept Surgery, Univ MS Medical Ctr, Jackson, MS; 2) Dept Medicine, Univ MS Medical Ctr, Jackson, MS; 3) Dept Biology, JSU, Jackson, MS.

Effectiveness of cytokine gene polymorphisms were evaluated in African-American (AA) and Caucasian (CAU) patients that had undergone cardiac transplantation (CTx). It has been suggested that allograft rejection is mediated by cytokines. Our working hypothesis is that the clinical condition of recipients before CTx might affect the outcome of allograft function through pre-existing genetic factors that are unique to each individual. Genomic DNA samples from 19 AA and 46 CAU recipients were tested by either single or multiplex PCR. Frequency distributions of genotypes were analyzed in respect to pre-CTx clinical characterization including coronary artery disease (CAD) and non-ischemic heart failure. The rejections were scored based on the number of biopsies graded greater than 2. Overall, the IL-10 high producer genotype was present in all patients graded as 1A and was significantly reduced in grade 2, 3A and 3B patients (28.6%, $p=0.02$; 23%, $p=0.001$; and 20%, $p=0.04$, respectively). IFN-g A/A and IL-10 low producer genotypes were significantly increased in AA grade 3A recipients compared to CAU grade 3A recipients (47% vs 16.1%, $p=0.04$; 76.5% vs 32.2%, $p=0.006$ respectively). Both racial groups showed a high frequency of TGF- β 1 high producer genotype compared with controls (AA: 70.5% vs 33.7%, $p=0.006$; CAU: 71% vs 26.2%, $p=0.0001$). There was a direct relationship between IFN-g T/T high producer and ischemic CAD as compared with IFN-g A/A low producer and non-ischemic heart failure, supporting the influence of immunological factors in vasculopathy. In contrast, IL-2 T/T and IL-6 G/G high producer genotypes were present at a high frequency in AA recipients compared with CAU, with notable racial differences. These data indicate the importance that genotype analysis may have in understanding the pathophysiology of CTx outcome and may lead to better treatment options.

Design approach for a database system integrating and interpreting demographic, clinical and biological data. S. Pelletier^{1,4}, J. Lyman^{1,4}, J. Dalton^{2,4}, S. Tropello^{2,4}, B. Dembling^{1,4}, K. Scully^{1,4}, J. Boyd^{3,4}, P. Beling^{2,4}, S. Guerlain^{2,4}, E. Bass^{2,4}, W. Knaus^{1,4}, D. Brown^{2,4}. 1) Dept of Health Evaluation Sci; 2) Systems Engineering; 3) Dept of Pathology; 4) University of Virginia Health System.

The rapid expansion of genetic, disease, health outcomes and treatment information will revolutionize clinical medicine, research and public health if the information can be integrated. Our approach to integration engages system users in the design phase and considers the user interface and required analyses as well as the data to be integrated. As part of a larger project to link demographic, clinical and biological data and provide an interface and tools for complex data analysis, we have assembled an interdisciplinary team (e.g. systems engineering, informatics, clinical, biological, mathematics, public health) for the design phase. This phase encompasses the first steps in the overall integration process; requirements analysis, prototype design and evaluation. Step 1) Requirements analysis: Potential users were asked how the system described could advance their research; data and analytical needs were addressed specifically. We documented their requirements as well as existing data sources and analytical tools. Step 2) Prototype design: Users' requirements drove prototype designs; multiple design alternatives were developed for the system architecture, analytical toolkit, and user interface. Step 3) Evaluation: Prototype designs were evaluated with users and performance matrices. Prototype redesigns continue iteratively with each evaluation. We present the results of the requirements analysis, prototype designs and the initial evaluations. We include key system architecture design findings (e.g. data standards, security, barriers to fulfilling user needs). We describe critical analytical needs identified (e.g. gene expression data analysis) and tool designs to address compliance of user queries to new regulations affecting electronic medical records (HIPAA). Lastly, we describe our approach to the design of a common user interface that addresses the query and data visualization needs of multi-disciplinary users.

Internet-based hereditary cancer susceptibility data system for genetic counseling and research. www.fcgn.org.

R. Sutphen^{1,2,4}, *J. Malloy*⁴, *L. Anderson-Dame*⁴, *J.P. Krischer*^{2,3,4} and Florida Cancer Genetics Network (FCGN). 1) Dept Clinical Genetics, #7815, All Children's Hosp, St Petersburg, FL; 2) Departments of Interdisciplinary Oncology and Pediatrics, University of South Florida College of Medicine, Tampa, FL; 3) Department of Computer Science and Engineering, University of South Florida College of Engineering, Tampa, FL; 4) H. Lee Moffitt Cancer Center and Research Institute, Tampa, FL.

We describe an internet-based system for cancer genetics risk assessment counseling, family pedigree illustration and research registry participation. The Florida Cancer Genetics Network (FCGN) automates collection of the family and personal medical history information required for these processes. Data may be 1) entered online or 2) entered on paper forms that can be faxed into a web server for direct (automated) data entry accomplished within minutes. Data is then available for viewing, editing and printing via a secure website. The system generates a family pedigree and risk calculation that can also be viewed or printed from the website. For research initiatives, data in the system can easily be queried to determine the number of individuals available who meet specific eligibility requirements. Authentication and authorization features allow easy access to all data for which the user has permission, while restricting all other data from access. Web access to the system requires a standard web browser (such as Microsoft Internet Explorer version 5.5 or higher) and use of free encryption software available on the internet (128-bit Secure Sockets Layer encryption). The system has two main uses - 1) it accomplishes the data collection, pedigree-drawing and risk assessment procedures of clinical genetic counseling for hereditary cancer susceptibility quickly and easily and 2) it automates enrollment of individuals with high cancer risk in a registry designed for individuals who are interested in participating in cancer research studies. The internet-based design of this system makes it accessible by cancer genetics centers around the world. To our knowledge, there is no comparable system in current use.

Prototype microfluidic devices for cell fractionation and isolation. *M. Caggana¹, A.P. Russo¹, A.J.H. Spence², S.T. Retterer², S.J. Duva¹, D.H. Szarowski¹, M.S. Isaacson², J.N. Turner¹, L.D. McCurdy¹.* 1) Wadsworth Ctr, New York State Dept Health, Albany, NY; 2) Departments of Applied Physics and Biomedical Engineering, Cornell University, Ithaca, NY.

The miniaturization of laboratory techniques and equipment for biological assays has become a dominating focus in research. The development of micro-total analysis systems (mTAS) has made striking progress but still remains a serious challenge. Several prototype devices have been described that perform analytical reactions and detection on a single platform. With few exceptions most devices described do not integrate sample preparation as a part of on-chip analyses. Sample preparation is often the most difficult step in an assay, especially when working with complex heterogeneous mixtures such as whole blood. The separation of cells from a complex suspension is desired for many purposes. Most of these applications can be divided into two categories: (1) depletion of undesired cell types from a population of desired cells (bone marrow purging for the removal of residual cancer cells) or (2) positive selection of a cell type for further analysis (isolation of fetal cells from maternal circulation). Using photolithography, replica molding, and soft lithography, we have constructed microfluidic devices to separate heterogeneous mixtures of cells. Device design is based upon arrays of microfluidic channels with decreasing widths; as cells navigate through the device they deform to either negotiate the microfluidic channels or are impeded by the rigid structure. Using human whole blood spiked with neuroblastoma cells, we demonstrate that normal red and white blood cells traverse the device at different rates while the cancer cells are retained; future device generations will incorporate components for on-chip genetic analyses. Selective capture and enrichment of neuroblastoma cells from peripheral circulation may allow for improved cancer detection and permit the discrimination between clinically favorable or unfavorable disease states. In addition to genetic diagnostic and/or prognostic purposes, this prototype device may prove useful for bone marrow purging prior to autologous transplantation.

PCR dosage-based testing for genes spanning the Williams-Beuren syndrome critical region. *M.J. Somerville, M. Hicks, R. Tomaszewski, K.A. Sprysak, B.G. Elyas, A.Y. Ng, S.M. Haase, L.M. Vicen-Wyhony.* Dept Medical Genetics, Univ Alberta, Edmonton, AB, Canada.

Deletions at the 7q11.23 locus have been identified in the vast majority of patients with Williams-Beuren Syndrome (WBS). This contiguous gene deletion disorder is defined by a number of clinical features including infantile hypercalcemia, supraaortic stenosis, and elfin facies. Routine testing for this condition involves cytogenetic fluorescence in situ hybridization (FISH) using a probe from the 7q11.23 deleted region. This method is however, relatively time-consuming and expensive, and may be of limited sensitivity. We have undertaken an assessment of deletion status in a total of 62 index cases, referred for confirmation of a tentative diagnosis of WBS from a wide variety of clinical sources. A real-time PCR assay was developed using multiplex quantitative analysis for sequences within unique open reading frame segments of the *ELN*, *LIMK1*, and *GTF2I* genes. Hemizygous deletions of *ELN* and *LIMK1* have been implicated in typical WBS. Isolated deletion of *GTF2I* resulting from inversion of the WBS critical region has been hypothesized as a possible cause of some atypical WBS cases (Osborne, et al. 2001). We observed a total 6 of 62 (9.7%) cases with hemizygous deletions that encompassed all 3 genes, and these findings were confirmed by cytogenetic FISH analysis. No isolated deletions of *GTF2I* were detected in our 62 index cases. The lack of isolated *GTF2I* deletions may be due to our limited sample size, or undefined diagnostic criteria for referral. We are currently screening a larger population of typical and atypical WBS cases using PCR dosage-detection of these 3 genes, in an effort to determine the frequency of isolated gene deletions within the WBS critical region. According to our findings, integration of molecular and cytogenetic services using direct DNA-based analysis results in higher throughput, substantial reduction of cost and turn-around-time, and potentially increased sensitivity for detection of WBS deletions. Osborne, et al. (2001) Nat. Genet. 29: 321-325.

MTHFR 677CC but not MTRR 66AA genotype may protect against Multiple Myeloma and Solid tumors. K.

Yanamandra¹, I. Gadi², T.F. Thurmon¹, S.A. Ursin¹, H. Chen¹, D. Napper¹, R. Dhanireddy¹, J.A. Bocchini Jr¹. 1) Dept Pediatrics, LSU Health Sciences Ctr, Shreveport, LA; 2) LabCorp of America, Research Triangle Park, North Carolina.

Multiple myeloma (MM) is characterized by neoplastic proliferation of a single clone of plasma cells which produces a monoclonal immunoglobulin. It accounts for one percent of all malignant diseases and more than ten percent of hematologic malignancies. Though MM is of unknown etiology, structural changes in chromosomes 1, 11, and 14 (frequently in 14q32), monosomies and trisomies, and translocations have been observed. Alterations in the expression of c-myc and H-ras have been reported.

Folate deficiency has been suspected of tumorigenesis of solid tumors such as breast, cervix, colon, pancreas, and liver, but there has been little study of enzyme gene polymorphisms in the folate and cobalamin (vitamin B12) pathway such as methylenetetrahydrofolate reductase (MTHFR) C677T, methionine synthase reductase (MTRR) A66G, and methionine synthase A2756G.

We have studied MTHFR and MTRR polymorphisms in cancer patients. Initial results of studies of one hundred patients suggest significant negative correlations of MTHFR 677CC normal genotypes with MM (Chi square 9, p value <0.003, odds ratio of <0.3 with a 95%CI of 0.1-0.7), and with solid tumors (Chi square 4, p value <0.05, odds ratio 0.4 with a 95%CI of 0.3-1), indicating protection by normal genotype. There was no correlation with the MTRR 66AA normal genotype. This being the first report of protection of 677CC normal homozygotes against MM and solid tumors, experience from other investigators would be helpful. Data on statistics, ethnic stratification of MTHFR and MTRR genotypes on various cancers and controls will be presented.

Hereditary Colorectal Cancer Registries: Current Status and Practices. *W.K. Kohlmann¹, C.H. Solomon², B. Allen³*. 1) Division of Molecular Medicine & Genetics, University of Michigan, Ann Arbor, MI; 2) University of Utah Huntsman Cancer Institute, Salt Lake City, UT; 3) Comprehensive Cancer Center & Department of Medicine, University of California-San Francisco, San Francisco, CA.

The Collaborative Group of the Americas on Hereditary Colorectal Cancer (CGA) was established to facilitate research, educate health care professionals, and provide guidance and support for hereditary colorectal cancer registries. As part of the 2001 annual CGA conference a survey assessing organizational structure, patient populations, consenting practices, family expansion strategies and IRB involvement was performed to determine the current status and practices of hereditary colorectal cancer registries. Twenty-five registries were identified through the CGA and a study announcement was posted on the National Society of Genetic Counselors' listserv. Twenty-three responses were received, 20 from CGA registries and 3 from registries identified through the listserv. Twenty-one were established registries, with an average of 9.4(range 1-31 years) years in operation, and 2 were in existence for less than 1 year. The 23 registries had different functions, with 18 (78.3%) providing clinical services and conducting research and 4 (17.4%) for research only. Seventeen registries responded to the following questions about consenting, confidentiality, and family expansion. Fourteen (82%) required written consent for registry enrollment, and 15 (88.2%) registries were IRB approved protocols. All 17 responding registries reported taking measures to protect patient confidentiality. Common measures included staff certification by the NIH Protection of Human Research Subjects Research module, certificate of confidentiality, use of numerical identifiers, and restriction of access to genetic testing information. Fourteen of the 17 responding registries (82.3%) obtained consent from the proband to contact extended relatives. Three registries reported that rather than actively contacting relatives based only on the probands consent, family members were required to contact the registry directly if they wanted to participate. Data from this study will serve as a guide for the development of new registries.

Program Nr: 1197 from 2002 ASHG Annual Meeting

Reverse-hybridization analysis of multiple genetic risk factors for cardiovascular disease. *C. Oberkanins, A. Moritz, F. Kury.* ViennaLab, A-1110 Vienna, Austria.

Background: A number of genetic and environmental risk factors have been found or suspected to predispose to cardiovascular disease (CVD), the term collectively used for disorders of the heart and blood vessels. Inherited susceptibility may be caused by mutations and polymorphisms in a variety of genes involved in blood coagulation, regulation of blood pressure, and metabolism of lipids, glucose, homocysteine or iron. **Objectives:** Our aim was to design and evaluate an assay capable of simultaneously analyzing multiple candidate markers for genetic CVD risk by reverse-hybridization. **Methods:** Two multiplex PCR reactions were set up to amplify and biotinylate DNA fragments covering the following 12 mutations: FV R506Q (Leiden), FV H1299R (R2), Prothrombin G20210A, MTHFR C677T, MTHFR A1298C, b-Fibrinogen -455 G-A, PAI-1 4G/5G, Factor XIII V34L, GPIIIa L33P (HPA-1), HFE C282Y, Apo B R3500Q, Apo E2/E3/E4. After careful selection of oligonucleotides specifically recognizing wild-type or mutant sequences, membrane teststrips were fabricated presenting a parallel array of allele-specific probes for each of the CVD risk factors. For a sample to be analyzed DNA has to be isolated and in vitro amplified, and PCR fragments are hybridized under exactly defined stringency conditions to a teststrip and detected by enzymatic color reaction. **Results and Conclusions:** We have developed a reverse-hybridization assay (CVD StripAssay) for the rapid and simultaneous genotyping of candidate CVD risk factors. The protocol was set up and validated using pretyped human DNA samples, as well as recombinant plasmid clones containing the mutant alleles as confirmed by DNA sequencing. The entire genotyping procedure from blood sampling to final result requires less than 6 hours, and hybridization and detection may be fully automated on existing equipment (e.g. TECAN profiBlot). The test is simple and convenient, requires very small amounts of samples, and can easily be modified to include additional markers of interest. (oberkanins@viennalab.co.at).

Is hyperhomocysteinemia a risk factor in preeclampsia for Korean pregnant women? *Y.J Kim^{1,3}, H.S Park^{2,3}, E.H Ha^{2,3}, W.K Kim⁴, N.S Chang⁵*. 1) Dept of OB/GYN, MokDong Hosp, Ewha Womans Univ, Seoul, Korea; 2) Dept of Preventive Medicine, Ewha Womans Univ, Seoul, Korea; 3) Medical Research Center, Ewha Womans Univ, Seoul, Korea; 4) Dept of Food Science and Nutrition, Dankook Univ, Seoul, Korea; 5) Dept of Nutritional Science, Ewha Womans Univ, Seoul, Korea.

Objective: The purpose of this study was to determine if an elevated plasma homocysteine level at the time of delivery is associated with the development of preeclampsia and to investigate whether 677(C->T) polymorphism in the 5, 10-methylenetetrahydrofolate reductase(MTHFR) gene, low folate status, and low vitamin B12 levels are risk factors for the development of preeclampsia in Korean pregnant women. Study Design: DNA was extracted from whole blood of 191 healthy pregnant women and 84 preeclampsia patients. All samples were genotyped for the 677(C->T) polymorphism in MTHFR gene by polymerase chain reaction followed by restriction fragment length polymorphism analysis(PCR-RELP). Serum levels of homocysteine, folate, and vitamin B12 were measured; by high performance liquid chromatography for homocysteine, and radioassay for folate and vitamin B12. Results were analyzed with the Chi-square test, ANOVA, and the logistic regression analysis. Results: Women with severe preeclampsia showed higher concentrations of serum homocysteine(10.5mmol/L) than healthy pregnant women(8.46mmol/L) and women with mild preeclampsia(8.24umol/L)(p=0.09). For serum folate levels, women with severe(12.7ng/ml) or mild(13.2ng/ml) preeclampsia showed increased levels than healthy pregnant women (9.23ng/ml) (p=0.0046). Hyperhomocysteinemia of homocysteine levels >14mmol/L was associated with preeclampsia(odds ratio=2.36, 95%CI: 1.09, 5.12). Conclusion: These findings suggest that hyperhomocysteine in pregnancy may be a risk factor for preeclampsia.

Folate and Cobalamin metabolizing enzyme gene polymorphisms and Orofacial Clefts in West Africa. *T.F. Thurmon¹, K.M. Layton², K. Yanamandra¹, D. Napper¹, S. Ursin¹, H. Chen¹, R. Dhanireddy¹, J.A. Bocchini Jr¹.* 1) Dept Pediatrics-Genetics, Louisiana State Univ, Shreveport, LA; 2) Mercy ships, Lindale, Texas.

Orofacial clefts (OFC) are multifactorial genetic defects consisting of cleft lip (CL) with or without cleft palate CL(P), and cleft palate (CP). There are syndromic and non-syndromic forms. One of the environmental factors responsible for these conditions is nutrition. Previous studies have revealed periconceptional supplementation of multivitamins, folic acid in particular, reduce the recurrence risk of neural tube defects (NTD). There have been reports that high doses of folate reduce the recurrence risk of OFC also. Gene polymorphism in 5,10-methylenetetrahydrofolate reductase (MTHFR) the rate limiting enzyme in the metabolism of folate in the C1 carbon-pathway has been implicated in the etiology of OFC. MTHFR 677TT homozygosity results in the generation of homocystinemia, and has been reported to be increased in patients with OFC. Methionine synthase reductase (MTRR) regenerates inactive methionine synthase-cobalamin II by reductive methylation to active methionine synthase-methylcobalamin III which participates in the regeneration of homocysteine to methionine. Thus vitamin B12 metabolism is part of folate pathway and provides methyl groups in the methylation of DNA. MTRR A66G polymorphism is reported to be involved in NTD and chromosomal defects. However, its involvement in OFC is unknown.

We are studying MTHFR C677T and MTRR A66G genotypes in patients with birth defects including OFC, NTD and chromosomal defects. We have genotyped fifty three West African patients with OFC and seventy seven controls. Data from our pilot studies suggest that neither MTHFR C677T (Chi square 1.1, p value 0.3, odds ratio 0.4 with 95% CI 0.1-1.7) nor MTRR A66G (Chi square 0, p value 1, odds ratio 1.3 with 95% CI of 0.2-11.7) polymorphisms are risk factors in the development of OFC. Our data about the MTRR polymorphism in OFC is the first to be reported. Data on statistics, MTHFR and MTRR genotypes in various OFC will be presented.

Framework for assessing impact and identifying public health interventions for severe combined immunodeficiency (SCID). *L.V. Kalman¹, M.L. Lindegren¹, L.J. Kobrynski², C.A. Moore¹, S.A. Rasmussen¹, R. Vogt¹, T. Spira¹, S. Grosse¹, M. Gwinn¹, R. Buckley³, M.J. Khoury¹.* 1) NCEH, Centers for Disease Control and Prevention, Atlanta, GA; 2) Emory University, Atlanta, GA; 3) Duke University, Durham, NC.

Background: In November 2001, CDC convened a panel of experts to apply a public health approach to primary immunodeficiency (PI) diseases, a group of 100 immune disorders that includes SCID. We applied a framework for assessing impact and identifying public health interventions to prevent morbidity, disability, and mortality to SCID. The framework has 4 components: epidemiologic assessment; evaluation of diagnostic testing; development, implementation and evaluation of population interventions; and information dissemination. **Assessment:** Current disease/mutation registries and surveys provide incomplete data on incidence, prevalence, and natural history. **Interventions:** SCID is characterized by profound deficiencies of T and B cell function. SCID is fatal in infancy unless identified and treated with a hematopoietic stem cell transplant. Research suggests that transplantation during early infancy can lead to higher survival rates. Public health intervention for SCID may be possible through newborn screening. **Testing:** Potential tests for population (newborn) screening could include quantitative T-cell tests. Data from one center show that low total lymphocyte counts at birth would identify at least 80% of SCID patients, and that testing for T-cell lymphopenia (TCLP) would identify almost all. TCLP potentially could be detected in dried blood spots collected routinely for newborn screening. A screening test may involve measuring soluble T-cell specific biomarkers (CD3 or CD4) that correlate with absolute T-cell counts. Potential tests must be evaluated for analytic and clinical validity and utility in pilot population-based studies. **Dissemination:** We reviewed strategies to increase awareness of PI. Population-based data are needed to assess the public health burden of SCID and effects of early intervention. Validated tests and pilot population studies are necessary to determine the potential of newborn screening for SCID.

CLINICAL AND MOLECULAR ANALYSIS OF THE FRAGILE X SYNDROME IN MENTALLY RETARDED MALES FROM THE VENEZUELAN NORTHWESTERN REGION. *W.M. Zabala, N. Nava, S. Gonzalez, W. Delgado, L. Borjas, E. Fernández, A. Rojas, L. Pineda.* Unidad de Genética Médica, Universidad del Zulia, Maracaibo, Zulia State, Venezuela.

The fragile X syndrome (SFX), is an atypical X-linked dominant inheritance condition. The prevalence of this disease is 1/4000 males and 1/6000 females. Affected males show a fragile site at Xq 27.3 (FRAXA), is usually caused by a trinucleotide (CGG)_n expansion (>230) in the first exon of the FMR1 gene. Expanded alleles are methylated at a CpG island just proximal to FMR1 gene and are expressed. A more distal fragile site, FRAXE, has been identified. Is associated with amplification of (CGG)_n repeat (6-25 normal range, up to 200, fully mutation). The aim of this study was the clinical and molecular evaluation of 98 males with mental retardation of unknown cause in patients with retarded mentally in Zulia state of Venezuela. A 13-item checklist (Hagerman,1987) was used. A total score of 16 or higher had a significant yield of fra(x) positive patients. PCR analysis was performed according to the method of Wang et al. Our studies showed that the proportion of patients with FRAXA in this sample is 4.08% (4/98). It was not significantly different to that reported in most populations (3-6%). PCR analysis detecting methylation of the CpG island confirmed the presence of an expanded FRAXA allele. The proportion of mental retardation associated with FRAXE was 1.02% (1/98). These results suggest that FRAXE is not a common etiological factor among this group of patients. The SXF is the second cause of RM. The prevalence of SXF in the Venezuelan population is unknown. The non-radioactive PCR appears to be a reliable, cheap and efficient test for initial screening of samples for the presence of FRAXA and FRAXE mutations.

MTRR A66G polymorphism and Prenatal risk for NTD and Chromosomal defects. *H. Chen, K. Yanamandra, D. Napper, S. Ursin, T.F. Thurmon, R. Dhanireddy, J.A. Bocchini Jr.* Dept Pediatrics, Perinatal Gen, LSU Health Sci Ctr, Shreveport, LA.

We have shown previously that the C677T polymorphism in the gene of methylenetetrahydrofolate reductase (MTHFR), a folate metabolizing enzyme, was associated with prenatal risk of birth defects. There was an increase in mutant 677TT homozygosity in the prenatally identified at risk women for neural tube defects (NTD) and chromosomal defects (CD) identified through our prenatal triple (MSAFP, MShCG, and MSuE3) screening program. We have also reported an association of MTHFR C677T polymorphism with abnormal fetal karyotypes other than Down syndrome and no association with Down syndrome.

In the present investigation we are studying the association of methionine synthase reductase (MTRR, a cobalamin metabolizing enzyme in folate pathway) A66G polymorphism with prenatal NTD and CD risks. We genotyped over one thousand pregnant women from our prenatal maternal serum screening program who were screened for NTD and CD using triple biochemical analyte method.

Although there were higher heterozygotes in the high risk CD group and similar number in NTD group, compared to controls, percent mutant allele was same in both cases and controls. Our results do not seem to support the findings from literature and do not indicate that MTRR polymorphism was a risk factor in the prenatal development of either NTD or CD. Data and statistics and ethnic stratification of genotypes among pregnant women with high and low prenatal risk for birth defects will be presented.

The practical aspects of integrated prenatal screening. CA. Gibbons¹, SA. Farrell², J. Kennedy¹, T. Huang¹, C. Meier¹, PR. Wyatt¹, AM. Summers¹. 1) Genetics Program, North York General Hospital, Toronto, Ontario, Canada; 2) Genetics Program, The Credit Valley Hospital, Mississauga, Ontario, Canada.

We review successes and problems of Integrated prenatal screening (IPS) in a community setting. IPS combines first trimester screening by ultrasonography for nuchal translucency (NT) and pregnancy associated plasma protein-A (PAPP-A), with second trimester biochemical screening by alpha-fetoprotein (AFP), unconjugate estriol (uE3), and human chorionic gonadotrophin (hCG). It gives the estimate of the risk of Down syndrome (DS) at the completion of all components. IPS is expected to detect 85% of cases of DS at term with a false positive rate of 1.5% at a risk cut-off of 1/200. Prior to implementation, there were concerns about a potential high drop out rate because of withholding results of first trimester screening until all assays are completed. In practice, drop out does not appear to be a major issue however limited availability of NT, discrepancies in pregnancy dating and sample misdirection can create problems for health care practitioners. In our IPS program, 6942 women have started IPS. 6579 women completed IPS, giving a drop out rate of 5.2%. 96 of the 363 dropouts had amniocentesis. The outcome of the 267 pregnancies is unknown. It would be expected that some miscarried. One problem has been accurate gestational dating. Discrepancies in dating from ultrasound laboratories resulted in women presenting at the wrong gestation for screening. This problem could be eliminated by using a single gestational dating source. In Ontario, the Daya' 93 crown-rump curve is used since it best fits Ontario data, based on a separate study. The major sample handling error occurs when the second blood sample is sent to a different laboratory. The problem can be reduced by use of the correct requisition by the physician, attention to laboratory information by transportation staff, and cooperation among laboratories. While there are some logistic problems with IPS, it appears that the benefits outweigh the inconvenience and women and physicians are willing to undertake this screen.

Cytogenetics and Prevalence of Down Syndrome: A Study from Saudi Arabia. *I.M. Amir¹, K. Al-Tawil², A. Al-Harbi²*. 1) Dept Pathology, King Fahad Natl Guard Hosp, Riyadh, Saudi Arabia; 2) Dept Pediatrics, King Fahad Natl Guard Hosp, Riyadh, Saudi Arabia.

Studies on Down syndrome in Saudi Arabia and other Arab countries are sporadic. We report the cytogenetic and prevalence findings of Down syndrome from 277 affected patients investigated at King Fahad National Guard Hospital, Riyadh, Saudi Arabia. The classical trisomy 21 non-disjunction type of Down syndrome was found in 264 patients (95.3% of cases), two of them were mosaic (0.72% of cases). Five patients had maternally inherited types of trisomy 21 that resulted from t(13;21), t(14;21) and t(15;21). Seven patients showed trisomy 21 karyotypes as a result of the i(21q) abnormality and one patient had a rare type of trisomy 21 that resulted from psu idic(21)(q22). Parental blood lymphocyte karyotypes of the last eight patients were normal. Two of the patients with i(21q) were monozygotic twins. One patient with i(21q) also has an older sibling with the classical non-disjunction type of Down syndrome, an indication for possible parental gonadal mosaicism. Out of the 277 patients, 145 were born at King Fahad National Guard Hospital between 1992 and 2001 among a total of 61861 live births. The prevalence rate of Down syndrome during this ten-year period was therefore estimated at 1 in 427 in the absence of an antenatal screening program for Down syndrome. Advanced maternal age at birth of Down syndrome patients was generally evident. Although the cytogenetic pattern of Down syndrome patients in our study is generally similar to that of major international studies, the incidence of this disease is distinctly higher. Currently, there is no official registry of Down syndrome patients in Saudi Arabia, however, in a country of about 21 million people with 3.1% annual population growth the number of Down syndrome patients will inevitably be very high and this emphasizes the need for an effective long-term antenatal screening program. Further studies are in progress to describe the clinical findings of Down syndrome patients in Saudi Arabia and to investigate the correlation between the incidence of Down syndrome and paternal age and maternal parity size.

Is Methionine synthase reductase 66G mutant genotype a risk factor for chromosomal defects? *S.A. Ursin¹, K. Yanamandra¹, I. Gadi², H. Chen¹, T.F. Thurmon¹, D. Napper¹, R. Dhanireddy¹, J.A. Bocchini Jr.¹*. 1) Pediatrics, Louisiana State Univ, Shreveport, LA; 2) LabCorp of America, Research Triangle park, North Carolina.

For a number of years, we have been studying the correlations between gene polymorphisms and genetic diseases such as single gene, multifactorial, and chromosomal disorders (CD). In recent studies of the MTHFR C677T polymorphism in pregnancies at risk for neural tube defects (NTD) or CD, we have found MTHFR 677TT homozygosity to be a risk factor for fetal chromosomal defects other than Down syndrome, with two-fold higher homozygosity over controls (24% vs 12%, p value <0.03, odds ratio 4.7). Fetal trisomy 18 amnios displayed four-fold higher homozygosity over controls (57% vs 12%, p value <0.02, odds ratio 12.6).

Because folate and cobalamin (vitamin B12) share similar pathway, we also studied the methionine synthase reductase (MTRR) A66G polymorphism in 50 amniocyte samples with abnormal karyotypes (trisomies - sex and autosomal, triploidies, translocations and deletions; half Down syndrome and half non-Down syndrome). Our data revealed that there was no correlation between the MTRR A66G polymorphism and the CD (Chi square 0.7, p value 0.4, odds ratio 0.8 with 95% CI 0.5-1.3), in contrast to reports in the literature.

Preliminary studies revealed a fifty percent increase in MTRR 66AG heterozygosity in Down syndrome fetuses, the significance of which is unknown. Data, statistics, and ethnic stratification of genotypes will be presented.

Medical Geneticists Duty to Warn At-Risk Relatives for Genetic Disease. *M.J. Falk^{1,2}, R.B. Dugan¹, M.A. O'Riordan², A.L. Matthews¹, N.H. Robin^{1,2}.* 1) Depts of Genetics; 2) and Pediatrics, University Hospitals of Cleveland, CWRU Sch Med, Cleveland, OH.

When a patient refuses to notify relatives who are at-risk for a genetic condition, genetics professionals are met with conflicting ethical obligations: the duty to respect and protect their patients' right to privacy and confidentiality vs. the duty to prevent harm. The latter duty suggests a responsibility to warn at-risk relatives of their genetic risk, even without their patient's consent. Little investigation has occurred into how genetics professionals view disclosure of genetic test results to at-risk relatives without patient consent. Prior studies have been limited to identifying motivating factors underlying genetics providers predicted responses in hypothetical scenarios. Previously, we examined the actual clinical experience of genetic counselors (GC) with this issue (Nation et al., in press). To further investigate this issue, we surveyed medical geneticists (MG) on their experiences warning at-risk relatives. A questionnaire was sent to 800 board-certified MG, with a 27% (213/800) response rate. 70% (148/213) believe they do bear responsibility to warn at-risk relatives, but most incorrectly answered questions on existing laws and guidelines on this subject. 60% (127/210) reported having had a patient refuse to tell their at-risk relatives. 33% (39/118) described 70 cases in which they seriously considered disclosure without patient consent. Only 4 proceeded to warn at-risk relatives in 5 cases. MG identified patient confidentiality and legal liability as major factors leading to non-disclosure. In Nation et al., GC cited emotional issues as key factors in their decisions not to warn. This study of MG and the previous one on GC show both that do encounter this scenario in clinical practice (60% & 46%, respectively). While disclosure to at-risk relatives without consent was rarely the outcome for either group, differences do exist in how MG and GC approach this delicate situation. The creation of guidelines that take into account the differing perspectives identified in this study would benefit future genetics practitioners faced with this dilemma.

Program Nr: 1207 from 2002 ASHG Annual Meeting

Development of a database to assess efficacy of pedigree analysis in genetics patients referred for routine indications. *W.S. Meschino, M. Care, E. Wen, L. Velsher.* Dept Genetics, North York General Hosp, Toronto, ON, Canada.

Our Genetics Program serves a large multicultural prenatal population, with over 3300 patient visits per year. The majority of referrals are for advanced maternal age (AMA) or a positive maternal serum screen (MSS), where the average risk of chromosome abnormalities is 0.7 - 1%. A detailed pedigree and reproductive/prenatal history are taken on all routine prenatal patients, a practice widely endorsed by the WHO and others. Through this process, the potential exists to uncover genetic or teratogenic risks that are above those associated with the reason for referral. These risks may be as high as 25 or 50%, much higher than the typical risks associated with AMA or a positive MSS. The pedigree component of the average genetic counselling session is substantial (20 minutes), totalling 1100 hours annually. How often are significant genetic disorders or other risk factors uncovered, which influence the choice of diagnostic tests or outcome of prenatal diagnosis? We present details of a database that was developed to answer these questions. The information recorded includes the patient's risk for a chromosome abnormality or open neural tube defect, as well as details regarding the prenatal history: maternal health and exposure to teratogens. Significant details of the pedigree, and results of all prenatal tests, including carrier screening for high-risk ethnic groups for the patient and her partner were also included. The database captures how often additional tests are offered and how often they are accepted. It was used in a retrospective analysis of 1000 prenatal genetics charts to assess the cost-effectiveness of routine pedigree analysis. It can also be adapted for prospective use.

Informed Decision-Making in Newborn Screening: Highly Variable Regulatory Language. *M.H. Lewis¹, L. McCabe^{1,2}, E.R.B. McCabe^{1,2,3}*. 1) Department of Pediatrics and; 2) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA; 3) Center for Society, the Individual and Genetics, UCLA, Los Angeles, CA.

Personal autonomy is a fundamental ethical concept and informed decision-making is one mechanism to support personal autonomy. The informed consent process is the formal vehicle for informed decision-making and is generally required prior to a medical test or procedure. The objective of this study was to evaluate the regulatory language governing informed decision-making in state newborn screening programs. To evaluate current practices regarding informed decision-making for newborn screening, statutes from all fifty states plus the District of Columbia, were analyzed. We found that these 51 jurisdictions address issues of informed decision-making for newborn screening in a highly variable fashion. Forty-four programs require mandatory newborn screening. Nine programs exempt newborns from screening based solely on parental objections. Twenty-six programs allow exemptions for religious reasons. Violation of newborn screening requirements is a misdemeanor punishable by fines in six jurisdictions, and by imprisonment in one jurisdiction. Three jurisdictions prohibit testing unless the parent is fully informed of the test purpose. Only five programs require informed consent from parents prior to newborn screening. Eight jurisdictions specifically exclude newborn programs from informed consent requirements for genetic testing. We conclude that the disparate manner in which informed consent issues are treated highlights the need for further study of, and model regulatory language for, informed decision-making. The completion of the Human Genome Project will provide tremendous potential to apply new technologies in newborn screening and expand test batteries. Use of stored newborn screening samples to develop these tests also should be addressed. The overarching goal should be to educate the public and professional communities about the purposes of newborn screening programs and the use of information obtained by newborn screening.

Unanticipated outcome from recent guidelines for CF carrier testing. *P.P. Hawley¹, R.B. Parad^{1,2}, A. Comeau², M.B. Irons¹.* 1) Childrens Hosp, Boston, MA; 2) UMass Medical School, Worcester, MA.

Recent ACMG guidelines for CF carrier testing include recommendations for reflexive testing for the poly T variant in intron 8 when the R117H mutation is detected. In keeping with these guidelines, poly T testing has been offered to R117H carriers seen in the Children's Hospital Genetics Program since 8/1/01. Carriers of R117H include newborns identified through the Massachusetts CF Newborn Screen (CFNS), as well as a parent of the newborn.

11 newborns with elevated IRT levels (10 females, 1 male) were identified with 1 copy of the R117H mutation. 5 with normal sweat tests were homozygous for the 7T allele, including the 1 male. One had a 7T allele trans to an R117H-5T allele. The remaining 5(4 normal, 1 indeterminate sweat test) had a 5T allele trans to an R117H-7T allele. For 2 of 5 newborns homozygous for the 7T allele, the possibility existed for a 5T allele trans to the R117H mutation in sibs. As for the newborn's parents, the R117H mutation was found in 7 fathers and 4 mothers, none of whom had a 5T allele trans to the R117H mutation. For 7 of 11 newborns found to be R117H carriers following CFNS, a discussion ensued with parents concerning variable phenotypes associated with a 5T allele trans to a CF mutation. Phenotypes include: asymptomatic; CBAVD(males); chronic pancreatitis; atypical or rarely classical CF. Relative risk for these outcomes is unknown. In view of possible CF related symptoms in persons with this genotype, consultation in a CF Program is recommended, with any ongoing monitoring to be determined by CF specialists.

The R117H mutation produces CFTR protein with some function. It is conceivable that more severe phenotypes may be seen more frequently when a 5T allele is trans to severe CF mutations. Yet these individuals are not being identified or offered consultation in a CF Program because ACMG guidelines do not recommend poly T testing for all identified carriers. Thus, in carriers identified through CFNS, adhering to guidelines regarding poly T testing of R117H carriers has inadvertently resulted in offering different levels of service to patients with different mutations.

Ethical Issues in Pre-symptomatic Genetic Testing: A Survey of Physicians' Knowledge and Attitudes in Taiwan.

W.H. Tsai^{1, 2}, P.L. Kuo³, C.N. Shiue⁶, C.C. Chen⁴, S.J. Lin⁵. 1) Department of Pediatrics, Chi Mei Foundation Hospital; 2) Inst Clinical Medicine; 3) Department of Obstetrics; 4) Inst Molecular Medicine; 5) Department of Pediatrics, College of Medicine, National Cheng Kung University, Tainan, Taiwan; 6) Department of Pediatrics, Dalin Tzu Chi Hospital, Chia Yi, Taiwan.

With the advent of genetic services in Taiwan, a variety of genetic tests are now available for prenatal diagnosis, carrier detection, and pre-symptomatic diagnosis of neuro-degenerative disorders. However, many problems related to ethical issues still exist, such as who should be tested, the process of informed consent prior to testing and methods of dealing with the test results. To understand the physicians' attitudes towards ethical issues, we conducted a survey among physicians focusing on pre-symptomatic testing for neuro-degenerative disorders. A self-administered questionnaire with 10 questions and a case scenario related to Huntington's chorea were used to test the surveyees' opinions about informed consent, children/fetal rights, and information disclosure in the process of genetic counseling. Results were obtained from 61 physicians in tertiary medical centers and community hospitals, including 28 pediatricians, 19 obstetricians and 14 neurologists. Ninety percent of the physicians followed the process of informed consent. With respect to autonomy, although 24.6% of the physicians stated that they would respect the child's decision, 60% considered parents to have the right to know their fetus's condition and would agree to perform prenatal testing on the fetus. However, some inconsistency exists in the fact that 52% of the physicians did not agree on termination of pregnancy if the fetus were found to be affected. While 64% of physicians indicated that the information should be passed on to family members, half of them thought that the decision to tell or not to tell should be left to the proband. In conclusion, while most of the surveyed physicians indicated that they would follow the principles of informed consent and autonomy, controversy exists regarding prenatal testing and termination of pregnancy.

Program Nr: 1211 from 2002 ASHG Annual Meeting

Importance of Telegenetics Services in India: A survey. *S.K. Pal, A. Kesari, G.S. Pandey, B. Mittal.* Medical Genetics, Sanjay Gandhi Postgraduate Ins, LUCKNOW, UP, India.

Communication and information have increasingly been considered important in helping patients to cope with chronic problems. Internet based health information can be shared with many people despite distance and time constraints. Videoconferences and data base facility are now effectively utilised for monitoring public health activity. High bandwidth services are creating a new way for patients and clinicians to interact and benefit from specialist services, which are available locally. Developing country has acute shortage of doctors and their services are concentrated in major cities, so in this situation telemedicine via Internet can play a crucial role in bridging this gap. A survey was conducted to assess the concept of telegenetic counseling by internet among 40 participants in a Genetic Counseling course in our department. The clinicians were from different states of India. A questionnaire was designed to know the general awareness regarding telemedicine and telegenetics. Centpercent of the participants agreed that the internet will play a major role in genetic counselling and patient's management at the peripheral level. Twenty(50%)of the participants were daily users of internet and 23% percent used it occasionally. Twenty eight (70%) thought that telegenetics can provide immediate accessibility of the experts and will greatly enhanced the scope of genetic services in the country. Thirty six(90%) of the clinicians agree to join the teleconsultant group and emphasized the idea of making an interactive websites in Indian context. All the participants wanted to be connected by net with the tertiary care hospitals after they completed the genetic counseling course.

Program Nr: 1212 from 2002 ASHG Annual Meeting

Tay Sachs Disease Screening, funding, publicity and community acceptance. *E. Sheffield, A. Gason, A. Bankier, M. Delatycki.* Genetic Health Services Victoria, Murdoch Childrens Research Institute, Melbourne, Australia.

The purpose of this study was to examine the roles of publicity, funding/sponsorship, education and other factors involved in bringing a genetic carrier screening program to a minority at risk group in a population, most of whom are unaware of the condition. The method used was that Tay Sachs Disease(TSD)screening was introduced to Jewish High School students in Melbourne in 1998. Funding for this program is limited. This program offers education to parents, students, and staff at 6 Jewish High schools. In 2000 it was extended to offer bi-annual community screening days to the Melbourne Jewish community. Financial sponsorship was provided from 1999 for a part-time genetic counsellor/educator, free testing for year 11 students, and subsidised testing for adults of child bearing age. Results showed that free testing of students increased the uptake from average 33%; (subsidised fee) to an average 67%; (free test and improved education program). Blood samples were used for tests. Surveys showed that a buccal smear would increase test uptake, and that students had a good knowledge about TSD following education sessions. In 2000, adults, of child bearing age, in the community were offered subsidised testing on community days. 15 people came to the first community day. An alternate publicity campaign increased this number to 70 in 2001. In conclusion, results indicate that it is possible to offer an effective and acceptable screening program on limited funding providing that it can tap into resources within the community and obtain the support of community leaders and relevant health professionals. The uptake of testing will increase if it is free; if it comes to the individual; if they understand why they are offered testing and if it is painless.

Impact of an Internet-based information service on the uptake of genetic services: the Orphanet experience. *S.M. Ayme, H. Nabarette, D. Oziel, S. Rastoul, B. Urbero.* INSERM SC11, Hopital Broussais, Paris, France.

The objectives were (1) to assess the influence of an Internet-based information service in the area of genetic diseases on the referral to appropriate health care services; (2) To compare the influence of this information on the patients and their relatives vs health care professionals; (3) To detect any harmful effect. Orphanet, a database of rare diseases and related services funded by the European Commission, was the internet resource facility which was evaluated. A survey was sent to the 500 clinics and the 350 laboratories which are referenced in the database and to 214 patients organizations. The survey aimed at assessing the impact of Orphanet on the number of referrals to specialized clinics and specialized laboratories. It included questions about the number of patients referred by an other professional and the number of patients having personally identified the clinics through Orphanet. It also included questions about the adequacy of referrals due to Orphanet. The response rate was 67% (144/214) for the support groups, 67,8% (460/678) for the clinics and 75,6% (229/303) for the laboratories. The clinicians are users of the website (80%), mainly to identify laboratories (60%), to refer a patient to an other specialist (52%), to find a support group (40%). The laboratories are also heavy users (76%). They look for other clinical (44%) or research (43%) laboratories. The support groups are users at 96.5%, mainly to refer patients to a specialized clinic. The assessment of the true impact is not yet finished but will be presented. This survey shows that the availability of information on highly specialized health resources may contribute to empowering consumers and to improve right use of these resources. The problems raised by such an information system are the validation of the information in areas where knowledge is scarce, the dissemination to the public of information which would be traditionally restricted to the professionals, the updating process, the legal issues, the criteria to classify places as expert centers and the extent to which some services can be delivered on line.

Iranian Human Mutation Gene Bank. *H. Najmabadi, M. Neishabury, F. Sahebjam, K. Kahrizi, N. Nikzat, M. Jalalvand, F. Aminy, S. Bani Hashemi, B. Moghimi, A.R. Noorian, A. Jannati, M. Mohammadi, M.K. Javan.* Genetics Research Center, The Social Welfare and Rehabilitation Sciences University, Tehran, Iran.

Completion of the Human Genome Project takes us to a new era in clinical genetics, where identifying the new genes responsible for the hereditary diseases. The existence of high genetic polymorphism within and between different communities in the world makes it necessary for the gene hunters to investigate many different populations. Iran, a large country with close to 66 million population, a land of different nationalities, tribes and religions offers a highly heterogeneous gene pool to the researcher in Genetics. The purity of many different races in this country has been greatly saved within the geographical borders and by an ancient culture that has always encouraged familial marriages. All these have created a remarkably heterogeneous population and yet high in consanguinity rate. During the last Five years investigation we have established a DNA bank (<http://www.IHMGB.com>) of all genetic diseases with Mendelian mode of inheritance studied in Iran. Some of the samples are assigned to common or novel mutations and some others belong to patients with clinical profiles associated with particular genetic diseases but undefined mutation. This bank stores patients and his/her first degree relatives DNA together with a comprehensive pedigree and clinical profiles for each sample. In order to facilitate collaboration with other scientists in the world with the same interests, we decided to present our experimental projects. This DNA bank providing opportunities for us to collaborate with outside, will offer a free of charge sample resource to all the research scientists in the world, , who are working on the various aspect on genetic disorders from prenatal diagnosis to gene structure and function. It is strongly stressed that no commercial benefit is involve in establishment of this DNA bank and the DNA samples are free of charge. However, to meet our goals and to respect the ethical values, DNA samples can only be used under certain conditions stated in the users consent form.

Newborn screening for treatable disorders in the Old Order Amish of Southwestern Ontario. *V.M. Siu^{1,2,3}, C.A. Rupa^{1,2,3}*. 1) London Health Sciences Ctr; 2) CPRI; 3) Departments of Pediatrics and Biochemistry, University of Western Ontario, London, ON.

The Old Order Amish in Southwestern Ontario represent a distinct, highly consanguineous population of about 2000 individuals. Their ancestors migrated directly from Europe to this area, and founding members are different from those of other colonies in the United States. In general, the Amish are quite knowledgeable about various diseases in their community, and keep excellent genealogical records. However, they tend to seek medical advice late in the course of illnesses, when treatment may be ineffective. One major factor contributing to the tendency to delay seeking help is the difficulty and expense of arranging for transportation, since the Amish usually utilize horse-and-buggy. Provision of medical care in their own community is likely to increase acceptance of medical intervention. Increased awareness of specific disorders and early identification of diseases allows targeted investigations and early treatment. Prenatal diagnosis of non-lethal disorders is generally not acceptable to the Amish, based on their religious beliefs. In this population, we have documented 5 disorders (PKU, galactosemia, cystinosis, cystic fibrosis, and juvenile glaucoma) amenable to treatment that may prevent or ameliorate morbidity if diagnosis is made at a presymptomatic stage. Previous work has identified the unique mutations for cystinosis and glaucoma in this group. Using a combination of molecular and biochemical tests, we will be initiating a neonatal screening program for the 5 treatable disorders. Discussions have taken place with Amish bishops and education sessions have been given to Amish women. The community has expressed its interest in early diagnosis and disease prevention. Support and ongoing education will be provided through public health nurses, local physicians, and a worker from within the community.

Survey of obstetrical providers' knowledge and attitudes regarding newborn screening. *S.M. Dolan¹, S. Gross¹, K. Damus², I. Merkatz².* 1) Division of Reproductive Genetics; 2) Department of Obstetrics & Gynecology and Women's Health, Albert Einstein College of Medicine and Montefiore Medical Center, Bronx, NY.

Newborn screening is the first example of population-based genetic testing. State programs have grown since they were first developed in the 1960s, but advocacy for broader testing and advances in genetic technology have allowed for recent rapid expansion. Obstetricians have been called upon by newborn screening advocates to provide information about newborn screening to patients during pregnancy. **Objective:** The aim of this study was to assess obstetrical providers' knowledge and attitudes about newborn screening in order to provide resources to assist obstetricians. **Methods:** On a pilot basis, we developed a two-page survey which was distributed at Ob/Gyn Grand Rounds at our institution. **Results:** Thirty-nine surveys were completed and included in this analysis (34 MDs, 3 CNMs, and 2 PAs). Regarding knowledge about newborn screening, 59% of respondents said they knew "some" about newborn screening and 31% said they knew "very little." Only one physician reported knowing "a great deal" about newborn screening. When asked to list conditions that newborns are screened for in New York State, 23 respondents (59%) correctly listed phenylketonuria, 11 (28%) listed hypothyroidism, 8 (21%) listed HIV, 7 (18%) listed sickle cell disease, and 2 (5%) listed galactosemia. Thirty-four respondents (87%) stated that they would be interested in further education about newborn screening and most reported that Grand Rounds would be the best format. Regarding attitudes, in response to the statement, "Newborn screening is relevant to my practice," 4 respondents (10%) strongly agreed, 17 (44%) agreed, 16 (41%) stated they were not sure, and 2 (5%) disagreed. When asked if newborn is a topic that should be covered by the obstetrician, 21 (54%) stated they agree, 11 (28%) stated they are not sure and 7 (18%) stated they disagree. **Conclusions:** Increased education regarding newborn screening targeted to obstetricians and providers of obstetrical services can allow information regarding this important public health program to be disseminated to families and strengthen newborn screening programs.

Program Nr: 1217 from 2002 ASHG Annual Meeting

Experience with preconception screening for cystic fibrosis (CF) in a clinical molecular genetics laboratory. *K.G. Monaghan, D. Bluhm.* Department of Medical Genetics, Henry Ford Hospital, Detroit, MI.

October 1, 2001 the ACOG and ACMG recommended CF carrier screening be offered to all Caucasian couples who are either pregnant or planning a pregnancy and that CF carrier screening be made available to individuals of other ethnic groups. To educate physicians, we sent a summary of ACOG/ACMG's statement to all primary care physicians (including obstetricians/gynecologists, internists and family practitioners) within our institution and outside physicians who send specimens to us. This summary was also printed in our department's quarterly newsletter that is distributed to all physicians and doctoral-level scientists within our institution, outside referring physicians and reference laboratories from which we receive specimens. We included a one page brochure for patients describing CF, its frequency, inheritance, treatment and carrier testing. We have since experienced a 14.5-fold increase in the weekly sample volume for CF testing. The number of specimens received for carrier screening has increased greater than 17-fold and accounts for 61% of specimens received compared to 38% prior to October 1, 2001. Because of the large increase in sample volume, we changed our method of molecular CF testing. We previously used heteroduplex analysis and RFLP analysis to detect 55 CF mutations, which included the 25 recommended by ACOG/ACMG. We now use an oligonucleotide ligation assay (OLA)(Applied Biosystems) on a 3100 Genetic Analyzer to screen for 31 CF mutations and a combination of heteroduplex analysis and RFLP analysis to test for 12 additional mutations, 3 of which are recommended by ACOG/ACMG but not included in the OLA kit. The number of carriers identified is within the expected range. Among specimens received for general carrier screening, 26% were from couples in whom both partners were tested for CF, either concurrently or sequentially. Only one positive-positive couple has been identified; their fetus was negative for both parental mutations. We encourage other laboratories to educate physicians regarding CF preconception carrier screening and to be prepared for an increase in sample volume.

Barriers to genetic screening in the Ashkenazi Jewish population: The Philadelphia experience 1999-2002. *R. Keep*¹, *J. Becker*², *A. Schneider*¹. 1) Pediatrics, Albert Einstein Medical Center, Philadelphia, PA; 2) Department of Health Studies, Temple University, Philadelphia, PA.

An estimated 240,000 Ashkenazi Jewish (AJ) individuals live in the city of Philadelphia and the surrounding counties (Jewish Federation of Greater Philadelphia, 1997). If approximately 1 in 4 individuals of AJ ancestry is a carrier of one of ten diseases that occur at a higher frequency in this population, there would be an estimated 60,000 carriers in this region.

The AJ Genetic Disease Screening Program at Albert Einstein Medical Center was established in 1999 in response to the large Jewish population in this area, with funding provided by the Albert Einstein Society. Since its inception, the Program has provided outreach, education, genetic counseling and carrier screening to individuals of AJ descent. Despite extensive efforts to educate local rabbis, OB/GYNs and the public, via synagogues, Hillels, participation in Community events, publication of an educational brochure and annual free screenings, the overall interest and response from the Jewish Community has been disappointing.

Our experiences have led us to postulate that several barriers may be preventing AJ individuals from seeking genetic screening. These include:

- cost of testing and uncertainty regarding complete coverage by health insurance companies
- lack of understanding of recessive inheritance; that the absence of affected relatives does not eliminate the risk to be a carrier
- inadequate knowledge about these conditions and the availability of screening on the part of many OB/GYN physicians and rabbis
- fear of being identified as a carrier

A qualitative study was conducted using focus groups to explore the validity of our proposed barriers and to gain insight into the perspectives of different segments of the Jewish community regarding this issue. Results of these discussions will be presented. ••

Accountability in Diagnostic Molecular Genetic Testing: The U.K. *S.A.R. Stenhouse¹, S. Ramsden², S. Patton² and Steering Committee of UK NEQAS for Molecular Genetics.* 1) Institute of Human Genetics, Newcastle-upon-Tyne, U.K.; 2) National Genetics Reference Laboratory (Manchester), Manchester, U.K.

External quality assessment for molecular genetics has been operating in the United Kingdom since 1991. Beginning as an initiative of the U.K. Clinical Molecular Genetics Society the scheme became independent in 1994 and has expanded from offering three disorders to offering thirteen on a rotating basis. 43 laboratories from the U.K., Ireland and The Netherlands participate. The scheme aims to assess the whole analytical process with marks being awarded for genotyping, interpretation and clerical accuracy. Errors have been identified in all of these areas but mechanisms have been developed to identify poor performance and provide education and training for such laboratories. Over the years the scheme has seen an increase in conformity to consensus best practice guidelines and a corresponding reduction in errors leading to higher quality testing.

The development and structure of the scheme will be described in detail and comparison of the results over the years will be presented. Analysis of these results demonstrates that a robust system of external quality assessment contributes significantly to improving standards of molecular genetic testing. The accountability provided by participation in such schemes should give patients confidence in molecular genetic test results.

Program Nr: 1220 from 2002 ASHG Annual Meeting

A dynamic informed consent process for population based genetic research. *M.E. Smith, P.K. Manasco, T. Arledge.*
First Genetic Trust, Inc, Deerfield, IL.

Patient participation in population based research involving genetics is critical to achieving the goals of developing personalized medicines and understanding the role of genetic alterations in complex diseases. The current standard of practice for consenting study participants in most cases includes obtaining “blanket consent” from research subjects—consent for unspecified future use of biological samples and data generated from clinical trials in which the study participant agrees to “medical research” that may include future use of their DNA. The study participant may not be aware of these future uses. We agree with Beskow et al¹ that this approach may not allow study participants to make the most informed choices about participation in population based research involving genetics. We have developed a solution to the informed consent process that involves the use of an internet enabled dynamic informed consent process that allows study participants to control access and use of their phenotypic and genotypic information over time and throughout multiple studies by extending or restricting permission regarding the use of their previously collected biological samples and medical and genetic data. The study participant also has ongoing access to study information, is able to update personal clinical information and learn about new research studies. This environment provides online genetic education that is study specific and required for providing consent to participate in each research study, and also includes general genetic and ethical topics associated with research. We will review the various issues raised by individual Institutional Review Boards regarding the use of this new informed consent process for genetic research. These issues have included concerns about transmission of sensitive genetic information over the internet, how privacy is protected for individuals involved in studies utilizing the dynamic consent process, what is done with a study participant's genetic, clinical, and identifiable information at the end of a clinical trial, and how this consenting process is compliant with US HIPAA privacy regulations and the European Council and Parliament Directive 95/46/EC.

The ophthalmological window for identification of patients with Fabry disease. *M. Cybulla¹, B. Bausch¹, G. Franke¹, D. Schmidt², F.X. Glocker³, A. Gal⁴, K. Rosenberg⁵, H. Neumann¹.* 1) Dept. of Medicine, University of Freiburg, Freiburg, Germany; 2) Dept. of Ophthalmology, University of Freiburg, Freiburg, Germany; 3) Dept. of Neurology, University of Freiburg, Freiburg, Germany; 4) Dept. of Human Genetics, University of Hamburg; 5) Institute of Medical Biochemistry and Genetics, Copenhagen.

Background: Fabry disease is a rare X-linked disorder with galactosidase-A deficiency due to mutations of the AGAL-Gene resulting in globotriasylceramid deposits in various organs. Lifespan is reduced by about 20 years. Since a few months introduction of enzyme replacement therapy has revolutioned actual wellbeing and long time prognosis. Our estimations expect approximately 200 patients in Germany. Methods: All members of the German society of ophthalmology have been contacted by a questionnaire for patients with cornea verticillata. Such patients underwent pedigree analysis, biochemical analysis of serum galctosidase activity and investigation for classical skin lesions and dysfunction of th CNS, heart and kidney. Furthermore EDTA blood was drawn for genetic testing. Results: Response rate was 36% e.g. 1751 out of 4900 ophtalmologists returned the questionnaire. 24 patients with cornea vericillata where registrated. All had Fabry disease. So far, by clinical and genetic reevaluation the diagnosis was confirmed in 5 cases by clinical, biochemical, and genetic investigations. Conclusion: Nation-wide epidemiologic efforts using single components of rare diseases are effective for identification of such patients as shown for Fabry disease using cornea verticillata.

A focus group study of public understanding of genetic risk factors: The case of "a gene for heart disease". *B.R. Bates*¹, *A. Templeton*², *P.J. Achter*¹, *T.M. Harris*¹, *C.M. Condit*¹. 1) Speech Communication, Univ Georgia, Athens, GA; 2) Biology, Washington Univ, St. Louis, MO.

There is growing concern in the medical community about public perceptions of genetic determinism or genetic fatalism in the patient population. Limited information about how the public actually understands reports of genetic risk factors in disease formation is currently available. To understand public perceptions genetic risk factors a focus group methodology was employed to evaluate the phrase a gene for heart disease. There were a total of 108 participants recruited from urban, suburban, and rural communities in Georgia in July through October 2001. Participants were recruited to balance sex and racial representation. There were multiple interpretations of the phrase, but dominant interpretations did emerge. A gene for heart disease was interpreted as meaning both environmental and genetic risk factors played a role in disease formation. Genetic predisposition was perceived as heightened, not absolute, risk. The dominant perceived health impact of having the gene was a greater risk of becoming sick. Minority interpretations were found under each measure. There were no significant differences in expressed attitudes by sex. African-Americans expressed a higher level of perceived risk than did European-Americans. African-Americans were also more likely to perceive the medical effect of having a gene for heart disease as death or premature death, whereas European-Americans were more likely to perceive the impact as illness of premature illness. In the main, participants had medically correct evaluations of genetic risk factors and their implications for health behavior and treatment. The phrase a gene for heart disease does not appear to have the feared deterministic impact on participants perceptions of the level of risk from non-modifiable genetic risk factors. Concerns of genetic fatalism in patient populations may be overstated. Important considerations for provider intervention and patient education are indicated.

Genetic disease registries and informed consent. *B.A. Bernhardt, L.A. Hamby, G. Geller.* Johns Hopkins Medical Institutions, Baltimore, MD.

Genetic disease registries have been established or supported by many voluntary genetic organizations as a means to foster research on rare diseases. Possible risks of registry participation have been identified and include potential threats to privacy and the confidentiality of information. No guidelines exist on how informed consent should be obtained, nor on how researchers should gain access to registry data or participants. The goals of the current study were to explore how genetic organizations describe and use their genetic registries.

A two-page survey was sent to the executive directors of organizations listed with the Genetic Alliance (GA) as having a disease registry. Questions were asked about the purpose of their registry, perceptions of the risks of registry participation, whether informed consent is obtained from participants, and how researchers gain access to registry participants or data.

Of 173 organizations surveyed, 80 (46%) responded. Only 53(66.3%) respondents indicated that they currently maintain genetic registries, in spite of being listed as such with the GA. Forty-five organizations with registries (85%) mentioned research as a purpose and/or indicated that their registry has a mechanism by which researchers can obtain access to registry information. Of these 45, 33% indicated that they do not obtain informed consent before enrolling participants into their registry. Organizations that identify research as a purpose were significantly more likely to obtain informed consent ($p=.012$). However, there was no association between providing access to outside researchers and the likelihood of obtaining informed consent. When asked about the risks associated with being part of a genetic registry, 76% of organizations with a registry indicated that there were no risks to potential participants.

A substantial minority of organizations that maintain a registry for research purposes do not obtain informed consent. Most of these organizations do not identify any risks to registry participants. There is a need for developing and disseminating guidelines for informed consent for registry participation.

Ethical issues among a low-income minority population participating in genetic research. *N.H. Arar, V. Sartorio, R. Plaetke, H. Abboud.* Dept Medicine, Div Nephrology, Univ Texas Health Sci Ctr, San Antonio, TX.

We explored diabetic nephropathy probands and their relatives perspectives on: (1) revealing health, demographic and identifiable information about relatives without first obtaining their written consent and (2) their awareness of ethical issues and risks associated with their participation. Structured interviews were conducted with 246 Mexican American participants using Contextual Assessment Approach Questionnaire. 105 DN probands and 141 relatives were enrolled at UTHSCSA, SA, TX. Data analysis included both qualitative and quantitative methods using the software package SPSS. Average age of subjects was 56 years (range: 33-76, $s=9.04$); 62% were female. 72% of participants were not formally educated beyond high school and reported an annual household income less than \$20,000. 84% agreed to provide researchers with information on relatives age, gender and income. 65% of participants were willing to provide identifiable information such as names, addresses and phone numbers of relatives compared to 35% who were undecided. 61% of participants felt that there were direct benefits (i.e. supporting research) to disclosing information on relatives. 76% stated that there were no risks associated with disclosing information on relatives (i.e., discrimination) compared to 10% who felt that there were. While discussing potential risks, subjects did not consider these issues to influence their decision to participate in GFS. Many similarities between DN patients' and relatives' perspectives regarding revealing information about relatives and awareness of risks associated with their participation were identified ($P > 0.05$). One major ethical finding is the pervasive lack of awareness regarding risks associated with participation in GFS. Consequently, individuals who are unaware of their risks cannot provide informed consent when they participate in a study. We suggest that researchers identify better ways to ensure voluntary and informed participation while conducting GFS among a low-income minority populations. This work has been funded by ELSI/NIH and an IRG from UTHSCSA. The ascertainment of families has been funded by NIDDK/NIH.

African-American Views on Ethics in Genetics. *J.C. Fletcher*¹, *D.C. Wertz*². 1) Keswick, VA; 2) University of Massachusetts Medical School, Shriver Div., Waltham, MA.

To study Americans' views on ethical issues in genetics, we surveyed 1000 members of the adult public, using anonymous questionnaires administered door-to-door by a professional survey firm. 988 (99%) responded, including 111 (11%) African-Americans, whose responses differed significantly ($p < .05$) from the total group on 26 (52%) of 50 ethical questions. More African-Americans than the total group showed concern about the needs and rights of blood relatives and spouses/partners, wanted professionals to make direct suggestions, and said don't know in response to questions about alternative reproductive technologies or PND for sex selection. Fewer would abort for genetic conditions or would support adoptees' rights to medical information about birth parents. 32% of African-Americans (compared with 44% of the total) thought professionals should preserve confidentiality of a patient who refused to share genetic information with relatives at risk; 37% (compared with 27%) thought professionals should tell a woman's partner about non-paternity; 33% (compared with 22%) supported involuntary hospitalization for a PKU mother who cannot stay a special diet; 36% (versus 43%) thought employers should have no access to genetic information, even with consent; 36% (versus 47% of the total) would abort if the child would be severely retarded unable to speak or understand; 30% (versus 41%) would abort if the child would be paralyzed from the neck down; 41% (versus 48%) would abort if the child would die soon after birth; 14% (versus 22%) would abort if the child would be moderately retarded (able to speak, but not live independently). African-Americans did not differ from the total in regard to individual confidentiality versus public safety, reports of refusals of employment or insurance on genetic grounds, genetic testing of children, preconception sex selection, genetic testing in the workplace, and legality of abortion after PND. Results indicate a need for further study of views of minority groups.

Effects of non-disease genetic information on the self-concept of individuals in the FAMuSS study. *E.S. Gordon¹, J.M. Devaney¹, B.T. Harmon¹, M.J. Hubal², P.M. Clarkson², E.E. Pistilli³, P.M. Gordon³, E.P. Hoffman¹.* 1) Ctr for Genetic Medicine, Children's Natl Med Ctr, Washington, DC; 2) University of Massachusetts, Amherst, MA; 3) West Virginia University, Morgantown, WV.

The use of SNPs in genetic testing and research is a rapidly expanding field. Already companies are offering genetic testing for non-disease traits. Before forging forward, we must consider the potential psychological impact of collecting and disseminating non-disease genetic information. Here we examine change in self-concept related to disclosure of non-disease genetic information regarding the ability to gain strength and muscle mass. We present preliminary data from the first 49 subjects of a 1400 subject, 4-year exercise/genotyping study at 7 universities (Factors Affecting Muscle Size and Strength; FAMuSS study). To begin to address the issue of "genetic self-knowledge" and self-concept, we asked subjects to enroll in a genetic disclosure and self-concept/ethics arm of the FAMuSS study. At the time of enrollment (T1), subjects completed a series of self-concept evaluations including: Tennessee Self-Concept Scale; Health Orientation Scale; and supplemental questions on knowledge of genetics designed for this study. Each subject donated a blood sample for genotyping of 4 SNPs previously shown to influence muscle performance: ACE, CNTF, g-Sarcoglycan, and UPC-2 genes. After completing a 12 week exercise program, we told subjects which SNPs they possess and we gave information about the traits associated with each SNP. The self-concept evaluation was then repeated (T2). 14% of subjects felt that the genetic information they received changed their self-concept and 32.6% said that the information would change their behavior. Comparing the perceived ability to gain strength and muscle mass, between T1 and T2, 18.4% perceived some change in ability to gain strength and 24.5% perceived some change in ability to gain muscle mass. These results indicate that non-disease genetic information has the potential to alter both self-concept and behavior. The effects of receiving non-disease genetic information should be investigated further before commercial genetic testing expands to non-disease factors.

Program Nr: 1227 from 2002 ASHG Annual Meeting

Multiplex Heterozygote Screening for Autosomal Recessive Conditions in the Ashkenazi Jewish Community An 8-Year Experience. *V.M. Jansen, L. Zajac, E. Reich, J. Borsuk, L. U, M. Bannerji, J. Li, H. Ostrer, C. Oddoux.* Human Genetics Program, New York Univ School of Medicine, New York, NY.
