Since 1975, the Human Genetics Program at New York University School of Medicine has provided heterozygote screening for members of the Ashkenazi Jewish community. Over 15,000 people have been tested. Initially, only testing for Tay Sachs disease was offered, but over the last 8 years, other tests have been added, including: cystic fibrosis (CF), Canavan disease (CD), Gaucher disease (GD), Bloom syndrome (BS), Fanconi anemia (FA), Niemann-Pick disease (NP) and familial dysautonomia (FD). The willingness of patients to participate in research trials has led to the ascertainment of allele frequencies and thus to the contemporary testing strategy (TS 1:25, CF 1:25, CD 1:41, GD 1:7, BS 1:107, FA 1:80, NP 1:90, FD 1:36). Collectively, the likelihood for an individual to be a carrier for at least one of these conditions is 30%. With education, currently via web-based video and genetic counseling, patients have made informed decisions regarding screening with 2/3 choosing multiplex testing, the majority of whom have elected to be tested for all 8 disorders. Many patients have returned to update their testing with subsequent pregnancies. All carrier couples identified through the program have opted for prenatal diagnosis. The identification of the IKAP gene for familial dysautonomia in 2001 led to a demand among the relatives of affected individuals for carrier testing. One of the most difficult outcomes of screening has been the identification of previously unknown homozygotes for Gaucher disease. Although these tests have been used principally for heterozygote detection, their availability has led to requests for diagnosis of suspected homozygotes/compound heterozygotes. The identification of prevalent founder mutations for mucopolysaccharidosis IV, familial hyperinsulinemia, glycogen storage disease Type I, lipoamide dehydrogenase deficiency, alpha-1-antitrypsin deficiency, and Usher syndrome suggests that screening for these conditions might also be important.

Living with BRCA1/BRCA2 test results: Women's social experiences. *I. Nippert¹, B. Teige¹, J. Horst².* 1) Women's Health Research, Universitaetsklinikum Muenster, Muenster, Germany; 2) Institut fuer Humangenetik, Universitaetsklinikum, Muenster, Germany.

Introduction: Since the introduction of BRCA1/BRCA2 tests into routine medical care in the late 1990's, more and more women at increased risk undergo predictive genetic testing. Little is known about women's long term social experiences. **Methods:** At the Department of Human Genetics, Universitaetsklinikum Muenster, Germany, women at increased risk are offered BRCA1/BRCA2 testing. Pre- and post-test counseling is mandatory. Out of 50 women who underwent testing the last 2 years and who have obtained test results at least 6 months ago were asked to participate in a follow-up interview. 46 women agreed to participate. A standardized questionnaire addressing questions such as: communicating risks to family members; conflicts with family members because of test results; positive and negative experiences; decision regret; availability of preventive surveillance; etc. was administered by telephone interview. **Results:** 58.7% report that their main reason to undergo testing was to know more about their personal risk; 60.1% wanted their children to have certainty about a hereditary risk; 23.9% wanted to know their risk in order to optimize personal future plans; 58.7% reported that their expectations were fully met. 23.9% reported that they only underwent testing because other family members asked them; 52.2% wanted to optimize prevention. More than 98% consulted with family members and all informed, albeit, selectively other family members about the result. 13% expressed decision regret and 87% would undergo testing again, 60.9% would recommend the test to other women at increased risk. **Discussion:** Few women who undergo predictive BRCA1/BRCA2 testing after a pre- and post-test counseling protocol express decision regret after a ≥ 6 month period.

The effect of gene patents on the provision of clinical services: a comparison of laboratory directors' and genetic counselors' practices. *M.A. Weaver¹, M.H. Henry², M.K. Cho¹, D. Leonard², S. Parthasarathy³, C.L. Bosk², J.H. Barton¹, J.F. Merz².* 1) Stanford University; 2) University of Pennsylvania; 3) Duke University.

There is growing concern about the impact of gene patents on the provision of clinical services. This research addresses laboratory directors' and genetic counselors' experiences, as the providers of clinical services, with 8 genetic diseases and provides new data on the extent to which patenting and licensing of disease genes are affecting the provision of DNA-based genetic testing. The two main research questions addressed are: 1) How are laboratories that perform DNA-based genetic tests affected by patents and licenses, and 2) What do genetic counselors perceive the impact of gene patents and licenses to be on the provision of clinical services. We sampled 118 U.S. laboratory directors who were members of the Association for Molecular Pathology (in 1998) or who were listed on GeneTests on 6/18/01. We also selected a random sample of 200 genetic counselors who have been counseling for three or more years and are full members of the National Society for Genetic Counselors. We conducted, taped, and transcribed semi-structured telephone surveys of roughly 30 minutes each. Preliminary findings from interviews with 45 laboratory directors and 63 genetic counselors show a wide range of familiarity with gene patents. Laboratory directors demonstrate a greater awareness of gene patents than do genetic counselors. When asked specifically about the 8 particular tests, laboratory directors indicated that the patents affected their ability to provide genetic testing in a variety of ways, including discontinuation of or a decision not to adopt a test, cost increases, and a need to develop alternative testing methods. In contrast, genetic counselors did not report a change in their counseling methods or a notable change in test quality or cost due to the existence of a patent. However, most genetic counselors reported that insurance coverage is currently the main obstacle to genetic testing. These findings suggest that gene patents have a greater impact on laboratory directors than on genetic counselors.

The significance of identical triplet repeat numbers for both X chromosomes in developmentally delayed/mentally retarded females negative for a FMR-1 mutation. *L.R. Shapiro^{1,2,3}, R.F. Walsh¹, R. Scott-Oresajo³*. 1) Department of Pediatrics, Westchester Medical Center, Valhalla, NY; 2) New York Medical College, Valhalla, NY; 3) Regional Medical Genetics Center, Hawthorne, NY.

Direct DNA analysis of the FMR-1 gene in developmentally delayed/mentally retarded children resulted in 237 (140 males; 97 females) who were negative for a Fragile X mutation. In 28% of the females (27/97), an identical number of CGG triplet repeats was found for each X Chromosome. In order to determine the significance of this observation and the probability that each of the mothers and fathers have identical CGG triplet repeat sizes, the triplet repeat size of each of the 237 patients was determined and the distribution frequency of each triplet repeat size was compared to the reports in the literature. The distribution of the CGG triplet repeats in this cohort was the same as reported in the literature with 29, 30 and 31 as the most prevalent triplet repeat size.

Direct DNA mutation analysis of 3 sets of parents whose daughters had the common 29, 30 or 31 CGG triplet repeat size on both of their X chromosomes revealed that both parents of each set had identical triplet repeat sizes. In 2/27 females, the infrequent 20,20 and 24,24 CGG repeats were found. In order to attempt to determine the significance of this observation and to determine if Uniparental Disomy X (UPD X) was present, direct DNA analysis of the FMR-1 gene of each of the parents revealed that the mother and father each possessed identical CGG triplet repeat numbers.

Thus, it can be concluded that in these families, UPD X was not present or responsible for their daughters' clinical status; however, additional cases will be necessary to further determine the parent of origin of infrequently occurring identical CGG triplet repeat numbers. It is possible that parents with the same infrequent CGG triplet repeat number may share other genetic similarities which could predispose to autosomal recessive etiologies of non-specific mental retardation in females.

Use of a birth defects registry to assess physician utilization of FISH analysis in children with cardiac defects.

*N.J. Carpenter*¹, *K. Pearson*². 1) HA Chapman Institute Med Gen, Univ Oklahoma Health Sci Ctr, Tulsa, OK; 2) Oklahoma State Department of Health, Oklahoma City, OK.

Birth Defects registries have typically been used to determine the prevalence of birth defects and to identify regional clusters of birth defects. They have not often been used to evaluate utilization of cytogenetic testing. We determined that the Oklahoma Birth Defects Registry (OBDR) could be used to assess the utilization of fluorescent in situ hybridization (FISH) analysis for children with cardiac defects. Congenital heart defects (CHD) are the most common malformations associated with the chromosome 22q11.2 deletion. Patients with this deletion may have other abnormalities including immunodeficiency, hypocalcemic hypoparathyroidism, palate defects, renal defects, hypotonia, developmental delay and psychiatric problems. An accurate diagnosis by FISH analysis is essential to provide appropriate clinical management, specific interventions, and recurrence risk counseling. All cases listed in the OBDR with tetralogy of Fallot, interrupted aortic arch, truncus arteriosus, double outlet right ventricle, aortopulmonary window, and vascular ring from January 1999 through December 2001 were reviewed to identify the hospital where the cardiac defect was diagnosed, the age at diagnosis, whether chromosome and FISH analysis were performed, and demographic data. Of the 144 cases identified, 10.4% (15 cases) had FISH testing, 29.9% had chromosome analysis without FISH testing, and 59.7% had no documentation of chromosome or FISH testing. FISH analysis identified the 22q11.2 deletion in 60% (9 cases). Tertiary hospitals in Oklahoma City diagnosed 63% of the cases whereas those in Tulsa diagnosed 37%. One-third of the FISH testing was ordered by Oklahoma City hospitals and two-thirds was ordered by Tulsa hospitals. The majority of infants (83.3%) were diagnosed at birth before discharge. The information from the OBDR is being used to follow-up patients and to develop educational materials for physicians and other health professionals about the appropriate utilization of FISH analysis for children with CHD. The OBDR will also be used to measure the effectiveness of educational programs.

Subtelomeric FISH analysis: Recent experience and referral trends in a clinical cytogenetics lab. *P.A. Ward, L.G. Shaffer, R. Saleki, C.A. Bacino, B. Bejjani, R. Naeem.* Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX.

We report our experience over the past 28 months (Jan 2000 - April 2002) using subtelomeric region-specific FISH probes (CytocellTM) to examine a total of 655 patients. The majority of patients (>97%) were referred for evaluation of unexplained mental retardation (MR) or developmental delay (DD). Referral sources included genetics professionals (64.1%); other physician specialists (21.5%); referral or cytogenetics labs (14.4%). A significant increase in referrals from other physician specialists was observed during the past 14 months. G-band analysis was previously or simultaneously performed on most patients, however these data were not provided on all patient samples submitted for testing.

Clinically significant rearrangements of subtelomeric regions were identified in 28 patients (4.3%). Seventy-five percent of these patients (21/28) was referred by a genetics professional. A variant or probable variant was identified in 49 patients (7.5%). Of these, 45 cases involved an apparent deletion of 2q37.3. No subtelomeric rearrangements were identified in the remaining 578 patients (88.2%). Parents for 5 of the 28 (17.9%) abnormal cases were studied and 3 parental balanced translocations were identified. Parents of 13 of the 49 (26.5%) variant cases were studied and all were found in one unaffected parent (10 were 2qter deletions).

These data support the use of subtelomeric region-specific FISH to fully evaluate patients with MR/DD. Our experience is consistent with recent reports showing subtelomeric alterations in 3-7% of such patients. Our data also confirm the identification of variants in >7% of individuals, particularly the 2q37.3 deletion. These test outcomes suggest that genetic counseling prior to telomere FISH analysis should include discussion of the significant likelihood (10-15%) that parental analysis will be recommended to clarify the significance of their child's results. The integration of genetic counseling and phenotypic evaluation will improve and guide future test utilization.

A novel approach for detection of DAZ gene copy number in male infertility. *A. Rossi, A. Tessari, E. Salata, L. Bartoloni, M. Simonato, G. Rizzo, A. Ferlin.* Medical and Surgical Sciences, University of Padova, Padova, Italy.

Introduction. The DAZ gene family constitutes the major candidate for the AZFc (azoospermia factor c) phenotype of male infertility, being deleted in about 10% of azoospermic and severely oligozoospermic subjects. Four nearly identical DAZ genes are arranged in two clusters in AZFc, and standard analysis by PCR cannot distinguish among the different copies. In fact, this analysis can detect only deletions removing the whole DAZ gene cluster. However, it can be assumed that the frequency of DAZ gene abnormalities in infertile men might even be underestimated. **Materials and methods.** By using particular sequence tagged sites (STSs) and restriction enzymes it is possible to differentiate the individual DAZ genes. This approach is based on subtle sequence differences, termed sequence family variants (SFVs), among members of the DAZ genes. We developed a PCR amplification-restriction digestion assay able to distinguish DAZ genes for three SFVs. PCR products were digested with *Sau3A* (sY581), *DraI* (sY587) and *TaqI* (sY586) and the obtained fragments were run on a 12% acrilamide-bisacrilamide gel electrophoresis and visualized by silver staining method. Direct sequencing on both strand was also performed for these PCR products and for another one (DAZ SNVII). We applied this approach to screen a group of 30 fertile men and 80 idiopathic severely infertile men (sperm count < 5 million/mL). **Results and discussion.** Combining the data obtained by these PCR-restriction digestions and sequencing, 6 patients out of 80 (7.5%) showed partial deletion of the DAZ gene clusters. These partial deletions were also confirmed by Real Time PCR using a specific TaqMan probe on ABI PRISM 7000 Sequence Detection System. Different deletions of DAZ genes may be present and can cause a severe spermatogenic damage. This preliminary screening demonstrate that deletions of copies of DAZ genes may be found with high frequency in severely infertile men and strengthens the role of this gene family in spermatogenesis. Furthermore, these methods could be used to screen a larger number of patients and to perform a more accurate diagnosis.

Quantitative assay for the detection of *Streptococcus* DNA in mouthwash samples. *P.K. Bender, W.R. Beggs, J.C. Beck.* Coriell Cell Repositories, Coriell Inst Medical Research, Camden, NJ.

The collection of biological samples from mouthwash is becoming an increasingly popular method as a source of DNA in large epidemiological studies. Mouthwash samples have the advantage of being cost effective, non-invasive, promote subject compliance, and provide a source of DNA that can be genetically analyzed. However, the analysis of DNA from mouthwash samples is complicated by the presence of extraneous DNA sources from oral bacteria and food particles, and suffers from a high variability in the amount of DNA obtained. The reason for the high variability is not understood. It may arise from phenotypic differences between individuals, behavioral differences, or from differences in the amount of bacteria and food particles that are obtained. In order to investigate the contribution of bacterial DNA in mouthwash samples, an assay was developed to measure *Streptococcus* DNA. The assay is based on the 5 fluorogenic real time method using primers and a fluorogenic probe targeting the amplification and detection of a 16S rDNA sequence. This sequence is shared among the four common *Streptococcus* species found in the oral cavity mutans, oralis, salivarius, and pneumonia. The assay does not detect human DNA or *E. coli* DNA. Using a standard of purified DNA from a culture of *Streptococcus mutans*, as little as 16 picograms of DNA can be measured even in the presence of excess human DNA. The method has been applied to the analysis of mouthwash samples collected in a pilot study that found the yield of total DNA to be significantly greater from samples collected under unsupervised conditions (at home) versus supervised conditions. The question arises as to whether unsupervised samples have higher amounts of bacterial DNA. However, measurements with this 5 fluorogenic assay reveal that although the amount of bacterial DNA present is highly variable, there is no significant difference between the unsupervised and supervised samples. Thus, the difference in total DNA yield between the two collection methods likely occurs from differences in human DNA. Further studies with mouthwash samples from larger collections are ongoing.

Program Nr: 1235 from 2002 ASHG Annual Meeting

ABCC7 S158N (605G>A) is a rare genetic variant found in coupling with DF508 in a cystic fibrosis family: why parents should also be genotyped. *A.E. Shrimpton, K.E. Hicks, W.V. Beadling.* Clinical Pathology, SUNY Upstate Medical Univ, Syracuse, NY.

The Molecular Diagnostics Laboratory at SUNY Upstate Medical University uses a home-brew 35 cystic fibrosis (CF) mutation detection method that includes an Mse I restriction digest of exon 4 amplicons. An unusual restriction fragment pattern was observed in a sibling of an individual with CF. A single nucleotide change, 605G>A, that causes a novel Serine (Ser) to Asparagine(Asn) change at codon 158 (S158N) in exon 4 of the CFTR gene, ABCC7, was detected in this individual, who was also heterozygous for delta F508. Family studies revealed that the CF affected sibling also had both mutations, however S158N was in coupling with delta F508, both having been inherited from the same parent. The mutation from the second parent has not yet been identified. The only other report in the CF mutation database involving this conserved codon was the report of S158R (604A>C) in a CBAVD patient. ABCC7 intragenic and extragenic markers confirmed that the original patient was a CF carrier. S158N is thus a rare genetic variant, of unknown clinical significance, in coupling with delta F508 in this family. Only by investigating the parents could phase be established. Relying on the CF affected patient's genotype alone may have lead to the incorrect conclusion that this individual also had CF molecularly. Whenever possible parents should also be genotyped so as to confirm phase and reduce the chance of mistyping from double mutants, deletions or amplification drop out.

New DNA Capillary Array for mRNA Expression Profiling. *Y. Hatta-Ohashi¹, E. Shinohara¹, T. Takahashi¹, K. Hashido¹, N. Morimoto¹, T. Makino², S. Karki¹, K. Tokunaga³.* 1) Genome Medical Business Division, Olympus Optical Co.,Ltd., Tokyo, Japan; 2) NovusGene Inc, Tokyo, Japan; 3) Department of Human Genetics, Graduate School of Medicine, University of Tokyo, Tokyo, Japan.

DNA microarray technology based on a highly parallel DNA hybridization assay is widely used for gene expression profiling and disease diagnostics. In the present study, a new gene-detection device was developed using a modified type of DNA microarray, which can operate samples as little as 3-5 microliters. This new DNA microarray system is characterized by 8 or 20 capillaries formed on the silicone rubber (polydimethylsiloxane), 100 microns in depth and 0.5 or 1.0 mm in width. In each capillary, 50 to 100 oligonucleotide probes can be immobilized. The use of capillaries enables us to test multiple samples simultaneously for examining expression levels of selected genes rather than those of numerous ones. The oligonucleotide probes to be attached on the capillary are designed by our new algorithm based on the tuple method. A tuple is a short sequence consisting of several bases. Each tuple contained in a candidate sequence for the probe is evaluated for its uniqueness in the all registered sequences of genes and ESTs in public databases. A sequence which contains a "frequent" tuple is not selected as a probe, allowing us to find a probe with high specificity. Our software with this algorithm consists of further several calculation filters for the determination of an optimal sequence that has an appropriate melting temperature and does not form an intramolecular structure. In order to evaluate a reproducibility of the DNA capillary array, mRNA expression levels of 60 genes were compared between two capillaries on the same substrate, using labeled mRNA samples from Jurkat T cells. The result showed a high correlation between the two capillaries ($R\text{-square}=0.97$). This new DNA capillary array is relatively inexpensive, because a semiconductor substrate is not necessary and regular glass can be used. Detailed comparisons of our method with other conventional ones will be described. (This work was supported by NEDO [New Energy and Industrial Technology Development Organization] in Japan.).

Diagnosis of haploinsufficiency and duplication of SHOX using a real-time PCR. *E.J. Seo^{1,2}, M.J. Park¹, S.M. Park¹, Y.O. Yoo¹, Y.L. Shin^{1,3}, H.W. Yoo^{1,3}.* 1) Genome Research Center for Birth defects and Genetic disorders, Asan Medical Center, Seoul, Korea; 2) Dept. of Clinical Pathology, University of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea; 3) Dept. of Pediatrics, University of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea.

Short stature homeobox-containing gene (SHOX) is on the pseudoautosomal region of the sex chromosomes and plays a role in bone growth and development. SHOX escapes X inactivation and relates to a gene dosage effect. Haploinsufficiency of SHOX is the cause of short stature in Turner syndrome, and has also been discovered in Leri-Weill dyschondrosteosis and idiopathic short stature. On the contrary, overdosage of SHOX usually leads to tall stature and gonadal dysgenesis. Current methods to determine gene dosage are time-consuming and labor-intensive. We present a rapid and accurate method to assess gene copy number for detection of haploinsufficiency and duplication of SHOX based on a real-time quantitative PCR. We studied 10 patients with Turner syndrome containing a karyotype of 45,X or Xp deletion, 12 patients with a karyotype of 47,XXY or 47,XXX, 45 patients with idiopathic short stature, and 40 normal control individuals. By using TaqMan probes specific to SHOX and PBGD genes as a reference gene, quantification of gene copy number was analyzed through the comparative CT method. The observed numbers of the SHOX gene per haploid genome were 0.940.14SD in 40 normal controls, 0.500.13SD in patients with Turner syndrome, 1.550.11SD in patients with extra sex chromosomes, respectively. One of 45 patients with idiopathic short stature showed a haploid copy number of approximately 0.5. Therefore, the dosage test using real-time PCR could be easily and accurately applied to the diagnosis of diseases caused by changes in gene dosage.

Comparison of SNP Detection Methods and Instrumentation Platforms. *C.M. Strom¹, W. Sun¹, M. Zoleikhaeian¹, C. Li², Y. Naidu², G. Milburn³, R. Fenwick⁴, M. York¹, T. Entwistle¹.* 1) Molec Gen, Quest Diagnostics, San Juan, Capist, CA; 2) Center for Advanced Genomic Technology, Quest Diagnostics, San Juan, Capist, CA; 3) Molecular Diagnostics and Virology Laboratories, American Medical Laboratories, Chantilly, VA; 4) Molec Endocrinology, Quest Diagnostics, San Juan, Capist, CA.

Accurate, robust, cost-effective and high throughput single nucleotide polymorphism (SNP) genotyping is essential for clinical diagnostics. Using detection of C282Y and H63D mutations in the HFE gene as a model system, we have evaluated several common methodologies and instrumentation platforms: allele-specific oligonucleotide (ASO) hybridization with chemiluminescent detection, 5-nuclease (TaqMan) assay with ABI7700 detection, MassExtend (Sequenom) assay with MALDI-TOF mass spectrometry, electronic hybridization on the NanoChip workstation, Pyrosequencing technology on PSQ96 system, fluorescent restriction fragment length polymorphism (RFLP) using ABI3100 genetic analyzer and PCR-ASO using the mDx reagents from BioRad. Over 1000 genomic DNA samples were analyzed using each of the methodologies and/or platforms listed above. Genotype results were compared among the methods and the discrepancies resolved through repeat testing and / or sequence analysis. Our findings in terms of assay accuracy, robustness, cost, and user-friendliness of the SNP detection platforms will be discussed.

An efficient application of MALDI-TOF/MS coupled with microarray for detection of microsatellite

polymorphisms. *Y. Yoshikawa*^{1,2}, *K. Nakajima*¹, *N. Kimura*², *M. Gonda*³, *K. Okamoto*¹, *G. Tamiya*¹, *H. Inoko*¹. 1) Sch Med, Tokai Univ, Isehara, Kanagawa, Japan; 2) Nisshinbo Industries, Inc. 1-2-3 Onodai, Midori-ku, Chiba, Japan; 3) Shimadzu Corporation, 1, Nishinokyo-Kuwabaracho, Nakagyo-ku, Kyoto, Japan.

We have investigated a genotyping method for microsatellite polymorphisms using matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF/MS) in combination with a microarray format. MALDI-TOF/MS offers unprecedented speed for analysis with excellent accuracy. However, the conditions for detection of large DNA fragments that is needed for the detection of microsatellites have not yet been determined. In order to optimize the conditions for the detection of large DNA fragments, we first examined matrices, small organic molecules, which are a key part of mass spectral methods. We have screened 147 compounds as potential matrices, and found several useful compounds for the analysis. Among them, the best results were obtained with 2,4-dehydroxyacetophenone. With this matrix, we successfully detected the combination of an 100-mer and 102-mer TC repeat nucleotides precisely. To overcome the problem of fragmentation of purine sequences, we have explored the effects of purine analogs on the stability of the oligomers. We have found the utilization of 7-deaza purine analogues allowed excellent detection with an improvement in sensitivity and a reduction in oligomer fragmentation. Next, we examined a microarray-based approach using carbodiimide-coated glass plates instead of expensive stainless-steel plates that are commonly used in MALDI-TOF/MS analysis. As a result, we detected DNA fragments on glass plates with extremely high-resolution that was sufficient to distinguish single-nucleotide differences. Furthermore, we developed an oligomer method to hybridize with the target DNA fragments on the glass plates for their final detection by MALDI-TOF/MS without any non-specific signals. These results indicate that MALDI-TOF/MS coupled with microarray technology is quickly emerging as a powerful approach for determination of polymorphic microsatellites.

Mutation analysis of Rett syndrome patients. *M. Ito, J.M. Milunsky, A. Milunsky.* Center for Human Genetics and Department of Pediatrics, Boston University School of Medicine, Boston, MA.

We have analyzed over 600 samples sent to the DNA Diagnostic Laboratory for Rett syndrome testing by mutation analysis of MECP2 gene, in which at least 140 patients are believed to exhibit classic signs of this disorder. To date we have identified 120 positive probands among them, in which the first 65 positive patients (out of approximately 300 analyzed) were reported in Milunsky et al., 2001 (*Genetic Testing* vol.5;321-325). Here, we report 55 additional patients (out of approximately 300 analyzed). The current five common mutation screen (T158M, R168X, R255X, R294X and R306C/H) detects only 33% of all patients that we identified as positives. In the past, however, the detection rate for these five mutations was as high as 50% (Milunsky et al.). The remaining positives were identified by bidirectional sequencing. All positives were females with no family history. One plausible reason for recent reduction in the detection rate of these five mutations would be a change in submitted patients' clinical features. In the past, we had a higher proportion of patients with classic clinical manifestations who had any one of these five mutations, however, currently we have a higher number of patients with atypical clinical presentations who have mutations other than these five. We have identified nine novel mutations; three point mutations (N126S, G238R and H368Y), five deletion mutations (495delC, 816delG, 995del258bp and 1163del39bp) and one insertion (902ins4bp). In addition, we have identified two novel polymorphisms and three novel possible polymorphisms (G161V, A357T and A378G). In these two novel polymorphisms, we have detected the same nucleotide change in the mother with random X inactivation in one case (P388L), and we found the same nucleotide in the father in the other case (P376S). Except for deletions and insertions that cause frame shift and point mutations that lead to nonsense mutations, we recommend all other novel base substitutions be tested in both parents to identify if the change is pathologic. In addition, if the mother has the same nucleotide substitution, a skewed X inactivation study should be performed.

A comprehensive method for GBA whole gene-sequencing with a rapid first step screening of known Gaucher Disease mutations. *M. Keddache, G. Grabowski.* The Children's Hospital Research Foundation, Division of Human Genetics, Cincinnati, OH.

Gaucher Disease, a common autosomal recessive glycosphingolipidosis, is characterized by hematologic abnormalities with hypersplenism, hepatomegaly, bone lesions, and the presence/absence of CNS disease. Certain mutations in the GBA gene reduce the levels of activity of acid-beta glucosidase, leading to the manifestation of the disease. But the genotype-phenotype (disease severity) is not well correlated, suggesting the existence of modifier mutations possibly within the GBA gene itself. A two-phase procedure was developed for the determination of GBA variants related to Gaucher Disease. The interrogation phase provides a rapid answer about known mutations and is appropriate for testing disease allele transmission to offspring of Gaucher patients, pre- or post-natally. The discovery phase is more time intensive, but provides a comprehensive answer about the sequence variations at GBA for any sample. A single ~ 7.5 kb PCR product containing the entire GBA gene is used as a template for both the interrogation and discovery phases. In the interrogation phase, 8 common mutations are tested for simultaneously using single nucleotide extension technology. The panel is being expanded to include additional interrogatable base changes. From receipt of the test sample, all SNPs in the panel are accessible within 48 hours. The discovery phase takes place when more information is needed about the patient's genotype than just the presence of the mutations in the interrogation panel. Complete sequencing of GBA is accomplished using the ~7.5 kb template and a set of 16 primers. The sequences are assembled into a single contig and the traces are visually inspected to confirm heterozygote base calls. Completion of the discovery phase is achieved within 72 hours. After screening 70 alleles from a cohort of Gaucher patients and relatives, 6 previously unreported polymorphisms were discovered. With additional data, a better understanding will be obtained for the contribution of silent or intronic mutation to the Gaucher phenotype in conjunction with mutations causing reduced enzymatic activity.

Is DG heterozygosity clinically significant? Literature review and analysis. *V.K. Proud¹, M.L. Lawson², M.A. Barnes², H.A. Creswick¹*. 1) Medical Genetics, Dept Pediat, CHKD/EVMS, Norfolk, VA; 2) Clinical Outcomes Research and Epidemiology, Dept Pediat, CHKD, Norfolk, VA.

Most infants found in newborn screening for galactosemia are simple heterozygotes. In Virginia (1998) out of 92,000 infants, 40 had abnormal tests, 6 had classic galactosemia (GG) with minimal galactose-1-phosphate uridylyltransferase (GALT) activity; while 34 had variants like Duarte/galactosemia (DG) with $\gg 25\%$ GALT. DG heterozygotes should be at minimal risk for complications, however, many are treated for the first year, and girls are more frequently treated than boys. We performed a comprehensive literature review and analysis to determine whether DG heterozygotes have medical complications. From 701 articles from Pub Med (1965-2002) using search strategy including "galactosemia OR Duarte OR genotype OR phenotype" and restricted to Human and English, 33 articles met inclusion criteria. There were 8 case series, 9 case-control, 11 cohort, and 5 cross-sectional studies. There was only one 35 year cohort study from Germany addressing outcome. Regarding complications in DG heterozygotes: 12/33 authors reported complications; 10/33 completely excluded complications; 7/33 neither supported nor denied and 4/33 both supported and denied clinical complications. In the 19 articles that focused on DG heterozygotes, 7/19 supported clinical findings and 4 had case reports of cataracts, liver dysfunction, or decreased ovarian function. One study reported increased frequency of Duarte alleles in families with a history of ovarian cancer. Biochemical studies predicted mixed results depending on parameters studied. Finally, in 7/19 there was data that clearly denied any abnormal phenotype in DG individuals. In conclusion, although rare case reports and some biochemical data suggest potential for long term medical complications in DG heterozygotes, there is no consistent outcome reported in the current literature. This study strongly supports the need to establish a registry of DG heterozygotes and to perform robust data analysis to determine if they are at risk, what enzyme level defines that risk, and what dietary intervention, if any, is needed.

Genetic testing for Gaucher Disease: simultaneous detection of common point mutations and pseudogene-derived complex alleles by reverse-hybridization. *G. Kriegshaeuser¹, D. Halsall², A. Moritz¹, F. Kury¹, C. Oberkanins¹.* 1) ViennaLab, A-1110 Vienna, Austria; 2) Dept. Clinical Biochemistry, Addenbrooks Hospital, Cambridge, UK.

Gaucher Disease (GD), the most frequent lysosomal storage disorder, is an autosomal recessive disease characterized by glucocerebrosidase (GBA) deficiency due to mutations in the GBA gene. Accumulation of glucocerebroside, mainly within cells of the monocyte-macrophage lineage, eventually leads to splenomegaly, hepatomegaly, thrombocytopenia, bone marrow suppression, or bone lesions. The disease is panethnic and has been divided into three major types on the basis of the absence (type 1) or the presence and severity of neurologic manifestations (types 2 and 3). The most common variant is type 1 GD, which is particularly prevalent among Ashkenazi Jews (disease frequency 1:850, carrier rate 1:15), and can be efficiently treated by enzyme replacement therapy. We have developed a reverse-hybridization assay (Gaucher Disease StripAssay) for the simultaneous detection of eight common point mutations (84GG, IVS2(+1)A, 1226G, 1297T, 1342C, 1448C, 1504T and 1604A) and two multiply mutated alleles (RecNciI, RecTL) derived from rearrangements between the structural gene and the GBA pseudogene. The test is based on two multiplex DNA amplification reactions and ready-to-use test strips presenting a parallel array of oligonucleotide probes for each wild-type and mutated allele. The entire genotyping procedure from blood sampling to final result requires less than 6 hours, and hybridization and detection may be fully automated on existing equipment (e.g. TECAN profiBlot). We have used this assay to screen a cohort of 91 English GD patients previously genotyped for five mutations by RFLP. While results were consistent for these in all samples, additional GD alleles were detected using the new StripAssay. (oberkanins@viennalab.co.at).

Program Nr: 1244 from 2002 ASHG Annual Meeting

Niemann-Pick Disease Type A and Type B Mutation Detection. *F. Hantash, S. Huang, N. Huynh, W. Sun, C. Strom.*
Dept Molecular Genetics, Quest Diagnostics Inc. Nichols Institute, San Juan Capistrano, CA.

Niemann-Pick Disease (NPD) is an autosomal recessive lysosomal storage disorder with significant morbidity and mortality. Mutations in the acid sphingomyelinase (ASM) gene lead to NPD type A and type B. Three mutations (R496L, L302P and fsP330) account for > 95% of mutations in Ashkenazi Jews. A deletion of 3 bp in the codon R608 of the ASM gene leads to NPD type B in homozygotes or in compound heterozygotes with another NPD mutation. We have designed an assay to detect these four mutations using single nucleotide primer extension. After duplex PCR amplification and purification of products, extension primers are added and primer extension is performed using fluorescently-labeled dideoxynucleotides. Purified extension products are separated on ABI 3100 Genetic Analyzer. The use of Biomeck 2000 and ABI 3100 Genetics Analyzer allowed for automated liquid handling and signal detection, and facilitating high throughput performance. Data from ABI 3100 are then analyzed with the aid of GeneScan and Genotyper software and the analyzed results automatically transferred to our patient database. Samples from cultured cell lines from Corriel Cell Repositories with known mutations for type A and type B were used to validate the methodology and 100% concordance was obtained. Furthermore, we exchanged specimens with another reference laboratory and there was 100% concordance. Thus, an automated approach for NPD mutation detection has been developed and validated for clinical patient sample analysis.

Relative incidence of congenital malformations at birth among different religious communities in Israel. . J.

Zlotogora¹, Z. Halai¹, N. Rotem², M. Georgi², I. Berlovitz¹, A. Leventhal¹, Y. Amitai¹. 1) Ministry of Health; 2) Central Bureau of Statistics, Israel.

From 1991 to 2000 there were 1,203,763 live born infants in Israel, including 832,662 Jews, 304,618 Muslims, 26,090 Druzes and 28,915 Christians. The rates of major malformations were in a similar range among Jews or Christians but much higher among Muslims or Druze. The differences may be explained by differences that exist between the communities in particular the rate of consanguinity and of therapeutic abortions. The Muslim and the Druze in Israel are the communities with the highest consanguinity rates (some 50% of the marriages are consanguineous) and the lowest rates of termination of pregnancy even when major malformations are diagnosed. The most significant differences were observed for open neural tube defects that for instance were 4 to 5 times more frequent at birth among either Muslim or Druze than among Jews or Christians. Significant differences were also observed for malformations usually not diagnosed during pregnancy such as congenital heart defects, cleft palate or choanal atresia. For very few malformations such as esophageal fistula and or atresia or small intestine atresia the differences between the communities were not significant.

Analysis of the differences in the rate of malformations at birth in different religious communities may help to delineate etiologic factors and serve as a basis for Public Health policies.

Prevalence survey of the Fragile X E syndrome referred for Fragile X syndrome testing in boys with mental retardation. *S. Chen^{1, 2}, J.M. Schoof¹, C.J. Lemoine¹, C.L. Gordon¹, C.R. Scott^{1, 2}.* 1) Molecular Diagnostic Lab, Children's Hosp/Reg Med Ctr, Seattle, WA; 2) Department of Pediatrics, University of Washington, Seattle, WA.

Fragile X E syndrome (FRAX E) is associated with mild to borderline (I.Q.= 50-80) mental retardation with no specific and consistent dysmorphology. For last 8 years, we have surveyed mentally retarded boys for FRAX E. The blood samples were sent to the lab for FRAX syndrome testing from clinics throughout the northwestern United States. After PCR and electrophoresis, then a chemilluminescence detecting method was used to identify both the number of the CCG repeats in FRAX E gene and the CGG repeats in FRAX A gene. Out of 1812 samples tested for FRAX E, we found 2 patients with >200 CCG repeats. Twenty-seven patients out of 1805 samples tested were identified with FRAX A. If we accept that the prevalence of FRAX A is about 1/4,000, then the prevalence of FRAX E could be about 1/60,000 in the population. Because the mild nature of FRAX E, the real prevalence might be higher than this estimation. The number of positive FRAX E patients in this sample is too small to make an accurate value. We will continue to compile the data in years to come.

During further studies on a three-generation pedigree in one of our FRAX E families, we found that, in contrast to FRAX A, the transmitting FRAX E male had resulted in a contraction of the CCG repeat in his daughter. The repeat then expanded in his grandson who had mild mental retardation. Current technology allows us to test expansion of FRAX A and E simultaneously, and a more accurate estimation of prevalence of FRAX E large alleles associated with mental retardation can be expected in the future.

A140V is a recurrent mutation in the MeCP2 gene that may be systematically screened in patients with idiopathic mental retardation. *B. Winnepenninckx¹, V. Errijgers¹, F. Hayez-Delatte², E. Reyniers¹, R.F. Kooy¹.* 1) Dept. of Medical Genetics, University of Antwerp, Antwerp, Belgium; 2) Hôpital Erasme, ULB, Brussels, Belgium.

Mutations in the methyl-CpG-binding protein 2 (MeCP2) cause Rett syndrome, a severe neurodevelopmental disorder occurring predominantly in females. Male patients with Rett syndrome are extremely rare as the Rett causing mutations in the MeCP2 gene are lethal in hemizygous males. In addition, different variations in the same gene were reported to cause mental retardation, both in sporadic non-syndromic males as in syndromic families with disease manifestation in carrier females. However, the majority of the reported MeCP2 mutations in mental retarded patients consist of amino acid substitutions and, especially in isolated cases, discrimination between a disease causing mutation and a rare polymorphism is not obvious and the significance of each individual variation should be verified. We mapped a new non-syndromic X-linked family (MRX79) to Xq27.3-28 and found an A140V mutation in the MePC2 gene in all patients with the disease haplotype. In addition to data published by others, this suggests that A140V is a recurrent mutation (and not a polymorphism) in patients with mental retardation. As a consequence, implementation of the A140V mutation in routine screening programs of the intellectually disabled should be considered.

Development of *Alu* PCR and *Alu* Real-Time PCR Methods for Quantitation of Human DNA in Forensic Samples. *J.A. Nicklas, E. Buel.* VT Forensic Laboratory, Department of Public Safety, Waterbury, VT.

There are a number of steps required to obtain a DNA profile from a crime scene sample. One critical step in this process is the determination of the amount of human DNA contained in the sample. The forensic community relies predominately upon a technique (slot blot) to quantitate human DNA that is imprecise, time consuming and very labor intensive. We have developed new, faster and more quantitative techniques based on PCR of the primate-specific *Alu* sequence that is found in over 800,000 copies in the human genome. Primers were used to amplify a 124bp fragment of *Alu* sequence in a reaction containing SYBR Green I stain. Quantitation was performed in a fluorescent plate reader (Bio-Tek FL_x800). This plate reader assay consisted of an initial zero time SYBR Green I fluorescence reading, 14 cycles of PCR and then a final fluorescence reading. Subtracting the initial time reading from the final reading removed the fluorescent contribution from the input DNA. Fluorescence background was decreased by using QSY7 labeled primers (method patented by Molecular Probes, Inc.). The QSY7 moiety quenches the background SYBR Green I fluorescence of the primers and of primer-dimers. We have explored a number of variables for this assay including: number of PCR cycles, multiple readings, annealing temperature, annealing time, extension time, specificity (test of animal and bacterial DNAs), Mg⁺⁺ concentration and SYBR Green I concentration. This assay has a dynamic range of 10ng to 10pg in a 25ul assay and is specific for human (or other primate) DNA. We have also performed experiments using *Alu* PCR in a real-time format also using SYBR Green I stain. These results indicate that this assay is also specific for human DNA and has a range of 16ng to 3.9pg in a 10ul assay. Our results indicate that use of *Alu* PCR can be a quantitative, fast and inexpensive way to quantitate human DNA for forensic or other studies. [Supported in part under award 2000-IJ-CX-K012 from the Office of Justice Programs, Natl. Institute of Justice, Dept. of Justice. This abstract does not necessarily represent the official position of the U.S. Department of Justice.].

The use of a 5 fluorogenic real time PCR assay for the specific quantitation of amounts of mtDNA in DNA

extracts. *J.G. Lorenz¹, E.K. Lin^{1,2}, W.R. Beggs¹, J.C. Beck¹, P.K. Bender¹*. 1) Coriell Inst Medical Research, Camden, NJ; 2) Brandeis University, Waltham, MA.

The use of mitochondrial DNA (mtDNA) in clinical, forensic and population genetic studies has become widespread within the last decade. Generally total DNA is extracted from the relevant biomaterial and total quantity of DNA (nuclear and mtDNA) is determined using any of several methods. When working with high quality biomaterials total DNA yields are generally sufficient and it may not be necessary to quantify the amount of mtDNA specifically. However, there are cases when it is desirable to know how much, if any, mtDNA is present in a sample either before or after a procedure. For example, when working with DNA extractions from bone, tissue or other portions of human remains from archaeological sites it is valuable to know whether or not any mtDNA is present in a given sample extract and thus whether it is worth investing the time and effort to proceed with the analysis. It is also of interest to know the relative contribution of the mtDNA component to the total DNA concentration from extracts from various sources such as mouthwash and whole genome amplified (WGA) materials. We have developed a 5 fluorogenic real time PCR assay using primers and a fluorescently labeled probe that targets a 70 bp segment of the mitochondrial cytochrome B gene. Using a standard derived from a plasmid containing a portion of the cytochrome B gene of known quantity it is possible to quantify the amount of mtDNA present in DNA extracted from a variety of sources including urine, plasma, buccal swabs, mouthwash, hair, blood spots, bone, teeth and various tissues. Using this technique it is possible to detect approximately 0.4 picograms of mtDNA in heterogeneous extracts containing various quantities of mitochondrial, nuclear and bacterial DNA. Although the current primer/probe combination is specific to human mtDNA it could easily be modified to detect a wider range of species.

Proficiency testing scheme results point to the need for a better validation of newly introduced methodologies in routine genetic testing. *E. Dequeker¹, E. Girodon², M. Schwarz³, M. Stuhmann⁴, J.J. Cassiman¹.* 1) Department of Human Genetics - University of Leuven, Belgium; 2) Service de Biochimie et Genetique Moleculaire, Hopital Henri Mondor, Creteil, France; 3) Paediatric Genetics Unit, N.W. Regional Molecular Genetics Laboratory, Manchester, United Kingdom; 4) Human Genetics, Hannover Medical School, Hannover, Germany.

DNA-based testing for genetic diseases has developed from nothing into a general part of laboratory medicine. Testing for genetic disorders is usually carried out in molecular genetic diagnostic laboratories. However, as commercial kits become available, molecular genetic testing for more common inherited disorders such as cystic fibrosis is increasingly being carried out in general pathology laboratories and commercial centers. External quality assessment (EQA) schemes (or proficiency testing) for cystic fibrosis have been organized over the past six years with 135 to 206 participating diagnostic laboratories. A significant improvement of the quality of genotyping results was obtained during subsequent QA schemes, coming from 65% of laboratories without errors in 1996 up to a more or less constant level of approximately 90% since 1999. During these years new commercial kits and methodology became available and were being applied in many diagnostic laboratories. However, the use of a commercial kit alone does not ensure high accuracy of mutation analysis: results of the EQA schemes demonstrated that laboratories which implement a new commercial kit or methodology for mutation analysis of cystic fibrosis (e.g. OLA, INNO-Lipa, Elucigene, DHPLC) made more mistakes during the implementation period. Nevertheless, these methods were already being used for mutation detection in their routine laboratory. External quality assessment schemes and the use of reference materials or certified test samples are possible routes to help the laboratories to improve their quality. Laboratories should be aware of the importance to implement quality assurance systems that include validation of the used procedures.

Mutation analysis of the early growth response 2 gene (*EGR2*) in a cohort of 5,000 patients referred with neuropathy. *J.A. Curran*¹, *U. Ananth*¹, *P. Smith*¹, *G.M. Saiji*², *J.R. Lupski*², *W.K. Seltzer*¹. 1) Research and Development, Athena Diagnostics Inc., Worcester, MA; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX 77030.

Charcot-Marie-Tooth disease Type 1 (CMT1) is a genetically heterogeneous neuropathy that results from an underlying defect in peripheral nerve myelination. Genes directly involved in myelination and shown to be pathologically associated with CMT1 include *PMP22*, *Cx32*, *MPZ* and *EGR2*. The early growth response 2 (*EGR2*) gene, encodes a zinc-finger DNA-binding transcription factor that is essential for the regulation of gene expression during myelination. Among patient specimens submitted for CMT1 mutation analysis, Athena Diagnostics, Inc. has analyzed over 5,000 DNA specimens for sequence variations within the *EGR2* gene using automated DNA sequencing. The entire coding region of the *EGR2* gene, including the highly conserved exon-intron splice junctions, was amplified as two PCR products and bi-directionally sequenced in four fragments. We have identified 38 new sequence variants and 5 previously reported variants. Of the 38 newly described variants, 26 were missense mutations, 1 was a 3bp in-frame insertion, and 11 were synonymous codon mutations. The known A362C common polymorphism was observed in 4.23% of patients and a second newly described variant A209G was observed in 0.54% of patients. The remaining variants were found to recur less than 5 times in the population tested. Sequence variants were found to be clustered in three regions of the *EGR2* gene; just prior to the Inhibitory Domain, within the zinc finger domain and just after the zinc finger domain. A list of the *EGR2* variants detected will be presented including the first variant detected in exon 1 of *EGR2*, and several new variants which may affect the zinc finger domains. Predicted functional consequences of selected mutant alleles will be presented.

Comparison of Direct Sequencing to Other Mutation Detection Methods for the TSC1 and TSC2 Genes. *K.-S. Au, A. Tucker Williams, M.W. Bishop, H. Northrup.* Dept Pediatrics, Univ Texas Medical Sch at Houston, TX.

Tuberous sclerosis complex (TSC) is a dominantly inherited disease of benign tumors occurring approximately 1 in 10,000 in the population. The diagnosis in clinically apparent affected individuals can easily be determined, but there is a demand/need for molecular testing in individuals with subtle findings as well as family members of affected individuals. Two genes, TSC1 and TSC2, have been identified as causative; however, development of a satisfactory mutation screening strategy for diagnostics has proven problematic. There are 62 coding exons with small mutations scattered throughout accounting for the majority (85%) of identifiable mutations resulting in the need to use detection methods that are labor-intensive. Further complicating testing is a significant percentage (8-15%) of large gene deletions/rearrangements in the TSC2 gene and a percentage of patients with no detectable mutation (7-13%). We tested direct sequencing as a potential method with a protocol beginning September 2000. We will compare our sample set for sensitivity and cost to other methods (SSCA, HA, and DHPLC) reported in the literature. We expect a total of 250 samples from definitively diagnosed individuals to be completed by September 2002. To date, 126 samples have been sequenced. Of the 126, 102 (89 with a Definite diagnosis) newly ascertained samples are completed, 11 previously screened as negative by SSCA are completed and 13 samples had variants (mutation v. harmless polymorphism) identified requiring further testing. Sensitivity of other methods have been reported as 61% (SSCA), 58% (HA) and 68% (DHPLC). Among our completed newly ascertained cases with a Definite diagnosis, mutations were detected in 69/89 (77.5%), the highest reported detection rate utilizing a single methodology. We identified mutations in 4/11 samples that were screened negative by SSCA. Our projected cost analysis based on testing 150 samples/year is approximately \$659/sample compared to other methods at \$373 (SSCA), \$414 (HA) and \$566 (DHPLC). Final results will be presented for the entire sample set assessing sensitivity and cost.

Mutational screening of Italian Wolfram Syndrome patients by DHPLC. A. Colosimo^{1,2}, V. Guida^{1, 3}, L. Rigoli⁴, C. Di Bella⁴, A. De Luca¹, G. Palka², D.C. Salpietro⁴, B. Dallapiccola^{1,3}. 1) CSS Mendel Institute, Rome, and CSS Hospital, San Giovanni Rotondo, Italy; 2) Department of Biomedical Sciences, University of Chieti, Italy; 3) Department of Experimental Medicine and Pathology, University La Sapienza, Rome, Italy; 4) Department of Paediatrics, University of Messina, Italy.

Background: Wolfram Syndrome (WS) is an autosomal recessive neurodegenerative disorder also referred to as DIDMOAD, since characterized by diabetes insipidus, diabetes mellitus, optic atrophy and deafness. The causative gene for WS (WFS1), mapped to chromosome 4p16.3, consists of eight exons, spanning 33.44 Kb of genomic DNA. A wide range of mutations and polymorphisms have been described in WFS1, so far. In this study we report on the mutational analysis of the WFS1 gene in a total of 19 Italian WS patients and 25 relatives, using a Denaturing High Performance Liquid Chromatography (DHPLC)-based protocol. Methods: The entire WFS1 coding region was amplified in 14 fragments of 220-400 bp and analyzed by DHPLC. We established the optimal DHPLC parameters of each coding exon using the WAVE Maker Software version 4.1.40. Each anomalous elution peak was then subjected to direct sequencing. Results: Our protocol enabled us to identify the causative mutations in all WS patients and the inherited WFS1 alleles within each nuclear family analyzed. Several novel mutations as well as neutral changes and uncoding polymorphisms were identified, mostly of them being localized in WFS1 exon 8. Neither false positive nor false negative DHPLC results were observed. Conclusions: The DHPLC-based protocol we have developed can be used for an efficient, cost-effective and reliable mutational analysis of the WFS1 gene. In addition, the present study represents the molecular characterization of the largest cohort of Italian WS carriers and patients studied so far and expands the spectrum of WFS1 allelic variants worldwide.

Program Nr: 1254 from 2002 ASHG Annual Meeting

Development of an Automated PCR-RFLP genotyping assay for the β 3-Adrenergic Receptor Gene. *U.R. Desai, C. Song, S.M. Sell.* Dept. of Nutrition Science, Univ. of Alabama at Birmingham, Birmingham, AL.

The β 3-adrenergic receptor is expressed in visceral adipose tissue and is assumed to play a role in the regulation of lipolysis and thermogenesis. A polymorphism in the β 3-adrenergic receptor gene at codon 64 is characterized by the replacement of tryptophan by arginine (Trp64Arg polymorphism) and is associated with the development of obesity and non-insulin dependent diabetes mellitus. Consequently, many gel-based assays have been developed for the detection of this polymorphism. Presented here is an alternative to the conventional PCR-RFLP assays, which use polyacrylamide or agarose gel electrophoresis. Here we have developed a fast and accurate PCR-RFLP based method, using automated capillary electrophoresis, for detecting the Trp64Arg polymorphism of the β 3-adrenergic receptor. DNA was amplified with specific PCR primers that flanked the Trp64Arg polymorphism of which the forward primer was labeled with a fluorophore, TET. The resulting product was then incubated with the restriction endonuclease, Bstn1 which distinguishes between the normal and mutant sequences. DNA fragment analysis was then carried out using an automated, capillary electrophoresis system with laser detection (ABIPrism310). We hope to apply this new assay to larger population studies, which are needed to corroborate and extend the evidence for disease association. This work was supported by NIH grant #P30DK056336.

Program Nr: 1255 from 2002 ASHG Annual Meeting

Development of a High Throughput Comprehensive Sequencing Assay for CFTR Gene Mutation Detection. *S. Huang, C. Chen, M. Peng, B. Anderson, M. Zoleikhaian, S. Olson, W. Sun, CM. Strom.* Dept Molecular Genetics, Quest Diagnostics Inc., San Juan Capist, CA.

Cystic Fibrosis (CF) is the most common lethal autosomal recessive disease among Caucasians and also affects smaller proportions of all other ethnic groups. >1000 mutations have been reported throughout the 27 exons and 26 introns in CFTR. The ACMG panel for CF carrier screening will detect both CF mutations only in <65% of CF patients. For these patients, accurate and comprehensive detection of mutations in CF is important for genetic counseling of relatives, prenatal diagnosis and genotype-phenotype correlation. We developed a full sequence analysis assay for all CFTR exons, splice sites and the promoter region using automated capillary sequencing. Results: The assay was validated using 18 patients with positive ACMG screening results. After blinding the samples, we confirmed all the screening results using our sequencing assay. For 5 affected patients with at least one CF allele not identified by carrier screening, our sequencing assay identified all the CF chromosomes. The genotypes were: F508/R1066C, homozygous 3154delG, F508/P205S, R553G/L1335P and L138ins/3272-26A->G. In addition we were able to resolve 5 ambiguous results of carrier testing using sequence analysis. Conclusion: Complete sequencing of CFTR will be an important adjunct to current methodologies for CF patients and their families.

A unified approach to diagnostic testing for single gene disorders. *L.S. Horrocks¹, L. Steele^{1,2}, N.L. Bulgin¹, T.L. Stockley^{1,3}, P.N. Ray^{1,2}.* 1) Molecular Genetics Laboratory, Department of Paediatric Laboratory Medicine, The Hospital for Sick Children; 2) Department of Molecular and Medical Genetics; 3) Department of Laboratory Medicine and Pathobiology, University of Toronto, Ontario, Canada.

Over 13,500 genetic disorders are listed in Online Mendelian Inheritance in Man, half of which are associated with single gene disorders. As a hospital-based Molecular Diagnostic Laboratory, establishing and executing a unique test for each of these disorders is logistically impossible and prohibitively expensive. We have developed a unified approach for identifying private mutations in rare diseases (i.e. Fabry, Hunter and Retinoblastoma) and have applied it to the diagnosis of relatively more common conditions (i.e. Duchenne/Becker MD). This strategy employs a modular approach using the following techniques 1) Quantitative Multiplex-PCR analysis (QMP) to look for gene deletions or insertions 2) Denaturing High Pressure Liquid Chromatography (DHPLC) to screen for small nucleotide changes followed by 3) Direct Sequencing (DS). These techniques are easily adaptable for use in any diagnostic laboratory setting and can be applied to the diagnosis of many single gene conditions. Depending on the frequency and types of mutations that cause disease, the modules are interchangeable in order to provide the most cost-effective strategy of mutation detection. Once the familial mutations have been identified, direct mutation detection in other family members is greatly simplified.

A Diagnostic Strategy for Molecular Genetic Testing of Hunter disease. *G. Koulchitski¹, L. Steele^{1,2}, Y. Yang¹, Q. Yi¹, T.L. Stockley^{1,3}, P.N. Ray^{1,2}.* 1) Department of Paediatric Laboratory Medicine, The Hospital for Sick Children; 2) Department of Molecular and Medical Genetics;; 3) Department of Laboratory Medicine and Pathobiology, University of Toronto, Ontario, Canada.

Hunter disease (MPS2) is a rare X-linked lysosomal storage disease with an incidence ~1 in 100,000 male births due to a deficiency of the enzyme iduronate-2-sulphase. The phenotype can vary from mild to severe depending on the level of enzyme deficiency and type of mutation in *IDS* gene, located at Xq28. Approximately 2/3 of mother of affected males are carriers of Hunter disease. A pseudogene, *IDS-2*, also exists telomeric to the *IDS* gene and shares a high degree of homology to the *IDS* gene. Many disease causing mutations have been reported in *IDS* gene including whole or partial gene deletions (10%), gene rearrangements due to recombination between the *IDS* gene and the *IDS-2* pseudogene (10%) and nucleotide substitutions (missense/nonsense/splice site) or small insertion/deletions (ins/dels) (80%). The objective of our study was to develop a cost-effective diagnostic strategy for the diagnosis of patients with Hunter disease using 1) Quantitative Multiplex-PCR (QMP) to look for gene ins/dels 2) Southern blot (SB) analysis to detect gene rearrangements and 3) Direct sequencing (DS) for point mutations & small ins/del. DNA was tested from 10 probands with Hunter disease, all of which were found to have mutations in the *IDS* gene. Seven had small mutations in the *IDS* gene picked up by direct sequencing which include missense (2), splice site (3) and small ins/dels (2). Two of the patients had partial gene deletions while a gene rearrangement was detected in one patient. All 4 mothers for which DNA was available were carriers of the family mutation. Based on these results, a sequential diagnostic strategy was developed which provides accurate diagnosis and prenatal diagnosis in families with Hunter disease.

Multicenter validation of a new reverse hybridization assay for CFTR mutation analysis. *L. Messiaen¹, M. Stuhmann², P.F. Pignatti³, G. Matthijs⁴, J. Poncin⁵, P. Cochaux⁶, P. Hendrix⁷, G. Verpooten⁷, A. Devos⁷, A. Verhelst⁷, C. Van Loon⁷.* 1) Dpt. of Medical Genetics, Ghent University Hospital, Ghent, Belgium; 2) Medizinische Hochschule Hannover, Hannover, Germany; 3) University of Verona, Institute of Biology and Genetics, Verona, Italy; 4) Center for Human Genetics, University of Leuven, Leuven, Belgium; 5) CHU de Liège Génétique, Domaine Universitaire Sart Tilman, Liège, Belgium; 6) ULB Hôpital Erasme, Laboratoire de Génétique Moléculaire, Brussels, Belgium; 7) Innogenetics NV, Gent, Belgium.

The performance of the INNO-LiPA CFTR12 and INNO-LiPA CFTR17+Tn for the detection and identification of 29 specified cystic fibrosis transmembrane conductance regulator (CFTR) mutations and their wild-type sequences, as well as the identification of a congenital bilateral absence of the vas deferens (CBAVD)-related polymorphism, were validated in a European multicenter study. Each center selected approximately 40 samples with a known mutation profile and 10 wild type control samples to be tested with the INNO-LiPA CFTR assays. A total of 364 CF and control samples were amplified, 360 of which were analyzed on the INNO-LiPA strips. For these samples, a 99.2% concordance with conventional genotyping methods was found. This was further improved to 100% after optimization of 4 probe concentrations on the LiPA strips. The specificity of the INNO-LiPA CFTR was further investigated at Innogenetics by testing possible cross-reactivity of benign polymorphisms or rare CF mutations located near or at the location of the mutations for which probes are present on the INNO-LiPA strips. No cross-reactivity was found. In conclusion, this study shows that the INNO-LiPA CFTR12 and INNO-LiPA CFTR17+Tn detect and reliably identify an important number of CF-related mutations, as well as the CBAVD-related Tn polymorphism in the CFTR gene region. For the U.S. market, a new strip was designed containing the probes already present on the CFTR12 strip, and to which 4 additional mutations recommended by the American College of Medical Genetics were added.

Results of reference testing of EBV transformed cell lines for performance evaluation and quality assurance in molecular genetic testing. *L.O. Williams¹, A.K. Stankovic¹, S. Bernacki², J.C. Beck³, K. Snow², V. Pratt², K. Monaghan⁴, K. Matteson⁵, F. Schaefer⁶, M. Friez⁷, A. Shrimpton⁸, D. Farkas⁹, T. Stenzel².* 1) Centers for Disease Control and Prevention, Atlanta, GA; 2) Duke Univ Med Ctr, Durham, NC; 3) Coriell Institute for Med Research, Camden, NJ; 4) Henry Ford Hosp; 5) Univ TN Med Ctr; 6) Chapman Inst Med Genetics; 7) Greenwood Genetic Ctr; 8) SUNY Upstate Med Univ; 9) Baylor Col Med.

The role of human molecular genetic testing (hMGT) expands as the number of mutations associated with disease increases. The need for stable sources of positive controls for performance evaluation and quality assurance (PE/QA) of hMGT persists. The CDC and Duke Med. Ctr., in collaboration with Coriell Inst., are conducting a project to establish stable EBV-transformed cell lines from residual blood samples containing targeted mutations associated with diseases of public health importance. The first set of ten cell lines were established from residual samples provided by consultants associated with the project or from pre-existing Coriell samples. After stable transformation of cell lines, frozen cell pellets were sent to outside laboratories for reference testing. Each sample was tested by five or more laboratories, most of which perform clinical testing for the targeted mutation. Targeted mutations were point mutations or small deletions. Eight laboratories participated. Each mutation was reference-tested by two or more technologies typically used in clinical laboratories for detecting that mutation. Seven different nucleic acid purification techniques and fifteen different detection techniques were used. The techniques used were dependent upon the targeted mutation. The presence of targeted mutations was confirmed in all cell lines regardless of nucleic acid purification technique or detection technique. In initial stability testing of other cell lines containing triplet repeat expansions, the number of repeats was constant through five culture passages and twenty population doublings. The transformation and verification process used in establishing these cell lines represents a successful approach for producing positive samples for PE/QA uses.

Program Nr: 1260 from 2002 ASHG Annual Meeting

Molecular Diagnostic Testing for Autosomal Dominant Hereditary Spastic Paraplegia: Identification of Novel mutations in the *SPG4* gene. J. Wang, A.N. Hennigan, A. Morini, U. Ananth, W.K. Seltzer. Athena Diagnostics, Inc., Worcester, MA 01605.

Hereditary Spastic Paraplegia (HSP) type 4 is the most common form of autosomal dominant HSP, a neurodegenerative disease characterized by progressive spasticity of the lower limbs and hyperreflexia. Studies have shown that mutations in the *SPG4* gene are responsible for approximately 40% of all diagnosed HSP cases. The *SPG4* gene maps to chromosome 2p21-p22 and encodes Spastin, a putative nuclear protein of the AAA (ATPases associated with diverse cellular activities) family. Molecular diagnostic testing for *SPG4* mutations is performed by DHPLC (denaturing high performance liquid chromatography) and automated DNA sequencing. The entire coding region and highly conserved splice sites of the *SPG4* gene were amplified as 17 gene segments (exons 1-17). Six of the 17 segments were sequenced directly in forward and reverse strands. The remaining 11 segments were screened by DHPLC and positives from the screen were further analyzed by bi-directional sequencing. Analysis of 223 DNA specimens submitted to Athena Diagnostics, Inc. for *SPG4* gene mutation identification yielded 30 sequence variants predicted to alter the primary structure of Spastin. Twenty three of these were novel mutations and 7 were mutations previously reported in the literature. The novel variants identified consisted of 6 nonsense, 12 missense, 4 deletions (one splice site) and 1 insertion. Interestingly, of these 23 new variants, 18 (82%) were located in the AAA cassette region, a previously reported protein functional domain. This study provides a spectrum of novel *SPG4* mutations, and implicates the AAA cassette region as critical to Spastin function.

Familial dysautonomia mutation frequency: clinical testing of greater than 2700 specimens confirms high frequency in Ashkenazi Jews. . E.A. Sugarman, B.A. Allitto. Genzyme Genetics, Framingham, MA.

Familial dysautonomia (FD) is an autosomal recessive neuropathy occurring almost exclusively among Ashkenazi Jews. Autonomic and sensory nervous system dysfunction lead to variable symptoms including decreased sensitivity to pain and temperature, labile blood pressure, vomiting, gastrointestinal problems, lack of overflow tears, hypotonia, and scoliosis. FD is progressive and fatal; 50% of patients survive to age 30. The responsible gene, IKBKAP, and two mutations accounting for >99.5% of alleles were recently identified.

An FD carrier frequency of 1/30 among Ashkenazi Jews, similar to that of Tay-Sachs, has been estimated from disease incidence. We report our experience in offering clinical testing for the 2 reported mutations: 2507+6T>C and R696P. From October 2001 to May 2002, 2,743 specimens were referred for FD mutation analysis. Of these, 2728 were for carrier testing: 2702 with no family history; 26 with a family history. Among 2148 individuals referred for carrier screening and self identified as Ashkenazi Jewish, 78 were carriers of 2507+6T>C and 1 was a carrier of R696P. The carrier frequency based on our testing was 1/27 - similar to the 1/30 predicted by disease frequency. Of 554 carrier screening individuals reporting either partial or no Ashkenazi Jewish ancestry, 4 were 2507+6T>C carriers (1/138). Prenatal diagnosis was performed for 7 fetuses: 5 fetuses (3 carriers; 2 noncarriers) from 3 families with a previous affected child; 2 fetuses (both negative) with one carrier parent. Of eight referrals for a suspected diagnosis (3 Ashkenazi, 5 other ethnicities), one Ashkenazi patient was homozygous for 2507+6T>C and the others were negative.

Our clinical testing experience confirms the high carrier frequency of FD in the Ashkenazi Jewish population. Current ACOG standard of care is to offer carrier testing for CF, Tay-Sachs and Canavan disease to Ashkenazi Jewish individuals. Given the significant morbidity of FD and a detection rate comparable to these diseases, the addition of FD to carrier testing recommendations may be warranted.

EPM1 methylation-analysis improves PCR testing of myoclonus epilepsy - type Unverricht Lundborg. A.S.

Weinhaeusel¹, M. Morris², P. Waldner¹, S.E. Antonarakis², O.A. Haas¹. 1) CCRI, St Anna Children's Hosp, Vienna, Austria; 2) University Hospital Geneve, Division of Medical Genetics, Geneve, Switzerland.

Progressive myoclonus epilepsy of the Unverricht-Lundborg type (EPM1; MIM 254800) is an autosomal recessive disorder caused by loss of cystatin B gene function. In the vast majority of cases, the loss of gene activity is caused by EPM1 dodecamer repeat expansions affecting both alleles within the 5-gene region, disabling proper mRNA transcription. Diagnostic procedures therefore rely on the determination of the extent of the repeat expansion. Up to now, this has been achieved with Southern blot analyses and PCR; due to the high CG content of the EPM1 region conventional PCR amplification of affected alleles fails and enhanced technical effort is necessary to overcome amplification failure. To resolve some of these problems, we have developed a methylation-sensitive PCR-test on sodium bisulfite treated DNA. We have designed primer sets that cover the methylated and non-methylated promoter, and the deaminated EPM1-repeat. With promoter primer-sets we are able to show that the normally unmethylated promoter region does not change along with repeat expansion. Thus unlikely fragileX syndrome, methylation testing does not enable indirect diagnostic testing for the EMP1 repeat expansion and the syndrome. In addition to determination of the methylation status in affected patients, we used bisulfite treated DNA for amplification of the EMP1 repeat expansion and could establish a novel PCR test for direct testing of EMP1 repeat expansion. Thus we were able to amplify the affected alleles in a series of full mutation patients and also within the heterozygous full mutation carriers, who are prone to misdiagnosis due to PCR-product competition of the normal allele. Our MS-PCR approach, thus provides proper PCR testing and would replace laborious Southern-blot analyses.

Modeling of periodic screening of smokers with increased genetic susceptibility to lung cancer: Impact on population-based mortality. *M. Kimmel*¹, *O. Gorlova*², *C. Amos*², *M. Spitz*², *C. Henschke*³. 1) Dept Statistics, Rice Univ, Houston, TX; 2) Department of Epidemiology, University of Texas MD Anderson Cancer Center, Houston, TX; 3) New York Presbyterian Hospital-Weill Medical College, Cornell University, New York, NY.

Previous studies indicate that genetic factors play a role in lung cancer susceptibility (reviewed in Amos et al., *Chemoprevention of Cancer*, 1999:3-12). We consider a population of individuals at high risk for lung cancer (smokers), additionally stratified by a genetic susceptibility variate. We use a stochastic model of disease progression and detection to estimate the mortality reduction associated with early detection of lung cancer followed by appropriate treatment. The estimates of model parameters have been obtained based on data from previous screening studies (Gorlova et al, *Cancer* 2001, 92: 1531-1540). Two theoretical possibilities are considered: (1) The highly genetically susceptible (HGS) smokers do not differ, with respect to the time-course of disease, from other smokers; (2) The HGS smokers have an earlier onset and/or faster progressing disease. Preferential screening of the HGS smokers is advisable based on cost-effectiveness considerations. Under scenario 2, the screening has to start earlier to ensure a meaningful reduction of mortality.

We evaluated our modeling approach using data from an ongoing case-control lung cancer study conducted in the Epidemiology Department at the MD Anderson Cancer Center. Smokers with upper quartile outcomes of both bleomycin and BPDE mutagen sensitivity assays represent a higher fraction of cases than controls. From these data, it can be estimated that the lifetime susceptibility to lung cancer of these HGS smokers equals approximately 0.5, as opposed to approximately 0.09 for the other smokers. Based on our calculations, although the HGS smokers constitute only around 10% of all smokers, they account for approximately 40% of lung cancers in the population.

Chromosomes 2 & 7 in AutD: Clinical comparisons of phenotypic subtypes. *S. Donnelly¹, C. Wolpert¹, L. Elston¹, S. Ravan², K. Decena², R. Abramson², H. Wright², M. Cuccaro¹, M.A. Pericak-Vance¹.* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) WS Hall Psychiatric Institute, Univ of South Carolina, Columbia, SC.

Autism (AutD) is a complex neurodevelopmental disorder characterized by social-communicative impairments and repetitive behaviors. Multiple genes may have etiologic relevance to AutD with at least 10 different genes suspected. Chromosomes 7 and 2 have demonstrated the strongest linkage to date when phrase speech delay (PSD) has been used to subset families. We used ordered subset analysis (OSA) to identify subsets of families for both Chr2 and Chr7. OSA is a statistical procedure in which a clinical covariate is used to identify a homogeneous subset of families that contribute to linkage in a chromosomal location. Using PSD (phrase speech onset >36 months) as a covariate, OSA identified 29 families for Chr7 and Chr2. All Chr7 families were in the Chr2 subset (n=17); a subset of Chr2 families were only linked to that chromosome (n=12). We compared the Chr2 and Chr7/2 subsets on the Autism Diagnostic Interview-Revised (ADI-R), Aberrant Behavior Checklist (ABC), and Vineland Adaptive Behavior Scales (VABS). The groups failed to differ on the ADI-R social algorithm total and repetitive behavior scores as well as the ABC Lethargy factor. However, the two groups differed significantly across each of the VABS indices. The Chr2 group showed consistently higher scores in social (p=. 0004), communication, (p=. 0189), and daily living skills (p=. 0006) domains as well as in overall adaptive functioning (p=. 0004). Further, the Chr2 group also demonstrated less impairment on two ADI-R measures of communication: gestures (p=. 003) and social imitative behaviors (p=. 0015). These findings suggest that the Chr2 and Chr7/2, despite being stratified on PSD, are distinctly and consistently different on several clinical dimensions including additional measures of communication. This shows that the Chr7/2 subset is more impaired than the individuals in the Chr2 subset alone. In addition, the Chr2 individuals may show a different trajectory of development particularly in language and communication.

Confidential pre-employment counseling and genetic marker screening. *L. Godmilow*¹, *D. Duebner*². 1) Genetics, University of Pennsylvania, Philadelphia, PA; 2) Occupational Medicine, Brush Wellman, Inc, Cleveland, OH.

Beryllium, an element mined commercially, is used in electronics components, fiber optics components, nuclear weapons, nuclear reactors and other important products. Brush Wellman, Inc (BWI) is a major producer of high-performance engineered beryllium materials which involves processes that produce fine beryllium particles. Workplace contact with beryllium particles may result in a severe inflammatory lung disease, chronic beryllium disease (CBD). There is evidence to suggest that a particular HLA marker, Glu⁶⁹, might increase the risk of developing CBD.

BWI approached the University of Pennsylvania about designing a pilot program to make confidential genetic counseling and HLA marker testing available to a group of persons considering employment at the BWI plant in Tucson, AZ. Current employees and outside scientific advisors supported the concept of making this testing available. IRB approval was obtained.

Sixty consecutive individuals who had been offered employment were given the opportunity to participate in the program. They were provided with a toll-free telephone number to call the genetic counselor if they wished to initiate genetic counseling and explore further the option of testing. Twelve persons were counseled and nine had their blood samples submitted (15% of the original 60 subjects). Of the 9 samples submitted, two (22%) were positive for the HLA Glu⁶⁹ marker and seven (78%) were negative.

All prospective employees who were counseled said they were going to accept the job offer (and all did) despite a positive result but were interested in knowing if they carried the HLA marker. Employment at the BWI plant is the highest paid in the Tucson area for unskilled workers. Counselees were positively impressed by the company's efforts to minimize exposure to beryllium and seemed to feel their risk to develop CBD was exceedingly small even if they carried the marker. The program is being considered for revision and expansion to two additional company plants.

Media Portrayal of Genetic Discoveries: A Comparison of Newspaper Stories and Peer Reviewed Research Papers. *T.A. Caulfield, T. Bubela.* Health Law Inst, Univ Alberta, Edmonton, AB, Canada.

Many commentators have speculated that the media inappropriately "hypes" the portrayal of genetic research. Likewise, numerous studies have reported that the popular media, including newspapers, are a primary source of genetic information for the public and health care professionals. It is also likely that media coverage of social issues associated with genetic discoveries has an impact on public opinion and an indirect impact on policy development. We will present a comprehensive review of existing international survey data on where the public, clinicians, and policy makers receive their information about genetic discoveries. In addition, we review existing and present original data on the manner in which genetic stories have been presented in the media since 1995. We examine 1330 newspaper articles in 28 newspapers in Canada, the UK, Australia, and the United States, reporting on 153 studies published in the primary scientific literature from 1995-2000. The focus is on the reporting of single gene discoveries. Using a standard questionnaire and project naive coders, we compare the accuracy of the description of the scientific research and the claims and conclusions made in the primary research article with those made in the newspaper article. We compare the level of hype associated with positively viewed discoveries such as disease genes and potential treatments with more contentious news items surrounding reproductive technologies and behaviour genes. We found that gene discovery stories are highly localized and generally have a short longevity in the media. Claims are more likely to be exaggerated in stories on reproductive technologies and behaviour genes than disease genes. Gene discoveries with the greatest longevity in the media are associated with the most social commentary and misinformation. Such ill-informed policy debates amplify many of the fundamental concerns by reifying genetic material and confirming notions of genetic essentialism. This impacts formal policy and regulatory responses to genetic research, many of which seem to be misplaced reactions to the hyperbole instead of thoughtful, sustainable, regulatory strategies.

Obstetricians Initially Appear to Find the ACOG/ACMG Cystic Fibrosis Screening Guidelines Difficult to Implement. *S.L. McAdoo, J.L. Simpson, A. Burke, M. Totorica.* Obstetrics & Gynecology and Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

Cystic fibrosis (CF) is a molecularly heterogeneous disorder that will probably be the prototype for population-based screening and, de facto, will be applied to pregnant women. In October 2001, ACMG/ACOG jointly proposed a codified approach for CF screening using a specified panel of 25 mutations. Carrier screening would be offered to Caucasian people of Northern European or Ashkenazi Jewish descent but would only be made available to those of other ethnic backgrounds. How practical have these logical but perhaps complex recommendations been? **PURPOSE:** Assess acceptance and identify problems practicing obstetricians encounter in adhering to these guidelines. **METHODS:** Our pilot study has begun within our primary medical school hospitals, after which we will extend to the broader base of referral physicians. An 18-item questionnaire inquired about the demographics and ethnic composition of each practice, manner in which screening was offered, and impressions regarding the practicality of guidelines. **RESULTS:** Even in this pilot study, a trend is apparent. The first 24 obstetricians surveyed were significantly discrepant from the ACOG/ACMG guidelines, especially concerning offering vs. making available. Only 17.4% of obstetricians followed the guidelines exactly. Most (65.2%) concluded the guidelines impractical or unclear; those practices containing a higher percentage of Caucasian/Jewish patients were more likely to view the recommendations as impractical. Physician gender, age, and practice size did not seem to alter feelings of practicality or adherence to the guidelines. **CONCLUSIONS:** This pilot study suggests a need for clarifying the ACOG/ACMG CF screening guidelines. This situation contrasts with experience initially encountered with the introduction of maternal serum analyte screening; recommended protocols for that purpose were conscientiously followed. This permitted knowledge concerning how to handle abnormal findings to be gained after a practitioner actually had his/her first abnormal test result. Different educational strategies may be needed for CF screening.

A decline in the incidence of Genetic Blood diseases in Bahrain. *S.S. Al Arrayed¹, A.Y Hamza³, D.K Shome², B. Sultan⁴, J.P Bapat².* 1) Genetic Dept, Salmaniya Medical Ctr, Manama, Bahrain; 2) Pathology department, Salmaniya medical complex, Manama, Bahrain; 3) Ministry of Health, Bahrain; 4) Maternity Nursing section. Salmaniya medical complex, Manama, Bahrain.

Genetic blood diseases are frequent in Bahrain. Previous neonatal screening done in 1985, showed that the incidence of Sickle cell disease (SCD) 2.1%, Sickle cell trait (SCT) 11%. Since then the ministry of health instituted a campaign for the prevention of these disorders. Measures included antenatal screening, student screening premarital counseling and newborn screening with health education and raising awareness among the people in the country. The incidence has been falling gradually during the years. A premarital study done in 1995, showed SCD incidence of 1.6%. Student screening done in 1999 and 2001 showed 1.3%, and 1% respectively. The Objective: to update the national data on the incidence of sickle cell disease, and compare it with previous statistics. This will help to design a future prevention program. Method: This is a collaborative project between Ministry of Health, WHO, and Bahrain Hereditary anemia society. Target Group: All Bahraini newborns delivered in the ministry of health maternity hospitals during February, to April 2002. This included 80-90% of all Bahraini newborns during that period. Types of tests: High performance liquid chromatography (Bio-Rad Variant) was used to analyze cord blood samples. Questionnaire was filled for each newborn. The form included demographic data, parental age group, and consanguinity. A coded computer program was used, data was analyzed. Results: 2000 Bahraini newborns constituted the study population. Only 17 babies were affected with SCD, with an incidence of 0.8%. 260 newborns (13%) carry the trait, the rate of 0.8 per cent represent a significant falls in the incidence (60%). report on paternal age, and consanguinity will be presented. Conclusion: Bahrain has, for the first time, recorded a less than one per cent birth rate of babies with sickle cell disease. If this trend continues, Bahrain could soon become the first country in the Gulf region to completely eliminate this disease.

“A Tale of Two SNPs” in routine genetic testing for cystic fibrosis mutations. *Y. Yang, R. Kornreich, L. Edelmann.*
Dept Human Gen, Box 1497, Mount Sinai Sch Medicine, New York, NY.

More than 1,000 mutations that cause cystic fibrosis (CF) have been described in the *CFTR* gene and hundreds of sequence variations, mainly SNPs, have been identified that either do not alter the amino acid sequence or introduce apparent benign changes. The frequencies of many of these changes, their potential cumulative effects or effects with known mutations have not been widely studied. SNPs can also interfere with PCR analyses. In our laboratory, genetic testing for CF is performed by multiplex PCR followed by ASOH, often employing previously reported primer pairs. During routine genetic testing, we discovered that two known SNPs, located on the distal primer of the exon 10 amplicon, were interfering with PCR amplification. The first SNP, 1713G>A, was identified in a delF508 carrier that appeared homozygous for the mutation. Sequencing revealed the presence of 1713G>A in trans with the delF508 mutation. This SNP coincides with the last nucleotide of the distal exon 10 primer and when present, disrupts amplification. The second SNP, 1716A>G, in the fourth position from the 3' end of the distal exon 10 primer, was also identified in a delF508 carrier. The presence of this SNP reduces amplification from the allele. We also identified this SNP in trans with delF508 in two males with infertility that were negative for the intron 8, 5T variant and are currently investigating whether this SNP, which occurs at the last position of exon 10, has any effect on splicing. We determined the frequencies of these two SNPs in 100 African American, Ashkenazi Jewish and European individuals by ASOH. We found a frequency of 7.7% for the 1713/1716 GG allele combination among African Americans and a frequency of 8.1% for the AA allele combination among individuals of European ancestry. The remainder of individuals in these two populations and all of the Ashkenazi Jewish individuals had the AG combination. We did not identify any individuals with the GA allele combination. The results indicate that these two SNPs may interfere with CF analyses in some individuals and exemplify the need to consistently examine PCR primers and probes for newly described polymorphisms.

Program Nr: 1270 from 2002 ASHG Annual Meeting

A novel PCR approach for detection of the common NEMO (IKBKG) rearrangement in Incontinentia Pigmenti.

*S. Hadj-Rabia*¹, *V. Raclin*¹, *A. Smahi*¹, *H. Woffendin*², *J. Steffann*¹, *A. Munnich*¹, *S.J. Kenwrick*², *J.-P. Bonnefont*¹. 1) Dept Genetics, Hosp Necker, Paris, France; 2) Wellcome Trust Centre for Molecular Mechanisms of Disease and Univ. of Cambridge, Cambridge, UK.

Incontinentia Pigmenti (IP, MIM 308300) is a rare X-linked dominant genodermatosis usually lethal in males during the prenatal period. Prior to identification of the IP gene (NEMO for NFkB-essential modulator), the diagnosis of mild clinical forms and genetic counseling were based on the study of the X-inactivation pattern in leukocytes, since extreme skewing of X inactivation is present in over 98 % of IP carrier females. However, X inactivation skewing is also observed in normal individuals (1%) and increases with age, so that this test lacks specificity. Recent identification of the NEMO gene enabled to show that over 80% of IP cases are accounted for by a large-scale deletion encompassing NEMO exons 4 to 10. A diagnostic procedure of this rearrangement, based on long-range PCR, has been reported (Smahi, *Nature*, 2000;405,466). However, this test was hampered by the large size of the amplification product, and additionally could not discriminate between the gene (NEMO) and pseudogene (DNEMO) deletions. We have devised a novel test based upon multiplex PCR that has proven to be NEMO-specific, robust, and reproducible. Implementation of this method markedly facilitates the detection of the common NEMO rearrangement both for postnatal and prenatal diagnosis purposes.

Development and evaluation of a model genetics screening program for multiple genetic disorders in Australian multicultural high school students: 1995-2001. *K. Barlow-Stewart¹, L. Burnett^{2,3}, A. Proos³, F. Huq¹, A. Gason⁴, M. Delatycki⁴, G. Turner⁵, H. Aizenberg⁶.* 1) Centre for Genetics Education, Royal North Shore Hospital, Sydney, Australia; 2) Pacific Laboratory Medicine Services, Northern Sydney Area Health Service, Australia; 3) Kolling Institute of Medical Research, RNSH, Sydney, Australia; 4) Genetic Health Services Victoria, Murdoch Childrens Research Institute, Melbourne, Australia; 5) Hunter Genetics, Waratah, Australia; 6) Institute of Community Genetics, Sydney, Australia.

From 1995-2000, 5,272 subjects in 20 Senior High Schools in two Australian States were offered education and the opportunity to voluntarily participate in cohort carrier genetic screening for up to three autosomal disorders relevant to the student population: Tay-Sachs disease, cystic fibrosis and thalassaemia. **METHODS:** Using de-identified coding, students were serially surveyed to measure changes in knowledge, attitude and concern about genetic screening prior to education, after education but before testing, twelve months after testing, regardless of their testing choice and 3-6 years post-testing using a mail survey. **RESULTS:** Informed choice was achieved when education was delivered in group-delivery mode combined with on-site access to testing, but not without on-site education, and also not when on-site education was provided without opportunistic access to testing. Informed choice was independent of gender, pre-existing knowledge, urbanisation, academic achievement, ethnicity and socio-demographic status. Extension of testing from one to multiple genetic disorders did not impact on informed choice or uptake. Maximal levels of uptake were achieved utilising novel result reporting systems involving holding test results in escrow until needed. Uptake levels were also maximised if genetic testing was performed without venepuncture. Long term follow-up of students showed high retention of knowledge, intended positive utility and that no harm had been done by offering testing to high school students. **CONCLUSIONS:** Cohort community genetic screening of senior high school students for multiple genetic disorders is feasible, provided certain key success factors are addressed.

Program Nr: 1272 from 2002 ASHG Annual Meeting

The CRMGEN Project: A New Reference Material for Hereditary Haemochromatosis Testing. *D.E. Barton, E. Donohoe for The CRMGEN Consortium.* National Centre for Medical Genetics and Department of Medical Genetics, University College Dublin, Our Lady's Hospital, Dublin, Ireland.

The use of appropriate Reference Materials (RMs) to validate test equipment or testing methods is an important part of any analytical testing system. Certified reference materials (CRMs) are RMs whose characteristics have been fully documented and validated. Currently, no CRMs are available for genetic testing. The CRMGEN project is a ten-centre collaboration funded by the European Commission's Measurement and Testing program (Contract G6RD-CT-2001-00581). We are developing reference measurement systems and producing CRMs for molecular genetic tests. Prototype RMs will be developed for a wide range of tests. These prototype RMs, developed in one of 4 genetics centres, will be validated in 7 other centres before extensive field trials. The knowledge gained in this process will be used to develop guidelines for the production of CRMs for any genetic test. Special emphasis will be given to the *commutability* of the candidate RMs, i.e. their ability to perform under a wide range of test protocols and conditions.

We have used the polymerase chain reaction (PCR) to produce prototype RMs for the common mutations involved in hereditary haemochromatosis (H63D & C282Y). Working from a 3kb master template, we have produced RMs for the individual mutations and for both together. The RMs have been tested in the Dublin laboratory, and are now undergoing testing in the laboratories of the other CRMGEN partners. As the RM production process requires these PCR products to be brought back into pre-PCR areas, serial dilutions are carried out for each PCR product, in order both to minimise the risk of contamination in second-round PCR reactions and to negate the need for scale-up in the production phase of the project. Strategies for decontamination of PCR reaction tubes and racks were also investigated, to allow future safe handling of the final product. It was found that HCl was ineffective (up to 4M), but the use of a 1/10 dilution of sodium hypochlorite eliminated all contaminating PCR products.

email: david.barton@olhsc.ie.

Genetic cancer risk assessment (GCRA) in an underserved setting: Survey of needs, knowledge and concerns. *R. Nedelcu¹, K.R. Blazer¹, S. Sand¹, C. Arbayo¹, S. Fuentes², G.C. Uman³, J.N. Weitzel¹.* 1) Clinical Cancer Genetics, City of Hope Cancer Ctr, Duarte CA; 2) QueensCare Foundation (QC), L.A. CA; 3) Vital Research, L.A. CA.

GCRA is an emerging standard of care to identify hereditary cancer risk and target appropriate cancer prevention and early detection measures, accessible primarily to insured populations. We report results from a survey exploring knowledge, risk perceptions and barriers to cancer screening conducted prior to initiating grant-funded GCRA services in the setting of QC, which provides healthcare for families at less than 200% of the poverty level. A survey designed for grade 4-5 literacy, translated into Spanish and Korean was distributed to sequential patients. 137 surveys were analyzed. Demographics: mean age of 42; 71% Hispanic; 74% female; 70% elementary or high school education; 28% had a history of smoking cigarettes; males were twice as likely to have smoked than females ($p < .01$); 35% had a personal and/or family history of cancer; 52% had none of these risk factors. Only a minority articulated their perception of personal cancer risk. Less than half correctly answered knowledge questions about hereditary cancer. Only 37% adhered to recommended cancer screening guidelines. Over half had no insurance, with females significantly less likely to have it ($p < 0.05$). Overall, respondents were very interested in learning more about their own cancer risk and were willing to invest the time to do so. About 50% were likely at higher risk for cancer than the general population. The most frequent perceived risk factors and causes of cancer after environment and tobacco were family history and genetics, while fatalistic views of cancer were among the least identified factors. This population has increased risk for late diagnosis of cancer due to less cancer screening. Most lack insurance coverage, but economic realities did not obviate cancer concerns. Most cancer screening information was obtained from television, boding well for acceptance of telemedicine as a modality for cost-efficient GCRA-greater access could have a dramatic positive impact on patients, families and the community.

Haemochromatosis-associated HFE genotypes in English blood donors: age-related frequency and phenotypic expression. A.S. Rigby¹, V. Chambers¹, L. Sutherland¹, K. Palmer¹, A. Dalton¹, R. Sokol², R. Pollitt¹, M.S. Tanner¹, D. Gleeson³. 1) Sheffield Children's Hosp, Univ Sheffield, Sheffield, England; 2) Trent Regional Blood Transfusion Service, Sheffield, UK; 3) Liver Unit, Sheffield Teaching Hospitals, Sheffield, UK.

There is limited data on the frequency and phenotypic expression of the haemochromatosis-associated mutations C282Y and H63D in healthy people. We studied 6261 randomly selected English male blood donors (≤ 4 units donated previously). Genotyping was performed in a random sample of subjects with wild/wild and wild/H63D genotypes and in most subjects with other genotypes. The overall frequency of the C282Y/C282Y genotype was 0.3%, C282Y/H63D 2.0%, H63D/H63D 2.0%, wild/H63D 21.7%, wild/C282Y 10.4%, and wild/wild 63.4%. Genotype distribution was within H/W equilibrium within each age band. Wild/C282Y frequency fell from 11.7% in subjects < 30 years to 8.2% in subjects > 50 years ($p < 0.005$). No such trend was seen for C282Y/C282Y or C282Y/H63D genotypes. In C282Y/C282Y subjects, serum iron saturation was 63 (15-80)%; median (range) serum ferritin was 247 (60-2449) $\mu\text{g/L}$ and exceeded $> 500 \mu\text{g/L}$ in only two of 18 subjects. C282Y and H63D heterozygotes also had higher serum iron and lower unsaturated iron binding concentration than did wild/wild subjects. For wild/wild, wild/H63D and wild/C282Y and H63D/H63D genotypes, serum ferritin rose with increasing age and fell with increasing donation number. This fall was greater in wild/wild subjects than in other genotypes. In conclusion, C282Y homozygosity shows limited phenotypic expression and no trend towards age-related attrition. C282Y and H63D heterozygosity are associated with minor changes in serum iron indices and a smaller fall in serum ferritin with repeated blood donation in wild/wild subjects suggesting that both these mutations protect against iron deficiency.

Accountability in Diagnostic Molecular Genetic Testing: Europe. *S.J. Patton¹, R. Elles¹, S. Stenhouse², D. Barton³, C. Mueller⁴, M. Losekoot⁵, B. Bakker⁵, M. Goossens⁶, E. Dequeker⁷, J.J. Cassiman⁷ and The European Molecular Genetics Quality Network (EMQN).* 1) European Molecular Genetics Quality Network (EMQN), c/o National Genetics Reference Laboratory, Manchester, UK; 2) Northern Genetics Knowledge Park, Newcastle-on-Tyne, UK; 3) National Centre for Medical Genetics, Dublin, Ireland; 4) University of Wuerzburg, Germany; 5) Leiden University Medical Centre, The Netherlands; 6) Hospital Henri Mondor, Creteil, France; 7) University of Leuven, Belgium.

Diagnostic molecular genetic testing is fast becoming a routine and important part of laboratory medicine. External Quality Assessment (EQA), or Proficiency testing, is one approach to quantifying laboratory performance. The European Molecular Genetics Quality Network (EMQN) was funded to raise and maintain the quality of diagnostic molecular genetic testing in Europe. In the 5 years since the network started, the EMQN has provided thirty-five EQA schemes for twelve different inherited genetic disorders. Each scheme tests the ability of laboratories to interpret data in the light of clinical information supplied with a referral, and to produce a clear and accurate report. Laboratories from all European Union countries have participated in these exercises. The structure and development of the schemes will be described. In 2001, the schemes evaluated 315 returns from laboratories, a 33% increase on 2000. The schemes can identify critical points in the pre-analytical, analytical and post-analytical processing of diagnostic cases. The results presented show that the majority of laboratories conform to best practice guidelines, have a high level of analytical and interpretative performance, and suggest that regular participation in EQA has a significant effect towards improving the standards of diagnostic molecular genetic testing in Europe. The accountability provided by participation in such EQA schemes gives patients confidence in the results of molecular genetic testing.

Program Nr: 1276 from 2002 ASHG Annual Meeting

Monitoring the clinical response of mucopolysaccharidosis diseases to therapy using the MPS Test™. *C.B.*

Whitley^{1,2}, D.C.C. Erickson¹. 1) Gene Therapy Program, Univ Minnesota Medical Sch, Minneapolis, MN; 2) Zebraic Corporation, Minneapolis, MN.

The clinical response of mucopolysaccharidosis diseases to current therapies (i.e., bone marrow transplantation) and future treatments (e.g., enzyme replacement therapy, gene therapy) can be monitored by measuring urine glycosaminoglycan (GAG) levels. A pattern of decreasing GAG/creatinine ratio is a surrogate marker of clinical efficacy. Zebraic's MPS Test™ allows one to send urine specimens for rapid measurement of the GAG/creatinine ratio by an automated method. For the MPS Test™, urine specimens are easily obtained by non-professional personnel (e.g., parents) from patients of any age, including infants. Specimens are easily sent through the mail without the cost or inconvenience that is required to send frozen urine specimens to other laboratories to measure GAG/creatinine by conventional methods. The availability of the MPS Test™ thus enables frequent, rapid and standardized monitoring of therapy. Importantly, every patient and healthcare provider can have access to rapid testing through a central laboratory. The broader availability of the MPS Test™ also facilitates future progress toward programs for early, presymptomatic screening of large populations to identify those individuals who are affected by mucopolysaccharidosis diseases.

Myotonic Dystrophy Type 2 (DM2) Diagnostic Testing: Results of the First Several Months of Testing in a Clinical Reference Laboratory. *J.G. Jones, S.K. Allen, L.A. Hayes, C.A. Titone, W.K. Seltzer.* Athena Diagnostics, Inc, Worcester, MA.

Myotonic Dystrophy Type 2 is associated with a CCTG repeat expansion located in intron 1 of the zinc finger protein 9 (*ZNF9*) gene. Diagnostic testing for the disease-causing expansion is challenging due to the large size (mean \gg 5000, maximum $>$ 11,000 repeats) and instability of expanded alleles. The diagnostic test involves 3 components. A PCR reaction across the repeat identifies specimens that are heterozygous for normal alleles. Expanded alleles (often 20 to $>$ 44 kb in size) cannot be amplified in this reaction, so samples that appear homozygous in this initial PCR are tested on a genomic Southern blot and PCR-based repeat assay. On genomic Southern blots, the instability of expanded alleles often leads to diffuse weak signals that span a broad size range and/or exhibit multiple band sizes. In order to maximize detection sensitivity, a DM2 repeat assay was developed by Ranum et al. (*Neurology* 58: Suppl:A317, 2002) to detect PCR products that extend partially across a long repeat region. In the repeat assay, a primer with the DM2 repeat sequence on the 3' end hybridizes every 4 base pairs along an expanded repeat to generate a broad size range of PCR products (300 to $>$ 1000 bp) that are otherwise completely absent when only normal alleles are present. Evaluation of the repeat assay PCR products by capillary electrophoresis is fast and provides high resolution, but the signals from expanded alleles gradually fade as PCR product sizes exceed about 400 bp. Detection of the same PCR products by Southern blotting and hybridization with a secondary DM2-specific oligo reveals products of much larger size ($>$ 1000 bp) and simultaneously confirms DM2 specificity. Clinical use of the diagnostic assay at Athena Diagnostics, Inc. began in May 2002. We present a summary of results on specimens submitted for clinical testing to determine (1) the number and size of expansions detected, (2) the relative proportion of DM2 to DM1 expansions, and (3) how the genomic Southern blot and repeat assay compare for detection of expanded alleles.

Program Nr: 1278 from 2002 ASHG Annual Meeting

Automated PCR Clean-Up Using the Novel Vacuum Drive Ultrafiltrations System Nucleofast. *T. Zinn, U. Schuebel, F. Hecht, M. Sieber.* Macherey-Nagel GmbH & Co. KG, D52355, Dueren,.

AUTOMATED PCR CLEAN-UP USING THE NOVEL VACUUM DRIVEN ULTRAFILTRATION SYSTEM NUCLEOFAST Thomas Zinn, Ulrich Schuebel, Frank Hecht, Manfred Sieber MACHEREY-NAGEL GmbH & Co. KG, D-52355 Dueren, Germany

Microarrays are a convenient tool for parallel analysis of gene expression. A flexible approach to investigate gene expression is the use of immobilized PCR products on microarrays. Nucleic acid purification is often the limiting step for manufacturing microarrays. The use of vacuum driven purification systems is a convenient method for automated high-throughput sample preparation.

The novel MACHEREY-NAGEL NucleoFast system for automated DNA purification provides a highly flexible purification system based on ultrafiltration. During the NucleoFast PCR 96 procedure, PCR products are transferred to a filter plate with a unique ultrafiltration membrane. Primers, non-incorporated nucleotides, and salts pass the membrane under vacuum or centrifugation while desired PCR products are retained by the membrane. Purified PCR products are resuspended and removed from the membrane. The membrane is optimized for recovery of PCR products >150 bp and shows a reproducible recovery of 50 - 95 %; for PCR fragments from 150 bp to 10 kbp. Furthermore, the permanently hydrophilized membrane shows no leaking of detergents which may have an effect on DNA spot morphology. The unique membrane allows easy removal of purified samples, even when touched with robotic tips or needles. The one-piece plate allows use under vacuum or in a centrifuge without breakage. Purification of 96 samples can be carried out in under 20 min.

In this presentation we show examples for automated PCR clean-up using NucleoFast 96 PCR on different robotic instruments. Sequencing and microarray data is presented.

Program Nr: 1279 from 2002 ASHG Annual Meeting

AUTOMATED GENOMIC DNA PURIFICATION FROM BIOLOGICAL FLUIDS. *C. Poggel, T. Zinn, U. Schuebel, F. Hecht, M. Sieber.* MACHEREY-NAGEL GmbH & Co. KG, D-52355 Dueren, Germany.

AUTOMATED GENOMIC DNA PURIFICATION FROM BIOLOGICAL FLUIDS Carsten Poggel, Thomas Zinn, Ulrich Schuebel, Frank Hecht, Manfred Sieber MACHEREY-NAGEL GmbH & Co. KG, 52355 Dueren, Germany

Clinical diagnostics require solutions for high-throughput DNA template preparation. MACHEREY-NAGEL has developed a method for fully-automated purification of up to 10 g of genomic DNA from up to 200 l whole blood or other biological fluids, starting with the blood tube and ending with highly pure genomic DNA in a 96-well format.

The Robot 96 Blood kit of MACHEREY-NAGEL adapted for use on all common liquid handling instruments provides a highly flexible purification system to the user, and ensures high reproducibility of DNA yield and purity. EDTA, citrate or heparine treated blood or frozen blood can be used. Genomic DNA purification is achieved after cell lysis and adsorption of nucleic acids in the presence of chaotropic salts to a DNA binding matrix. The proteinase K treatment is sufficient at room temperature. A processing under centrifugation is not required. Contaminants are removed by subsequent washing steps. Finally, highly pure genomic DNA (A_{260}/A_{280} : 1.8-1.9) is eluted from the matrix with low-salt Tris-buffer and can be used for downstream applications like PCR, TaqMan, Light Cycler, Southern Blot, and restriction analysis directly. Genomic DNA can be isolated with MACHEREY-NAGELs Robot 96 Blood kit in a 96-well format and even in multiples of 96. The system is free of cross-contamination, as shown by PCR. Integration of a gripper and shaker tool allows the fully automated nucleic acid purification without manual interactions.

Development of an inner ear cDNA microarray. *A.B.S. Giersch^{1,3}, K. Lyall¹, S. Hamaker¹, B.J. Quade^{1,3}, C.C. Morton^{1,2,3}.* 1) Department of Pathology, Brigham & Women's Hospital, Boston, MA; 2) Department of Obstetrics, Gynecology, and Reproductive Biology, Brigham & Women's Hospital, Boston, MA; 3) Harvard Medical School, Boston, MA.

A variety of techniques are available for detecting gene expression levels, including sequencing of cDNA libraries and analysis of Northern blots. Both techniques have been used by our research team to study individual mRNA abundance in the human inner ear. However, both techniques are limited by their inability to look at multiple messages simultaneously and under a variety of conditions.

In order to analyze transcriptional profiles of thousands of cochlear mRNAs simultaneously, we are developing a human and mouse inner ear cDNA microarray. None of the cDNA microarrays or oligonucleotide chips that are commercially available contain a collection of human and mouse cochlear ESTs. Over the past several years, more than 15,000 human cochlear ESTs have been created from the Morton human fetal cochlear cDNA library and deposited in GenBank. Over 9,000 ESTs have been generated from the mouse organ of Corti cDNA library created in the Kachar lab at NIDCD/NIH. At least one copy of each gene represented among all the human cochlear and mouse organ of Corti cDNAs will be included on the final microarray. Also included will be at least one cDNA of each known deafness gene, as well as appropriate controls. In total, there will be over 5,400 mouse organ of Corti genes and over 4,400 human cochlear expressed genes present. Up to 10% of these transcripts may be cochlear specific. We will present an update of the progress of the cochlear cDNA microarray development and preliminary data on hybridization results using a variety of human and mouse tissues.

This work is supported by NIH/NIDCD grant DC03402 to CCM and an NOHR research award to ABSG.

Modeling and Identification of Genetic Networks. *M. Xiong.* Human Gen Ctr/Houston HSC, Univ Texas, Houston, TX.

Modern biology will increasingly require quantitative analysis of the complex behavior of cellular systems and biochemical pathway. The identification and modeling of large and complex genetic networks (or pathways) are important steps toward this goal. The systematic approach provided by statistical and computational modeling and analysis has become central to unraveling genetic networks underlying biological processes. The widely used methods for construction of genetic networks have been a bottom-up approach and a top-down approach. In a top-down approach the models which can reproduce the data are constructed based on the variables measured in the whole system. This approach is gaining increased interests due to microarray technology and large-scale gene expression data. Due to the complexity of the genetic networks and experimental limitation, to precisely identify the genetic networks, which describe the direct activation and inhibition of the genes, is difficult to achieve. In this report, we present a modified concept of genetic networks which describe the quantitative relationships between genes in a broad sense and develop a mathematic framework for their modeling and identification. We provide (1) mathematic representation of genetic networks, (2) statistical methods for estimation and testing of the parameters in the models, (3) probabilistic criteria for assessments how well the models of the genetic networks explain observed data and (4) the optimization procedures for searching structure of the genetic networks. The proposed model and computational algorithms will be applied to several real data sets. The preliminary results show that the reconstructed genetic networks are consistent with the experiments.

Discovering of human cancer-related genes by EST cluster-sorting approach. *A.V. Baranova¹, D.V. Lobashev¹, D.V. Ivanov¹, L.L. Kroukovskaya², N.K. Yankovsky¹, A.P. Kozlov².* 1) Genome Analysis Lab, Vavilov Inst General Genetics, Moscow, GSP-1, Russia; 2) Biomedical center, Research Institute of Pure Biochemicals, St.Peterburgh, Russia.

Comparing patterns of gene expression in different cell lines and tissues has important applications for a variety of biological problems. Developing a computer-based procedures for subtraction of different EST pools instead of traditional experimental approaches is an attractive way to compare expression profiles. We have developed a program called HSAlyst to classify data from original dbEST and UNIGENE databases in a table form. HSAlyst software is able to arrange EST data according to any given parameter, e.g. tissue type or the number of ESTs contained in a cluster. We have tried to implement CDD approach to the searching of the human tumour-specific genes which can serve as a putative tumor markers. We performed a differential displaying of all available tumour libraries against all available normal libraries instead of pairwise comparison of each tumour and corresponding normal tissue. A comparison between the expected and observed tumor-derived EST contents shows that found tumor-related clusters are not accidental but represent a natural phenomenon. Totally 195 tumour-related clusters were found. 97 of them do not contain easily recognized open reading frames. They may be considered as an evidence in favor of the expression of newly evolved DNA sequences in tumour cells or as a manifestation of the phenomenon of the background or illegitimate gene expression, which may be enhanced in tumour cells due to deregulation of the house-keeping processes. Other 98 clusters are encode protein that can have tumor-related function. At least six of them represent well-established tumor markers, e.g. MAGEs and cancer-testis antigens. We have probed a subset of EST clusters found by HSAlyst software by both confirmatory RT-PCR and Northern experiments. The results are reassuring as mRNA corresponding to one of the probed clusters, Hs. 133294, shows an expression in four different tumour cell lines but in none of the 16 normal tissues included in MTN blot.

Analysis of the human and mouse full-length cDNA clone sets generated by the NIH Mammalian Gene

Collection. *L.H. Grouse*¹, *MGC Project Team*². 1) National Cancer Institute, NIH, Bethesda, MD; 2) Multi-Institution NIH Supported Project.

The NIH Mammalian Gene Collection (MGC) was launched two years ago with the goal of identifying and sequencing a full open reading frame (ORF) clone for each human and mouse gene. To support this goal the MGC has produced cDNA libraries from more than 100 human cell lines and tissues and 30 mouse tissues. Standard, normalization and size-selected methods are being used to produce libraries enriched for full-length clones. Initially, several hundred 5' ESTs from each library are generated and assessed to estimate the fraction of full-ORF clones and gene diversity within a library. For libraries that have a high percentage of full-ORF clones, an additional 10,000 5' ESTs are then generated. A set of algorithms, developed for the MGC, is used to analyze these ESTs for the presence of the 5' most end of an ORF. This analysis includes comparison of the MGC ESTs to the sequences of known or predicted proteins and intrinsic properties that indicate transitions between coding and non-coding sequences. Putative full-ORF clones are then sequenced to high quality and analyzed for the presence of complete ORFs. To date, approximately 65 % of the sequenced clones were found to have complete ORFs. Currently the MGC has generated approximately 8,500 human and 6,500 mouse verified full-length clones and additional putative full-ORF clones have been selected for full-insert sequencing. A list of the full-length verified genes, as well as a list of MGC libraries can be viewed on the MGC web site (<http://mgc.nci.nih.gov>.) Analysis of 5,602 of the human verified MGC full-ORF clones, revealed that for 856 of these genes, the MGC was first to provide the complete gene sequence and full-ORF clone. All full-ORF sequences and clones generated by the MGC are available to the research community through public molecular databases and clone distribution networks.

Program Nr: 1284 from 2002 ASHG Annual Meeting

The Skeletal Gene Database: A comprehensive resource for skeletal gene information. *C.A. Francomano, N.C. Ho, S. Park, D. Dudekula.* Laboratory of Genetics, National Institute on Aging, Baltimore, MD.

The Skeletal Gene Database (SGD) has been expanded to include a comprehensive catalogue of all genes and expressed sequence tags (ESTs) from skeletal tissues in the NCBI databases. A total of approximately 80,000 ESTs from 301 libraries derived from cartilage, bone, bone marrow, synovium, chondrosarcoma and osteosarcoma are now included. The database is set up to search by NCBI accession number, chromosome location or by gene name. The preliminary search pulls up a screen offering links for the relevant gene, EST or chromosomal region to GenBank, UniGene, LocusLink, Online Mendelian Inheritance in Man (OMIM) and PubMed, allowing quick access to relevant genomic resources on the internet. Users may link directly to the SNP, SwissProt, gene ontology, EC and human chromosome mapping data sets for specific information about their gene or EST of interest. The Skeletal Gene Database may be accessed at the URL <http://sgd.nia.nih.gov> after August 1, 2002.

A functional genomics approach of multigenic Hirschsprung disease: comparative transcriptome expression of predicted and known genes in candidate intervals. *M. Clement-Ziza¹, T. Attié-Bittach¹, J. Amiel¹, J. Audollent¹, M. Vekmans¹, A. Chakravarti², A. Munnich¹, S. Lyonnet¹, C. Besmond¹.* 1) INSERM U393, Hopital Necker Enfants Malades, Paris, FRANCE; 2) Departement of Genetics, University Hospitals of Cleveland, Cleveland, Ohio 44106, USA.

Hirschsprung disease (HSCR), the most common hereditary cause of intestinal obstruction (1/5000), shows considerable variation and complex inheritance. HSCR is ascribed to an abnormal migration of the neural crest cells leading to the absence of enteric nervous system in the colon. The mutations identified in the RET, GDNF, EDNRB and SOX10 genes fail to explain the transmission of the most common form of the disease: short-segment HSCR. Recently, a large non-parametric study led to the identification of three susceptibility loci on 3p21, 10q11 and 19q12 respectively (Nat Genet. 2002; 31:89-93). RET, which maps to chromosome 10q11.2, is the major disease gene and accounts for largely 50% of mutations.

In order to identify the genes located at these loci and involved in the disease, we carried out a comparative transcriptome expression study of the genes included in the physical intervals defined by our non-parametric study. Known and predicted cDNA sequences, along with their structural and functional annotations (when available), were extracted from Ensembl and NCBI databases. These data were ordered according to objective criteria such as number of exons, location within the interval or functional annotation. Specific 50-mer oligonucleotides from the cDNA sequence of 700 genes were designed and spotted onto an aldehyde-coated slide in order to make an expression microarray.

We analysed the differential expression of these genes in HSCR vs normal colon, as well as in fetal gut tissues before vs after neural crest migration. The differentially expressed genes are candidate genes in HSCR.

Computational Analysis of Pharmacogenetic Variations. *A. Brower, F. Cao, B. Hurwitz, D. Machmeier, I. Trifunovich, B. Neri, L. Fors, V. Lyamichev, A. Lukowiak.* Bioinformatics, Third Wave Technologies, Madison, WI.

Pharmacogenetics provides the experimental framework for dissecting the effects of genetic variation on human drug response. The application of genetic variation profiles promises to foster the application of personalized medicine and to avoid the occurrence of adverse drug responses. Identifying the sequence variations that are involved in drug response is an important step in designing meaningful pharmacogenetic studies.

To date there are over 3 million sequence variations have been deposited in public databases as a result of the Human Genome Project, the SNP Consortium (TSC), the Japanese Millenium Project, and several other SNP discovery projects. Only a fraction of these variants may be important in the genetics of drug response. The current challenge is to identify a collection of variations for use in drug discovery, clinical trials, and association studies. We present a computational method that markedly accelerates these types of pharmacogenetic studies by integrating sequence variation with gene annotation & literature mining. Our approach uses novel algorithms applied to a curated set of Human genes and results in the annotation of over 50,000 variations in 1003 genes that are thought to be involved in drug response. The sequence variations were derived from various public sources such as NCBI's SNP database (dbSNP) & Online Mendelian Inheritance in Man (OMIM), Japan's JSNP, gene specific web resources, medical literature, as well as proprietary sources. All SNPs were mapped to the April 2002 hg11 human genome assembly (NCBI Build 29). Based on the mapped positions, SNPs were grouped into several functional locations that included locus, gene, CDS, intron, exon, and splice sites. The computational program facilitates the study design to focus on genetic variations that are predicted to make a functional impact on the protein product and/or on covering the genic region to capture haplotype information. This set has been used to populate panels of Invader® SNP assays targeted to address specific questions related to pharmacogenetics.

Program Nr: 1287 from 2002 ASHG Annual Meeting

Software Agent to Automatically Update Genomic Information. *D. Chen*^{1,2}, *H.F. Orthner*¹, *S.M. Sell*². 1) Health Informatics Program, Department of Health Services Administration, School of Health Related Professions. University of Alabama at Birmingham, Birmingham, AL, USA; 2) Genetic Core Facility, NIDDK-Clinical Nutrition Research Center, Department of Nutrition Sciences. School of Health Related Professions, University of Alabama at Birmingham, AL, USA.

The rapid growth of genomic information, especially genetic maps available from NCBI and various online sources raises questions about how to update them in a timely fashion. The objective of this study is to automatically retrieve, store and visualize the updated genomic information based on user preferences on genes, chromosomal locations and preferred sources such as National Center for Biotechnology Information (NCBI) MapViewer, Sanger Center, UC Santa Cruz (UCSC) Genome Browser and the Medline. The related topics or databases are visualized over the Web through the wired or wireless network. In our case, we focused on human chromosome 20 and mouse chromosome 2. We have developed a Medline searching agent called EZbutton that retrieves the above information in a predetermined schedule. The EZbutton was built on a personalized domain-specific vocabulary (PDSV) database that stores the user preferences. Web-based user and administrator interfaces were created to facilitate the user-friendly and individualized presentation and user account management. The preliminary results based on user satisfaction survey showed that the individualized information retrieval increased both efficiency and relevancy. We hypothesize that the Medline agent (EZbutton) has potential to be an efficient tool for genomic research scientists to get relevant information from various sources especially from the NCBI GenBank. (This project has been funded in part with funds from the NIH grants F38LM07185, P30DK056336 and R21HD040788).

Comparative analysis of SNPs to define a putative long-range control element. *Y. Chen, S.M. Sell.* Dept. of Nutrition Sci., Univ. of Alabama at Birmingham, Birmingham, AL.

Over 2.8 million SNPs have been submitted to the NCBI SNPs database (dbSNP). However, many more SNPs are still to be discovered, and the functions of most SNPs need to be identified. Conserved noncoding sequences (CNS) could play an important role in genetic control processes, although the precise role and mechanism are also poorly understood. VISTA (Visualization Tools for Alignment) is a set of tools for comparative genomics. It was designed to visualize long sequence alignments of DNA from two or more species with annotation information. Here we present an example. We analyzed a 100kb block of sequence upstream of a candidate gene for insulin resistance. The results show that most CNS peaks (25/32) contain SNPs. The distribution of SNPs is similar to the distribution of CNSs. We also analyzed a 10 kb sequence (30 kb-40kb upstream of the gene). For most CNS peaks (5/6), there exist SNPs. Also most SNPs (28 out of 30) are in a CNS region or within 500b of a CNS. Certain of these SNPs could play a very important role in the regulation of the candidate gene. We then checked the sequence of CNS for SNPs in our study population. Some new SNPs (UABSNP58, UABSNP57) in this area were verified. Among these SNPs, UABSNP58 has been shown to be associated with insulin resistance. This research can provide some background information for development of a tool to predict the existence and function of disease SNPs. This work was supported by funds from NIH grant DK056336.

Microarray analysis of a cell culture model of early onset dystonia linked to Torsin A mutations. *M.J. Baptista¹, C. O'Farrell², R. Ahmad¹, M.R. Cookson¹.* 1) Neurogenetics, NIA/NIH, Bethesda, MD; 2) Neurogenetics, Mayo Clinic, Jacksonville, FL, 32224.

Early-onset torsion dystonia is a movement disorder characterized by sustained muscle contractions and abnormal posture. A deletion in a conserved region of the torsinA gene, resulting in the loss of one of a pair of glutamate residues (DE302/303), has been detected in a large number of patients with chromosome 9-linked primary dystonia (DYT1). However, mutations in torsinA are not fully penetrant and some genetic heterogeneity has been noted, suggesting that additional genetic factor(s) may play a role in the development of this disease. The first aim of the current study was to use a cell culture model of torsinA over-expression to identify additional genes relevant to dystonia. The second aim was to identify genes whose expression is altered by torsinA in the hope of identifying novel markers of cellular dysfunction caused by the presence of these mutations. Clonal cell lines over-expressing either wild type torsinA or the DE302/303 mutation were generated by stable transfection of HEK293 cells. We measured torsinA expression using both RT-PCR and protein and identified several clones of both wt and DE302/303 with similar levels of expression. We then used the oligo-based U95A GeneChip (Affymetrix, Santa Clara, CA) to globally compare the expression levels of 12,500 non-redundant cDNAs and ESTs. Sixty-five probe sets were identified showing differential expression levels when compared to cells transfected with the empty vector. Of particular note are the family of heat shock proteins, and their transcription factor (hsf-2). While hsf-2 displayed a reduced expression, the expression of heat shock proteins 70 and 90 was increased approximately six fold. The microarray data will be confirmed by quantitative RT-PCR using SYBR green as a reporter. It is expected that identification of additional gene families regulated by over-expression of torsinA, both wild type and the DE302/303 mutation will provide additional information towards defining a pathway leading to dystonia.

Program Nr: 1290 from 2002 ASHG Annual Meeting

Mutation detection and candidate gene resequencing using the ABI Prism 3100-Avant Genetic Analyzer. K.

Gunning¹, R. Brugada², K. Hong², A. Oliva², K. Chansky¹, L. Joe¹, Q. Doan¹. 1) DNA Platforms Business Group, Applied Biosystems, Foster City, CA; 2) Masonic Medical Research Center, Utica, NY.

In order to determine the genes involved in autosomal dominant disease we require a flexible detection system capable of performing a variety of applications. The ABI Prism 3100-Avant Genetic Analyzer has proven to be an adaptable platform for generating data of the highest quality. We have used the instrument to generate both sequencing and fragment analysis data for our research endeavors in the area of cardiovascular disease. We have previously identified one gene responsible for Brugada syndrome on 3p, the cardiac sodium channel SCN5A. We have collected more than 200 probands and families with the disease. The analysis of segregation of new families with the locus is performed efficiently with the fragment analysis application. The analysis of the gene and mutation detection is powerfully enhanced by the higher throughput of the equipment and the availability of new software for sequencing comparison. The use of this capillary electrophoresis platform greatly reduces the degree of hands on time required and is a low maintenance system, allowing us time to perform the other tasks associated with the development of our research. Integration of SeqScape Software version 1.1 into our analysis pipeline has further advanced our research by providing a tool for data analysis. We will discuss the role of the ABI Prism 3100-Avant Genetic Analyzer, along with SeqScape Software v 1.1, in the human disease research laboratory for the purposes of mutation detection.

DNannotator: a web-based sequence annotation tool kit and its application on analyses of 13q32-33 sequence.

C.Y. Liu^{1,3}, T.I. Bonner², Y.W. Liu⁴, S.L. Christian¹, J.L. Lyons¹, E.S. Gershon¹. 1) Dept Psychiatry, Knapp Res Ctr, Univ Chicago, Chicago, IL 60637; 2) Laboratory of Genetics, National Institute of Mental Health, Bethesda MD 20892; 3) National Lab of Medical Genetics of China, Central South University, Changsha, P.R. CHINA; 4) Center for Human Genetics, Duke University Medical Center, Box 3445 Durham, NC 27710.

Annotated sequence is the basis of positional cloning and association studies searching for susceptibility genes, and it is also important for managing sequence-related data and guiding experimental design in "wet" labs. DNannotator, a web application, was designed to address the problem of automatic, customized, high-throughput annotation on sizeable genomic region. It simplifies sequence annotation, merging of annotation data and re-annotation when sequence is updated. DNannotator takes two basic approaches to annotation: 1) BLAST match-based approach that is based on the filtered BLAST matches of annotation source and target sequences; and 2) Direct parsing of outputs of third-party software such as e-PCR and Sim4. Annotation data are generated in Genbank format, along with a feature table in plain text format, which can be imported and managed in a user-preferred database or spreadsheet. Feature-related sequence fragments can be extracted from annotated sequences for further study or for annotation transfer. DNannotator was used to do de novo annotation for 43 known full-length genes and their 561 exons, 557 primers, 431 TSC SNPs and more than 400 STSs to 3 different versions of ~ 20 Mb genomic DNA assemblies of human 13q32-33. Annotations from NCBI build 27 were transferred to NCBI build 28 to demonstrate the functionality of preserving annotations in DNannotator. The results show that DNannotator is efficient and accurate. The quality of 4 gDNA assemblies of the same region is evaluated, based on the annotation results. The comparisons reveal a potential "in-region duplication" and "flip block" problem in current public draft sequence assemblies. Results provide a preliminary evaluation of these assembled sequences of this region, and a basis for searching for a susceptibility gene of Bipolar Disorder on 13q.

Program Nr: 1292 from 2002 ASHG Annual Meeting

Comprehensive Resource: The Cancer Genome Anatomy Project. *L. Jia, CGAP Project Team.* Office of Cancer Genomics, NCI/NIH, Bethesda, MD20892, USA.

The National Cancer Institute implemented the Cancer Genome Anatomy Project (CGAP) to create an information infrastructure of the genes associated with cancer development, and to develop technological tools to support the analysis of the molecular profile of cancer cells and their normal counterparts. The current CGAP program comprises Tumor Gene Indices for the human and mouse (hTGI and mTGI), a Genetic Annotation Initiative (GAI) and the Cancer Chromosome Aberration Project (cCAP). The TGI and GAI, are focused toward building a catalog of annotated genes associated with cancer. The third component, cCAP, is developing resources to catalog and facilitate the molecular characterization of cancer-related chromosomal aberrations. The presentation will highlight online tools for accessing the CGAP data as well as informatics tools for in silico analysis.

A computational/functional genomics approach for the identification of positional candidate retinopathy genes.

N. Katsanis¹, K.C. Worley², G. Gonzalez², S.J. Ansley¹, J.R. Lupski². 1) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Baylor College of Medicine, Houston, TX.

Grouping genes by virtue of their sequence similarity, functional association or spatiotemporal distribution is an important first step in investigating function. Given the recent identification of >30,000 human genes either by analyses of genomic sequence or derivation/assembly of ESTs, automated means of discerning gene function and association with disease are critical for the efficient processing of this large volume of data. We have designed a series of computational tools to manipulate the EST sequence database (dbEST) to predict EST clusters likely representing genes expressed exclusively or preferentially in a specific tissue. We implemented this tool by subtracting 40,000 human retinal EST sequences from a total of 1.4 million ESTs represented in over 100 tissues, and identified 925 ESTs likely to be specifically or preferentially expressed in the retina. Upon verification of the computational predictions by RT-PCR and microarray analysis with RNA from 24 adult and fetal tissues, we mapped the retinal-specific/predominant sequences in the human genome and produced a web-based searchable map of the retina transcriptome. To expedite the identification of disease-causing candidate genes, we incorporated into this map the positions of all mapped but uncloned retinopathy loci. This resource has provided positional candidates for 42/51 uncloned retinopathies and may expedite substantially the identification of disease-associated genes. More importantly, the ability to systematically group ESTs according to their predicted expression profile is likely to be an important resource for studying gene function in a wide range of tissues and physiological systems and to identify positional candidate genes for human disorders whose phenotypic manifestations are restricted to specific tissues/organs/cell types.

Evaluation of Gene Expression in Fetal Mice Molars through SAGE. *M.M. Michalec¹, M.J. Gorry², W. Wang², L. Lu², P.S. Hart¹, T.C. Hart²*. 1) Human Genetics, Univ Pittsburgh, Pittsburgh, PA; 2) Dept Oral Med/pathology, Univ Pittsburgh, Pittsburgh, PA.

Candidate gene studies of tooth defects are hampered by the fact that all gene in the development of teeth are not known. Serial analysis of gene expression (SAGE) is a robust method for global gene expression profiling. In order to catalog genes important in tooth development, a SAGE library was made using pooled fetal mice molars (14-18 days gestation) and the I-SAGE kit (Invitrogen). 5,000 clones were selected from the library for study. Of 57,477 tags sequenced, a total of 9925 unique tags were obtained (tags with hits of 2 or greater). Not surprisingly, the most highly expressed gene was amelogenin, a tooth specific gene highly expressed in enamel. Also highly expressed were collagen 1A1 and collagen 1A2 and dentin sialoprotein, all three proteins are known to occur at high amounts in tooth dentin. In addition, a large number of genes were identified that were not previously known to be expressed during tooth development. Comparison with available SAGE databases allowed the identification of several tooth-specific tags that presumably correspond to previously unknown genes. As it has become increasingly apparent that a given SAGE tag may correspond to more than one gene, we sought to verify tag identification through 3 methods: rSAGE, GLGI, and Western blot analysis. As an example, using rSAGE, we identified the highly expressed unknown TGGAAATGAC tag as myristoylated alanine rich protein kinase C substrate (Macs). This study will be useful in identifying genes involved in tooth development and patterning, as well as identifying candidate genes for genetic tooth defects, such as amelogenesis imperfecta.

Characterization of lung allograft rejection using microarray gene expression profiling. *J.D. Lande, V.J. Gimino, M.I. Hertz, R.A. King.* Medicine & Inst Human Genetics, University of Minnesota, Minneapolis, MN.

Obliterative bronchiolitis (OB) is a fibroproliferative process that blocks small airways and is the most significant limiting factor for long term survival of lung transplant recipients. Acute rejection, characterized by lymphocytic inflammation of small blood vessels and airways, is a major risk factor for chronic rejection. We are using oligonucleotide microarrays to identify reproducible patterns of gene expression that characterize acute and chronic lung rejection. Total RNA isolated from bronchoalveolar lavage (BAL) cells from lung transplant recipients (n=16) was processed and hybridized to U133A human GeneChips. Two different software applications were applied to estimate transcript abundance measurements: Affymetrix Microarray Suite version 5 (MAS 5), that calculates signal, which is applied to each array individually and can be compared if all arrays are scaled or normalized; and DChip, that integrates data from all arrays being compared for the calculation of model based expression index (MBEI), a measure of transcript abundance. The coefficients of variation ($CV = \text{standard deviation}/\text{mean}$) were calculated for both signal and MBEI. Those transcripts that were present in at least 20% (>3 of 16) of all arrays and having a $CV > 1$ were considered candidates. There were 177 candidate transcripts using MBEI to measure transcript abundance and 158 using Affymetrix signal. Of these, 97 transcripts were common between the two sets. Functional analysis of these common transcripts, using annotations from the Gene Ontology database, indicate that many of the genes expressed differentially across arrays are relevant to processes believed to be involved in the pathogenesis of acute and chronic rejection. Cluster analysis of these transcripts using Cluster (Eisen) suggest that much of the variation is due to two individuals with distinct profiles of genes that appear to be involved with immunological processes. Microarray analysis of RNA isolated from BAL samples of lung transplant recipients may be helpful in identifying genes related to lung transplant rejection.

Program Nr: 1296 from 2002 ASHG Annual Meeting

Genetic Control of Gene Expression: A study combining Gene expression with Genebased haplotypes in Immortalized B-cells. *B.T. Koshy, M. Kumar, A. Windemuth, K. Nandabalan, R. Judson.* Bioinformatics, Genaissance Pharmaceuticals, New Haven, CT.

Expression arrays provide a global view of transcriptional regulation. To derive meaningful biological insight about regulatory mechanisms, most published studies are limited to clustering genes with similar expression patterns. We use a novel approach that combines gene expression with gene based haplotypes to provide clues about genetic control of regulatory mechanisms in biochemical pathways known to operate in B lymphocytes. Using a statistical screening method called Ruler Finder that searches for associations between genetic markers and expression levels on a matrix of 5,500 gene-based haplotypes by 9,500 expression levels, we provide evidence for genetic control of previously recognized as well as novel regulatory elements in the NF-kB pathway. The power of our combined approach is that it provides evidence of the directionality of regulation within a pathway which cannot be deduced from expression clustering alone.

Program Nr: 1297 from 2002 ASHG Annual Meeting

Designing LIMS to bundle with high-throughput production systems for resale: Wildtype Linx™ lab tracking software and Illumina, Inc's BeadArray™ technology platform. *T.J. Stevens, J. Thompson.* Wildtype Informatics LC, San Diego, CA.

LIMS software bundled into a resalable high-throughput production system is subjected to very different demands than lab tracking software customized for a single lab's needs. Unlike a primary LIMS purchase, bundled LIMS arrives in the lab as one component in a proprietary package of SOPs, instruments, and automated liquid handling workstations. The purchasing lab's goal is to simply turn the key and start producing thousands or millions of data points as promised by the vendor.

We set out to design and build a LIMS software platform that would win over new owners of bundled high-throughput production systems, and still remain flexible enough to address the highly custom requirements of single-site LIMS projects. The result, Wildtype Linx, offers a long list of features including a high-performance Java and XML architecture, support for web browser clients, easy integration with robotic processors and other clients via XML over HTTP, sub-second response on most LIMS transactions, and few maintenance needs.

In this presentation, we evaluate how well Wildtype Linx has met its design goals in its first bundling, as a component in Illumina Inc.'s (San Diego, CA) world-leading throughput systems built on their proprietary BeadArray technology platform.

Program Nr: 1298 from 2002 ASHG Annual Meeting

Disordered Defensins and Perplexing Polymerases. *M.W. Wright, E.A. Bruford, R.C. Lovering, M.J. Lush, S. Povey, H.M. Wain.* HUGO Gene Nomenclature Committee, The Galton Laboratory, Department of Biology, University College London, Wolfson House, 4, Stephenson Way, London, NW1 2HE, UK. Email: nome@galton.ucl.ac.uk.

The HUGO Gene Nomenclature Committee (HGNC) strives to avoid confusion when talking about genes by creating a common nomenclature, so that each gene has its own unique symbol that everyone can recognise. This ongoing project has so far given approved symbols to almost 15,000 genes.

Many journals appreciate how important a common language is for enhanced communication, and The American Journal of Human Genetics, Annals of Human Genetics, Cytogenetic and Genome Research, Genomics, Human Mutation, Molecular Therapy, Nature Genetics and Radiation Research actively support our efforts by insisting that authors only use HGNC approved symbols. However, there is plenty of room for improvement by other genetics journals; each year several new genes are published with a variety of different names, and different genes are published with the same name. Promisingly, the need for standardisation is being recognised by the community, as more and more authors publishing in other journals contact us prior to publication, because they want their work to be readily accessible via the use of approved symbols in the public databases. To this end we edit Genew our online nomenclature database (<http://www.gene.ucl.ac.uk/nomenclature/>), and NCBI's LocusLink (<http://www.ncbi.nlm.nih.gov/LocusLink/>), and this information proliferates to many other databases.

With the help of the genetics community, we have recently resolved the very perplexing polymerases and the disordered beta defensins, along with other examples of gene confusion as we will show.

The work of the HGNC is supported by NIH contract N01-LM-9-3533 (60%) and by the UK Medical Research Council (40%). Please come and see us at the Nomenclature Booth.

Program Nr: 1299 from 2002 ASHG Annual Meeting

Bioinformatics for DHPLC. *P.D. Taylor, Y. Lui, G. Narayanaswami, M. Piff.* Dept R&D, Transgenomic, Inc, San Jose, CA.

The procedural flow for DHPLC can be described as: a)genomic context selection, b)amplicon design, c)sample preparation, d)data acquisition, e)data analysis, f)confirmation of polymorphism, g)archiving of results and finally, h)application of results. Using the data acquisition step d as the center, the steps a-c may be termed pre-processing and the steps e-h may be termed post-processing. This work describes some of the problems encountered during pre- and post-processing of many DHPLC studies and the solutions and recommendations developed. A small Microsoft SQL Server 2000 database was developed to contain the selected contexts and annotations including intron/exon boundaries. Target sequences are retrieved from the database, submitted to PCR design and the melting properties scanned for DHPLC suitability. Amplicons can be redesigned in-silico and finally added to the database along with the melting properties and PCR annealing conditions. After sample preparation and data acquisition the traces are grouped and results displayed as a scattergram. When groups containing the mutations have been confirmed by sequencing, a number of SQL stored procedures in the database assist with the correct annotation of the fragment and mutation with minimal manual intervention. There is a clear need for database tools which ease the process of SNP data entry and check for inconsistency in the information both during and after input.

Primer Design and Marker Clustering for multiplex primer extension SNP genotyping assay using statistical modeling. *A. Yuryev, J. Kuebler, M. Donaldson, K. Scott, J. Studebaker, J. Huang, M. Pohl, M. Boyce-Jacino.* Bioinformatics & Genetics, Orchid Biosciences Inc, Princeton, NJ.

The size of SNP genotyping projects is rapidly expanding as more information is gathered to prove the utility of SNP markers in association studies, linkage studies and mapping projects. Methods of reducing cost and increasing genotyping throughput are required in order to take full advantage of SNP markers in the genome studies. One strategy is to multiplex the genotyping reactions. We have successfully demonstrated multiplexing SNP-IT in groups (multiplex fold) of 12 and 24 markers. Using data collected from multiplex studies, we have developed a statistical algorithm that is used to design assay primers and group SNP markers together in a cluster. This algorithm has enabled us to improve our success rate of multiplexing (number of valid assays per cluster) from 75% to 96%. Our clustering algorithms are reminiscent of two major classes of clustering algorithms: hierarchical and non-hierarchical. The statistical model for multiplex SNP-IT reaction was developed using logistic regression analysis and a set of 23,525 SNP markers. The set had both successfully genotyped (passed) markers and failed markers. The model was trained to distinguish failed and passed markers by assigning them the failure probability score in the range of 0 to 100%. The model calculates the failure probability of individual SNP markers based on the internal marker sequence characteristics and external interference from other markers in a multiplex cluster. The combination of external statistical scores contributing to the multiplex model was chosen as minimization function for clustering algorithms. The first clustering algorithm randomly exchanges markers between clusters and accepts only those marker swaps that decrease the combined failure rate of two multiplex clusters. The second algorithm does pair-wise clustering of markers and smaller size marker clusters until the necessary cluster size (equal to multiplex fold) is reached. Based on the average failure probability, we found that random clustering performs better for most of the marker sets.

Program Nr: 1301 from 2002 ASHG Annual Meeting

Integrating Genomic Laboratory Data with Whole Genome Annotation Using Ensembl-DAS. *H. Xu, J.M. Vance, J.E. Stenger.* Center for Human Genetics, Duke University Medical Center, Durham, NC.

We have developed perl programs to integrate our laboratory data into a local version of Ensembl with the distributed annotation system (DAS) developed by Dowell, Eddy and Stein. Ensembl is open source and was set up on our local server using instructions provided at ensembl.org. The DAS database has one table to hold genomic locations for all DAS features. Each type of DAS features has one or more tables to hold the detail information. DAS features are linked to their genomic location through their IDs. There are several tables containing internal research project information and external database information. DAS features are also linked to project and external database information through their IDs. Data that we have already included are genetic linkage, variation, microarray, and serial analysis of gene expression (SAGE). They were mapped to human genome assembly through three-stage pipeline: First, database lookup located experiment features that were already mapped in public genome annotation databases. If the experiment features have known IDs, such as GenBank accessions, HUGO gene symbols, or genetic marker names, the IDs were used to query local Ensembl, NCBI, or UCSC tables to get their genomic locations. If no location can be found, those features were passed to the next stage. Next, electronic PCR located features that have PCR primers available. If the experimental features have PCR primers and PCR fragment size, they will be mapped to human genome by electronic PCR. If no location can be found, those features were passed to the next stage. Thirdly, BLAT located features that have sequences available. If the experimental features have surrounding sequence information, they will be put into a FASTA format file. Then this file will be used as query for a BLAT search of the human genome assembly. All the feature locations were put into DAS database. The feature information is parsed to put into DAS tables as well. Finally local Ensembl displays our experimental features in a contig view of the human genome.

Program Nr: 1302 from 2002 ASHG Annual Meeting

A comparison of software tools for comparative sequencing. *J.M. Sorenson¹, K. Gunning¹, S. Kumar¹, Q. Doan¹, P. Suri¹, R. Paul¹, A. Pradhan¹, P. Honebein², G. Denisov⁴, M. Schoppe³, A. Pronyaev³, L. Johnston-Dow¹.* 1) Applied Biosystems, Foster City, CA; 2) Systems Integration Solutions, San Francisco, CA; 3) Group Logic, Arlington, VA; 4) Paracel Inc., A Celera Business, Pasadena, CA.

The release of version 1.1 of SeqScape™ software marked the introduction of basecalling quality values and assembly-based SNP identification into a desktop comparative sequencing software tool. SeqScape™ software is compatible with Windows NT®/Windows® 2000 OS and contains fully integrated basecalling, trimming, sequence assembly, alignment, and sequence comparison tools for fast and accurate sequence comparisons and variant identification. We present here a comparison of the features, ease of use, and robustness of algorithms between SeqScape™ software and other available comparative sequencing software tools. We also critically evaluate the accuracy of analysis results from SeqScape™ software version 1.1 versus Sequencher™ software. Highlights are presented of new algorithm features in development for the next version of SeqScape™ software, including the ability to detect and identify heterozygous frameshift mutations using direct sequencing.

Use of a custom oligonucleotide microarray to study imprinting in the mouse CNS. *V.L. Buettner*¹, *M.E. Barish*², *J.A. Longmate*³, *J.R. Mann*¹, *J. Singer-Sam*¹. 1) Division of Biology, Beckman Research Institute, Duarte, CA 91010; 2) Division of Neurosciences, Beckman Research Institute, Duarte, CA 91010; 3) Department of Biostatistics, City of Hope National Medical Center, Duarte, CA 91010.

Imprinted genes play an important role in mammalian growth and development and are known to be involved in certain genetic disorders of the CNS [i.e., Prader Willi and Angelman syndromes(PW/AS)]. There is, however, no rapid assay for imprinting or for the identification of novel imprinted genes. We have developed an oligonucleotide microarray-based assay using mice carrying maternal or paternal duplications of chromosomal regions of interest. As a model system, we are analyzing RNA from brain tissues of neonates carrying only maternal or paternal copies of proximal chromosomes 7 and 15 (the T9H translocation), including the region of chromosome 7 corresponding to human PW/AS. The custom array contains probes for housekeeping genes, known imprinted genes and an additional ~300 CNS-enriched genes critical for neurotransmission and/or mapping to proximal 7 or 15. Prior to microarray analysis, we compared mat7dup and pat7dup RNA from neonatal cerebellum, cortex, prefrontal cortex, and diencephalon by use of quantitative RT-PCR to verify imprinted expression of the known imprinted genes included on the array: *Ndn*, *Snrpn*, *Zfp127*, *Ipw*, *Magel2*, *Peg3* and *Ube3a*. Comparing these RT-PCR results with those obtained by microarray analysis, we found that sensitivity of the microarray varies depending upon the brain region analyzed, an important factor being tissue-specific background values. The most abundantly expressed imprinted genes, *Ndn*, *Snrpn* and *Ube3a*, were detectable in all brain regions analyzed while genes expressed at a lower level were most easily detectable in cerebellum and cortex. We have found no evidence for imprinting of any of the genes that map to proximal chromosome 7 or 15, nor of secondary effects of the chromosomal duplications on unlinked genes involved in neurotransmission.

Analysis of the human phenome by clustering xenoscapes in *Drosophila*. E. Bier, L. Reiter. Cell and Developmental Biology, Univ. of Cal., San Diego, La Jolla, CA.

A variety of seemingly dissimilar phenotypes can result from various mutations in the same human gene or by inappropriate spatial or temporal expression of that gene. We refer to this array of phenotypes as the phenoscape of a gene and the genome wide collection of phenoscapes as the phenome. With the advent of GAL4/UAS misexpression system in the model organism *Drosophila melanogaster* it is possible to create a genome wide collection of xenoscapes, or the set of *Drosophila* loss-of-function and misexpression phenotypes generated for all human genes. Although the *Drosophila* xenoscape of a human gene may bear little if any resemblance to the phenoscape of that gene in humans, we suggest that clustering human genes based on *Drosophila* xenoscapes of normal and mutant forms of human genes should result in a grouping of human genes into coherent functional subsets, and may provide valuable information for the eventual assembly of the human phenome. The ability to screen for multiple dominant alleles of a gene of interest in *Drosophila* using the recently devised NOVA method on human transgenes should greatly increase the informational content of particular xenoscapes. This type of semantic translation between *Drosophila* and human phenoscapes can already be applied to known homologous pathways like the Notch signaling pathway and herein we discuss how it might be used to identify new genes involved in identifying cardiac disease candidate genes. We also discuss the importance of creating controlled vocabularies to define phenoscapes for comparisons between species.

Identification of differentially expressed genes during development of cardiac hypertrophy in rat by subtractive hybridization. *T. Hahn, D. Schlote, I. Hansmann, M. Schlicker.* Institut fuer Humangenetik & Medizinische Biologie, Halle (Saale), Germany.

Cardiac hypertrophy is an adaptive response to chronically increased workload. It appears to be associated with altered gene expression leading to cardiomyopathy and heart failure. To identify candidate genes contributing to the initiation or progression of cardiac hypertrophy we have screened differential gene expression in the heart of spontaneously hypertensive rats (SHR) at different stages of their development. During first weeks after birth the SHR rats are normotensive. Males first develop hypertension around 12 weeks pp and hypertrophy of the left heart ventricle around 26 weeks pp. We established a subtractive hybridization and cDNA cloning system based on cDNA selection and suppression PCR using mRNA from these stages. Subtractive hybridization using age groups 4- versus 12- as well as 12- versus 26-weeks identified 145 different cDNA clones. Screening of these clones revealed 56 cDNAs as candidates for differentially expressed genes during development to cardiac hypertrophy. Northern blot analysis of 42 cDNAs identified 16 genes to be upregulated in cardiac tissue of SHR in comparison to the wild type Wistar-Kyoto rat. In silico analysis of cDNA sequences identified several known genes which are being discussed already in the context with cardiomyopathy (g-sarcoglycan) or cardiac hypertrophy (acyl-coA dehydrogenase) which can be used as an argument in favor of the validity of our concept. In addition to these genes our analysis revealed so far 8 novel genes which are differentially expressed in the heart of SHR. Mapping of these novel genes with respect to rat chromosome segments harboring known QTLs for cardiac hypertrophy and analysis of their expression pattern might be relevant to understand processes leading to cardiac hypertrophy in rat and man.

ELUCIDATION OF PATHOGENIC GENETIC PATHWAYS IN THE HYPERTROPHIC AND FAILING HEART BY MICROARRAY TECHNOLOGY. *H. Smeets*^{1,2}, *B. Van den Bosch*^{1,2}, *S. Van der Vlies*^{1,2}, *J. Geurts*^{1,2}, *I. De Coo*³, *H. Scholte*³, *D. Lips*², *P. Doevendans*². 1) Dept Genetics & Cell Biol, Univ Maastricht, Maastricht, Netherlands; 2) CARIM, Univ Maastricht, Maastricht, The Netherlands; 3) Dept Pediatric Neurology and Biochemistry, Erasmus University, Rotterdam.

Gene expression differences between normal, hypertrophic and failing heart may provide therapeutic targets for interventions in patients. To circumvent the complexity and scarcity of human biopsies, we used inbred mice, in which Transverse Aortic Banding (TAC) was applied to induce cardiac hypertrophy, followed by heart failure. Left ventricle RNA of these mice and controls (48 hours, 1, 2, 3,6 and 8 weeks after operation) was labeled with Cy3/Cy5 (indirect amino-allyl-labeling) and hybridized to microarrays containing ~4,000 cDNA clones derived from adult and fetal mouse heart. Experiments were performed in quadruplicate, using at least 3 mice per time point. Scatter plots showed that expression levels of the majority of genes was unaltered. Known hypertrophy markers (f.e. betaMHC, ANP, SPARC, CARP) were elevated as expected. Initial results showed >2-fold altered gene expression of a number of unknown and known genes, including connective tissue growth factors, imprinted mesoderm specific embryonic genes and calcineurin-interacting proteins in the hypertrophic myocard after 7 days. Specific mitochondrial genes displayed a decrease after 42 days, when heart failure could be observed. Gene expression changes were confirmed by quantitative PCR and related to functional changes, in the latter case for example by measuring respiratory chain enzyme activities. Our next step will be to test the differentially expressed genes in human biopsy specimens of non-diseased, hypertrophic and failing myocard. The newly identified genes will be evaluated for a role in familiar hypertrophic or dilated cardiomyopathy by their map position and segregation in families.

Clinical and molecular delineation of the 22q11 deletion syndrome. *E.H. Yeon¹, E.J. Seo^{1,2}, M.J. Park¹, S.M. Park¹, Y.O Yoo¹, Y.H. Kim^{1,3}, J.K. Ko^{1,3}, H.W. Yoo^{1,3}, I.S. Park^{1,3}.* 1) Genome Research Center, Asan Medical Center, Seoul, Korea; 2) Dept. of Clinical Pathology, University of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea; 3) Dept. of Pediatrics, University of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea.

The 22q11 deletion syndrome is the most common genomic disorder on 22q11 caused by chromosomal rearrangements. The main clinical findings include characteristic facial appearance, velopharyngeal insufficiency, conotruncal heart defects, thymic hypoplasia or aplasia, and hypocalcemia. More than 90% of patients with 22q11 deletion have a similar 3-Mb hemizygous deletion, and 7 % of deleted patients have a nested distal breakpoint resulting in a smaller 1.5-Mb deletion. With the deletion of large genomic region, altered dosage of several contiguous genes is responsible for their etiology. To define the deletion boundaries and evaluate if the size of the deletion is correlated with the degree of severity of the phenotypes, we examined the genotype of the deletion and clinical features from 46 patients with the 22q11 deletion syndrome. Copy number to detect haploinsufficiency was analyzed in nine genes which are located within or in boundaries of 22q11 deleted region. These were CECR6, TUBA8, DGCR6, TUPLE, TBX1, COMT, MAPK1, VPREB1 and BCR. By using TaqMan probes specific to each genes, copy number of each gene was quantitated with a real-time PCR assay. The deleted maps in all of the patients were defined and compared with their clinical features. Twenty-five percents of patients had a smaller deletion spanning from TUBA8 to COMT. And we were unable to find any correlations between the size of the deletion and the phenotypic severity.

Identification of a gene as a candidate for involvement in the aetiology of premature ovarian failure. *S. Burnham*¹, *M. Waters*¹, *J. Wood*², *D. Vetrie*³, *E.M. Kendall*¹. 1) School of Biology, University of Leeds, Leeds, England; 2) Guys Hospital, Sts Thomas Street, London, England; 3) The Wellcome Trust Sanger Centre, Hinxton, Cambridge, England.

Premature ovarian failure affects approximately 1% of the female population. Several different types of chromosomal rearrangements have been described in patients with premature ovarian failure, these include deletions, X:Y translocations and X:autosome translocations. In 1998, Bione et al published details of a gene disrupted by the breakpoint of a X:autosome translocation in which the patient suffered from premature ovarian failure. The gene involved being the human homologue of the *Drosophila* diaphanous gene, mutations of the diaphanous gene are responsible for sterility in the fruit flies. Other genes have since been identified as candidates for involvement in the aetiology of premature ovarian failure by the virtue of their being located at translocation breakpoints of other patients, these include XPNPEP2 and FOXL2. We have been studying the location of the breakpoints of two further patients with balanced X:autosome translocations, the breakpoints being located in Xq21.3 and Xq22.3. We have narrowed down the positions of the breakpoints by using a series of methods including restriction mapping, the production of sub-clones, vectorette-PCR and Southern hybridisations. Sequence produced in this way has been compared with the public databases to identify transcripts from within the regions. The searches of the databases identified a gene which is disrupted by the translocation breakpoint of one of the patients we have been studying. We have performed RT-PCR using ovary RNA and have shown that this gene is expressed in the ovaries. We propose that this is another candidate gene for involvement in premature ovarian failure.

Human chromosome 21 gene expression atlas in the mouse. *V. Marigo*¹, *A. Reymond*², *M.B. Yaylaoglu*³, *A. Leoni*¹, *C. Ucla*², *N. Scamuffa*², *C. Caccioppoli*¹, *E.T. Dermitzakis*², *R. Lyle*², *S. Banfi*¹, *G. Eichele*³, *A. Ballabio*¹, *S.E. Antonarakis*². 1) TIGEM, Naples, Italy; 2) Division of Medical Genetics, Geneva University Medical School, Geneva, Switzerland; 3) Max Planck Institute of Experimental Endocrinology, Hannover, Germany.

The study of gene expression patterns is of crucial importance to the understanding of gene function. We set out to systematically analyze the expression patterns of genes from an entire chromosome. We chose human chromosome 21 (HC21) because its entire finished nucleotide sequence was available. Furthermore trisomy 21 (Down syndrome, DS) is the most common genetic cause of mental retardation. This chromosome-based approach has advantages over the study of an arbitrary set of genes, as it provides information on the consequences of aneuploidy, and may allow the identification of clusters of co-regulated genes. All identifiable murine orthologs of human chromosome 21 genes (161 out of 178 confirmed human genes) were analyzed by RNA in situ hybridization on whole-mounts (E9.5, E10.5) and tissue sections (E14.5), and by RT-PCR on adult tissues. These stages correspond to mid and late embryonic and fetal human periods, when the major organs and body regions are organized. Patterned expression was observed in several tissues including those affected in trisomy 21 phenotypes (i.e. CNS, heart, gastrointestinal tract, and limbs). Furthermore, statistical analysis suggests the presence of clusters of genes with significant patterns of either coexpression or lack of expression in specific tissues. The entire data set was incorporated in a web site that will be made available to the scientific community. This high resolution expression "atlas" of an entire human chromosome is a new level of gene annotation, which is likely to advance our knowledge on gene function and regulation and to the understanding of human aneuploidies, such as DS.

Characterizing the D21Z1 alphoid junction regions in the centromere of human chromosome 21. *M.R. Bozovsky¹, M.J. Roy¹, M. Flisak¹, J. So¹, M.R. Cummings², J.L. Doering¹*. 1) Dept. of Biology, Loyola University Chicago; 2) Dept. of Biological Sciences, University of Illinois at Chicago.

Centromeric and other heterochromatic regions are not included in the human genome sequence, although they comprise 10-15% of the genome. Sequences required for a fully functional centromere have not been fully defined, but alphoid repetitive sequences clearly play a role. We have constructed a detailed physical map of the centromere of chromosome 21 by direct pulsed field mapping. This map is linked to the q arm by the marker D21S190. The major centromeric alphoid cluster, D21Z1, is a 1.0 Mb long homogeneous array. A 0.3 Mb long satellite I cluster is located 0.25 Mb from the p arm end of D21Z1, and a TPTE gene is 0.3 Mb from the p arm end of the satellite I cluster. Characterizing the ends of the D21Z1 cluster may clarify evolutionary events in centromere formation and identify sequences potentially important for centromere function. The p and q arm ends of D21Z1 have distinctly different restriction maps, indicating the edges of the array do not have the similar organization predicted by the out-of-register recombination model for alphoid cluster evolution. BAC clone 21B49A22, the last clone in the q-arm sequence, spans an alphoid junction region containing non-repetitive DNA adjacent to 31.2kb of alphoid DNA. Analysis of this alphoid DNA shows no evidence of any of the regular repeating restriction sites or CENP-B boxes characteristic of higher-order alphoid repeats. Dot-plot analysis further indicates that this is monomeric alphoid DNA. The entire length of this region has a uniform 77-79% sequence similarity to D21Z1. The monomeric sequence forms an evolutionary clade distinct from D21Z1 and may contain chromosome specific sequences. We searched 1kb intervals of the monomeric alphoid DNA for regions with low similarity (<90%) to others in the current NCBI database, and identified several regions as putatively chromosome specific based on BLAST results. A chromosome 21 specific centromeric marker would be useful to definitively score parent of origin and stage of meiosis of a nondisjunction event or diagnose aneuploidy.

Evolutionary transposition of 4 unique genes mediated by flanking duplicons in the Prader-Willi/Angelman syndromes deletion region. *J-H. Chai*¹, *D.P. Locke*², *E.E. Eichler*², *R.D. Nicholls*¹. 1) Department of Psychiatry, University of Pennsylvania, Philadelphia, PA; 2) Department of Genetics, Case Western Reserve University, Cleveland, OH.

Prader-Willi and Angelman syndromes (PWS and AS) typically result from an ~ 4 Mb deletion of human chromosome 15q11-q13, with clustered breakpoints (BP) at either of two proximal (BP1, BP2) and one distal (BP3) site. *HERC2* or other duplicons at these BP regions are thought to mediate homologous recombination to generate 15q11-q13 deletions and duplications. We previously identified four non-imprinted genes (*GCP5*, *CYFIP1*, *NIPA1* and *NIPA2*) between BP1 and BP2, and have now characterized in detail the function and evolutionary origin of the BP1-BP2 region, particularly the *NIPA1/NIPA2* gene family. *NIPA1* and *NIPA2* each encode polypeptides with 9 transmembrane domains, suggesting function as receptors or transporters. Whereas *NIPA2* is constitutively expressed, *NIPA1* shows a central nervous system-specific expression pattern. By fusion to EGFP and microscopy, *NIPA1* is localized to vesicles within the cytoplasm and long processes of several cell lines (HeLa and mouse HN33 hippocampal neuronal cells), and similar studies with transgenic mice are under way. Phylogenetic analyses in 9 vertebrate, invertebrate and plant species indicates that *NIPA1* evolved ~ 450 million years ago by a genomic duplication of an ancestral *NIPA2* gene, whereas *NIPA2* is found in all multicellular organisms. Further evolutionary studies indicate that the 4-gene cassette between BP1 and BP2 in human is conserved but located adjacent to the single *Herc2* and flanking *p* (*OCA2*) genes in mouse and *Fugu*, genes that are adjacent to BP3 in human. These observations suggest a model in which duplications of the *HERC2* gene in primates first flanked the 4-gene cassette at the homologous position to 15q13 (BP3), with subsequent transposition of the entire cassette by a *HERC2*-duplicon mediated process to form the BP1-BP2 region 4 Mb proximal of the ancestral location. Duplicons appear therefore to mediate genomic fluidity in both disease and evolutionary processes.

Chromosomal evolution of human chromosomal region 11p14-15.5 and chromosome 12. *D. Prawitt, T. Enklaar, B. Keller, L. Brixel, C. Spangenberg, B. Zabel.* Molecular Genetics Lab, Children's Hospital, Univ. of Mainz, Mainz, Germany.

In an effort to localize all genes of the nucleosome assembly protein (hNRP) family, we isolated a PAC-clone specific for hNRP. FISH mapping experiments placed the gene into chromosomal region 12q21, providing further evidence for structural similarities between subregions on chromosome 11 and 12. Well known is the fact that the genes LDHA, HRAS1 and IGF2 on 11p14-15.5 have corresponding paralogous genes (LDHB, KRAS2 and IGF1) on chromosome 12 and because of their high genomic similarity, a common evolutionary descent of the two chromosomes was presumed (Walter et al., 1991). To analyse this situation in more detail we generated a list of paralogous genes on human chromosome 11p and on chromosome 12 enabling us to explain the genomic data as result of an evolutionary early duplication of a large genomic area, which then was further modified (under reduced selection pressure) by additional steps which might have included inversions or translocations. This model also explains the arrangement of the 11p gene group on two distinct chromosome 12 areas and the localization of corresponding orthologous murine genes on at least two chromosomes (6, 10). To our estimate the regions of chromosomes 11/12 paralogy seems to be limited to 11p14-15.5 on chromosome 11, since we could not determine genes located more centromeric on 11p characterized by gene family members on chromosome 12. An interesting consequence of a duplication event is the redundancy of gene products. According to Sidow (1996) two mechanisms could regulate a resulting increase of gene products: an alteration in the sequence of the duplicated gene leading to a different function of the produced protein, or a modification of a cis-regulating region that results in an altered gene expression. Cis-regulating genomic domains defining expression specificity of genes could be binding sites for transcription factors or modifiers. In this regard it is of interest that 11p15 is subject to epigenetic regulation, whereas this is not reported for the paralogous regions on chromosome 12.

Construction of Large Insert BAC Libraries of Gibbon and Spider Monkey. *R. Indugula¹, Y. Qian¹, L. Jin¹, B. Su^{1,2}*. 1) Center for Genome Information, Department of Environmental Health, University of Cincinnati, USA; 2) Key Laboratory of Cellular and Molecular Evolution, Kunming Institute of Zoology, Kunming, China.

Large insert genomic DNA library is a critical resource for genome-wide genetic dissection of target species. We constructed two high quality bacterial artificial chromosome (BAC) libraries of nonhuman primate species, the siamang (*Hylobates syndactylus*) and the black-handed spider monkey (*Ateles geoffroyi*). The clone vector, pBACe3.6 was used. A total of 240,000 and 200,000 BAC clones were generated respectively for the siamang and spider monkey libraries, respectively. The average insert size of the BAC clones was estimated to be about 135kb for the siamang library and 186kb for the spider monkey library. The small inserts (50-100kb) are less than 3% for both of the libraries constructed. Assuming a similar genome size with humans, the two libraries have about eleven times coverage of their genomes. Therefore, these two BAC libraries would serve as valuable resources in comparative genomic study and large-scale genome sequencing of non-human primate species. They will be made available for distribution upon request.

Program Nr: 1314 from 2002 ASHG Annual Meeting

Isolation of the full-length cDNAs for "predicted genes" and "novel genes" on human chromosome 21. *J. Kudoh, K. Shibuya, J. Wang, I. Obayashi, T. Sasaki, A. Shimizu, S. Asakawa, S. Minoshima, N. Shimizu.* Department of Molecular Biology, Keio University School of Medicine, Tokyo, Japan.

The chromosome 21 mapping and sequencing consortium including us finished 33.83-Mb genomic sequencing of chromosome 21 and identified 225 genes including 98 predicted genes (Nature, 405:311-319, 2000). We are now performing full-length cDNA isolation of "predicted genes" which were identified by sequence similarities to known genes and/or spliced EST matches and/or exon prediction programs. Putative exon sequences were used to amplify cDNA fragments by PCR using cDNAs from various human tissues. We identified nearly full-length cDNAs for predicted genes including DSCR6 (Down syndrome critical region gene 6), ANKRD3 (ankyrin repeat domain 3), ZNF295 (zinc finger protein 295), C21orf25 (chromosome 21 open reading frame 25), ZNF298, UMODL1 (uromodulin-like 1), TMPRSS3 (transmembrane protease, serine 3), TSGA2 (testis specific gene 2), SNF1LK (SNF1-like kinase), WDR9 (WD repeat domain 9), PRED44/C21orf11, and C21orf30, and two clusters of keratin-associated protein (KAP) genes on 21q22.11 and 21q22.3 which consist of at least 46 KAP genes (See abstract by Shibuya et al., this meeting). Many genes have various transcripts produced by alternative splicing and/or alternative use of transcription start sites. The detailed transcript map and sequence information are available through our Web site (<http://www.dmb.med.keio.ac.jp>). These information and resources will be useful for identification of disease related genes, especially those responsible for a particular phenotype of Down syndrome or bipolar affective disorder, and structural and functional analysis of each of these genes.

Towards a comprehensive understanding of LINE-1 evolution in hominoids. *L. Mathews, S. Chi, N. Greenberg, M. Ulz, I. Ovchinnikov, G. Swergold.* Department of Medicine, Columbia University, New York, NY.

Even though substantial physical and behavioral differences distinguish humans and the other great apes, many studies indicate that these species are very similar at the nucleotide sequence level. This raises the possibility that other types of genetic changes may account for some of the phenotypic differences between them. For example, the activities of retrotransposable elements may play important roles in species and genomic evolution. To investigate the role of LINE-1 (L1) amplification in the genomic evolution of the great apes we have created LOAF (LINE One And Flanking DNA) libraries of full-length, recent L1 insertions from their genomic DNA. Comparison with data from the human genome sequence indicates that the LOAF libraries contain random samplings of L1 insertions that amplified during recent hominoid evolution as well as a reduced sampling of older hominoid insertions. By determining the species distribution of many L1 insertions we have assembled the first description of the evolutionary ages of the L1PA# subfamilies. These data indicate that the different subfamilies have been amplifying for varying lengths of time. L1s that inserted during each of the major branches of hominoid evolution have been isolated and sequenced. These studies have yielded the first molecular phylogeny of hominoid L1s. Our data indicate that LOAF libraries are a potent method for studying L1 evolution and for developing powerful molecular characters for phylogenetic studies. Surprisingly, we have measured substantial differences in the rates of L1 amplification in humans, bonobos, and common chimpanzees. Because the activities of L1 insertions may have large effects on genome structure and function, we suggest that differences in L1 amplification rates between humans and other great apes reflect important differences in their evolutionary history. L1 amplification may have played an important role in the phenotypic divergence of humans and the great apes.

Haplotype analysis of the HLA-DR subregion belonging to the DR53 group. *H. Hohjoh*¹, *J. Ohashi*¹, *M. Takasu*¹, *T. Ishida*², *K. Tokunaga*¹. 1) Human Gen/Grad School Medicine, Univ Tokyo, Tokyo, Japan; 2) Biol Sci/Grad School Science, Univ Tokyo, Tokyo, Japan.

Phylogenetic trees for DRB1 alleles constructed by the neighbor-joining (NJ) and UPGMA methods using nucleotide sequences of the alleles suggest that DRB1*0701 (DR7 haplotype) may have diverged from other DRB1 allelic lineages before the separation of human and chimpanzee because of a large number of nucleotide changes in DRB1*0701 compared with any of the other DRB1 alleles. In our previous study, we found a processed pseudogene encoding the protein kinase, interferon-inducible double-stranded RNA-dependent activator (PRKRA), in the telomeric region of the HLA-DRB7 pseudogene. Interestingly, the PRKRA pseudogene appears to be specifically present in the DR4, 7, and 9 haplotypes belonging to the DR53 group, suggesting that the PRKRA pseudogene may have been generated in the common-ancestral genome of the DR53 group. Based on nucleotide changes in the PRKRA pseudogene, the divergence times of the DR4, 7, and 9 haplotypes were estimated to be 0.38~0.30 Myr ago. Thus, there is a significant difference between the phylogenetic trees and our observations. To examine this issue, we investigated haplotypes with the PRKRA pseudogene and the centromeric flanking region of DRB1 and also examined chimpanzee genome carrying Patr-DRB1*0701. Results indicate that the DR53-common ancestral haplotype carrying the PRKRA pseudogene may have been present before the separation of human and chimpanzee, and lead to the possibility that there may be a difference in the mutation rate of DRB1 gene among DR4, 7, and 9 allelic lineages.

Comparative analysis of gene expression patterns in human and African great ape cell lines. *M.W. Karaman¹, L.G. Chemnick², M.L. Houck², D. Sudano³, D. Chawannakul¹, S. Nagpal¹, O.A. Ryder², J.G. Hacia¹.* 1) IGM, USC, Los Angeles, CA; 2) CRES, San Diego, CA; 3) NHGRI, NIH, Bethesda, MD.

Little is known about the variations in gene expression patterns in human and the African great ape (chimpanzee and gorilla) populations. Since all three species have high protein sequence identity (>98.4%), differential gene expression may play a significant role in their phenotypic differences. A clear understanding of the intra- and interspecies variations in gene expression patterns is needed to uncover changes that lead to distinct phenotypes in these species.

We have used oligonucleotide microarrays to quantify mRNA levels in 22 human, 11 chimpanzee, and 11 gorilla early passage fibroblast cell lines from donors of different ages. Over 12,500 genes in every cell line were individually assigned a numerical 'expression level' score. Expression data from all cell lines from a given species were electronically pooled and used to generate average 'human', 'chimpanzee', and 'gorilla' expression level scores for all 12,500 genes. Approximately 40% of genes analyzed were expressed at appreciable levels in every cell line. Human and African great ape gene expression scores were compared and statistical measurements of intra- and interspecies variations in gene expression in relation to donor age and gender were calculated.

We identified genes expressed at significantly different (>3 fold) levels among the human and the African great ape cell lines. Greater than 70 genes were over-expressed in human relative to African great ape fibroblasts. Conversely, there were 16 genes that were over-expressed in African great ape relative to human fibroblasts. Several of the differentially expressed genes between human and African great ape fibroblasts were involved in oxidative stress responses and hereditary neurological disorders. Hierarchical clustering analysis was used to compare the relatedness of the gene expression profiles. Human, chimpanzee and gorilla gene expression profiles all clustered according to the species of origin. These experiments could shed light on fundamental biochemical differences among human and non-human primates.

Nine-bp deletion polymorphism of mitochondrial DNA in Korean population. *M.M. Oh, S. Han, Y. Jung, J. Oh.*
Dept Biol, Col Natural Sci, Cheju Natl Univ, Cheju, Republic of Korea.

We investigated the 9-bp deletion motif of the mitochondrial DNA (mtDNA) in Korean population. The 9-bp deletion motif is caused by the loss of one unit of the tandem repeat sequences in the tRNA^{Lys}/cytochrome oxidase 2 (*CO II*) intergenic spacer in human mtDNA. By the report, the coalescent time of the 9-bp deletion haplotypes has been estimated about 50,000-70,000 years before present (YBP), suggesting multiple independent origins from Africa, Europe, and Asia. In East Asia, the frequencies of the 9-bp deletion haplotypes were broadly different among various populations showing geographic cline. In this study, we analysed the 9-bp deletion motif using polymerase chain reaction, polyacrylamide gel electrophoresis, and DNA sequencing. Korean population showed polymorphic patterns in this mtDNA region as previous reports and the frequency was 17.9% (34/190). The hominid fossils identified as modern human, and the Paleolithic archeology records found in Korean peninsula, were estimated from 40,000 to 100,000 YBP. Consequently, the existence of 9-bp deletion leads an opinion that some maternal lineages of the ancient ancestors probably immigrated via ocean or continent after the first ancestors' settlement. We suggest that this study will give a good information to explain the history for the prehistorical migration pattern and tracing population affinities of Korean population.

Characterizing pericentromeric duplications: An expanded analysis of 2p11. *J.E. Horvath¹, M. Rocchi², S. Schwartz¹, E.E. Eichler¹*. 1) Dept Genetics, Case Western Reserve Univ, Cleveland, OH; 2) Istituto di Genetica, Universita di Bari, Bari, Italy.

Recent work in pericentromeric and subtelomeric regions of the human genome indicates that these regions are mosaics of paralogous segments. In an effort to better understand the evolutionary origin of the genomic structure in these regions we have focused our efforts on characterizing the pericentromeric region of chromosome 2 in detail. We have developed a ~650kb BAC contig from 2p11 abutting alpha satellite DNA and flanking 7 partial gene duplications and 3 pericentromeric interspersed repeats (PIR). The duplicated genic segments arose from 1p13, 2p12, 4q24, 7, 11p15, 22q11, and Xq28 and show 94-97% sequence identity to the ancestral loci. Based on PCR and FISH analyses, there are 5-8 copies of each duplicated genic segment distributed across multiple chromosomes. In contrast, there are more than 65 copies of PIR4 distributed among half of all human chromosomes suggesting multiple copies exist on each chromosome. Our analysis also indicates that larger blocks of sequence are shared between a subset of pericentromeric regions, such as 2, 10, 16 and 22, suggesting that these regions have undergone vast restructuring events in recent evolutionary time. PCR and comparative FISH data indicate that both the genic duplicons and PIRs are multicity in chimpanzee and gorilla but are single copy in orangutan. Phylogenetic analysis suggests that five of the seven genic duplicons were transposed to an ancestral pericentromeric region around the same time (5-8 mya). The duplicated PIR4 element, however, arose earlier in evolution (>12 mya) and may have pre-existed many genic duplicons. Combined, the data indicate that this region of 2p11 has accepted duplicated material at a punctuated time in evolution. Consequently, there is significant variation between closely related species. Based on our data we propose a model to explain the organization of human pericentromeric DNA and more importantly, a mechanism of rapid evolutionary turnover involving the transposition and juxtaposition of genic and repetitive segments.

Nature and Pattern of Primate Genomic Variation. *G. Liu*¹, *NISC Comparative Sequencing Program*², *E.D. Green*², *E.E. Eichler*¹. 1) Department of Genetics, Center for Human Genetics and Center for Computational Genomics, Case Western Reserve University School of Medicine and University Hospitals of Cleveland, Cleveland, OH; 2) NIH Intramural Sequencing Center, Gaithersburg, MD.

We performed a detailed analysis of both single nucleotide and large-scale insertion/deletion (indel) events based on large-scale comparative analysis of 15 Mb of sequence from baboon, chimpanzee and human. Optimal global alignments were constructed from 40 orthologous loci and examined for the pattern, frequency and nature of mutational events over an estimated 25 million years of human evolution. Partitioning the genome sequence into different classes reveals significant differences between exonic, non-coding unique DNA and repetitive DNA with higher rates being observed for Alu/L1 DNA when compared to non-coding DNA. The overall single-base pair mutation rate was calculated as $\sim 1.15 \times 10^{-9}$ events per site per year which is significantly lower than the previously reported values. Mutation rates were very comparable between two sets of sequence alignments (human vs. chimpanzee and human vs. baboon) supporting a constant molecular clock hypothesis while arguing against the hominoid rate-slowdown hypothesis. We investigated the potential origins of large-scale indel events (>100 bp). Alu and L1 were found to mediate the majority of recent retrotranspositions showing strong species bias. Based on 5 Mb of aligned orthologous sequence, we identified 153 Alu events in baboon while only 96 in human, suggesting a slowdown of Alu activity within the hominoid lineage. Further, for human-chimpanzee sequence alignments, a two-fold increase in Alu (22:11) and L1 (9:5) insertions was detected in human when compared chimpanzee. Finally, an analysis of de novo deletion events found that more than two-thirds of them shared a SINE or LINE element precisely at the deletion boundaries, suggesting homologous recombination between common repeat elements as a mechanism for their origin. The data provide the first global insight into the mutational forces that have shaped the human genome and provide a valuable baseline for the identification of regions that deviate from the neutral expectation of genomic mutation.

Evolutionary Genomics of Transcription Factor Brain-2 in Mammals. *L. Wang*¹, *F. Mizuno*², *S. Ueda*². 1) Medical & Animal Gen, Inst Gen, Chinese Academy Sci, Beijing, China; 2) Department of Biological Sciences, Graduate School of Science, University of Tokyo, Tokyo, Japan.

We have previously found a unique evolutionary feature of transcription factors; (1) transactivation domain of the transcription factors had amino acid structure unique to each class of vertebrates, and (2) those unique features were represented by the presence of homopolymeric amino acid repeats (sequences without interruptions in the run of a single amino acid residue) including alanine, glycine, and proline. Presence/absence of these amino acid repeats, which are encoded by triplet codons GCN, GGN, or CCN, are well concordant with GC contents of their genes. Transcription factors having higher GC contents show higher contents of alanine, glycine, and proline residues, while transcription factors having lower GC contents show lower contents of these amino acid residues. This correlation is observed even among various types of transcription factors from vertebrates and invertebrates, regardless of functional and structural constraints inherent to each transcription factor. Here we newly obtained three hominoid (chimpanzee, gorilla and orangutan) Brain-2 genes and compared their nucleotide and amino acid sequences with those of the vertebrate orthologues including the human and mouse ones. Brain-2 is one of the transcription factor class III POU, which plays an important role in nervous system. All of the mammalian Brain-2 had alanine-, glycine-, proline-, and glutamine-repeats, which are missing in the non-mammalian orthologues. Moreover, these characteristic homopolymeric amino acid repeats are highly conserved in both position and repeat number among mammals.

Program Nr: 1322 from 2002 ASHG Annual Meeting

Mutation, methylation, mismatch, and Man: exploring the human mutome. *A. Platt.* Organismic and Evolutionary Biology, Harvard University, Cambridge, MA.

Recent large-scale SNP-mapping techniques have given us unprecedented tools in examining evolutionarily recent mutations in humans. By describing the distribution of 8.2×10^5 SNPs described by The SNP Consortium in terms of short (six flanking nucleotides), medium (sequence words within 50 nucleotides), and long (GC content of 100 nucleotide neighborhood) distance sequence contexts I show dramatic (260 fold) variability in levels of polymorphism at different classes of sites. This genomic approach offers insight into the mutational propensities of human DNA replication and includes implications for an extended role of CpGs beyond deamination-induced hypermutability.

Biases against Microsatellites in the Human Genome: implications for genomic instability. *J.E. Stenger, Y. Liu.* Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC.

Whether microsatellites are advantageous or pose a threat to DNA stability is dependent on their length. We, therefore, undertook a study to find all microsatellites with repeat units under seven nucleotides (homonucleotide runs through hexanucleotide runs) in the UniGene set to identify biases against length. First we looked at homonucleotide runs since their hypermutability in mismatch repair and DNA polymerase proofreading yeast mutants was experimentally demonstrated (Tran et al., 1997). Only the mismatch repair system prevents frameshift mutations in runs greater than or equal to eight consecutive nucleotides. So we decided to determine if there was a bias in the genome of against such tracts. We looked independently at the four possible types of homo-nucleotides (A, C, G and T runs) greater than or equal to runs of six homo-nucleotides. Of these tracks of length six, the A tracks were most common: 6,296 occurrences of six As versus 4444 for C, 2711 for G and 2574 for T. The number of occurrences dropped off dramatically between length 8 runs and length 9 runs. The number of occurrences for A, C, G and T of length 9 were 124, 10, 6, and 41 respectively. Thus, the experimental data was corroborated by a bias against sequences that are potentially unstable and we can see this reflected in the genome following computational analysis. We then reasoned that for more complex microsatellite repeats, observing such drop-offs in the number of occurrences, as the number of iterations of the repeat increases would also reflect instability. So we did an analysis of singly interrupted homo-nucleotides (as these are predicted to have a similar effect on DNA structure as homo-nucleotide repeats, if the sequence is long enough), and di- through hexa-nucleotide repeats. We found biases against interrupted nucleotides with an overall length of greater than 11. In addition we found that di-nucleotide repeat numbers dropped off significantly after 5 iterations (overall length 10), tri-nucleotides after 8 iterations, tetra-nucleotides after 3 iterations, penta-nucleotides after 2 iterations, and hexanucleotides after three iterations.

Missing in action: search for unsequenced human genome regions. *J.R. Korenberg¹, X-N. Chen¹, P. Bhattacharyya¹, SY. Zhao², H. Shizuya³, M. Simon³.* 1) Med Genet, Cedars-Sinai Med Ctr/UCLA, Los Angeles, CA; 2) TIGR, Rockville, MD; 3) Caltech, Pasadena, CA.

The human genome reflects a rich history of duplication events that mark regions of contemporary variability and instability. In order to provide an alternative approach to identifying unstable and duplicated regions that does not depend on internal analyses of the draft sequences, we analyzed BAC end sequence (BES) from a subset of 6,000 BAC clones identified at random (BAC Libraries A & B) that generate multiple signals by FISH on human metaphase chromosomes. A total of 580 BES representing 397 multiple-site BACs were analyzed against the UCSC draft sequence (Aug 01 & Apr 02) and Celera draft (2001). The results of the UCSC Aug 01 searched in masked format against unmasked BES revealed that from the 580 BES (179 BACs with both BES), 293 had no hits, 137 were low hits (90-97% homology) and 150 were high hits (98%). However, 8 of 13 BACs that hit the same chromosome were at the correct spacing (80-300Kb). The results of the UCSC Apr 02 searched in unmasked format against unmasked BES showed from a subset of 98 BES (49 BACs with both ends), 32 BACs had high hits, of which 13 hit the same chromosome, although only 10 out of 32 had the correct spacing. When searched masked, one out of 32 remained a high hit with both ends matching to the same chromosome albeit with incorrect spacing. These results indicate that the progress of the draft sequencing had little effect on the set of BES with no match. The Celera database search revealed that out of 580 BES, 5 had no hits, 575 had hits, of which, 132 were low hits and 443 were high hits. However 168 of 443 hit the same chromosome, of which 54 had the correct spacing. In addition, 61 BACs hit orphan contigs, with 27 that had both BES hit only orphan contigs. Analyses of both draft sequence sources suggest that at least 65% (UCSC) and as much as 90% (Celera) of multisite BACs identified above were not included or misassembled in the current draft sequence. Therefore, these missing sequences identify gaps in the draft sequences and provide links for defining regions of genomic instability involved in germline and somatic disease.

Human Genes of Ancient Origin. *G.A. Bruns*^{1,2}, *R.E. Eisenman*¹. 1) Genetics Division, Children's Hosp, Boston, MA; 2) Dept of Pediatrics, Harvard Medical School, Boston, MA.

Various categories of human genes of unknown function may be of interest to identify. Examples include those with predominant expression in one organ system; those with expression at very early stages of development or fleeting expression in a developmental process; or those with significant expression only in primates. We have focused on finding novel human genes that have extensive homology in *D.melanogaster* and *C.elegans* but do not recognize known proteins, protein families or motifs in current databases. These encode new families of proteins of ancient origin. As extensive cross-phylum AA sequence conservation is frequently a hallmark of proteins involved in fundamental cellular processes, function analysis of some of the proteins may elucidate priorly unknown pathways. Mutation at loci encoding ancient sequences also often underlie human inherited disorders.

More than 40 genes of this class were recognized by database search. Human unique Unigene sequences were BLAST analyzed to find those with significant homology (E values, e^{-005} to e^{-067}) in the *D.melanogaster* EST database. Any initial match to a homolog of known function or a defined motif in the Unigene or nr db was excluded. For each candidate the human protein was sought from the nr database which often yielded the *D.melanogaster* relative. The fly homolog was also obtainable from FlyBase. For all but 4 genes, a *C.elegans* homolog was retrieved from the nr or Wormpep databases. In some cases Wormpep or FlyBase gave identification of a gene not available from the nr annotation. Such loci were excluded. This indicates the importance of using multiple databases when seeking novel genes. All candidate genes were analyzed with pfam. The human proteins were aligned to the fly and worm homologs using the NCBI BLAST 2 Sequences algorithm. The E values ranged from e^{-05} to e^{-135} with the majority at least e^{-30} . EST representation for the human genes was retrieved from the Unigene db. The gene identifiers, homology relationships of the proteins plus RNA data will be presented and posted at <http://tnt.tch.harvard.edu/bruns/>.

Finding of New Genes from Proximal One-Third (cen-q11.2) of Human Chromosome 22. *T. Sasaki, A. Shiohama, K. Hosono, H. Yang, S. Asakawa, J. kudoh, S. Minoshima, N. Shimizu.* Dept Molecular Biol, Sch Med, Keio Univ, Tokyo, Japan.

We previously reported the first sequence analysis of human chromosome 22q (33.4 Mb) and identified 545 genes including 298 related and predicted genes (*Nature* **402**: 489-495, 1999). Since then, we have continued more extensive analysis by manual evaluation of the computer predictions and experimental isolation of cDNAs aiming at a complete transcript map. To date, we finished analyzing the proximal one-third of 22q (10 Mb), which includes the Cat Eye Syndrome (CES) region, the DiGeorge Syndrome (DGS) region and the IGL-IGLL region. We identified 15 new genes from these regions. Here, we report the initial characterization of some of these new genes.

DGCRK7 is located between T10 and HTF9c genes in the DGS region. Northern blot analysis revealed that DGCRK7 is transcribed in three forms, and expressed ubiquitously in various organs/tissues of both human and mouse origins. We also isolated a cDNA of mouse homolog Dgcrk7 that has 95.3% amino acid identities with human DGCRK7. The protein domain analysis revealed one WW motif and two double stranded RNA binding motifs. This gene may be associated with some clinical phenotypes of DGS.

PIWIL3 is a novel member of the PIWI/eIF2C family, and is located between GGT.2 and TOP1P2 in the IGL-IGLL region. A cloned cDNA was 3,504 bp in length including ORF of 2,652 bp. The PIWIL3 protein has PAZ and Piwi motifs as a common architecture of the PIWI/eIF2C family. PIWIL3 is expressed mainly in the testis. It is noted that the *Drosophila piwi* is associated with self-renewing of germline stem cell.

LUK1 locates between PPIL2 and PRKM1 in the IGL-IGLL region. LUK1 homolog is found in many eukaryotes including animal, plant and fungus, and hence this gene is considered to have a fundamental function. Through searching the human genome database, at least 4 more genes with high homology were found. The full-length cDNA cloning and functional analysis of all the remaining genes are in progress.

Functional autosomal copies of the X-linked human ribosomal protein genes. *N. Kenmochi*¹, *T. Uechi*², *T. Tanaka*².
1) Central Research Labs, Miyazaki Medical College, Kiyotake, Miyazaki, Japan; 2) Dept of Biochem. School of Med. Univ of the Ryukyus, Nishihara, Okinawa, Japan.

The mammalian ribosome is a massive structure composed of 4 RNA species and 79 different proteins (RPs). Unlike the RNA constituent, each protein is typically encoded by a single intron-containing gene. However, there are dozens of intronless copies of the active gene by retrotransposition at sites dispersed throughout the genome, though the majority of these copies are inactive. In this study, we have identified functional autosomal copies of the X-linked human RP genes and have designated these genes as *RPL10L* (ribosomal protein L10-like gene), *RPL36AL*, and *RPL39L* after the original ones. Because these genes have no introns in the coding regions, they are likely retrotransposed from the X-linked genes. The identities between the retrotransposed and original genes are 89%-95% in the nucleotide sequences and 92%-99% in the amino acid sequences, respectively. The Northern blot and PCR analyses revealed that *RPL10L* and *RPL39L* were expressed only in testis, whereas *RPL36AL* was expressed ubiquitously. Although the role of the second genes remains unclear, they might have evolved to compensate the dosage of the X-linked RP genes.

From Genomic to Representational Mismatch Scanning. *H.G. Thormar^{1, 3}, G.H. Gunnarsson^{1, 2}, B. Gumundsson², S.M. Gustafsdottir¹, S.M. Weissmann⁴, J.J. Jonsson^{1, 3, 4}.* 1) Dept. of Biochem. and Mol. Biol., Univ. of Iceland Medical School, Reykjavik, Iceland; 2) BioCule Inc., Reykjavik, Iceland; 3) Dept. of Clin. Biochem., Landspítali-University Hospital, Reykjavik, Iceland; 4) Dept. of Genetics, Yale School of Medicine, New Haven, Connecticut.

Genomic mismatch scanning (GMS) to identify identical-by-descent (IBD) sequences shared by affected relatives would have many potential applications. The human genome is too complex for efficient reannealing following denaturation, a requirement for GMS. We have developed a method Representational Mismatch Scanning (RMS) to generate and process representations of the human genome for various genomic applications including mismatch scanning. Adenine-rich sequences flanking 3' ends of Alu repeats (AluR3'Fl), many of which are highly polymorphic, were amplified from genomic DNA. Estimation of efficiency of reannealing and isolation of polymorphic, reannealed AluR3'Fl was done using two-dimensional conformation-dependent electrophoresis (2D-CDE) developed by our lab. Three rounds of subtractive hybridization were performed to identify non-fixed Alu repeats (polymorphic as to presence or absence) and recovered material cloned and analysed. Sequence analysis and Blast search on 27 clones from AluR3'Fl amplification confirmed that these were all AluR3'Fl and placed 21 of them on 11 chromosomes. In contrast to whole genome preparations AluR3'Fl representations could reanneal efficiently. Using subtractive hybridization we were able to clone AluR3'Fl adjacent to non-fixed Alu repeats further confirming favorable reannealing characteristics and demonstrating use of this technology in genome biology. Seven out of 14 (50%) reannealed AluR3'Fl sequences isolated after 2D-CDE were heteroduplexes due to polymorphism. The AluR3'Fl representations have several characteristics associated with an ideal human genome representation for mismatch scanning. They can be used in subtractive hybridization to isolate polymorphic non-fixed Alu repeats and in junction with 2D-CDE to isolate polymorphic AluR3'Fl. Polymorphic AluR3'Fl appear to have characteristics favorable for comparative genome hybridization to directly identify IBD sequences.

Characterisation and modification of human alphoid BACs and PACs for chromosome formation in mammalian cells. *T. Kaname*^{1, 4}, *K. Osoegawa*², *P.J. de Jong*², *P.A. Ioannou*³, *K. Naritomi*⁴, *C. Huxley*¹. 1) MAC group, MRC Clinical Sciences Centre, Imperial College, London W12 0NN, UK; 2) Childrens Hospital Oakland Research Institute, Oakland, CA-94609; 3) The Murdoch Institute for Research into Birth Defects, Royal Childrens Hospital, Melbourne, Australia; 4) Department of Medical Genetics, University of the Ryukyus School of Medicine, Nishihara, Okinawa, Japan.

Mammalian artificial chromosomes (MACs) are a potential tool for gene therapy, for transgenic animals, and for study of chromosome biology. Towards making reliable MAC vectors, we are investigating which alphoid DNA can frequently form a centromere *de novo* after transfection into cells.

We investigated the structure of 30 alphoid BACs and 20 alphoid PACs selected by screening human BAC and PAC genomic libraries with alphoid DNA. According to their sequences at both ends, FISH onto human metaphase spreads, and the pattern of digestion with several restriction enzymes, we have characterised BAC and PAC clones which have pure alphoid DNA from chromosomes 1, 7, 17, 18, 19, 21/13, and 22/14. In order to introduce and monitor these BACs and PACs in mammalian cells, we modified them by retrofitting with newly constructed plasmids using Cre-*loxP* recombination. The plasmids contain a *loxP* site for retrofitting, a spectinomycin resistant gene for selection in bacteria, a neomycin resistant gene expression cassette for selection in mammalian cells, and an EGFP expression cassette driven by the very strong CAG promoter. Retrofitting of a variety of BACs and PACs with these plasmids was frequent and accurate. Using the modified BACs and PACs, we could easily monitor the presence of the vector in HT1080 cells and mouse embryos. Then we investigated the potentiality of *de novo* MAC formation for the modified clones. All the vectors harbouring alphoid DNAs from chromosomes 17, 18, 21/13, 22/14 formed MACs with the frequency between 8.0×10^{-7} and 4.3×10^{-5} /lipofected HT1080 cells.

Trinucleotide repeats database from human chromosome 21 and 22. *H. Rhee*¹, *Y.-M. Lee*², *J.-S. Lee*^{1,2}. 1) Brain Korea 21 Project, Yonsei University College of Medicine, Seoul, Korea; 2) Department of Clinical Genetics, Yonsei University College of Medicine, Seoul, Korea.

Trinucleotide repeats (TNRs) are frequently found in the protein coding regions of human genome and the copy number polymorphisms of TNRs are associated with the various neurodegenerative disorders like Huntington's disease, spinocerebellar ataxia and spinobulbar muscular atrophy. These trinucleotide repeat expansion (TRE) diseases commonly show the genetic anticipation feature which refers to increased disease severity and earlier age of onset in successive generations. Because major psychoses like schizophrenia and bipolar disorder also show the genetic anticipation feature, the candidate causative genes for these diseases are actively investigated among the genes which have TNR copy number polymorphisms. In this study all the 64 types of TNRs in the genomic sequence draft data of human chromosome 21 and 22 are scanned *in silico* using locally developed computer program eTRF(Exact Tandem Repeats Finder). The results are integrated into the database to facilitate the identification of the various disease genes showing TRE and genetic anticipation.

Program Nr: 1331 from 2002 ASHG Annual Meeting

Sequence Validation of Cystic Fibrosis Mutations Detected with PCR/OLA Technology. *S.M. Koepf, L.Y. Nguyen, E. Schreiber.* Celera Diagnostics, Alameda, CA.

The cystic fibrosis transmembrane conductance regulator (CFTR) gene spans over 250 Kb with 27 exons and codes for a protein of 1480 amino acids. Mutations in this gene are responsible for causing Cystic Fibrosis (CF), the most common severe, autosomal recessive disease in caucasian populations. There have been over 1000 variants identified in this gene since it was first sequenced in 1989. Because heterozygosity of CF mutations can be quite common (1/25 in caucasians) and certain mutations have more severe consequences than others, there has been an increase in the demand for genetic testing of CF. In 2001, the American College of Medical Genetics (ACMG) set up guidelines for such testing and recommended 31 informative loci for screening. We have developed a simple, one tube assay, which follows the ACMG guidelines. This assay is based on a multiplex PCR followed by an oligo ligation assay (OLA). The OLA products are fluorescently labeled with one of 3 different dyes and separated and sized on an Applied Biosystems ABI Prism® 3100 Genetic Analyzer. Along with a review of this technology, fluorescent sequencing data are shown that validate the OLA results. Data are shown for several samples from Coriell's CF mutation panel, with special attention given to the 5/7/9 T polymorphisms located in intron 8 associated with splicing defects of exon 9.

Characterization of a duplicon unit, LCR7-20, in the human genome. *X.D. Liu, X. Li, M. Li, S.W. Scherer, Y.J. Acimovic, X. Estivill, L.C. Tsui.* Department of Genetics, Hospital for Sick Children , Toronto, Ontario, Canada.

DNA sequence duplication plays a pivotal role in genome evolution. Our previous study described the amplification of a genomic sequence containing exon 9 of the CFTR gene in human genome. We hereby report that this CFTR sequence is part of a large duplicated sequence unit, named LCR7-20 (low copy repeat 7-22). By constructing a human chromosome 7-specific cosmid contig and partially genomic sequencing in combination with existing human genome sequences, we assembled a 373 kb genomic sequence containing a prototype LCR7-20 sequence (LCR7-20.1) located on 7p11-12. Sequence search in the public databases revealed six additional copies of LCR7-20 with more than 90% sequence identity. Among them, two genomic contigs on chromosome 20 (LCR7-20.2) and 15 (LCR7-20.4) contain the complete LCR7-20 sequence and the others are single BAC/PAC clones containing the unfinished sequence fragments assigned to the chromosomes 6, 12, 15 and 20. Sequence alignment of seven LCR7-20 sequences suggested a unit length of LCR7-20 to be between 68.5 to 245 kb. Among them, three LCR7-20 sequences contain the CFTR exon-9 insertion. Detailed sequence analysis revealed that LCR7-20.1 is positioned by two 53 and 61 kb reverse repeats at both ends. The similar result was also observed on LCR7-20.2, which contains two highly identical 92-kb reverse repeats at its ends. Screening human BAC/PAC libraries, restriction mapping and sequencing the regions without short interspersed repetitive sequences, we found that there are more than 30 copies of LCR7-20 in the human genome and these LCR7-20 are roughly more than 120-kb long. FISH and comet-FISH analyses revealed that LCR7-20 units are located on different chromosomes, mainly in the centromeric and pericentromeric regions, as both single repeat and multiple tandem repeats. LCR7-20 therefore represents a duplicated unit that could undergo large complex sequence amplification during the human genome evolution. Our study also pointed a number of large sequence segments that may be mis-assembled. Further characterization of additional segmental duplication units will be important in correct assembly of the complete human genome.

Program Nr: 1333 from 2002 ASHG Annual Meeting

The Complete DNA Sequence of the Human Dystrophin Gene. *M. Maheshwari¹, S. Scherer¹, K. Worley¹, D. Wheeler¹, F. Yu¹, E. Sodergren¹, D. Muzny¹, J. Belmont¹, G. Weinstock¹, R. Gibbs¹, A. Coffey², G. Howell², D. Grafham², K. McLay², C. Bird², S. Whitehead², J. Ashurst², J. Rogers², M. Ross² and The DMD Gene Sequencing Collaboration**. 1) Dept Molec/Human Gen, Baylor College of Medicine, Human Genome Sequencing Center, Houston, TX; 2) Wellcome Trust Sanger Institute, Cambridge, UK.

Duchenne muscular dystrophy (DMD) is one of the most common and severe forms of muscular dystrophy and is caused by mutations in the dystrophin gene located at Xp21. Though the gene was cloned many years ago, its complete genomic structure has only recently been determined. It is one of the largest known genes; with a coding sequence of 14 kb spread over 2400 kb of genomic DNA. Much of the genomic sequence was included in the international collaborative effort that resulted in a draft Human sequence in June 2000. Subsequently a collaborative effort between the Baylor College of Medicine Human Genome Sequencing Center and the Wellcome Trust Sanger Institute has finished all BACs and PACs in a minimal tiling path across the whole gene. Analysis of the gene is underway, including precise definition of repeat content, gene prediction by different algorithms and cross species comparisons. In addition we are genotyping multiple markers to examine the conservation of linkage disequilibrium across the locus. These studies will show both the interesting architecture of this large gene and offer new reagents for DMD diagnosis.

Program Nr: 1334 from 2002 ASHG Annual Meeting

Genomic Sequencing and Analysis of the Human Chromosome 8q22-q24.1. *A. Shimizu, S. Asakawa, T. Sasaki, S. Yamazaki, S. Ishikawa, J. Kudoh, S. Minoshima, N. Shimizu.* Dept Molecular Biol, Keio Univ Sch Medicine, Kanagawa, Japan.

The human genome sequencing project is approaching to the proposal goal in Spring 2003 by the enormous efforts of international genome sequencing consortium. As a member, we have been involved in the sequencing and analysis of human chromosome 8q22-q24.1 This region contains several disease genes responsible for developing such as glaucoma, Cohen syndrome and myoclonic epilepsy and so on. The length of 8q22-q24.1 (SGC35251-D8S1804) region was estimated to be about 30 Mb which we completely covered with more than 400 Keio BAC clones. These BAC clones were processed for shotgun sequencing in combination with primer walking. To date, we finished sequencing of 140 BAC clones, covering 57% (~17.2 Mb) of this region. Together with the sequence data generated by other groups, 87% (~25.9 Mb) of this region has been covered with finished sequence and processed for exon prediction analysis and homology search with the database. We have so far found 18 novel genes (C8ORFK1, C8ORFK2, C8ORFK3, C8ORFK4 etc.) which have been confirmed by RT-PCR assay using the predicted exon sequences, RACE and Northern blot analysis. We also identified 96 known genes (PGCP, LC27, MATN2, RPL30, UK114, POP1, PRO1097, KRS1, GEM, CDH17, PABP, HTPHLP, P53R2, HYD, ODFPG, TIEG, DPYS, ST7, OXR1, INT6, ANGPT1, DC6, EBAG9, TRPS1, EXT1, EIF3S37 etc.) and 65 pseudogenes. The status of gene finding and mutations search will be presented.

Program Nr: 1335 from 2002 ASHG Annual Meeting

Reduction in feature size allows for accurate resequencing and SNP discovery for less than \$0.02/base. *N.A. Shah, Z. Zhang, J.A. Warrington.* Health Management Research, Affymetrix, Santa Clara, CA.

Oligonucleotide microarrays are a very powerful tool for gene expression monitoring. Here we describe another application for oligonucleotide microarrays, resequencing and SNP discovery. With the recent completion of the draft sequence of the human genome and the completion of sequencing projects for dozens of model organisms, this technology provides a rapid, economical and competitive method for identifying sequence variants. We have demonstrated that we are able to query 60 kb of sequence on a 1.28 x 1.28 cm microarray containing a total of ~340,000 unique probes. Ideally, genomic regions are amplified by long distance PCR, LPCR, and several fragments are pooled together at equimolar concentrations. Pooled amplicons are fragmented by DNASE 1 and end labeled using terminal transferase and biotinylated ddATP. The labeled target is hybridized to the microarrays overnight; arrays are washed, stained and scanned using an Affymetrix GeneChip system. Data is analyzed using GeneChip software. Using this system, excluding labor, the cost for 2x resequencing is less than \$0.02/base. In recent experiments, we are evaluating performance of a smaller feature size which increases the amount of sequence read per microarray and reduces the cost of labor and reagents per sample. Results of these experiments including validation data addressing accuracy and reproducibility will be reported.

Mapping the Methylation Status of CpG Islands located in upstream promoter regions and its relevance in Complex Genetic Disorders. *I. Yakub, R.A. Gibbs.* Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX.

Changes in DNA methylation profiles have been associated with a number of human diseases such as cancer and imprinting disorders like Beckwith-Wiedemann and Prader-Willi/Angelman syndromes. Variations in methylation status of CpG islands have also been linked to a number of mental disorders such as Rett Syndrome and X-linked alpha-thalassemia/mental retardation syndrome (ATR-X). Abnormal methylation patterns are known to alter levels of gene expression that may produce disease phenotypes. Although, analyzing the global methylation status of genomic DNA from patients is a good first step, it is not sufficient. A more detailed mapping of methylation patterns of individual CpG dinucleotides located in the promoter regions of candidate genes is essential if we are to fully understand the biological processes responsible for gene silencing in cancer and other genetic disorders as well as gene regulation of imprinted genes.

Methylation patterns are being mapped by scanning the CpG islands in the promoter regions of candidate genes from patient genomic DNA. The CpG islands are determined by the CpG plot software available on the European Bioinformatics Institute website. The assay involves the initial treatment of genomic DNA with sodium bisulfite, which chemically modifies all unmethylated but not methylated cytosine to uracil. Next, the CpG islands of interest are amplified with primers designed to amplify sodium bisulfite modified DNA only. These PCR amplified fragments are sequenced using the ABI Prism 3700 DNA Analyzer. Unmethylated Cytosines that have been modified to uracil will base pair with Adenine and therefore show up as As in the sequence while methylated cytosines will show up as Gs in the sequence. CpG islands from bisulfite modified patient DNA will be compared to sequence from bisulfite modified control genomic DNA to study the difference in methylation profiles and determine the functionality of the CpG islands. This method is being applied to study methylation profiles of CpG islands located in promoter regions of candidate genes in Schizophrenia and other complex genetic disorders.

High-throughput and cost-effective SNP typing method using single-molecule fluorescence detection system. *M. Bannai*^{1, 2}, *T. Akesaka*¹, *K. Hori*³, *K. Sato*³, *M. Kawashima*¹, *K. Tokunaga*¹. 1) Department of Human Genetics, University of Tokyo, Tokyo, Japan; 2) Genome Medical Business Division, Olympus Optical Co., Ltd., Tokyo, Japan; 3) NovusGene Inc., Tokyo, Japan.

Fluorescence correlation spectroscopy (FCS) is a powerful tool for characterizing fluorophores in solution at the single-molecule level by analyzing fluorescence fluctuations. The FCS method measures two important molecular parameters: average number and size of molecules in a tiny volume of solution (1 femtoliter). In combination with the PCR-sequence specific primer (PCR-SSP) method, we developed a high-throughput and accurate typing system of single-nucleotide variations. Sequence-specific primers separately labeled with different fluorescent dyes were used for dimorphic alleles and PCR-SSP reaction was performed competitively in the same solution. Since movements of DNA fragments in a solution depend on their sizes, primers (smaller molecules) move faster than PCR-amplified fragments (larger molecules) in the PCR product solution. After a narrow laser beam spots DNA fragments at a very small area in the solution, the signals of fluorescence-labeled molecules are detected by a highly sensitive spectrometer, then the numbers and sizes of both primers and amplified fragments are determined. A novel automated instrument for the FCS measurement allows almost-hands-free genotyping of hundreds of samples. For assay validation, one hundred different genomic samples that had been typed by PCR-single-strand conformation polymorphism (PCR-SSCP) were analyzed using this system. The genotypes determined by the PCR-SSP-FCS method were 100% concordance with the results determined by the PCR-SSCP method. More than 200 different SNPs have been tested so far, and more than 95 percent of them could be successfully distinguished. Even whole-genome-amplified samples could be typed, thus valuable samples with small amounts of genomic DNA are applicable to SNP typing. Accordingly, PCR-SSP-FCS is a useful method for reliable, cost-effective, and high-throughput typing of various SNPs.

Clinical application of a high resolution genomic microarray: detection of 6p25 deletions and duplications in patients with eye anomalies. *R. Ekong¹, S. Jeremiah¹, D. Judah², O. Lehmann³, F. Mirzayans⁴, M.A. Walter⁴, S. Bhattacharya³, T. Gant², S. Povey¹, J. Wolfe¹.* 1) The Galton Laboratory, Department of Biology, University College London, UK; 2) MRC Toxicology Unit, University of Leicester, Lancaster Road, Leicester, UK; 3) Dept. Molecular Genetics, Institute of Ophthalmology, Bath Street, London, UK; 4) Ocular Genetics Laboratory, University of Alberta, Edmonton, Canada.

Defining the extent of chromosomal anomalies by conventional methods is time consuming. Comparative genomic hybridisation has been used on arrays of BAC and PAC clones to detect copy number changes. We evaluated whether smaller clones (cosmids and cosmid-sized restriction digested (RD) fragments) provided a higher resolution using clinical samples from patients with duplications and deletions in 6p25.

We established a genomic array of BACs, PACs, cosmids and cosmid-sized RD fragments on aldehyde treated glass slides. These clones included the region of interest on chromosome 6p25, and other human chromosomes including X and Y. Patient and reference genomic DNAs were differentially labelled with fluorochromes and co-hybridised. After post-hybridisation washes, the slides were scanned and analysed.

Patient samples and unaffected controls were analysed blind and the extent of each chromosomal aberration was correctly identified in all cases using the PACs/BACs in the array. Results from cosmids and RD fragments within the region were consistent with those from the larger insert clones. These results have been confirmed independently by other methods.

This study demonstrates that cosmid-sized genomic clones can be successfully used in genomic microarrays and that they potentially provide a higher resolution than PACs and BACs. Their use should facilitate identification of cytogenetic breakpoints and assist in patient diagnosis.

2-D Conformation-Dependent Electrophoresis for analysis of complex DNA samples (2D-CDE). G.H.

Gunnarsson^{1,2}, H.G. Thormar^{1,3}, L. Akesson¹, J.J. Jonsson^{1,3}. 1) Dept of Biochem and Mol Biol, University of Iceland Medical School, Reykjavik, Iceland; 2) BioCule, Reykjavik, Iceland; 3) Dept. of Clin Biochem, Landspítali University Hospital, Reykjavik, Iceland.

DNA fragments containing mispaired and modified bases, bulges, A-tracts, and cruciform structures have altered conformation. Methods for separating DNA fragments based on difference in conformation but independent of length would be of great interest. Such methods could be used for analyzing complex DNA samples containing many fragments of different length. We constructed a collection of tripartite 298 bp DNA fragments containing all 8 single-base mismatches, 5 C-bulges ranging from 1 to 5 nucleotides, and the 3 major UV-induced DNA lesions. This collection was used to develop a 2-D PAGE electrophoresis method for separating DNA fragments based on length and conformation in the 1st dimension and on length in the 2nd dimension. Most DNA fragments with altered conformation had reduced migration rates due to curving. This curving was minimized during 2nd dimension electrophoresis by introducing intercalators or using denaturing conditions. This resulted in DNA fragments with altered conformation migrating in front of an arc comprising fragments of different length but regular conformation. We noted a relationship between the degree of alteration in conformation and separation. DNA fragments containing from 1 to 5 C-bulge showed progressively increased separation. In contrast, DNA fragments containing single-base mismatch did not resolve. Applications of this simple and robust method includes simultaneous mismatch scanning of multiple fragments for length polymorphisms, isolation of damaged DNA molecules from intact molecules, and estimation of reannealing efficiency after hybridization of complex DNA samples.

Comparison of Three Different Amplification Protocols on Small Amounts of Total RNA for Microarray Analysis. *L.M. Barnes, C.D. Wolfgang, C. Lavedan.* Pharmacogenetics, Novartis Pharmaceuticals Corp, Gaithersburg, MD.

The introduction of DNA microarray technology has provided a powerful tool for genome-analysis of RNA.. This technology is of particular interest to the Pharmaceutical Industry because of its capability to provide a molecular signature of drug action that may lead to information about drug efficacy and toxicity. There are several different DNA Microarray platforms available. Our laboratory uses the Affymetrix GeneChip System. The current protocol from Affymetrix requires a minimum of 5g purified total RNA starting material. However, this valuable tool cannot be used for studies where small biopsies are harvested because they do not yield large amounts of RNA. The purpose of this study was to survey three different amplification protocols (Phillips and Eberwine et al 1996, Wang et al 2000, and Van Gelder et al 1987) to determine if the profiles generated by them are similar to the profile generated by the Affymetrix protocol. For this study, samples of total RNA from a breast tumor were processed using the standard Affymetrix protocol. Dilutions of this sample were later amplified using the three different methods described above. All samples were hybridized to the Affymetrix human microarrays (HuGeneFL and Human U95Av2) which contain probe sets for 6,000-12,000 genes and ESTs respectively. The number of genes detected on these arrays varied between 7% (Wang et al 2000 protocol) to 37% (Affymetrix standard protocol) using the Affymetrix algorithm. Direct comparison of the profiles from the amplified samples indicates that there were greater than 1,000 genes different from the profile of the sample processed using the standard Affymetrix protocol. An inspection of the housekeeping genes beta-actin and GAPDH showed significant variation compared to the unamplified sample. Similar differences were detected in many other genes when a similar comparison was done. The finding from this study suggests that amplification of total RNA may alter the global expression profile of a sample, warranting caution when using amplified sample data to make inferences about mechanism of action, efficacy and toxicity.

A rapid, simple and automatable DNA purification system for diverse sample types. *L. Flanagan, P. Mandrekar, R. Bitner, S. Koller, A. Tereba.* Genetic Analysis, Promega Corporation, Madison, WI.

With the advent of cloning, PCR amplification and sequencing the human genome, DNA analysis is now able to answer diverse questions in cell regulation and disease development. With these advances, reliable extraction of DNA from various sources has become important in basic and clinical research. Many methods currently involve the use of hazardous chemicals, are labor intensive and require different approaches for different sample types. In addition, most purification schemes are not automatable. We report here a simple, rapid and automatable system that can handle a wide range of samples. Based on a paramagnetic particle that binds DNA in the absence of hazardous organic solvents, DNA is rapidly obtained, free of PCR inhibitors from samples like whole blood and urine. Using a Proteinase K pre-treatment, hair, bone and tissue, including formalin fixed paraffin embedded thin sections, are easily processed. The ability to obtain PCR amplifiable DNA from this latter sample type allows a correlation between pathology and molecular analyses. DNA purification from blood cards and buccal swabs is accomplished using a heating step and centrifugation followed by the standard purification protocol. For all sample types, both genomic and mitochondrial DNA is isolated.

To increase efficiency in the analysis of DNA, our paramagnetic particles are designed to bind a limited amount of DNA. Thus, for common reference samples the particles deliver a uniform amount of DNA regardless of the amount of DNA present in the sample. This eliminates the need to quantitate DNA and gives uniform results in DNA analysis. The amount of DNA recovered can be modulated between 50ng and 1ug. This DNA purification system has been automated on the Beckman Biomek 2000, F/X and Tecan Genesis 150 systems allowing for high throughput purification from diverse sample types.

DNA yields from buccal swabs: self-collection vs. nurse/nurse-supervised collection. *J. Chang, K. Heard, S. Roberts, K. Steinberg, M. Gallagher.* CDC, Atlanta, GA 30341.

Buccal cell collection is a noninvasive alternative to whole blood collection that provides means for obtaining DNA suitable for clinical and research studies. Self-collected buccal swabs can be returned by mail, making self-collection an economical approach particularly for collecting samples from a cohort of widely dispersed individuals. However, buccal swabs yield varying amounts of DNA, unlike whole blood samples where collection always involves a trained health professional. To assess different collection methods, we compared DNA yields from two groups: 95 self-collected mail-returned buccal swabs from adult female subjects in a case-control study of birth defects in the metro Atlanta area, and 119 nurse-collected (or nurse-supervised self-collected, referred to here as nurse-collected) buccal swabs from subjects in a case-control study of ischemic stroke in women in the Maryland-DC area. DNA was isolated using a rapid method yielding about 600 μ L of buccal cell lysate. Human genomic DNA was quantified by real-time quantitative PCR. Average total yields were 1.13 ± 1.34 mg (range 0-7.43, median 0.80) for self-collected brushes and 0.84 ± 0.91 mg (range 0.05-4.47, median 0.47) for nurse-collected brushes. No significant difference existed between average total DNA yields of self- and nurse-collected buccal brushes. However, when standard extraction volume was used, 21% of the self-collected samples had a concentration ≤ 0.10 mg/mL, but $<1\%$ of the nurse-collected samples did. Buccal samples with concentrations ≤ 0.10 mg/mL are problematic when amplified by standard PCR methods, and allele dropout may occur. In some cases, DNA concentrations may be increased using additional steps that concentrate the DNA lysate, but this may limit the extent to which the sample can be used in future studies. Though collection of buccal swabs by mail is convenient and economical, the likelihood of obtaining samples with low DNA concentration may have significant impact on downstream applications. Thus, the method of collection should be carefully considered.

Program Nr: 1343 from 2002 ASHG Annual Meeting

Novel approaches to visualizing and analyzing array-based comparative genomic hybridization data. *J. Greshock, T.L. Naylor, S.H. Cleaver, M.R. Gererro, A. Margolin, M.L. Liebman, B.L. Weber.* University of Pennsylvania, Philadelphia, PA.

Recent advances in microfabrication and genome sequence assembly facilitate accurate measurements of genomic gains and losses using array-based comparative genomic hybridization (aCGH). Defining disease-related genomic changes in human tissue at a high resolution is relatively novel unto itself and efforts to standardize aCGH data analysis and to develop tools for data visualization are limited. We have developed several software packages devoted to array CGH analysis and data visualization that are downloadable as a part of a larger on-line resource for array CGH development and analysis. The CGH Browser experiment viewer plots clone ratios vs. genomic location by chromosome. Unlike typical methods for generating these plots, the CGH Browser can handle multiple experiments simultaneously (including dye swap analysis), allow users to annotate experiment results, export results to files or databases, and ultimately link mapped clones to several on-line line genome feature databases (e.g. NCBI MapViewer and Ensembl). The CGH Circle Viewer is another downloadable visualization tool that efficiently displays an entire CGH experiment in a single circular format and allows overlay of data from multiple experiments, identifying common gains and losses. In addition to these CGH analysis tools, we have developed novel means of visually integrating mapped genome features and their associated annotations with aCGH data in the circular format. One can effectively link an aberrant region of the genome seen in an aCGH experiment to features on a physical map (e.g. Unigene genes, STSs, etc). We will demonstrate all these tools using data from a melanoma tumor progression series as a model. Standardizing statistical methods and creating publicly available tools devoted to CGH data analysis will greatly facilitate data exchange and regiment a language of analysis. This is of particular importance because of the increasing volume of aCGH in public data repositories and the need to integrate expression data and genome map features with aCGH data.

Automated Nucleic Acid Purification in DNA Banking. *K. Heard¹, E. Heath², B. Carr², L. Wöhr¹, D. O'Brien², K. Steinberg¹, M. Gallagher¹.* 1) CDC, Atlanta, GA; 2) Genra Systems, Minneapolis, MS.

The National Health and Nutrition Examination Surveys (NHANES) are conducted by the CDC to assess the health of the U.S. population. In anticipation of advances in genetic research, a DNA bank was established in 1988. In the current survey, whole blood is being collected for DNA isolation. This type of specimen also affords the opportunity for the separation of plasma that can be analyzed for toxins, heavy metals, and micronutrients. The purpose of this study was to determine the feasibility of using a combination of workflow management and automated instrumentation to process these samples in a high throughput laboratory environment. We investigated 1) separating whole blood into plasma and packed cells, which could be stored frozen during peak periods and 2) incorporation of laboratory automation for DNA processing. Packed cells were prepared from 1,444 paired whole blood samples (8 ml) collected in ACD anticoagulant from 722 adult subjects. The samples were stored at -80C until processing on the Autopure LS (Genra Systems, Inc.), an automated nucleic acid purification instrument. DNA yield and purity were determined and reproducibility was assessed by comparing the paired samples. Samples with DNA yields of <50ug were scored as invalid, and of the 1,444 packed cell samples, 19 (1.3%) were invalidated and omitted from the analysis. The results showed that the average DNA yield was 204 ug (range 50-610ug) and the average UV absorbance ratio A260/A280 was 1.98. Comparison testing showed that 82% of the paired samples differed by less than 50 ug. We also compared the DNA yield and purity of samples prepared using automated vs. manual processing. Sixteen blood samples were collected in duplicate: one set was purified using the AUTOPURE LS and the other was purified manually using Puregene reagents. The results showed the two sample sets to be highly correlated and the DNA yield and purity were comparable between the two methods. This investigation demonstrated that large quantities of high quality DNA could be obtained from frozen packed cells using an automated process, providing a means to increase throughput, improve workflow, and reduce human error.

Effect of Multiplex PCR Conditions on the SNPstream® UHT Genotyping System. *M. Mody¹, J.C. Myler¹, M.J. Thomas², S. Varde¹, C.A. Gelfand¹.* 1) Applications Research, Orchid BioSciences, Inc., Princeton, NJ; 2) DNAPrint genomics, Sarasota, FL.

Single Nucleotide Polymorphism (SNP) genotyping has important implications in the fields of gene mapping, pharmacogenetics and drug discovery as scientists investigate the relationship between gene structure and function and the effects of gene variation in disease and drug development. Orchid BioSciences, Inc. has developed an ultra high-throughput system called the SNPstream UHT Genotyping System that is cost-effective, reliable and accurate. The assay utilizes multiplex PCR followed by multiplex SNP-IT™ tag array, Orchid's next-generation proprietary single base primer extension technology. We have investigated the effect of different multiplex PCR conditions on SNP genotyping using the SNPstream UHT Genotyping System. Two marker panels of 12 SNPs (24 total) were each assayed with three multiplex PCR conditions, including a ramp-up protocol, a touchdown protocol and a standard cycling protocol with a constant annealing temperature. Initial findings suggest that all three methods worked equally well in the SNP-IT assay, indicating the robustness of the system and the flexibility of the multiplex PCR conditions for SNP analysis on the SNPstream UHT Genotyping System.

Gene expression in a partial trisomy 16 animal model of Down syndrome. *R. Lyle, C. Hendrichsen, C. Gehrig, S. Deutsch, S. Antonarakis.* Dept Medical Genetics, Centre Medicale Univ, Geneva, Switzerland.

Down syndrome (DS), caused by trisomy for chromosome 21 (T21), is the most common genetic cause of mental retardation with an incidence of approximately 1/700 live births. In addition to the mental retardation and facial characteristics, there are many other phenotypes, including congenital heart disease, early onset Alzheimer's disease and an increased risk of leukemia. With the development in recent years of mouse models of DS, and the completion of the chromosome 21 sequence, we are poised to gain a greater insight into the underlying molecular biology of DS. The presence of an extra copy of certain but not all of the approximately 225 HC21 genes are predicted to contribute to aspects of the complex DS phenotype. It is often assumed that all genes from the extra chromosome 21 will be expressed at a level 1.5x relative to diploids. However, since regulation of gene expression is complex, involving regulatory loops, many genes may not conform to this prediction. Identifying which genes are overexpressed, and to what levels, is obviously important to understand genotype-phenotype correlations in DS. The development of microarray technology has allowed the simultaneous examination of expression levels of many genes to be compared across tissues. However, there are certain limitations to microarray experiments: sensitivity and dynamic range of detection, large RNA quantities required. We have used a high-throughput real-time quantitative PCR (qPCR) assay to examine the expression level of 115 genes (including 82 HC21 orthologues) in the Ts65Dn mouse model of DS. Tissues examined so far include brain, heart, fibroblasts, and blood. The qPCR assay has enabled us to detect genes which are overexpressed, and those which are not, in Ts65Dn thus helping to identify those genes contributing to the DS phenotypes.

Towards assembling genome-on-a-chip using DNA representation array. Z. Yuan¹, K. Zhang^{1,2}, R. Zhang³, D. Yoon³, J. Jeong³, X. Chen⁴, J. Korenberg⁴, S. Shearer⁵, B. Czerniak³, L. Jin¹ and *The first two authors have equal contribution to this work.* 1) Center for Genome Information, University of Cincinnati, Cincinnati, OH; 2) Human Genetics Center, University of Texas-Houston, Houston, TX; 3) Department of Pathology, MD Anderson Cancer Center, Houston, TX; 4) Department of Pediatrics, Cedars-Sinai Medical Center, Los Angeles, CA; 5) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX.

The integration of CGH and microarray technology provides a high-resolution and quantitative tool to identify copy-number variation across the genome. The existing array-based methods for CGH are generally marred by laborious DNA preparation and purification procedures, which make them practically difficult to be scaled up. So far, even the highest density CGH-array provides less than 10% genome coverage, and leaves genetic imbalance in the rest 90 percent of genome undetected. We report a novel approach to generate genome-scale CGH arrays for the detection of gene copy number imbalance in a variety of diseases. A species-specific whole genome amplification method, which we refer to as human-specific SOGA, enables the preparation of sufficient amounts of array probes (DNA representation) by PCR using bacteria lysates instead of purified DNA as template. By avoiding laborious procedures of large-volume bacteria culture, plasmid isolation and contamination checking, the labor and cost of making CGH arrays can be reduced by 10~100 folds, and implemented in semi-automatic manner. Furthermore, the species-specific amplification also removes efficiently the repetitive structures in the genome and reduces the background noise drastically with both high sensitivity and high specificity. This approach makes possible the realization of a genome-on-a-chip approach, which requires arraying approximately 20,000 BAC clones covering the whole human genome on a single microscope slide, and will promote the clinical application of array-based CGH technology as a powerful diagnostic tool.

RT-coupled 5' nuclease assay — A general and high throughput method for detection of gene differential allele expression using transcribed SNPs as endogenous reporters. *G. Zhu¹, R.H. Lipsky¹, K. Xu¹, S. Ali¹, T. Hyde², J. Kleinman², L.A. Akhtar¹, D.C. Mash³, D. Goldman¹.* 1) NIAAA, NIH, Rockville, MD; 2) NIMH, NIH, Bethesda, MD; 3) Department of Neurology, University of Miami, Miami, FL.

Detection of unequal expression of maternally and paternally derived gene copies depends on the availability of gene polymorphisms in transcribed sequences. Single nucleotide polymorphisms (SNPs) represent the most common type of sequence variation and are frequently found in transcribed regions. Such SNPs are endogenous reporters for detecting differential allele expression in heterozygous individuals. To facilitate detection and functional analysis of cis-acting regulatory alleles and imprinting, we developed a simple and high throughput quantitative method, designated the RT-coupled 5' nuclease assay, for measuring allele expression ratio. We chose human COMT as a model gene. A transcribed SNP, rs-4818(C>G) [dbSNP], was used as maker for detecting allele ratio. Heterozygous individuals for rs4818(C>G) were identified through genotyping genomic DNAs by high throughput 5' nuclease assay using two allele-specific fluorescent-labelled probes. Total RNAs were isolated from these individuals and reverse transcription (RT) was performed. 5' nuclease assay was performed again but using the cDNA as the template instead of genomic DNA. Heterozygous genomic DNA was used as 1:1 allele ratio control. Fluorescence signal was collected after each cycle of amplification and allele ratio was calculated from the adjusted difference in threshold amplification cycle between the two alleles. Using this method, we discovered differential allele expression of human COMT both in lymphoblastoid cell lines (17/22) and postmortem cerebellar cortex samples (13/15), with one allele consistently more highly expressed than the other, ranging ratios from 1.5 to 4. These results were verified using quantitative RFLP of RT-PCR products. In summary, RT-coupled 5' nuclease assay is a simple, rapid, and reliable general method for quantitating differential allele expression, and can thereby greatly aid in the detection and evaluation of cis-acting functional DNA polymorphisms potentially in any gene and genomic imprinting.

PCR system to reduce allele drop out and preferential amplification in genotyping low concentration/low quality DNA samples. *S. Roberts, J. Chang, K. Heard, K. Steinberg, M. Gallagher.* Centers for Disease Control, Atlanta,GA.

Although allele drop out(ADO) and extreme preferential amplification(EPA) are well-studied phenomena in PCR amplification of single cells, much less attention has been paid to their roles in genotyping low concentration/low quality DNA samples, e.g. DNA from blood spots or buccal swabs. Increasing denaturation temperature and denaturation/annealing times, decreasing cycle number, and use of alternate polymerases have previously been shown to decrease ADO/EPA in single-cell PCR. We examined the effects of the following modifications on ADO/EPA in low concentration/low quality DNA samples. Human genomic DNA was quantified using real-time quantitative PCR. Three PCR protocols were evaluated for amplification of microsatellite marker D13S317: 1)TaqGold protocol, 2)TaqGold/modified cycling, and 3)Roche Expand High Fidelity PCR System/modified cycling. Low concentration samples consisted of diluted DNA isolated from whole blood. Low quality samples consisted of buccal cell DNA samples (0.17-2.2 ng/uL). Fragment analysis was performed using the ABI 3100. ADO, EPA, peak height ratios, and overall quality of results were analyzed. Using 25 pg of high quality template, ADO occurred only in protocol 3 (15.8% of samples). EPA occurred in protocols 1 and 3 (15.8% and 20% of samples). Using 12.5 pg, the ADO rate was observed in 60% of samples amplified using protocols 1 and 2 and 27% of samples using protocol 3. EPA also increased overall, occurring in 14.3%, 10%, and 10% of samples for protocols 1, 2, and 3, respectively. Amplifications done on low quality templates showed ADO and EPA in 5.5% of samples for protocol 1 and in no samples amplified by protocols 2 and 3. In conclusion, recommendations made to minimize ADO/EPA in single-cell PCR can also be effective in the amplification of low concentration/low quality DNA. Using alternate polymerases decreased ADO at extremely low concentrations. For moderately low concentration samples, the best results were achieved using TaqGold with modified cycling. When using low quality samples, modifying PCR conditions decreased ADO and improved peak balance, regardless of the type of polymerase used.

Program Nr: 1350 from 2002 ASHG Annual Meeting

High Throughput Wizard® SV 96 Genomic DNA purification from human buccal swab samples. *T. Worzella, C. Cowan, T. Grunst, K. Hooper.* Promega Corp., Madison, WI.

Purification of genomic DNA from human buccal samples is challenging and difficult to automate for high throughput processing. Here we demonstrate a high throughput, fully automatable, genomic DNA purification procedure from buccal swab samples. Genomic DNA is purified using Promega's Wizard® SV 96 Genomic DNA Purification System either manually or by using an automated liquid handler such as a Beckman Biomek® FX. Purified genomic DNA is high quality and suitable for downstream applications such as PCR.

Program Nr: 1351 from 2002 ASHG Annual Meeting

Molecular haplotype determination using Pyrosequencing™ technology. *M. Pettersson, M. Bylund, A. Alderborn.*
Pyrosequencing AB, Vallongatan 1, SE-752 28 Uppsala, Sweden.

The identification of haplotypes from a combination of single nucleotide polymorphisms (SNPs) on one chromosome is a powerful tool for genetic research. Haplotyping is usually performed statistically by computational analysis, or by time consuming cloning techniques. Here we present a simple molecular approach for reliable haplotype determination on an individual basis. The procedure is based on allele-specific PCR (AS-PCR) in combination with Pyrosequencing™ technology.

AS-PCR primers for each allelic variant of a SNP, with their 3' ends located at the SNP position, were used. A mismatch introduced in the second base from the 3' end was shown to dramatically improve allele-specificity. Analysis of multiple SNPs on amplified fragments using Pyrosequencing technology allowed determination of haplotypes. Genotyping of heterozygote positions after AS-PCR gave typical homozygous patterns, where the identity of the present allele depended on the allele-specific initial amplification.

Haplotype determination by the described procedure proved to be highly reliable. The results obtained by Pyrosequencing technology have the benefit of being quantitative, enabling detection of any non-specific allele amplification. In addition, the possibility of multiplex SNP genotyping using Pyrosequencing technology makes the described method an efficient solution for molecular haplotyping.

High Throughput Genotyping using a Microfluidic System that Integrates, Reagent Assembly, PCR, Homogeneous Phase Detection and Data Analysis on Nanoliter Volumes. *C. Peponnet, V. Phillips, C. Brooks, J. Coffin, Y. Yurkovetsky, J. Lai, J.A. Ferguson, E. Li, M. Strachan, A.R. Kopf-Sill.* Caliper Technologies, Mountain View, CA.

Numerous studies are performed in an attempt to understand the correlation between disease risks or drug response and individual genetic variations such as single nucleotide polymorphisms (SNPs). These association studies often necessitate millions of genotypes (thousands of patients X thousands of SNPs). Current study sizes are limited by the absence of a sufficiently low cost, high throughput genotyping platform. The microfluidic system that we are developing for genotyping integrates the reaction assembly, the PCR, the homogenous detection and the data analysis using only nanoliter reaction volumes. DNA samples are sipped from a microplate through a capillary connected to a channel inside a microfluidic chip. The sipped sample while flowing through the main channel is mixed with polymerase, dNTPs and MgCl₂ coming from a side channel. This sample/reagent mixture is then split equally into 8 independent channels whereupon 8 different SNP specific reagents (ie. primers and probes), are added -1 per channel. These 8 complete PCR mixes continue to flow through the thermocycling zone of the channels. The reactions then pass the detection zone and flow to the waste wells. The presence or absence of each allele is determined by measuring the fluorescence emission signal for two fluorescent reporters (one per allele) resulting from a 5 nuclease assay. The data is then automatically processed and genotypes are called. Samples are sipped serially, one after another, while they are genotyped on 8 SNPs in parallel, like on an assembly line. The reaction transit time from sample to detection, is approximately 25 min. DNA samples are sipped every 4 min. from a microplate and are separated by buffer spacers. Reaction volumes vary from 3 to 10 nanoliters and PCR concentrations are in the 100nM range. This microfluidic system, comprising instrument, chip and software offers a low-cost (very low volume) and high-throughput alternative to SNP identification (integrated system).

LNA nearest neighbor energy rules. *R.J. Peterson*¹, *P.M. McTigue*², *J.D. Kahn*². 1) Celadon Laboratories, Inc, College Park, MD; 2) Dept. of Chemistry & Biochemistry, University of Maryland, College Park, MD.

The industrialization of genomics demands DNA methods that provide accurate results on the first try. Primers and probes comprised solely of natural DNA may not suffice. Locked Nucleic Acid (LNA) is an RNA derivative that stabilizes hybridization, reportedly by 1.0° C to 5.0° C per LNA incorporation, due to more rigid structure and/or improved base stacking. Oligonucleotide primers and probes that incorporate LNA bases can be shorter and thus showed increased sensitivity and specificity. However, since no systematic assessment of sequence dependence has been performed, it has been impossible to predict accurate melting temperatures (T_m) for oligos of varied sequence and length, and for varied salt concentration. To address this deficiency, an extensive set of absorbance melting curves was obtained (using a Cary 100 spectrophotometer) on duplex 8-12 bp oligos, each with a single LNA modification in one strand (from PrOligo). Comparison to reference DNA allowed estimation of enthalpy and entropy increments (DDH° and DDS°) attributable to the LNA modification, for the entire set of 64 XLY perfect match triplets, where X and Y are DNA bases and L is a LNA base. A salt correction factor to adjust DS° was found to differ between LNA and DNA. In combination with energy rules for DNA, this data set allows T_m prediction for arbitrary LNA:DNA hybridizations. As is the case for DNA, LNA energy rules are strongly sequence dependent. The average T_m increases were as follows: LNA-A: 1.9+/-1.6° C; LNA-G: 3.0+/-2.1° C; LNA-T: 3.6+/-1.2° C; and LNA-C 4.4+/-1.7° C, with standard deviations reflecting sequence context. The effect on oligo T_m varied from -0.5° C to 7.8° C. Surprisingly, both DDH° and DDS° were generally positive, suggesting that LNA:DNA stability is due primarily to decreased single-stranded flexibility, not to improved base stacking. This work shows that sequence-dependent energy rules are likely to be essential for robust prediction of LNA primer and probe T_m for varied sequences, lengths, and salt concentrations. LNA:DNA design rules have been incorporated into Celadon's primer design package, Probity.

Automation of genomic DNA purification from cell cultures on Beckman Coulter's Biomek® 2000 laboratory automation workstation and Biomek FX liquid handling system using Promega's Wizard® Genomic DNA

Purification kit. *K. Roby*¹, *H. Wai*¹, *M. Cu*¹, *D. Campbell*¹, *T. Grunst*², *D. Kephart*². 1) Automated Solutions Dev Ctr, Beckman Coulter, Inc, Fullerton, CA; 2) Applications, Promega Corporation, Madison, WI.

With the advent of the post-genome era comes the need for fast and elegant methods for purification of genomic DNA, that embrace the simplicity of automation and the robustness of PCR¹-based analysis such as forensics, genotyping, HLA typing, and SNP detection. We present here a rapid fully automated method for the isolation of genomic DNA using the Promega Wizard Genomic DNA Purification Kit on Beckman Coulter's Biomek 2000 Laboratory Automation Workstation and Biomek FX Liquid Handling System. Genomic DNA is bound to the Wizard SV 96 DNA binding plates, which makes the process simple and easy to implement in the DNA research laboratory. Evaluation of the purified DNA was done by analysis of the generated PCR products. Four MapPairs[®] were used from the microsatellite marker set available from ResGen@ Invitrogen Corp. The generation of labeled PCR products was achieved using the microsatellite marker set labeled with Beckman Coulter's WellRED Dyes. These products were then run on Beckman Coulter's CEQ[™] 8000 Genetic Analysis System. Automation logistics (i.e. labware, timing and robotics control) are also discussed. [®]All trademarks are property of their respective owners. ¹PCR is covered by patents owned by Hoffman-La Roche, Inc.

Fine-mapping of segmental duplications on human chromosome 7. *J. Cheung, J.R. MacDonald, R. Khaja, A.K. Hudek, L-C. Tsui, X. Estivill, S.W. Scherer.* The Centre for Applied Genomics, Dept. of Genetics, The Hospital for Sick Children, and Dept. of Molecular and Medical Genetics, University of Toronto, Canada.

The presence of segmental duplications of DNA (duplicons) in the human genome can predispose and cause the occurrence of chromosomal rearrangements that are sometimes associated with disease (often called genomic disorders). In an effort to further annotate human chromosome 7, we have performed in silico detection and FISH experiments aimed at identifying the precise locations and orientations of all large (≥ 10 kb) and nearly identical ($\geq 90\%$) segmental duplications. We have generated a high quality DNA sequence map of human chromosome 7 (HSC7) by combining both public and Celera sequences. The resulting HSC7 assembly consists of 154Mb of sequences with four gaps (two sequence gaps and two physical gaps). The sequence was masked for repeats and then compared against itself using MegaBlast2. The results were initially parsed under these criteria: $\geq 90\%$ sequence identity, ≥ 80 bp in length, and expected value $\leq 10^{-30}$. In addition, identical hits (same coordinate alignments) as well as mirror hits (reverse coordinate alignments) were removed. Transchromosomal duplication analysis was performed against the NCBI build 29 genome assembly using the same criteria. Contiguous modules of duplicated sequences with size over 10kb were kept in the analysis. These results were subsequently converted into a coordinate file as an input for display using GenomePixelizer. As well, Blast was performed against a local Genbank NR database to identify clone and gene names that match to these duplicated regions. Overall, 5% (8/154 Mb, 190 modules) of chromosome 7 is composed of duplicated sequences (4% intrachromosomal and 2% transchromosomal), with an average size of 40kb and 94% sequence identity for each duplicon. Moreover, several large duplicons were identified in 7p22, 7p14/15, 7q11.21, 7q22, 7q36 as well as the pericentromeric region. Many of these duplications, showing chromosomal and temporal specificity, vary greatly in size, content, and organization. The characterization of these regions will allow us to examine their potential involvements in genomic disorders.

Duplication-mediated rearrangements detected by array comparative genomic hybridization. *D.P. Locke¹, R. Segraves², L.D. Carbone³, M. Rocchi³, S. Schwartz¹, R.D. Nicholls⁴, D.G. Albertson², D. Pinkel², E.E. Eichler¹.* 1) Department of Genetics, CWRU, Cleveland, OH; 2) Cancer Center, UCSF, San Francisco, CA; 3) Instituto di Genetica, Universit di Bari, Bari, Italy; 4) Department of Psychiatry, UPenn, Philadelphia, PA.

Array comparative genomic hybridization (CGH) is a high throughput method of detecting copy number changes between genomes, allowing simultaneous assessment of thousands of genomic loci. We utilized a human BAC array composed of 2,460 target sites, representing ~360 Mb of sequence distributed across the genome, to assess copy number difference between Asian and African great ape species as well as isolated human populations. A subset of the array CGH findings were verified by comparative FISH and molecular analyses. A total of 58 events were ascertained in the comparison of pygmy chimpanzee, common chimpanzee, gorilla and orangutan. Lineage-specific large-scale rearrangements, as well as events shared between species were detected. Interestingly, 60% of the verified rearrangements occurred within close proximity to segmental duplications. Compared to prior cytological and karyotypic analyses, these results suggest that hominoid genomes have been subjected to considerably more microdeletion and microduplication than expected. To complement these studies we developed a smaller-scale array focused on a region of the human genome rich with segmental duplications, 15q11-q13. We have tested the potential of array CGH to detect large-scale genomic rearrangements in this region in a variety of human clinical samples. Our results show this smaller array accurately detected both gains and losses across this region in a reproducible manner. Recent computational analysis of segmental duplications within the human genome identifies 169 regions of potential genomic instability (Bailey et al., 2002). These regions will be targets for future comparative array CGH analysis, as well as potential sites of large-scale variation and genomic disease within the human population. Based on these analyses, targeted array CGH is an extremely effective technique for detecting genomic imbalance in both comparative and clinical settings.

Genome architecture, low-copy repeats and genomic breakpoints in 17p. *P. Stankiewicz*¹, *J. Dapper*¹, *C. Shaw*¹, *S.-S. Park*¹, *L. Potocki*¹, *J.R. Lupski*^{1,2,3}. 1) Dept. of Molecular & Human Genetics; 2) Pediatrics, Baylor College of Medicine, Houston, TX; 3) Texas Children Hospital, Houston, TX.

Over 90% of SMS patients are deleted for an identical ~4 Mb genomic region in 17p11.2, whereas in the remainder both smaller and larger sized deletions were identified. The recurrent common deletions and reciprocal duplications dup(17)(p11.2p11.2) occur via non-allelic homologous recombination utilizing flanking low-copy repeats (LCRs), termed proximal (~256 Kb) and distal (~176 Kb) SMS-REPs as substrates. A third LCR copy, middle SMS-REP (~241 Kb) maps between them and is inverted in orientation. In addition, portions (~10-25 Kb) of the SMS-REPs were identified along the entire chromosome 17, on 17p13.1, 17p12, 17q11.2, 17q12, 17q21.2, and 17q23.2. To further investigate the relevance of SMS-REPs structures to chromosome rearrangements, using FISH with BACs, PACs, and long-range PCR products and PCR on somatic cell hybrids we analyzed the breakpoints of unusual sized deletions in eleven patients with SMS and six patients with chromosome translocation breakpoints involving 17p11.2. The analysis of five breakpoints of larger sized deletions led to the identification of novel, large LCRs: LCR17pA (~410 Kb), LCR17pB (~210 Kb), LCR17pC (~90 Kb), and LCR17pD (~150 Kb). Smaller sized deletions enabled us to narrow down the SMS critical region to ~1.1 Mb, and possibly to ~210 Kb. Interestingly, five chromosome breakpoints involved the inverted middle SMS-REP. Two 17p11 translocation breakpoints were found to be located within the centromere, two within ~0.5 Mb segment from cen17 and one within the distal SMS-REP. Four out of six partner chromosome breakpoints were mapped within the most telomeric sub-bands: 1p36.3, 2p25.3, 10q26.3, and Xp22.3. Our data further supports previous observations that (peri)centromeric and subtelomeric chromosome regions together with higher order genomic architecture involving low-copy repeats play a significant role in origin of different genome rearrangements.

Gene expression via DNA microarray of anterior lens epithelium from patients with and without

Pseudoexfoliation Syndrome(PEX). *K.F. Damji^{1,2}, L. Wang¹, S. Xiao²*. 1) Eye Institute, University of Ottawa, Ottawa, ON, Canada; 2) Ottawa Health Research Institute, Ottawa, Ont, Canada.

Purpose: To compare the mRNA expression pattern from lens epithelium in patients with and without PEX.

Methods: Presence or absence of PEX was determined preoperatively by dilated, slit lamp examination. The lens capsule was removed during capsulorhexis at the time of phacoemulsification cataract extraction (PCE), collected and snap frozen to 80C. The experimental group consisted of 30 pooled lens capsules from PEX patients. The control group contained the same number of capsules from patients over age 60 without PEX. RNA was extracted from the capsules using RNeasy Mini kit from QIAGEN. The quality of RNA was tested with the Agilent Bioanalyzer. The Affymetrix microarray was run for both groups by Expression Analysis (EA), Durham, North Carolina. **Results:** The anterior lens capsule, removed during PCE, contained a confluent layer of lens epithelium by light microscopy. 10ug total RNA was obtained from the pooled capsules in each group. Total output genes from the microarray are more than 20,000. Two fold or more over expression in PEX vs. control was found in 16 genes. Conversely, there were 6 genes showing 2-fold or more under expression. The balance of genes showed either equal or slight under or over expression, in both groups.

Conclusion: We have demonstrated that it is possible to compare lens epithelial gene expression in PEX and normal controls via DNA microarray technology. PEX showed significant over or under expression of genes vs control. Further study needs to be done to confirm these differences. **Acknowledgements:** Technical assistance: Feisal Adatia, Sanjoy Gupta, May Griffith and her lab staff; Contributing surgeons: Sherif El-Defraway, George Mintsioulis, William Rock, William Hodge, Ralf Buhrmann; Eye Institute operating room nurses.

***In silico* discovery of gene coding and regulatory variants in mouse QTLs using strain-specific genome sequence databases.** *J.M. Sikel*¹, *K. Marshall*¹, *S. Burgers*¹, *E. Godden*¹, *F. Yang*¹, *K. Buck*², *M.F. Miles*³. 1) Human Medical Genetics Program, Univ Colorado Health Sci Ctr, Denver, CO; 2) Oregon Health Sciences University and VA Medical Center, Portland, OR; 3) Virginia Commonwealth University, Richmond, VA.

We have developed a high throughput pipeline for the *in silico* discovery of gene variations that lie within mouse QTLs. To identify coding region sequence differences the coding sequences of QTL localized genes are retrieved from strain-specific whole genome sequence databases and altered genes identified by *in silico* sequence alignment. To test this approach we first focused on two C57BL/6J (B6) x DBA/2J (D2) QTLs involved in chronic ethanol withdrawal severity (physical dependence) that lie on chromosomes 1 and 13. The sequences for 199 QTL-localized genes from these strains were aligned and interstrain variations directly identified *in silico*. Sixteen QTL genes were found that had altered coding regions, several of which represent promising candidates to underlie these QTLs.

To identify regulatory changes that may underlie QTLs high-density microarray studies of selected strains are used to identify genes differentially expressed between strains and the regulatory sequences of genes that map to QTLs are then compared between strains *in silico* to identify altered transcriptional control sites. To demonstrate this an 11,000 gene Affymetrix chip (U74Av2) was probed with B6 and D2 prefrontal cortex brain mRNAs and 165 differentially expressed genes were identified, 26 of which mapped to known B6xD2 alcohol-related QTLs. One of these genes had a 4-fold higher expression level in B6 compared to D2, was known to be involved in alcohol action, and had a regulatory sequence variation that, in B6 mice, completely disrupted the core binding site for *Ikaros*, a known transcriptional repressor. Finally, the above approaches have wide general utility, and should be applicable to any of the several hundred QTLs that have been identified using strains for which relatively complete genome sequences are now available. This work was supported by NIH grants AA11853, AA03527 (JMS), AA1114, AA13433 (KJB) and AA13200 (MFM).

Program Nr: 1360 from 2002 ASHG Annual Meeting

Gene Expression Assays To Enable High Throughput Genomics. *K.E. Rogers, K. Lazaruk, M. Rhodes, C. Walworth, E. Spier, F. de la Vega, D. Gilbert.* Genomic Assays Business, Applied Biosystems, Foster City, CA.

The draft of the human genome enables scientific discoveries in many fields. The challenge is to make this wealth of genome information available to the laboratory.

Real time PCR using 5 nuclease chemistry with Taqman® MGB probes is the gold standard for gene expression studies. Experimental setup is simple consisting of addition of two reagents (assay mix and universal master mix) to the Target DNA. Applied Biosystems has launched two complementary product offerings that together provide a complete solution for ready to use assays for gene expression studies. These assays use the 5 nuclease chemistry with Taqman® MGB probes. All assays are provided in an easy to use single tube format.

The Assays-on-Demand™ gene expression products, will provide a validated assay for every Human gene. The initial release set is 12,000 assays targeted at all the known Refseq transcripts. Assays can be selected via gene name, NCBI reference or functional attributes. To complement the pre-designed assay products the gene expression Assays-by-DesignSM service, allows customers to submit a target sequence of interest from any organism. Applied Biosystems uses proprietary algorithms to design an assay for each target. Following synthesis and formulation, the assay is analytically tested for integrity before shipping to the customer. Genomic assays provided by both the Assays-by-DesignSM service and Assays-on-Demand™ products are delivered in an easy to use single tube format. Experimental setup is minimized consisting of addition of two reagents (assay mix and universal master mix) to the Target cDNA. Details on the design, production and testing of these assays will be presented.

Differential gene expression patterns identified in Sjogren's Syndrome patients using microarray analysis. *M.E. Grandits, D.B. Machado, C.M. Meyer, E.C. Baechler, K.M. Hughes, S.J. Lippert, A.N. Leiran, J.A. Ermer, W.A. Ortmann, P.M. Gaffney, T.W. Behrens, N.L. Rhodus, K.L. Moser.* University of Minnesota, Minneapolis, MN.

Sjogren's syndrome (SS) is a chronic heterogenous autoimmune and lymphoproliferative disorder primarily affecting salivary and lacrimal glands. The molecular events that lead to SS are poorly understood but thought to involve multiple components of immune dysregulation. The goal of this study was to identify genes that are aberrantly expressed in blood cells of patients with SS. We have used microarray analysis to compare genomic-scale gene expression profiles of peripheral blood mononuclear cells (PBMCs) in 22 SS patients and 23 healthy controls. All patients fulfilled the 2002 Revised European Criteria for Classification of SS recently proposed by the American-European Consensus Group. SS patients were thoroughly evaluated for exocrine and extraglandular manifestations. Total mRNA was isolated from PBMCs, reverse transcribed into cDNA, and used to generate labeled cRNA. The cRNA was then hybridized to oligonucleotide microarrays to determine the level of expression in over 12,600 known genes. Over 630 genes were found to be differentially expressed between patients and controls using t-tests with nominal significance of $p < 0.001$. Expression levels of over 80 of these genes differed by at least 2-fold. Dysregulation of pathways important in apoptosis, ubiquitin/26S proteasome degradation, lymphoproliferation, and responses to interferon were apparent in these data. Multiple genes in each pathway were expressed differentially, including many genes previously implicated in autoimmune processes such as FAS, Ro/SSA, several HLA loci, and BAFF. The genes identified in this analysis impart a comprehensive view into potential pathogenic mechanisms of disease and provide an important source of potential targets for development of novel diagnostic and therapeutic approaches.

Chromosome-wide discovery of imprinted and differentially expressed genes for disease study. *K. Nakabayashi*¹, *S. Minagawa*¹, *L. Bentley*², *L. He*¹, *R. Kapur*¹, *A.C. Smith*¹, *J.S. Bamforth*³, *M. Oshimura*⁴, *R. Weksberg*¹, *G.E. Moore*², *S.W. Scherer*¹. 1) The Centre for Applied Genomics, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Fetal and Maternal Medicine, Institute of Reproductive and Developmental Biology, Faculty of Medicine, Imperial College, London, UK; 3) Department of Medical Genetics, University of Alberta, Edmonton, Alberta, Canada; 4) Dept. of Molecular and Cell Genetics, Faculty of Medicine, Tottori University, Yonago, Tottori, Japan.

Genomic imprinting is a phenomenon whereby genes are differentially expressed according to their parental origin. Systematic discovery of imprinted transcripts will facilitate the identification of genes involved in diseases showing parent-of-origin effects (e.g., growth abnormalities and malignant tumors). To develop methodologies for rapid identification of imprinted and differentially expressed genes, initially we are using human chromosome 7 as a model. Three imprinted loci (*GRB10* at 7p12, *SGCE/PEG10* at 7q21.3, and *MEST* at 7q32) are known to reside on chromosome 7. Moreover, imprinted gene(s) on chromosome 7 may be involved in Russell-Silver syndrome based on the fact that ~10% of patients have maternal uniparental disomy of chromosome 7 (UPD7). We are using (i) somatic cell hybrids containing a paternal or maternal human chromosome 7 and (ii) lymphoblastoid cell lines established from patients having UPD7, as RNA sources for RT-PCR and microarray experiments (Affymetrix GeneChip Array) to screen for differentially expressed genes. Initially, we identified 17 genes mapped on chromosome 7 showing at least three-fold difference in expression level between paternal and maternal alleles. Three of these were the known imprinted genes, *SGCE*, *PEG10*, and *MEST*. To confirm the imprinting status of the remaining 14 candidate genes, we are using somatic cell hybrid assays and allelic expression analyses in human fetal tissues. Two new genes, one being a coding transcript at 7q21 and the other a non-coding antisense transcript at 7q32 (*MESTITI*) have already been identified to be imprinted. Experiments are underway to characterize all of the transcripts on human chromosome 7.

A whole-genome linkage disequilibrium SNP map and validated assay resource. *D. Gilbert, C. Scafe, Y. Wang, M. Laig-Webster, X. Su, R. Koehler, H. Avi-Izthak, J. Ziegle, L. Wogan, E. Spier, F. De La Vega.* Applied Biosystems, Foster City, CA.

We developed a set of 5' nuclease allelic discrimination assays to score single nucleotide polymorphisms (SNPs) with the aim of creating a reference map for use in candidate-gene, candidate region and whole-genome linkage disequilibrium (LD) mapping studies. The assays were validated by individually genotyping 90 DNA samples, 45 from African-American and 45 from Caucasian individuals, selected from the Coriell Human variation collection. Our goal is to define a set of >150,000 assays distributed across all the genes in the genome for SNPs of high heterozygosity in at least one population. Candidate SNPs were prioritized from the Celera RefSNP database which contains 4 million unique SNPs from combined Celera and Public sources, through a triage process that requires evidence of independent discovery of the minor allele. We selected SNPs on 27,007 Celera gene predictions, in a gene focused picket-fence with an average density of one SNP per 10 kb of gene length, including 10 kb upstream and downstream of the predicted gene boundaries. PCR primers and TaqMan® probes for the 5' nuclease assay were then designed by a software pipeline that picks oligonucleotide sequences and then screens the assays against the genome database for potential artifacts. Following genotyping of 90 individuals, the performance of each assay is benchmarked against stringent criteria for background signal, adequate signal generation, and specificity. Our validation results showed that 94% of the SNPs tested in the population panels were polymorphic and about 90% of the assays passed our stringent performance criteria. Of those, 86% have minor allele frequencies ≥ 0.1 in Caucasian panel and 84% in African-American samples. These figures represent an extremely high SNP validation rate, and an unprecedented yield of common SNPs useful in LD mapping. The individual genotypes being generated have enabled us to identify blocks of LD and survey the haplotype diversity across all gene regions of the genome for these populations. This information is being used to refine the SNP set coverage.

Program Nr: 1364 from 2002 ASHG Annual Meeting

SNP assays to enable high throughput genomics. *A.H. Dodge, D. Dailey, P. Dong, M. Rhodes, L. Smith, F. de la Vega, G. Spier, C. Walworth, D. Gilbert.* Genomic Assays Business, Applied Biosystems, Foster City, CA.

The draft of the human genome enables scientific discoveries in many fields. The challenge is to make this wealth of genome information available to the laboratory. The 5 nuclease chemistry with Taqman®MGB probes has many attributes that lend itself to analysis of Single Nucleotide Polymorphisms. It has a high throughput, with 90k genotypes possible in a 8hr day from a single ABI Prism®SDS 7900HT and low DNA input, (1ng/5ul). Experimental setup is simple consisting of addition of two reagents (assay mix and universal master mix) to the Target DNA

Applied Biosystems has launched two complementary product offerings that together provide a complete solution for ready to use assays for genotyping via SNPs. These assays use the 5 nuclease chemistry with Taqman®MGB probes. All assays are provided in an easy to use single tube format.

The Assays-on-Demand™ SNP Genotyping products, provide 150K ready-to-use assays to pre-validated Human SNP targets which customers may select by, SNP, gene or genomic location. Each assay has been validated on two populations.

To complement the pre-designed assay products the SNP Assays-by-DesignSM service will allow customers to submit a target sequence of interest from any organism. Applied Biosystems uses proprietary algorithms to design an assay for each target. Following synthesis and formulation, the assay is analytically tested for integrity before shipping to the customer.

Genomic assays provided by both Assays-by-DesignSM service and Assays-on-Demand™ products are delivered in an easy to use single tube format. Experimental setup is minimized consisting of addition of two reagents (assay mix and universal master mix) to the Target DNA.

Details on the design, production and testing of these assays will be presented.

Long Distance Linkage Disequilibrium in the Han Chinese and Mixe Amerindians in four genomic regions. *K.A. Mather¹, M. President¹, S. Easteal², J. Hollenbach¹, W. Klitz³, G. Huttley², G. Thomson¹*. 1) Integrative Biology Department, The University of California, Berkeley, CA; 2) The Australian National University, Canberra; 3) Children's Hospital of Oakland Research Institute, Oakland, CA.

Analysis of linkage disequilibrium (LD) in the CEPH population revealed a pattern consistent with the action of natural selection; a few large genomic regions with a high density of markers in significant LD. In ten regions of the genome, this clustered LD is greater than that found in the HLA (Human Leukocyte Antigen) region (Huttley et al. 1999). The high LD regions identified are likely to be experiencing selection in the CEPH, making them good candidates in a search for regions under selection in other populations. However, if selection pressures vary among populations, patterns of LD may differ between populations. In order to determine if the high LD regions identified in CEPH also exhibit high LD in other populations, we analyzed microsatellite LD. We examined four genomic regions (ranging in size from 5 to 9 Mb) on chromosomes 6 (the HLA region), 20 (a control region without high LD in the CEPH), 7 and 22 (two CEPH high LD regions) in two non-Caucasian populations: Mixe Amerindians (n=46) and Southern Han Chinese (n = 48). We find evidence for LD between markers separated by several Mb, distances which are much greater than the sizes of the recently described haplotype blocks (Daly et al. 2001, Jefferys et al. 2001). The Mixe population had more LD than the Han in all four regions, consistent with the theoretical expectation (Slatkin 1994) that small populations will have more LD than large populations which have expanded. The ordering of regions by amount of LD (as measured in a variety of ways, including proportion of loci in significant LD and the length of tracts of LD) is similar in the two populations. The regions on chromosomes 6 and 7 have the greatest amount of LD, while those on chromosomes 20 and 22 have the least. These results are consistent with similar selective pressures (as reflected in long distance LD patterns) among regions in the two populations. This work is supported by NSF-DDIG, NIH grants and an IB summer fellowship to KAM. KAM is an HHMI Predoctoral Fellow.

Comprehensive setting of 30,000 polymorphic microsatellite markers throughout human genome. *A. Oka¹, K. Okamoto^{2,3}, S. Makino², T. Endo⁴, H. Hayashi², K. Fujimoto², E. Tokubo², A. Takaki², Y. Nagatsuka², T. Imanishi¹, T. Gojobori⁴, G. Tamiya^{1,2}.* 1) Integrated Database Group, Japan Biological Information R, Koto-ku, Japan; 2) Tokai University, School of Medicine, Isehara, Japan; 3) Chugai Pharmaceutical Co., Ltd, Gotemba, Japan; 4) National Institute of Genetics, Mishima, Japan.

The aim of this study was to identify novel polymorphic microsatellite markers throughout human genome. Our previous data indicated that microsatellite markers showed a linkage disequilibrium with disease-related alleles spanning from 100 to 200 kilobases (kb). Based on this evidence, we made a plan to identify a total of 30,000 polymorphic markers throughout human genome with 100 kb intervals. In order to investigate the microsatellite polymorphism, we performed genotyping using pooled DNA from 100 healthy Japanese individuals. 31,135 markers were identified as a polymorphic in Japanese pool. Furthermore, we investigated the characteristics of these polymorphic markers, including heterozygosity, allele number, and length of repeated unit. Mean heterozygosity and allele number were approximately 0.6 and 6.0 respectively. These data strongly suggest that we did obtain highly informative genetic markers. Next, we have mapped newly identified polymorphic markers into chromosomes, composed of the assembled genomic sequences from the repository of International Human Genome Sequencing Consortium. With these mapping data, we plan to submit the our novel the polymorphic markers to the public genomic repository. A total of 31,135 markers will aid the construction of a useful marker map of the human genome and will be a powerful tool for fine mapping of disease-susceptibility genes in genome-wide association studies. In addition, they should be applied for other purposes such as population studies.

Chromosomal regions containing high-density and ambiguous-mapped putative single nucleotide polymorphisms (SNPs) correlate with segmental duplications in the human genome. X. Estivill^{1,2}, J. Cheung², M.A. Pujana¹, K. Nakabayashi², S.W. Scherer², L-T. Tsui². 1) Genes and Disease Program, Genomic Regulation Center, Barcelona, Catalonia, Spain; 2) Program in Genetics & Genomic Biology, Research Institute, The Hospital for Sick Children, and Department of Molecular and Medical Genetics, University of Toronto. Toronto M5G 1X8, Canada.

We have explored the NCBI single nucleotide polymorphisms (SNPs) database for a correlation between the density of putative SNPs, as well as SNPs that map to different chromosomal locations (ambiguously-mapped SNPs), and segmental duplications of DNA in chromosome regions involved in genomic disorders. A high density of SNPs (14.4 and 12.4 SNPs per kb) was detected in the low copy repeats (LCRs) responsible for chromosome 17p12 duplications and deletions that cause peripheral neuropathies. None of the SNPs at the PMP22 gene were ambiguously mapped, but 93% of the SNPs at LCRs mapped on both LCR copies, indicating that they are in fact variants in paralogous sequences. Similarly, a high SNP-density was found in the LCR regions flanking the neurofibromatosis type 1 (NF1) gene, with 80% of SNPs mapping on both LCR copies. A high density of SNPs was found within LCR sequences involved in the deletions that mediate contiguous gene syndromes on chromosomes 7q11, 15q11-q13 and 22q11. We have analyzed the whole sequence of chromosome 22, which contains 14% of ambiguously-mapped SNPs, and have found a good correlation between these SNPs and segmental duplications detected by BLAST analysis. We have identified several segments of ambiguously mapped SNPs, four corresponding to LCRs involved in the chromosome 22q11 microdeletion syndromes. Our data indicate that most SNPs in LCR segments are in fact paralogous sequence variants (PSVs), and suggest that a significant proportion of the SNPs in the NCBI database correspond to PSVs within segmental duplications of the human genome sequence. These PSVs should be useful, in conjunction with BLAST approaches, to further characterize segmental duplications in the human genome. PSVs could be useful in tracing variability in copy number at these loci and in studying their potential link to human genetic disease.

Program Nr: 1368 from 2002 ASHG Annual Meeting

Verification of the efficacy of BAC restriction fingerprint physical maps for sequencing projects using the *Salmonella typhimurium* genome. *D. Layman, M. Sekhon, J. McPherson.* Genetics , Washington University - GSC, St. Louis, MO.

The Mapping Group at the Genome Sequencing Center provides high quality whole genome physical maps using BAC restriction fragment fingerprints. These fingerprint maps have been used to derive the minimal tiling path that represents the genomic sequence for a number of organisms, including *C. elegans*, *C. briggsae*, *Arabidopsis thaliana*, Mouse, Human, and *Salmonella typhimurium*. The construction of the physical map of the 4.8 Mb genome of *S. typhimurium* provided a unique opportunity to verify the accuracy of the BAC fingerprint maps. Most physical maps precede genome sequencing; however the construction of the *S. typhimurium* BAC map began after the sequence was finished so that a tiling path of BAC clones would be available to the scientific community for research. This tiling path was verified by comparison of BAC end-sequence to the finished genomic sequence. Once the BAC fingerprints were generated and assembled into a physical map of ordered clones the quality of the map was analyzed by comparison to the finished sequence. The completed genome sequence was divided into overlapping segments to mimic the BAC clones. Each segment was then divided into its corresponding restriction fragments to generate an in silico fingerprint. All of the in silico fingerprints were successfully incorporated into the physical map using the same software that was used for the initial physical map assembly. The ordered in silico fingerprints regenerate the finished genomic sequence indicating the accuracy of the BAC clone map.

Physical map and sequence analysis in the mouse t-complex inversion 2 region and comparison to the human syntenic region. *P. Waeltz, M. Brathwaite, M. Schroeder, D. Schlessinger, R. Nagaraja.* Laboratory of Genetics, NIA/NIH, Baltimore, MD.

The t-complex in the proximal half of mouse chromosome 17 has unusual features, including loci for many recessive embryonic lethal mutations and segregation distortion. It has been demonstrated that 20-30% of wild mice carry the t-haplotype, containing four large inversions when compared to laboratory mouse strains. In addition, there are many small duplications and deletions in the region. During the mapping of collections of cDNAs from the preimplantation and periimplantation stages, it was shown that many ESTs cluster within the t-complex region. A systematic functional study of all the genes responsible for these phenotypes and a detailed characterization of inversions and duplications require they be identified, mapped and characterized to define their biological role. Towards this goal, we have undertaken an effort to build a STS/BAC based physical map of the mouse t-complex, corresponding to a 20 cM region in an estimated 30 Mb physical distance. The current map contains 250 BACs and 570 STSs, which covers about 12 Mb of the region's total span. Contigs range in size from 300 kb to 5 Mb. The map is supported by STSs designed from BAC end sequences and the fingerprinting data.

Regarding the region of concentration to date, the physical map covers ~ 8Mb, between Brachyury (proximal end) and D17Leh55 (distal end) with one gap. Via targeted sequencing of selected clones from a minimal tiling path in this region, it is apparent that in the human syntenic region on chromosome 6, the gene content and its order is well conserved between Brachyury and Plg and the chromosomal segment has undergone an inversion during evolution between Plg and Sod2. Ongoing sequencing efforts and analysis will catalog the region's complete gene content and are also expected to a) define the inversion 2 breakpoint in greater detail and b) identify candidate gene(s) for T-associated sex-reversal, which maps here.

A Modular Approach to High-Throughput SNP Genotyping. *S. Duan¹, E. Lovins¹, R. Donaldson¹, R. Miller¹, P. Taillon-Miller¹, P. Kwok².* 1) Dermatology, Washington Univ., St. Louis, MO; 2) Cardiovascular Res. Ins. and Dermatology, Univ. of California, San Francisco, CA.

To construct high-density haplotype maps of the human genome based on single nucleotide polymorphism (SNP) markers and to perform whole genome genetic association studies of common diseases, millions of genotypes must be obtained over 2 to 3 years. In these applications, thousands of SNPs are genotyped on a few hundred samples. We report here a flexible, modular approach to SNP genotyping that emphasize low start-up instrumentation and assay development costs. We have previously described a primer extension genotyping method called the FP-TDI (template-directed dye-terminator incorporation with fluorescence polarization) assay. We have designed PCR and primer extension primers for over 1.4 million human SNPs found in public databases. The only assay development cost is therefore the 3 unlabeled PCR-grade primers for each assay. Using the 384-well reaction format, we have established procedures to obtain 9,216 to 18,432 genotypes per day, depending on the liquid handling equipment and number of workers utilized. For example, with 2 teams of 2 workers, PCR machines with twelve 384-well heating blocks, one low-end liquid handling workstation, and one FP plate reader, 9,216 genotypes (24 X 384 reactions) can be obtained per 8-hour working day. Assuming 250 working days a year, >2.4 million genotypes can be obtained with this procedure. If a high-end liquid handling robotic workstation is used in conjunction with PCR machines with 24 384-well heating blocks and the same fluorescence polarization plate reader, 3.5 workers can obtain 18,432 genotypes (48 X 384 reactions) per day. The yearly genotyping rate is therefore >4.6 million genotypes. Because the reaction protocol is extremely simple, new workers can be trained in days. Establishing new modules is therefore an easy matter. We have implemented this modular approach at two different sites with minimal effort. The procedure we report here is easily transferable and can be adopted by any group with minimal start-up cost or training. It will be able to meet the needs of all study designs that require high throughput genotyping.

Quantitative prehybridization quality assessment using three-color cDNA microarrays. *M. Hessner*^{1,2}, *X. Wang*¹, *K. Vaughan*², *L. Meyer*¹, *S. Khan*², *J. Tackes*², *M. Schlicht*³, *M. Datta*³, *H. Jacob*², *S. Ghosh*¹. 1) Department of Pediatrics, Medical College Wisconsin, Milwaukee, WI; 2) The Human and Molecular Genetics Center, Medical College Wisconsin, Milwaukee, WI; 3) Department of Pathology, Medical College Wisconsin, Milwaukee, WI.

DNA microarrays have great potential to generate new insights into human disease, however, construction methodologies still lack the ability to determine array quality and integrity prior to hybridization. We have solved this problem through printing fluorescein-labeled cDNA probes, which are compatible with target labeling dyes (Cy3 and Cy5) when using confocal laser scanners possessing narrow bandwidths. High-density arrays were evaluated using a version of Matarray [Wang et al., 2001, NAR 29, E75] modified to measure multiple prehybridization array quality parameters including correct probe address through the mapping of unique plate-specific negative controls. The average fluorescein signal/slide (1500 RFU to >15000 RFU) and the overall slide signal to noise values (calculated signal/signal+noise; 0.65 to 0.95, mean=0.92+/-0.03) varied considerably between processed slides. Comparison of hybridization results from arrays with high DNA/element and low background to those with low DNA/element and/or high background values (n=50 replicate pairs) revealed a direct and significant relationship ($R^2=0.80$, $p<0.001$) between prehybridization fluorescein image quality and replicate consistency, illustrating that microarray data quality can be improved through quality-matched prehybridization slide selection. Currently we are selecting arrays with signal to noise values >0.85, average element fluorescein intensity >3,000, and CV (coefficient of variation) of element fluorescein intensity <10%. Our approach, separates slide coating, printing, and processing from hybridization and provides a direct method for probe amplification control and plate tracking, direct examination of array/element morphology including identification of elements not printed, determination of post-process probe retention, and a means of quantitative prehybridization array quality control and selection that results in improved data quality.

Comparison of data concordance between cDNA and Affymetrix oligonucleotide microarrays. *X. Wang¹, N. Jiang², K. Vaughan³, L. Meyer¹, H. Khoo¹, S. Khan³, S. Ghosh¹, P. Tonellato², H. Jacob³, M. Hessner¹.* 1) Department of Pediatrics, Medical College of Wisconsin, Milwaukee, WI; 2) Bioinformatics Research Center, Medical College of Wisconsin, Milwaukee, WI; 3) The Human and Molecular Genetics Center, Medical College of Wisconsin, Milwaukee, WI.

The cDNA array offers design flexibility and independence of sequence knowledge as attributes. However, clone handling, clone authentication, and possible cross hybridization between related genes and splice variants are potential caveats. Alternatively, the Affymetrix oligonucleotide array offers probe sequence control, multiple interrogations per gene, and high density, while its downsides are cost, lack of design flexibility, and potentially uneven element performance. We compared the concordance of expression data between these two platforms, utilizing human (9,200 clones) and rat (18,400 clones) cDNA arrays as well as Affymetrix U95Av2 human and U34A rat arrays. The correlation and concordance between the U95Av2 and human cDNA arrays were investigated through hybridizations of UACC903 and Jurkat RNA. 4733 genes were common to both human platforms, and the correlation coefficient between detected ratios was >0.80 ; when carrying the analysis through to lists of genes differentially expressed more than 2-fold, the concordance was found to be $\sim 65\%$. Furthermore, many genes have multiple representations on each human or rat cDNA array, targeting different regions of the corresponding full-length cDNA. Among probes common between the two human platforms, nearly 21% ($\sim 1,000$) had multiple representations on either array. This enabled a probe location (5' to 3') comparison of the two systems, and an evaluation of how this parameter impacted overall data concordance. Finally, since the Affymetrix analysis involves RNA amplification, we also conducted a three-way comparison between Affymetrix, and cDNA arrays using amplified and directly labeled targets. An understanding of the characteristics of both platforms allows investigators to capitalize on the advantages that each system has to offer.

Program Nr: 1373 from 2002 ASHG Annual Meeting

Quantitative analysis of methylation status at CpG islands using Pyrosequencing™ technology. *S. Eriksson, A. Alderborn, M. Pettersson.* Pyrosequencing AB, Vallongatan 1, SE-752 28 Uppsala, Sweden.

Methylation of cytosines at CpG dinucleotides is an epigenetic modification of DNA that has profound effects in the mammalian genome. The methylated status of CpG islands present in the promoter region of a gene has a significant influence on its expression. DNA methylation has been shown to play important roles during embryonic development and X chromosome inactivation. In addition, tumorigenesis is characterized by aberrant methylation patterns resulting in, for example, silenced expression of tumor suppressor genes.

Methods for analysis of methylation patterns usually rely on bisulfite treatment of denatured DNA which converts non-methylated cytosines to uracils. Since methylated cytosines are resistant to this treatment, differentially methylated CpGs can, by this procedure, be analyzed as artificial C/T single nucleotide polymorphisms (SNP). Pyrosequencing™ technology is a rapid and accurate real-time sequencing method for analysis of short to medium length DNA sequences. Multiplex genotyping of SNP can be accurately performed and the allele frequencies of several SNPs in a pooled sample correctly quantified. We show that Pyrosequencing technology is a fast and reliable method for the detection and quantification of methylation differences at multiple specific CpG sites.

Multiplex Detection of 10 SNPs Located in the Coding Region of the Mitochondrial Genome. *J.M. Butler¹, M.D. Coble², I. Letmanyi², T.J. Parsons², P.M. Vallone¹.* 1) Biotechnology Div, Natl Inst Standards/Technology, Gaithersburg, MD; 2) Armed Forces DNA Identification Laboratory, Rockville, MD.

Single nucleotide polymorphisms (SNPs) represent an important class of DNA variation in which sequence differences between individuals are examined. A number of different SNP detection and typing technologies exist. This work focuses on the use of a SNP typing approach that works on a multi-color fluorescence capillary electrophoresis platform. Fluorescent SNP detection is accomplished (through a mini-sequencing assay) by using the commercially available SNaPshot multiplex kit.

Mitochondrial DNA (mtDNA), which is maternally inherited, can play an important role in many aspects of human identity testing due to the fact that it is more resilient to environmental degradation. A desire to gain more information than can be provided by the hypervariable regions of the mtDNA control region has led to a search for informative sites outside the control region around the remaining 15,000 base pairs of the mtDNA genome. A set of 10 highly informative sites from around the mtDNA genome has been combined into a multiplex PCR and SNP detection assay that can be detected in high-throughput fashion using multi-color fluorescence and multi-capillary instrumentation.

Experimental conditions for the multiplex amplification of nine regions in the mitochondrial genome containing ten SNP sites have been optimized. Using the multiplex generated PCR amplicons as templates ten different SNP sites are probed simultaneously in the same tube using tailed extension primers and reagents contained the ABI SNaPshot multiplex SNP kit. The products of the fluorescently labeled primer extension reactions are separated and detected on the ABI 3100 16 capillary electrophoresis instrument. The design of the multiplex PCR and extension primers as well as data interpretation will be discussed.

Genome-wide molecular and computer-based evaluation of mitochondrial pseudogenes in human nuclear DNA.

J.R. Lupski^{1,2,3}, P. Stankiewicz¹, P.E. Chen⁴, C. Kashuk⁴, M. Withers¹, A. Chakravarti⁴, N. Katsanis⁴. 1) Department of Molecular & Human Genetics; 2) Department of Pediatrics, Baylor College of Medicine; 3) Texas Children Hospital, Houston, TX; 4) Institute of Genetic Medicine and Wilmer Eye Institute, Johns Hopkins University, Baltimore, MD.

The human genome contains various higher-order structures that are often present in multiple copies and can serve as template for variation and evolution. The mitochondrial genome (mt) can be considered such a structure, since recent computational analyses of human genome sequence have predicted the presence of as many as 600 fragments of mtDNA in the nuclear genome. We have evaluated the presence, position and composition of mtDNA in nuclear DNA (*numts*) by computational analysis of four assemblies of the human genome (public and private) and by in vitro studies on nuclear DNA from several primate species. We report the mapping of 142 and 996 *numts* in mouse and human respectively, which we have validated by performing FISH with mtDNA as a molecular probe and interphase and metaphase nuclei of mtDNA depleted cells as target DNA, and by amplifying junction fragments of mtDNA insertions from human-rodent monochromosomal hybrids. In contrast to current belief, our detailed evaluation of the position and composition of each insertion suggests that clusters of seemingly independent *numts* are single mt insertions, followed by non-random divergence, which creates the "pseudoappearance" of multiple independent *numts*. Our data also indicate that a significant percentage of *numts* is transcriptionally active, as demonstrated by analysis of the presence and distribution of *numts* in dbEST and by RT-PCR on various adult and fetal tissues. Intriguingly, as much as 12% of all *numts* are intragenic, suggesting a non-random distribution in the genome. Furthermore, the sites of increased transcriptional activity correlate with positions of increased mt sequence conservation, suggesting that some portions of the mtDNA may preferentially provide material of potential functionality in nuclear DNA, although the mechanism and role of this material will require further study.

Mapping genes for human mitochondrial ribosomal proteins. *T.W. O'Brien¹, H.-R. Graack², N. Fischel-Ghodsian^{3,6}, E.B. Mougey⁴, B. Wittmann-Liebold⁵, J.E. Sylvester⁴.* 1) Biochemistry and Mol Bio, University of Florida, Gainesville, FL; 2) MediTarget GmbH, Breddinerweg 5 D-13591 Berlin, Germany; 3) Cedars-Sinai Medical Center, Los Angeles, CA; 4) Nemours Children's Clinic, Jacksonville, FL; 5) Max-Delbruck-Center for Molecular Medicine, D-13122 Berlin-Buch, Germany; 6) UCLA, Los Angeles, CA.

Mitochondrial DNA encodes tRNAs and rRNAs, but the other genes for the mitochondrial translation system are found in nuclear DNA. Upward of 85 mammalian mitochondrial ribosomal proteins (MRPs) are imported into mitochondria where they assemble into ribosomes that are responsible for translating the 13 mRNAs for essential proteins of the oxidative phosphorylation system. Since mutations in mitochondrial tRNA and rRNA can cause various pathological states, we hypothesize that mutations in MRP genes are also candidates for human disorders. Our approach is to use N-terminal and internal amino acid sequence data obtained from purified bovine MRPs (O'Brien, et al. (2000) *J Biol Chem.* 275: 18153) to search EST databases. Chromosome map positions for the MRP genes are ascertained by in situ hybridization (FISH) with genomic sequences and/or by using in silico methods to search Genbank and GeneMap through NCBI. At present, we have over 78 different human MRPs at various stages of characterization. We are currently investigating one MRP as a potential candidate for Russell-Silver Syndrome (RSS), a dwarfism characterized by low birth weight and lateral asymmetry, characteristics that are consistent with reduced mitochondrial function. DNA from RSS patients is being analyzed for possible mutations in MRPs. In addition to studying their clinical relevance, long term characterization of MRP genes should lead to important insights into mammalian evolution, coordinate regulation of nuclear and mitochondrial gene expression, and ribosome function. This work is being done as part of the Mammalian Mitochondrial Ribosomal Consortium and is supported by NIH/NIDCD grant RO1DC04092 and the Nemours Research Program.

Program Nr: 1377 from 2002 ASHG Annual Meeting

High Throughput Automated Mutation Discovery. *P.S. Andersen¹, C. Jespersgaard¹, C. Brown², J. Vuust¹, M. Christiansen¹, L.A. Larsen³.* 1) Dept Clinical Biochemistry, Statens Serum Inst, Copenhagen, Denmark; 2) Applied Biosystems, 850 Lincoln Centre Drive, Foster City, CA 94404; 3) Wilhelm Johannsen Institute of Medical Biochemistry and Genetics, University of Copenhagen, Denmark.

Screening for unknown mutations has been dependent on several methods, all of which have a relatively high sensitivity. In the present study we describe a mutation discovery procedure that is applicable when screening a large number of samples for unknown mutations where we use automated capillary array electrophoresis single strand conformation polymorphism (CAE-SSCP). Using DNA sequencing as the golden standard we validate the method by using a number of in vitro constructed mutations. We have determined the sensitivity and specificity of the system and shown the high throughput capacity of the screening procedure.

Program Nr: 1378 from 2002 ASHG Annual Meeting

Full multiplexing of up to 48 SNP genotypes on the SNPstream® UHT Genotyping System. *M.A. Kunkel, J. Baisch, C. Barceleau, C-Y. Huang, C. Gelfand.* Orchid BioSciences, Inc, 303A College Road East, Princeton, NJ 08540.

Wide-ranging commercial applications for SNP genotyping are enabled by the accuracy, flexibility and cost-effective platform scalability of SNP-IT™, the core genotyping technology of Orchid BioSciences. Adaptation of this single biochemistry to a variety of novel microarray platforms, known as SNP-IT *tag-array*, provides the necessary flexibility to enable studies ranging from research bench-top applications to the highest industrial throughput needs. Ultimately, the utility of genetic variability in pharmacogenetic and pharmacogenomic studies is dependent on flexible, cost effective genotyping systems.

The flexibility of any platform is directly related to its ability to scale to the users requirements for a particular study. Higher levels of multiplexing allow for both ease of use in experimental design and reductions in overall reagent and sample costs. The SNPstream UHT Genotyping System, currently used routinely at the 12-plex level, is being expanded to 48-plex reactions. Higher multiplexing is of particular utility for human parentage/forensic testing, where 48 genotypes can provide sufficient confidence in the resultant genetic profile to distinguish one individual from another. A single individual paternity result can therefore be collected utilizing only one well of the assay plate. As well, SNPs for mapping studies can be batched into moderate-sized SNP panels, to quickly identify areas of association. By automating the process, throughputs of vast proportions, potentially in excess of several million genotypes per day, can be achieved on a single instrument. With the assays and data formats standardized, small and large cross-study analyses are intrinsically compatible. Application of this higher multiplexing with the SNPstream UHT Genotyping System will be demonstrated, featuring paternity and other identity studies.

Digital Oligonucleotide Tiling (DOT): A novel genome scanning assay. *A.P. Shuber, K. Boynton, J. Skoletsky.*
EXACT Sciences Corp, Maynard, MA.

Background: Genomic scanning methods such as restriction fragment analysis, allele specific oligonucleotide hybridization chips, and single nucleotide primer extension can be powerful assays for the detection of mutations. One drawback of using these methods is that the mutations must be known and primers specific to these mutations must be utilized. We have developed a simple and efficient assay capable of scanning for unknown point mutations. We report the use of this assay in the detection of single base mutations in a model APC polymorphism system, as well in colonic tissues from colorectal cancer (CRC) patients. **Methods:** The DOT assay was developed with a model system comprised of a 221 bp target region consisting of a polymorphism (A/G) at codon 1493 in the Mutation Cluster Region (MCR) of the APC gene. Scanning was performed by hybridization with an array of 17 bp oligonucleotides, in solution, to a sequence of APC MCR DNA amplified from PBMCs. After hybridization, an S1 nuclease cleavage was performed and target template DNA that had not been fully hybridized to the wild type oligonucleotide array due to mismatches was cleaved. The presence of a mutation was determined by the detection of strand truncation. Additionally, this assay was performed on DNA from colonic biopsies in CRC patients. **Results:** When template DNA containing a mismatch was hybridized to the wild type oligonucleotide array, cleavage was detected. When template DNA without a mismatch was assayed, no cleavage product was detected. When the DOT assay was used on DNA from microdissected tissue mutations were detected and confirmed by standard DNA sequencing methods. **Conclusions:** We have developed an in-solution Digital Oligonucleotide Tiling (DOT) genomic scanning assay that is a simple and efficient method of screening for mutations. Additionally, we have demonstrated that this assay is capable of mutation detection in DNA purified from clinical samples (CRC tissues). This novel method should be a valuable addition to other methodologies that scan for unknown mutations.

Four-color multiplex PCR assay for the simultaneous detection of four allelic variants in a closed tube using a single thermal cycler program. *L.A. Ugozzoli, D. Chinn, K. Hamby.* Life Science Group, Bio-Rad Laboratories, Hercules, CA.

The 5' nuclease assay is one of the most widely used allele-specific homogeneous assays. The assay takes advantage of the 5'→3' nuclease activity of Taq DNA polymerase to cleave fluorescently labeled allele-specific oligonucleotide (ASO) probes when they hybridize to PCR products during the PCR annealing phase. We developed a real-time multiplex assay for the simultaneous detection of up to four allelic variants in one closed tube. The assay combines the power of multiplex PCR with the specificity provided by ASO hybridization using the 5' nuclease assay format. We applied the four-color assay for the simultaneous detection of the factor V Leiden (FVL) G1691A and prothrombin (PT) G20210A mutations, the two most common known genetic risk factors for venous thrombosis in Caucasians. Human genomic DNA is prepared from whole blood using standard procedures. A 97 bp DNA sequence of the coagulation factor V gene is co-amplified with a 111 base pair DNA sequence of the coagulation factor II (prothrombin) gene using four PCR primers. In addition, the PCR reactions included four differentially labeled ASO probes for the specific detection of the different FVL/PT G20210A genotypes. To evaluate the assays performance characteristics, we performed a method-comparison study. Results generated with the four-color assay were compared with those obtained with a reference method based on the use of PCR and restriction enzymes. We analyzed 52 DNA samples with known FVL / PT G20210A genotypes that were previously genotyped with the reference method. We found a 100% correlation between the results generated by both methodologies. We conclude that the four-color assay is specific and reproducible for the detection of the FVL/PT G20210A mutations, and it can be easily adapted for the detection of other SNPs. The assay, which will be useful for both molecular diagnostic and research laboratories, offers numerous advantages over more traditional methods for the detection of the FVL and PT G20210A mutations. The advantages include speed and simplicity of the method, reduced labor, reduce risk of cross-contamination, and higher throughput.

Application of a DNA microarray-based comparative genomic hybridization (Array-CGH) method to the study on the genetic effects of Atomic bomb radiation; Report 2. *N. Takahashi¹, K. Sasaki¹, N. Tsuyama¹, M. Kodaira¹, K. Sugita², H. Katayama², K. Hiyama³, E. Hiyama³.* 1) Lab Biochem Genetics/Dept Gen, RERF, Hiroshima, Japan; 2) Dept Info Tech, RERF, Hiroshima, Japan; 3) Sch Med Hiroshima Univ, Hiroshima, Japan.

For over 50 years, the Foundation has conducted a study on the effects of A-bomb radiation on human germ cells. For the purpose of conducting the study at the genome-level, it is essential to efficiently collect a large volume of genetic information from a sufficient number of samples. It is also important to accurately detect a deletion which occurs on the gene on autosome (in most cases, radiation-induced mutations appear to be about 1 Mb deletion), since the deletion appears as a change of 2 copies of alleles to one. An Array CGH can detect single-copy decrease and increase from normal diploidy. For this, the Array CGH is considered to be an effective method for our study. Last this meeting, we reported that trial experiments using about twenty clones had proven this method could reliably detect deletion-type mutations. Here, we examined the feasibility of this method by using the arrays having numerous Bac- or Cosmid-clones, and also developed a computer-based speedy data processing method. We constructed arrays to which 676 cloned DNAs have been immobilized. Genomic DNA from cell lines established from children of A-bomb survivors or myeloma patients were used as test samples. In first stage, DNA to be used as an internal control was labeled with Cy5, and each test DNA was labeled with Cy3. After they were mixed, they were hybridized and quantified. By using software developed by our foundation, we determined the presence and absence of abnormality from the fluorescence intensity ratio of Cy5 to Cy3. Next stage, conversely, mixture of Cy3-labeled control and Cy5-labeled test samples were used as probes. We identified putative polymorphic variations in some spots. These results indicate that the array CGH, together with computer-based data analysis, can detect changes in the copy number of specific DNA fragments speedily and efficiently. Thus, this means that this method is one of the most useful for our study.

A Survey of Sequence Divergence of Genes on Human Chromosome 21 between Human and Other Primates Reveals Variation of Evolution Rhythms among Transcription Units. *J. Shi¹, H. Xi^{1,2}, Y. Wang¹, C. Zhang¹, L. Jin¹, Y. Shen¹, L. Jin^{1,2}, W. Huang¹.* 1) Chinese National Human Genome, Shanghai, China; 2) The Institute of Genetics, Fudan University, Shanghai, China.

The study of genomic divergence between human and primates, our living relatives will shed lights on the origins of human being, unique human traits and even the genetic basis for some human diseases. Chromosome 21 is the smallest chromosome in human genome and has important regions related to mental retardation and other diseases. In this study, we sequenced the coding and regulatory regions of 127 known genes on human chromosome 21 in DNA samples from human and chimpanzees, and a part of the corresponding genes from orangutan, gorilla and macaque. We identified 3,003 nucleotide variations between Human and Chimpanzee over a total of 399,264bp sequences. The difference of coding, promoter and coding boundary regions were 0.51%, 0.88% and 0.85% respectively, much lower than the previously reported 1.23% of randomly sequenced genomic regions. Significant variations in divergence between human and chimpanzee were observed among the genes. An Ka/Ks analysis allows identification of genes and their segments that possibly went through positive Darwinian selection. Furthermore, the variations that are specific to human lineage might lead to the functional evolution and attribute to the humanness phenotype through changing structure and/or dosage of the proteins expressed. A phylogenetic analysis unambiguously showed that chimpanzees were our closest relatives to the exclusion of other primates.

Pyrosequencing™ assess the most common Cystic Fibrosis mutations. *S.I. Toth¹, A.L. Schiller², J. Dunker², U. Larsson², M. Storgards², A. Alderborn².* 1) Pyrosequencing AB, Westborough, MA; 2) Pyrosequencing AB, Uppsala, Sweden.

Cystic Fibrosis is a lethal recessive genetic disorder in Northern European populations affecting 1 live birth in 1600-2500. In contrast to many other recessive disorders, the carriers of CF mutations (1 in 25 Caucasians) have no biochemical or physiological alterations by which they could readily be identified. As a consequence the search for genetic markers became a matter of decisive importance. Thirteen years after the discovery of the cystic fibrosis transmembrane conductance regulator (CFTR) gene and the characterization of over 1000 mutations, CF is now to become the first disease targeted for population-wide genetic screening.

Pyrosequencing AB (Sweden) offers several genotyping systems well suited to meet the demand for research and routine testing of mutations in the CFTR gene, providing simple, rapid, cost efficient and accurate detection of relevant mutations. Pyrosequencing is a DNA sequencing technology based on real-time detection of pyrophosphate released upon nucleotide incorporation. Highly reliable CF assays have been designed and developed for 61 of the most common CFTR mutations, including point mutations as well as insertions and deletions. The assays are greatly condensed including multiplex design of both PCR and sequencing reactions. The assays have the potential to easily include less common mutations in the same analysis simply by extending the number of nucleotide dispensations in each pyrosequencing reaction. In addition, the same assays have been used for population-based determination of carrier frequencies using allele quantification.

Transcriptional response to ionizing radiation exposure. *K. Jen, V.G. Cheung.* Department of Pediatrics, University of Pennsylvania, Philadelphia, PA.

Medically, ionizing radiation (IR) is commonly used for diagnostic and treatment protocols. However, IR poses a major threat to healthy cells by compromising genomic integrity and cellular viability. To identify genes involved in the cellular response to IR stress, we used oligonucleotide microarrays to examine the transcriptional changes that occur following IR exposure.

We irradiated lymphoblastoid cells at a dose of 3Gy or 10Gy and tracked the mRNA levels of approximately 12,000 genes at 1hr, 2hr, 6hr, 12hr, and 24hr after IR exposure. An unirradiated sample was prepared to assess baseline gene expression levels. We determined expression changes by comparing irradiated samples to the unirradiated control. Among the genes surveyed, 329 and 864 genes changed transcript levels in response to 3Gy and 10Gy of IR, respectively. Genes that showed the largest expression changes include *ATF3*, *GADD45A*, *PPM1D*, *CDKN1A*, and *FDXR*. As expected, a large portion of the characterized genes (22%) are involved in pathways associated with IR stress response including DNA damage repair, cell cycle regulation, cell proliferation, and/or cell death. We also identified many genes not known previously to be involved in the IR-response.

We describe two classes of expression changes following IR stress: (1) rapid early expression changes and (2) gradual expression changes at later time-points (6 hr post-irradiation and beyond). We denote these IR-responsive genes as early or late response genes. Different genes associated with cell cycle regulation and apoptosis are involved in these two phases of the IR response. For example, *TNFRSF6* (Fas/Apo-1) and *TNFRSF10B* (DR5) show early expression changes while *BAX* changes expression levels at later time-points. Our data also indicate dose-dependent effects on temporal patterns of gene expression. At a lower IR dose, most early response genes return to basal levels shortly after induction. However, at a higher dose, early response genes exhibit more rapid gene expression changes that are greater in magnitude and last longer in duration. In this presentation, we will describe results from our genomic approach in studying the process of cellular adaptation to IR stress.

A single-tube multiplex minisequencing assay for simultaneous genotyping of 6 single nucleotide polymorphisms (SNPs) of the MDR1 gene. *C.G.L. Lee^{1,2,4}, P.C. Gwee¹, K. Tang¹, J. Chua¹, S.S. Chong^{3,5}.* 1) Div Medical Sci, Natl Cancer Ctr, SINGAPORE; 2) Biochemistry; 3) Paediatrics, Natl Univ Singapore, SINGAPORE; 4) Medicine; 5) Paediatrics, Johns Hopkins School of Medicine, Baltimore, MD.

Responses to different drugs can vary widely between different individuals as a result of genetic variations in drug metabolizing enzymes, transporters, receptors or other co-factors. The MDR1 multidrug transporter has been shown to efflux a wide variety of structurally and functionally unrelated drugs. Genetic polymorphisms within the MDR1 gene have recently been intensively studied, and the C3435T single nucleotide polymorphism (SNP) has been associated with differences in drug response. However, this SNP, a silent polymorphism, was found to be contradictorily associated with different changes in MDR1 phenotype. We recently demonstrated through haplotype analyses that this SNP is in linkage disequilibrium (LD) with two other SNPs within the MDR1 gene. We hypothesized that strong LD between C3435T and different unobserved causal SNPs in different study populations may explain the association of the 3435T allele with different MDR1 functional changes. To simplify the genotyping process, we have developed a rapid single-tube minisequencing assay that simultaneously genotype 6 common SNPs spanning approximately 80 kb of the gene. In this assay, a multiplex PCR amplification of 5 different fragments containing the 6 MDR1 SNPs is performed. Excess primers and unincorporated nucleotides are enzymatically degraded prior to addition of SNP-specific minisequencing primers which contain non-specific tails of differing lengths. Single nucleotide primer extension was performed using the SNaPshotTM kit. Unincorporated fluorescent ddNTPs were enzymatically inactivated and SNP-specific primers with fluorescently incorporated ddNTPs were resolved by capillary electrophoresis on the ABI 3100 and analyzed using Genotyper 3.7TM. The development of this rapid and robust assay will greatly simplify multiple MDR1 SNP genotyping and subsequent haplotype construction, thus facilitating more efficient identification of the causal SNPs in linkage disequilibrium with C3435T in the different study populations.

Program Nr: 1386 from 2002 ASHG Annual Meeting

Miniaturization and automation of SNP genotyping using AlphaScreen. *J.-A. St-Pierre, J. Lian, D. Rivard, E. Robitaille, D. Chan, L. Beaudet.* PerkinElmer Life Sciences, 1744 William, Montréal, QC, Canada H3J 1R4.

In AlphaScreen homogeneous assays, signal is generated when a donor and an acceptor bead are brought into proximity. Laser irradiation of the donor beads generates singlet oxygen that reacts with the acceptor beads in close proximity, resulting in an amplified light signal. AlphaScreen beads, with oligonucleotides attached at their surface, can be used to perform very rapid and accurate single-nucleotide polymorphism (SNP) typing assays. In these single-well assays, based on allele-specific hybridization, AlphaScreen beads and probes are combined with the PCR reagents and added to PCR plates with the genomic DNA prior to amplification. The assay set up requires only two additions to the plates and is easily automatable. After amplification and probe hybridization, genotypes are analyzed without having to purify the PCR products or to perform additional enzymatic reactions. We will present genotyping data for several SNP assays that were miniaturized and automated using the PlateTrak liquid handling workstation (PerkinElmer Life Sciences). The accuracy of the AlphaScreen assays in 384-well format will also be evaluated.

An updated physical map encompassing the HCHOLA3 region at 1p34 and analysis of 37 functional and positional genes. *C. Boileau*^{1,3}, *M. Abifadel*^{1,2}, *L. Villegier*¹, *M. Varret*¹, *JP. Rabes*^{1,3}, *D. Allard*¹, *A. Robin*¹, *M. Devillers*¹, *M. Krempf*⁴, *C. Junien*^{1,3}. 1) INSERM U383, Hosp Necker-Enfants Malades, Paris, France; 2) Saint-Joseph University, Beirut, Lebanon; 3) Hosp Ambroise Pare, Paris, France; 4) Hosp Hotel Dieu, Nantes, France.

Autosomal dominant hypercholesterolemia (ADH) is mainly caused by mutations in the low density lipoprotein receptor gene (LDLR) or in the gene encoding its ligand: apolipoprotein B (APOB). However, we have shown that more than 30% of ADH cases are not associated with mutations in either these two loci. We reported one French pedigree with ADH in which we excluded linkage to the LDLR and APOB genes and mapped a new locus HCHOLA3, (previously named FH3) in a 9 cM region at 1p34-p32. Hunt et al. confirmed our results with the study of an Utah ADH family and localized the HCHOLA3 locus in an overlapping 16 cM region. The 1.6 cM common interval between D1S211 and D1S2130 maps at 1p34. We have constructed a 2.9 Mb BAC transcript map encompassing the candidate interval and bridged the four sequence contigs of this region available from the working draft sequencing program. We localized 26 transcripts and identified 11 new genes using Genscan exon prediction program. Several of these genes could be implicated in lipid metabolism. We have sequenced over 300 exons from 37 genes. We identified more than 90 single nucleotide polymorphisms (SNP) with 15 new non-synonymous amino acid changes. As yet, no ADH causing mutation has been found in the original family nor in 3 newly identified French pedigrees linked to this genetic interval. In conclusion, we report the continuous physical map of the FH3 region, the exclusion of 37 regional candidate genes and describe 40 SNPs newly identified. This work should facilitate identification of HCHOLA3 as well as other genes mapped at 1p34.

Program Nr: 1388 from 2002 ASHG Annual Meeting

Genomic Hybrid Identity Profiling (GenomeHIP) of chromosomal regions Identical By Descent. *P. Brooks, J. Hager, S. Maillard, J.-P. Saraiva, M. Vanpeene, C. Marcaillou.* IntegraGen, SA, 4 rue Pierre Fontaine, 91000 Evry, France.

We have elaborated a procedure to identify chromosomal regions that are identical by descent (IBD) between two related individuals. The approach combines and improves on some previously described concepts, in that genomic DNA from two individuals is fragmented, mixed to form hybrids and then challenged with DNA mismatch repair proteins (Nelson et al.), and IBD-enriched clones are identified by two color hybridization to arrays of marker DNA's (Snijders et al.). The novel procedure has been designed for high throughput production starting with modest amounts of DNA samples. Treatment of paired samples includes internal quality controls that enable simultaneous validation of the elimination of mismatch-bearing fragments and the preservation of perfectly paired hybrid fragments. Whole genome amplification (WGA) of the final product of the procedure produces sufficient DNA for labeling for hybridization. BAC generic amplification (BGA) is used to generate DNA for printing arrays. A novel method has been developed to assess WGA and BGA protocols for preservation of complexity and relative representation. Addition of pg amounts of lambda DNA or of varying ratios of rice BAC DNA's showed that the procedure can discriminate between one, two and five human genomic copy equivalents. We have validated the entire procedure using CEPH family DNA's and chromosome-specific BAC arrays. Clusters of clones with high fluorescent signals corresponded to regions of known IBD.

Graphical tools for visualizing the Human Genome. *R.L. Gibson, R. Little.* Genome Therapeutics Corp., Waltham, MA.

There is now more sequence data available for the human genome than for any other organism. This data, which consists of a combination of genomic and derived sequence data (e.g. cDNAs and ESTs), provides invaluable resources for the investigation of the molecular basis of diseases in humans. However, the search for causes of genetic disease requires a large amount of molecular and genetic information to be presented in various displays in order to enable researchers to interpret and utilize the data. We have created 3 Perl/Tk programs to help visualize data in this pursuit: **transcript_map**, which assists in ordering genetic markers by visually displaying clones and the markers they contain; **gene_view**, which displays low-level details of a gene, showing contigs, primers, exons, and polymorphism; and **snp_view**, which provides a high-level view of a chromosome region, showing clones, SNPs, exons, markers, genes, and promoters. These applications provide the basis for viewing all of the commonly available forms of sequencing and cloning data used in these studies.

Construction of a physical map of the distal tip of human chromosome 21p. *H. Dimitropoulos*¹, *S.M. McCutcheon*¹, *Z. Burki*², *J. Doering*², *M.R. Cummings*¹. 1) Dept. of Biological Sciences, University of Illinois at Chicago, Chicago, IL; 2) Dept. of Biology, Loyola University, Chicago, IL.

The short arm/telomeric region of chromosome 21p is a model for understanding the organizational landscape, sequence and eventually, the function of a heterochromatic region of the genome. We are creating a physical map of the short arm subtelomeric region of human chromosome 21 using a combination of somatic cell hybrids, Southern blotting and FISH. This region, called the distal tip, spans the distance from the distal rDNA junction to the telomere. We are using a hybrid cell line, X;21, carrying a translocated copy of chromosome 21 as the only human component. The X;21 translocation retains only the distal tip of chromosome 21. Our data indicates that the distal tip of this copy of chromosome 21 is 1.6 Mb long and contains more than a dozen different repetitive sequence families organized in a complex fashion. Using blots from pulsed field gel electrophoresis we have established that b satellite, satellite I and satellite III are highly represented in this region. An analysis of digests using over 20 restriction enzymes shows a complex pattern of linkage relationships among b satellite, satellite III, satellite I and AK500 in this small region of the genome. As an example, we have identified a 53 kb *NcoI* fragment that contains b satellite, satellite III and AK500, further underscoring the complexity of this subtelomeric region. Additionally, at least two types of the b satellite family have been identified on the distal tip: b₂ and b₇. These linkage relationships provide a framework for the construction of a detailed physical map of this region of the short arm. Most of the repetitive sequences on the distal tip are also found in the proximal region of the short arm of chromosome 21 where they are organized into larger, more homogeneous blocks. This physical map represents the first detailed analysis of an acrocentric short arm subtelomeric region.

Characterization of the organization of the 9-kb subtelomeric repeat on human chromosome 21. S.M.

*McCutcheon*¹, *H. Dimitropoulos*¹, *E. Kalinina*¹, *J. Doering*², *M.R. Cummings*¹. 1) Dept. of Biol. Sci., University of Illinois, Chicago, IL; 2) Dept. of Biology, Loyola University, Chicago, IL.

Little is known about the organization of the repetitive sequences on the subtelomeric region of the human acrocentric p-arms. Thoraval *et al.* (PNAS 93:4442,1996) isolated a 9-kb subtelomeric repeat which was localized by FISH analysis to all acrocentric p-arms and the centromeric region of chromosomes 3 and 4. Additionally, they showed this repeat is similar to a chimpanzee telomere-associated sequence. To further characterize the 9-kb repeat, we initiated an analysis of the organization of this sequence on a single acrocentric chromosome using a deletion hybrid panel and telomere-anchored PCR analysis. Two cell lines derived from a translocation between HC 21 and HC X were critical in this analysis. One cell line contains the distal region of the 21 p-arm from the telomere to the rDNA genes, while the other cell line contains the reciprocal translocation chromosome containing HC21 sequences from the rDNA locus to 21qter and two additional chromosomes (HC 3, HC 5). Southern analysis using these and additional deletion hybrid cell lines localized the 9-kb repeat to regions both proximal and distal to the rDNA locus. Additionally, preliminary data indicates the repeat organization on HC 3 is different from the organization on HC 21. To determine the proximity of this repeat to the telomeric repeats on HC21, the same PCR strategy as Thoraval, *et al.* was employed. When using total genomic DNA, we isolated the same junction site as Thoraval *et al.*. However, PCR analysis using DNA from a hybrid cell line containing HC 21 as the only human genomic component yielded a different junction sequence. The cloned HC21 junction sequence is at a different location in the 9-kb repeat than the junction site isolated from genomic DNA. However, only a few telomeric repeats are present in this clone which may represent the junction of the 9-kb repeat with other sequences, perhaps from the proximal locus. The organization of this and other cloned junctions are currently under investigation.

Putting SNPs to the test: Retrieval rates and coverage using public SNP databases. *B. Burwinkel, U. Nentwich, S. Steinlicht, S. Bangert, S. Grant, R. Tolle.* Genetic Epidemiology, LION bioscience AG, Heidelberg, Germany.

Single nucleotide polymorphisms (SNPs) are of ever increasing importance as markers for gene discovery, target validation or as diagnostic markers for genes involved in complex diseases. Today, the vast majority of SNPs in databases are neither validated nor are frequency data available. So it is of great interest to know what verification rate can be expected from database SNPs, how many new SNPs might be expected with own SNP detection efforts and the rate of SNPs in allelic association. 33 cardiovascular disease candidate genes were analyzed with a focus on 26 nuclear receptor (NR) genes, 2 NR cofactor genes, 5 lipid metabolism related enzymes and transporter genes. An analysis of public SNP databases yielded 1278 polymorphisms for these genes. From this list 266 SNPs were chosen for further analysis according to the following criteria:

SNPs that lead to amino acid changes or might have a regulatory influence e.g. affecting splicing, transcription efficiency or mRNA stability. Uniform distribution of SNPs across the genetic locus was an additional criterion. SNPs with several submissions or SNPs with available frequency data greater than 5% were preferably chosen. We avoided choosing SNPs lying in repetitive sequences or in regions with ambiguous mapping positions. The selected SNPs were verified in 24 unrelated German individuals by PCR amplification and direct sequencing of approximately 250 bp surrounding the respective SNP. Of the 266 tested SNPs, 141 SNPs (53%) were verified. The success rate was higher when analyzing SNPs that had several submissions (66%) than for SNPs with single submitters (45%). 104 new SNPs were detected and finally 108 SNPs were screened in assays.

As just approximately a half of the annotated SNPs were reproducible and occur with a frequency above 5%, it is advisable perform a pre-selection of database SNPs and validated SNPs prior to mass screening. Despite the increasing number of SNPs in databases, there is still a remarkable success rate in finding new SNPs with in-house screening efforts.

SNP allele frequency determined for pooled samples in multiplexed assays. *C.A. Gelfand, K.E. Scott, S.A. Varde.*
Orchid BioSciences, Inc., Princeton, NJ.

Studies associating phenotype to genotype are becoming increasingly prominent in the post-genomic era. As a first step for many association studies, the analysis of so-called “pooled” samples provides a simple way to screen SNPs for any potential correlation to phenotypes, or vice versa. A pooled sample is simply an equal mixture of any desired number of individual DNA samples, which can be grouped together randomly or, often, grouped by having similar phenotypes, such as disease versus control populations, selective breeding traits, or any other quantitative or qualitative traits. When used as an input into a SNP genotyping assay, the resulting data reflects the allele frequency of the population compiled into the pool, rather than the simple heterozygote or homozygote alternatives for individual samples.

We have used SNPstream® UHT Genotyping System, one of Orchids tag-array SNP genotyping platforms, to determine allele frequency in pooled samples. Representative data will be shown comparing the allele frequency calculated from genotyping of a panel of individual SNPs to the observed frequency of the pooled sample of the same DNAs. Such experiments demonstrate the basic ability to analyze pooled samples. Further control experiments, with the input samples being mixtures of various ratios of known individual samples, demonstrate the accuracy of SNPstream UHT Genotyping System to report allele frequency. Importantly, the allele frequency data is collected in the same multiplex assays, including both PCR and SNP-IT™, that give SNPstream UHT Genotyping System its inherent flexibility and throughput.

Program Nr: 1394 from 2002 ASHG Annual Meeting

Solution for high throughput SNP validation. *D. Bishop, C. Brown, E. McIntyre, C. Frantz, Y. Lou, G. Mitra, T. Hatch.* Applied Biosystems, Foster City, CA.

Genomic variation, as identified by single nucleotide polymorphisms (SNPs), provides key information to understanding biological mechanisms and disease susceptibility. However, to effectively use this information for pharmacogenomic or association studies SNPs should be validated to determine allele frequency and the correlation between phenotype and genotype prior to completing large genotyping projects. Applied Biosystems offers a complete solution for performing high throughput SNP validation by combining various capillary electrophoresis instruments, reagents and software applications. We present here the workflow for generating over 15,000 genotypes within 24 hours using the ABI PRISM® 3100 Genetic Analyzer on a 22-cm capillary array. SNP genotypes were produced using the ABI PRISM® SNaPshot® Multiplex Kit, a single-base extension chemistry kit that utilizes a fifth-dye labeled size standard to interrogate multiple loci within a single capillary. Prior to using the SNaPshot® Multiplex Kit, the SNaPshot® Primer Focus™ Kit was used to evaluate potential SNP probes and provide key information to enable automated analysis within GeneMapper™ Software Version 3.0. This workflow provides the research community with a convenient method of completing their SNP validation studies with a high degree of accuracy in a short amount of time.

Plurex™ Multiplexing System: High-throughput production of PCR amplicons for genetic analyses. *D. Albagli, B. Chen, A. Sassi, D. Siu, R. Anderson.* Aclara BioSciences, Mountain View, CA.

Generation of the tens to thousands of amplicons needed by genetic analysis platforms (arrays, mass spec, electrophoresis) is a bottleneck in experimental designs and a high-cost step. Typically amplicon generation is done as (a) a single-plex reaction, necessitating high reagent and template consumption, or as (b) a tube multiplex reaction, requiring extensive development to ensure the primer pairs are compatible. Even if multiplexed primer sets have been developed, amplicon drop-out is not uncommon. Modifying a multiplex set also requires full validation of the new set because the effects of primer-primer interactions are poorly understood.

At ACLARA we have developed the Plurex device to overcome the bottlenecks and limitations of tube-based multiplexed PCR reactions. In the device each PCR reaction occurs in a spatially distinct region, substantially isolated from one another, and so occur as a collection of single-plex reactions.

The Plurex device is an injection-molded part that contains 96 sample channels in standard SBS plate format. A channel is a narrow spiral that has wells at each end designed for manual or robotic fluid I/O. Each channel has 10 distinct zones to which 10 different primer sets may be spontaneously attached. User-defined primer sets are first added and bound in the channel, and then all other reagents, e.g. enzyme, dNTP's and buffer, are added to the channel and shared across all the reactions. The Plurex device is then thermocycled on standard flat-block instruments.

Users can further multiplex reactions within each reaction zone of the channel. Multiple primer sets may be programmed to segregate within each zone, to enable for example a 50-plex reaction in each channel in which there are 10 different localized 5-plex reactions. In a Plurex device the design and validation of multiplex PCR is significantly simplified while yielding highly multiplexed performance, high productivity and reduced costs and sample usage.

Program Nr: 1396 from 2002 ASHG Annual Meeting

Understanding the microsatellite mutation mechanism in the human genome in silico. *Y. Lai*¹, *F. Sun*^{2,1}. 1) Department of Mathematics, University of Southern California, 1042 West 36th Place, DRB142, Los Angeles, CA 90089-1113; 2) Department of Biological Sciences, University of Southern California, 1042 West 36th Place, DRB142, Los Angeles, CA 90089-1113.

Microsatellite markers are widely used for genetic studies, but their mutation mechanism remains unclear. To investigate the relationship between the mutation rate and the number of repeat units, we collect dinucleotide microsatellites distributions of different motifs in the human genome. We consider a model that microsatellite mutations consist of point mutations, single stepwise extension slippage and contraction slippage. We explore the mutation mechanism using the equilibrium equation of a continuous time Markov process. We first study the widely used symmetric model assuming that the extension rate equals the contraction rate. We find that the total slippage rate decreases when the number of repeat units is above a threshold. This conflicts with experimental observations. We develop a novel approach to understand the mutation mechanism of microsatellites. We cluster microsatellites with similar number of repeat units into groups and assume that microsatellites within the same group have the same extension and contraction rates. We estimate the extension and contraction rates using the observed distribution. For poly-CA, we find that the contraction rate increases while extension rate slightly decreases with the number of repeat units. The results are consistent with experimental observations. This is the first study to show such phenomena based on genomic sequence data. We also estimated the extension and contraction rates for other motifs.

Program Nr: 1397 from 2002 ASHG Annual Meeting

Genotyping with Orchid's SNP-IT™ Technology Using Singlex and Multiplexed Tag-based Platforms. *B.C. Sundaresan, J.C. Mylet, T. Mulcahy, C. Crego.* Application Res, Orchid BioSciences Inc, Princeton, NJ.

With the increasing availability of information on DNA sequence and single nucleotide polymorphisms (SNPs), it has become increasingly important to develop effective assays for SNP scoring. As part of our Platform Propagation™ strategy, Orchid has developed several platforms with varying throughputs, harnessing the power and flexibility of SNP-IT™, Orchid's proprietary single base primer extension technology. Having a range of platforms provides not only a choice of instrumentation for the customer but also facilitates moving from one platform to another as their study scope changes, without changing the basic assay chemistry. Here we demonstrate that genotyping results obtained with the various platforms are highly concordant, supporting the platforms' flexibility and compatibility, without compromising data quality.

Loss of Heterozygosity Studied using SNPs as Markers. *S.A. Varde¹, J.A. Lathrop¹, M.A. Donaldson¹, J.M. Maris², G. Hii², P. Fortina², E. Rappaport², W.M. Ankener¹, J.F. Studebaker¹, S.V. Alfisi¹, M.S. Phillips¹, M.T. Boyce-Jacino¹, C.A. Gelfand¹.* 1) Research and Development, Orchid BioSciences, Inc., 303 College Road East, Princeton, NJ 08540; 2) The Childrens Hospital of Philadelphia, Division of Oncology, ARC902A 34th and Civic Ctr. Blvd., Philadelphia, PA 19104.

The task of elucidating the human genome sequence has led to a wide range of projects that utilize the genome sequence as a starting point, such as genotyping of single nucleotide polymorphisms (SNPs). Orchid BioSciences, Inc. has developed a new generation of SNP genotyping technology based on SNP-IT tag array, a next generation technology that combines multiplexed PCR and Orchid's proprietary SNP-IT single-base extension genotyping with a generic tag-array readout. Multiplexed SNP-IT reactions are spatially sorted into singlex for analysis by hybridization to the tag arrays. Among the advantages of SNP-IT tag array is its generic nature, allowing the same single array design to be used to genotype any SNP of interest. Representative SNP genotyping using this tag-array approach will be presented.

The flexibility of the SNP-IT tag-array allows SNPs to become straightforward tools for a wide range of genetic studies. Our collaborators at The Childrens Hospital of Philadelphia are conducting loss of heterozygosity (LOH) studies on human-derived neuroblastoma cell lines and primary tumor samples. We will present SNP genotyping data showing LOH chromosome band 1p36 in cell lines and clinical samples. Forty-one SNPs were selected within 1p36.3, and also sixty SNPs at 16p12-13 served as a negative control. This study indicates the power of the use of SNPs for studies not only of LOH, but also gene mapping, linkage disequilibrium and haplotype mapping.

Examples of the Plurex™ Multiplex PCR System for Genotyping Analysis Platforms: Primer Extension and Microsatellite Analysis. *A.P. Sassi, M. Satya, D. Albagli, R. Anderson.* ACLARA BioSciences, Inc., Mountain View, CA.

For high-throughput genotyping to be cost-effective, systems are needed which can streamline the genotyping process from crude sample through to genetic information. Multiplexing can accomplish higher throughput by processing many samples through one stage (purification, amplification, extension, detection) at a single time. For example, a variety of analytical techniques exist in which many samples can be detected at one time, such as electrophoresis, mass spectrometry, and array hybridization.

ACLARA's Plurex™ Multiplexing System is a plastic microfluidic device designed to address high-throughput sample preparation by multiplexing PCR amplification. The device is an array of 96 spiral channels contained in a standard SBS 96-well plate footprint. Each channel contains ten spatially isolated reaction zones that perform up to 50 individual PCR amplifications in each channel. Thus, in a single device, up to 4800 amplicons can be generated.

We have used amplicons from multiplexed reactions in the Plurex device to demonstrate compatibility with several downstream genotyping platforms. Here we present data from three genotyping demonstrations: primer extension/array hybridization, primer extension/mass spectrometry, and direct analysis by capillary electrophoresis for microsatellite-based genotyping. In each case, results are compared to pooled tube-based controls.

Active L1 retrotransposons in the human genome. *B. Brouha*¹, *R. Badge*², *J. Schustak*¹, *J. Moran*³, *H. Kazazian*¹. 1) Dept Genetics, Univ Pennsylvania, Philadelphia, PA; 2) Department of Genetics, University of Leicester, Leicester, UK; 3) Dept Genetics, Univ Mich., Ann Arbor, MI.

Though most are inactive, L1 retrotransposons comprise 17% of the human genome. There are 14 known cases of an insertion causing disease. Full-length L1s are ~6kb and move by a copy and paste mechanism. According to Boissinot et al, (2000), the non-Ta category, characterized by GAG at L1 positions 5926-8, is the oldest L1 family. The pre-Ta family, with ACG at these positions, is the next oldest and the Ta family, with ACA, is the youngest. The Ta family is subdivided, from oldest to youngest, into Ta-0, Ta-1nd, and Ta-1d subfamilies. We isolated all 89 potentially active L1s (full length with 2 intact ORFs) from the sequenced human genome. Three of the 89 elements were non-Ta, 26 were pre-Ta, 60 were Ta, and 2 did not fall into any category. Of Ta elements, 17 were Ta-0 elements, 1 was a Ta-0/Ta-1 intermediate, 3 were Ta-0 elements with the Ta-1d deletion, 16 were Ta-1nd, and 21 were Ta-1d. We tested 81 of the 89 elements for presence in 23 individuals from 5 ethnic groups and found 37 were not fixed in the population, making them useful phylogenetic markers. Putative younger elements tended to be rarer than older ones. To date, 46 of the 89 have been cloned and assayed in cell culture for retrotransposition activity relative to L1RP (a highly active element). We found activity for 4 of 13 pre-Ta elements (average activity 2.6% of L1RP); 6 of 11 Ta-0 (1.9% of L1RP); 4 of 9 Ta-1nd (3.4% of L1RP); and 9 of 12 Ta-1d (24.75% of L1RP). Putative younger elements had higher average activities and greater variation in activity. Extrapolation by category indicates that 45 of the 89 elements will be active. With a finished genome we expect about 48 active elements per haploid genome or 96 in the diploid genome. This work triples the number of known active human L1s from 10 to 34. Upon completion, we will know the number, genomic location, activity level, and polymorphism information content of all active L1s in the sequenced human genome. The data provide further evidence that L1s continue to retrotranspose, causing genomic expansion and insertional mutagenesis.

A Novel Structural Domain in the L1 Retrotransposon. *A.H. Farley, H.H. Kazazian Jr.* Department of Genetics, University of Pennsylvania School of Medicine, Philadelphia, PA.

LINE-1 (L1) retrotransposons constitute ~17% of the human genome and are thought to integrate into genomic DNA through an endonuclease (EN) nick and target primed reverse transcription (RT) mechanism. We identified a mutation at residue 364 of L1 ORF2 in an uncharacterized region between the EN and RT domains that had an effect in reducing retrotransposition activity and insertion length in a cell culture based assay of retrotransposition. Iterative BLAST searches (PSI-BLAST and XBLAST), resulted in several significant hits to proteins rich in α -helices. This finding was reinforced by 2 structure prediction programs (COILS and PHD), which divided residues 318 to 374 into three helices, the first having a high probability of forming a coiled-coil motif. This arrangement is a general hallmark of helix-turn-helix DNA binding motifs, but especially homeobox proteins. A ClustalW alignment using this segment of L1 and human HoxB1 resulted in 35% identity. We used this alignment to generate a three-dimensional model of the L1 segment using the homology-modeling program MODELLER 6. The model was verified using the energy profile program PROSAAII and conformation validation program PROCHECK. A three-dimensional alignment of the L1 model with the template HoxB1 structure had a root mean squared deviation of less than 1.0 Å. We made six selective mutations based on the L1-HoxB1 alignment two unconserved mutations and four conserved mutations. We assayed the ability of the six mutants and the wild type (wt) parental construct (L1_{RP}) to retrotranspose in the cell culture assay using the EGFP retrotransposition marker and 143B osteosarcoma cells. The two unconserved mutants A334W and N360A have 100% of wt activity. The four conserved mutants L324P, K342A/I343A, R364G, E369A/R370A have 9, 4, 60, and 8% of wt activity respectively. The contrast between the effects of mutating conserved versus unconserved residues points towards a relationship between L1s and homeobox/helix-turn-helix proteins.

The A-tail length controls active SINE elements in populations. *P.L. Deininger¹, A.M. Roy-Engel¹, A.-H. Salem², T. Oyeniran¹, L. Deininger¹, N. West¹, D.J. Hedges², G.E. Kilroy², M.A. Batzer².* 1) Tulane Cancer Center, New Orleans, LA; 2) Dept. of Biology, LSU, Baton Rouge, LA.

There are over 1 million Alu inserts in the human genome, yet very few of these elements are capable of amplification. Most recent Alu inserts in the human genome have very long A-tails. Because the A-tails are coded from the source Alu element, this observation suggests that only Alu elements with A-tails greater than 40 bases in length may be capable of amplification. There are only a few hundred such Alu elements in any given genome. Furthermore, the long A-tails seem to be evolutionarily unstable. However, although the tendency is for the A-tails to shorten, older Alus with shorter tails may also sporadically increase their A-tail length and become reactivated. These findings help explain the amplification dynamics and subfamily structure of SINEs. We also find that Alu RNAs with these long A-stretches are in RNP complexes with poly A binding protein (PABP). We describe a model which explains both the population dynamics of these active elements and the role of the long A-tail and PABP in the amplification process.

Molecular evolution of human LINE-1 retrotransposons since before the human-chimpanzee divergence. *G.D. Swergold, A. Rubin, I. Ovchinnikov.* Columbia Univ, New York, NY. 10032.

The goal of this study was to fill a large gap in our knowledge of the evolution of L1 elements in the human genome. This gap stretched from the time of divergence of the gorilla and human lineages, usually estimated as between 8 and 11 million years ago, till the rapid expansion of the human-specific L1Hs-Ta elements approximately 2 million years ago. Our approach relied on the use of shared sequence variants (SSVs) that differentiate the currently amplifying L1Hs-Ta elements from the last insertions that amplified prior to the hominid-chimpanzee divergence (L1PA2). We performed a series of 12 BLATN searches against GenBank using a query sequence derived from the L1 3' UTR that contained various combinations of the SSVs. A total of 155 insertions that matched the query sequences were identified. These could be separated into several groups of insertions that are estimated to be between 2 and 8 million years old. The relationships among the groups was investigated by human population and species-level genotyping, and by structural studies (insertion length, poly-A tail, open reading frames), sequence alignments, and phylogenetic analyses. Our results indicate that the new L1 groups account for much of the molecular evolution of human L1s since the time of the hominoid-great ape divergence. We report the first identification of a L1 subfamily that amplified both before and after the divergence of humans from our closest relatives. Our data are consistent with the hypothesis that the rate of L1 amplification has been increasing during recent human evolution.

Characterization of Mutations in Severe Methylenetetrahydrofolate Reductase Deficiency Reveals an FAD-Responsive Mutation. *S. Sibani, E. O'Ferrall, C. Artigas, D. Rosenblatt, R. Rozen.* Human Genetics, Pediatrics and Medicine, McGill University, Montreal, Quebec, Montreal.

Methylenetetrahydrofolate reductase (MTHFR) synthesizes 5-methyltetrahydrofolate, a major methyl donor for homocysteine remethylation to methionine. Severe MTHFR deficiency results in marked hyperhomocysteinemia and homocystinuria. Patients display developmental delay and a variety of neurological and vascular symptoms. Cloning of the human cDNA and gene has enabled the identification of 24 rare mutations in homocystinuric patients, and two common variants (677CT (A222V) and 1298AC (E429A)) with mild enzymatic deficiency. Homozygosity for 677CT or combined heterozygosity for both polymorphisms is associated with mild hyperhomocysteinemia. In this communication, we describe three novel mutations in patients with homocystinuria: a missense mutation (1025TC, M338T), a nonsense mutation (1274GA, W421X) and a 2-bp deletion (1552delAG). We expressed the afore-mentioned missense mutation as well as 2 previously-reported amino acid substitutions (983AG (N324S), and 1027TG (W339G)) and observed decreased enzyme activity at 10%, 36%, and 21% of control levels, respectively, with no effect on affinity for 5-methyltetrahydrofolate. One of these mutations, 983 AG (N324S) showed FAD responsiveness in vitro. Expression of these mutations in cis with the 677CT polymorphism, as observed in the patients, resulted in an additional 50% decrease in enzyme activity. This report brings the total to 32 severe mutations identified in patients with severe MTHFR deficiency.

Novel mutations in the AASS gene and molecular consequences in patients with Familial Hyperlysinemia. *N. Braverman¹, L. Chen¹, L. Bowe¹, N.M. Kim¹, E. Christenson², A. Lossos³, M.T. Geraghty⁴*. 1) McKusick-Nathans Inst Genet Med, Johns Hopkins Univ Sch Med, Baltimore, MD; 2) Rigshospitalet, Copenhagen, Denmark; 3) Hadassah Univ Hospital, Jerusalem, Israel; 4) CHEO, Ottawa, Canada.

Familial Hyperlysinemia (FH) is a rare autosomal recessive disorder characterized by elevated lysine in blood, urine and CSF. The relationship of hyperlysinemia to a clinical phenotype is unclear, as mental retardation, neurological abnormalities and asymptomatic individuals have been described. In mammals, the major lysine catabolic pathway requires the bifunctional enzyme, α -amino adipic semialdehyde synthase (AASS), which has both α -ketoglutarate reductase (AKR) and saccharopine dehydrogenase (SDH) activities. We previously identified the AASS gene and reported a homozygous frameshift mutation in a child with mental retardation and lens dislocation.

We now report 7/8 possible AASS mutant alleles in 4 additional probands with hyperlysinemia (R132H/R132H, R910P/R910P, L602X/L602X, L804P/unknown). We show by RTPCR that the normal AASS gene is alternatively spliced in a tissue dependent pattern, resulting in either a full-length transcript, a transcript encoding SDH only, or both. We suggest that the variable FH phenotypes might result from different effects of the mutations on the encoded transcripts and thus different residual activities of AKR and SDH. In *S. cerevisiae*, AKR and SDH are synthetic enzymes with significant amino acid identity to AASS. We are evaluating an assay in yeast deletion strains *lys1* (AKR), *lys9* (SDH) and the double mutant by transforming these cells with human AASS constructs that include the patient mutations and determining their growth ability on lysine free media. Since LYS1 is a peroxisomal matrix protein, we are determining the intracellular localization of epitope tagged AASS and the putative AKR and SDH proteins in mammalian cells.

Outcome of Child Protective Services referrals in children with PKU and other inborn errors of metabolism. *G.L. Arnold, J.M. DeLuca, E.M. Blakely.* Division of Pediatric Genetics, University of Rochester School of Medicine and Golisano Children's Hospital, Rochester, NY.

Since 1990 the Inherited Metabolic Disorders (IMD) Clinic in our institution has made 14 Child Protective Services (CPS) referrals on behalf of 8 children with PKU, 2 with OTC, and 1 with biotinidase deficiency. Indications included failure to thrive and poor management (1 PKU, 2 OTC) elevated phenylalanine (phe) levels (7) and failure to administer biotin (1). Three repeat referrals were required. No children were removed from a parent's home solely for poor metabolic disease control, but as a result of the CPS home investigation 2 children with PKU were permanently removed to foster care for severe abuse/neglect and another father was jailed for sexual abuse. A fourth PKU child was temporarily removed to grandmother, and a fifth was permanently removed to father. For the PKU group, there was a significant and sustained improvement in metabolic control in the referred children. In this group mean age at referral was 6.5 years (range 8 mos-11 yrs), and mean phe level for the six months before the referral was 15.2 mg/dl. Mean phe level for the six months after the referral was 11.4 mg/dl ($p=0.05$), and from 6-12 months after referral it was 9.7 mg/dl ($p<0.04$). For the 2 children with OTC one family moved away after a second referral by our clinic, and the child was later removed to foster care after a CPS referral initiated by the new IMD clinic found physical abuse. The other child died during an episode of hyperammonemia. The child with biotinidase deficiency experienced developmental delays that improved after CPS ensured consistent biotin supplementation.

We found that poor metabolic disease control rarely existed alone, and was nearly always a function of other psychosocial problems in the home. For the children with PKU, CPS intervention resulted in sustained improvement in disease control. Although referrals to CPS are time-consuming and frustrating, we found that children with metabolic disorders benefited from them. In addition several children were rescued from severe abuse/neglect that had not been previously recognized.

Carrier and Newborn Diagnostic Test for the Common Y438N Maple Syrup Urine Disease Allele by DHPLC.

J.Z. Kessler¹, L.J. Matthews², R.E. Hillman³, C.L. Phillips^{1,3}. 1) Biochemistry, Univ of Missouri, Columbia, MO; 2) PTC Laboratories, Columbia, MO; 3) Child Health/ Medical Genetics, Univ of Missouri, Columbia, MO.

Maple Syrup Urine Disease (MSUD) is a recessive metabolic disorder resulting from defects in the branched chain α -keto acid dehydrogenase complex (BCKAD). Infants with classic MSUD appear normal at birth, become symptomatic within 3-7 days, and may die within 2-3 weeks if untreated. Although generally rare (1:200,000 births), the incidence of MSUD in certain Mennonite communities is high (1:150 live births), and results from a specific defect (Y438N; previously referred to as Y393N) in the BCKAD E1a subunit gene. Accumulation of branched chain amino acids in infants with MSUD is necessary for diagnosis by classic serum amino acid analysis, increasing the risk of the infant to becoming clinically symptomatic. Diagnosis within the first few hours of life would allow early treatment and improved prognosis for infants homozygous for the Y438N E1a defect. We describe development of a new DNA-based PCR-DHPLC (denaturing high-performance liquid chromatography) assay for the Y438N BCKADHA allele (E1a gene), with a turn around time of 4 hours. Genomic DNA from normal control, heterozygote, and Y438N homozygous individuals were amplified by PCR, the PCR products denatured, and allowed to gradually reanneal. PCR products were then separated using a WAVE™ DNA Fragment Analysis System (Transgenomic). We could easily distinguish heterozygotic individuals from homozygotic individuals by partial denaturation and with maximum separation at 61°C. To resolve homozygous Y438N individuals from normal control individuals we modified the DHPLC protocol to include two additional analyses in which the PCR product to be tested was also mixed in a 1:1 ratio with the PCR product from (1) a normal control individual and (2) a homozygous Y438N individual, prior to denaturation and reannealing. This allowed for detection of all three genotypes, and makes this technology applicable to newborn diagnosis as well as carrier testing for the Y438N E1a defect responsible for MSUD in the Mennonite community.

The investigation of genetic background effects in mouse phenylketonuria by transgenesis: Altered blood phenylalanine levels and susceptibility to epileptic seizures. *D. McDonald, K. Panchapakesan, V. Velamakani.* Dept Biological Sci, Wichita State Univ, Wichita, KS.

We have undertaken a study of the contribution of genetic background effects to the phenylketonuria phenotype in the genetic mouse model for phenylketonuria BTBR/Pas-Pah^{enu2}. To accomplish this, we have introgressed the Pah^{enu2} mutation, originally induced in the BTBR/Pas genetic background, onto the C57Bl/6J genetic background through a classical transgenic mating strategy.

By the time that the C57Bl/6J-Pah^{enu2} transgenic line was four generations away from the BTBR/Pas background, several phenotypic aspects of the phenylketonuria syndrome were noted as being distinctly different. The hallmark phenotype of phenylketonuria is elevated blood phenylalanine levels. The average blood phenylalanine level is significantly higher ($P < 0.0001$) in C57Bl/6J-Pah^{enu2} homozygous mutants (1601 ± 57 mM) than in BTBR/Pas-Pah^{enu2} homozygotes (1139 ± 53 mM). Another phenotypic trait that is observed in untreated human phenylketonuria is epileptic seizures. This trait is not seen in untreated BTBR/Pas-Pah^{enu2} homozygotes. However, untreated C57Bl/6J-Pah^{enu2} homozygous mutants are prone to such seizures upon tactile stimulation. Of 25 homozygous mutants produced to date, 13 have been observed to experience a seizure at least once. Of those that have been observed to seizure, over half experience seizures on a daily basis. The age of the observed onset of seizuring ranges from 340 days to 559 days.

The C57Bl/6J-Pah^{enu2} transgenic line is currently eight generations away from the BTBR/Pas background. It is clear from our results that the phenylketonuria phenotype is more severe in several important respects on the C57Bl/6J genetic background than on the BTBR/Pas background. Having discovered this, our goal is to define the genetic basis of this difference. We are especially interested in seeking out the specific genes that modify the phenylketonuria phenotype.

Program Nr: 1409 from 2002 ASHG Annual Meeting

A short program for detection and quantification of isoleucine, leucine, valine, phenylalanine and tyrosine using a Beckman 6300 amino acid analyzer. *P.A. Levy.* Center for Congenital Disorders, Children's Hospital at Montefiore, Bronx, NY.

Quantification of physiologic amino acids using a Beckman 6300 amino acid analyzer is generally done using a 3 buffer (Li-A, Li-B, Li-C) or 4 buffer (Li-A, Li-D, E and a mixture of Li-C and Li-F) method. These methods usually require about 2 hours per run plus recycling time.

Management of patients with newly diagnosed Maple Syrup Urine Disease (MSUD) and Phenylketonuria (PKU) requires frequent monitoring of plasma amino acid levels. For PKU monitoring Phenylalanine and Tyrosine levels is generally sufficient. For patients with MSUD, levels of Leucine, Isoleucine and Valine should be monitored as well as measurement of Allo-isoleucine is needed initially on an frequent basis. Periodically, the full run of amino acids is necessary to correctly manage these patients.

This abstract reports a short method (26 minutes) that quantitates the levels of Valine, Isoleucine, Leucine, Phenylalanine, Tyrosine, and reliably detects Allo-Isoleucine, which co-elutes with another amino acid and is difficult to detect on the longer runs. Comparisons were done with split samples comparing the short run with the full run and showed good correlation for the amino acids measured. Norleucine was used as an internal standard to account for injection errors.

Chronological change of serum amino acid pattern and mechanism of citrullinemia in infancy in a patient with citrin deficiency. *M. Yoshino¹, I. Yohida¹, K. Kobayashi², T. Shinka³, T. Kuhara³, T. Saheki².* 1) Dept Pediatrics & Child Health, Kurume Univ Sch Medicine, Kurume, Japan; 2) Depart of Biochem, Faculty of Medicine, Kagoshima Univ, Kagoshima, Japan; 3) Division of Hum Genet, Medical Research Institute, Kanazawa Medical Univ, Kanazawa, Japan.

Deficiency of citrin, the mitochondrial aspartate/glutamate carrier, causes adult-onset type II citrullinemia in adulthood, whereas in infancy it presents with cholestatic liver disease as transient citrullinemia. Chronological change in serum amino acid pattern in a female patient with this disease was studied from the neonatal period up to twenty years of age. Findings suggested that citrin deficiency caused insufficient aspartate supply from mitochondria for argininosuccinate synthesis, and predisposed the patient to develop citrullinemia when, in early infancy, she was exposed to relatively excessive protein load. After two years of age, serum aspartate concentration continued to decrease in an age-related manner to reach a subnormal level at twenty years of age, which is likely to cause hyperammonemic crisis with citrulline elevation in conjunction with hepatic argininosuccinate synthetase deficiency. As the patient grew older, concentration of glutamate in serum decreased, whereas the ratio of concentration of glutamine to that of glutamate (Gln/Glu ratio) increased. This observation implies that diversion of glutamate to glutamine synthesis increased as the patient grew older and it limited supply of glutamate available for aspartate export out of mitochondria. Such a decrease in glutamate supply in mitochondria could still be compatible with normal aspartate export required for normal argininosuccinate synthesis in healthy individuals, but such a decrease in aspartate export could be rate-limiting in argininosuccinate synthesis in patients with citrin deficiency. Conclusion: In citrin deficiency, insufficient aspartate supply predisposes the patient to develop citrullinemia in the early infancy when the protein load is superimposed, and can be a precipitating factor for hyperammonemic crisis with citrullinemia in adulthood.

Treatment experience of neonatal hyperammonemia. *W. Shu-Mei, J. Hou, J. Lin.* Division of Medical Genetics, Chang Gung Children's Hospital, Taoyuan, Taiwan.

Hyperammonemia associated with inherited disorders of amino acid and organic metabolism is usually manifested by irritability, somnolence, vomiting, seizures, and coma. The majority of these patients present in the newborn period, and the aim of therapy should be to normalize blood ammonia levels. Treatment guidelines include minimizing endogenous ammonia production and protein catabolism, restricting nitrogen intake, administering substrates of the urea cycle, administering compounds that facilitate the removal of ammonia through alternative pathways, and, in severe cases, dialysis therapy. Three cases of neonatal hyperammonemia were treated in our hospital during the past four years. Ornithine transcarbamylase (OTC) deficiency was suspected in the first two cases, and the last one was methylmalonic acidemia. They all had the symptoms of poor activity, poor feeding and respiratory distress. They were admitted within four days after birth and were intubated. Severe hyperammonemia and acidosis were found soon after admission. Peritoneal dialysis, continuous arteriovenous hemofiltration (CAVH), and continuous arteriovenous hemodialysis (CAVHD) had been applied to all three cases. Ammonia decreased after treatments. But eventually they died. Before they died, multiple bullae and generalized erythema were found. The causes of death and the dermatological changes will be discussed. Besides, the effects of different therapies during the acute phase of hyperammonemia will be analyzed.

Program Nr: 1412 from 2002 ASHG Annual Meeting

Effects of liver transplant & bone marrow transplant upon amino acid homeostasis & the neuropathology of maple syrup disease. *D.L. Robinson, K.A. Strauss, E.G. Puffenberger, D.H. Morton.* Clinic for Special Children, Strasburg, PA.

The Clinic for Special Children was founded in 1988 as a non-profit medical clinic for Amish & Mennonite children who have genetic disorders. We now follow more than 80 patients with classical maple syrup disease (MSD). In patients with MSD acute imbalances in plasma amino acid levels provoke vomiting, encephalopathy, movement disorders, behavioral changes, focal and generalized brain edema while chronic imbalances, especially during infancy, cause poor brain growth & mental retardation. Liver is the primary site of regulation of the plasma neutral amino acid concentration ratios and these ratios determine the rate of uptake of essential amino acids into brain. A 9 year old patient of ours with MSD underwent liver transplant for hepatic failure. At the time of transplant her neurological findings included stupor, irritability, ataxia, tremor, intermittent dystonia, hyperreflexia with + Babinski signs. Her plasma amino acid profiles were markedly abnormal because of advanced liver failure and GI hemorrhages. Five years after liver transplant her neurological examination is normal. On an unrestricted protein intake & during catabolic illnesses, her plasma amino profiles & the calculated brain uptake rates for neutral amino remain normal. We have recently managed a neonate with MSD & severe combined immune deficiency. At one week of age he was lymphopenic (ALC <100/mm) & markers were negative for T-lymphocytes & positive for B-cell & natural killer cells. An uncomplicated bone marrow transplant was done with marrow from from an HLA matched normal sibling. Within 6-12 months after bone marrow transplant we predict a significant number of hepatocytes with normal BCKD activity will have developed from donor stem cells transplanted with the bone marrow. Detailed records of his tolerance of dietary leucine, plasma neutral amino acid ratios, and molecular markers have provided us with a unique opportunity to study the effects of bone marrow transplant upon amino acid homeostasis in MSD. These observations may have important implications for the use of bone marrow or hepatic stem cell transplants to treat such disorders as Crigler-Najjar disease and PKU.

PHENOTYPIC VARIABILITY OF CARNITINE PALMITYL TRANSFERASE I DEFICIENCY (CPT I)

WITH NOVEL MOLECULAR DEFECT IN SAUDI ARABIA. *A.I. Al-Aqeel¹, M.S. Rashed², L. Ijst³, J.P.N.*

Ruiter³, R.J.A. Wanders³. 1) Dept of Pediatrics, Riyadh Military Hospital, Riyadh, Saudi Arabia; 2) Dept of Genetics, King Faisal Specialist Hospital & Research centre, Riyadh ,Saudi Arabia; 3) Dep of Clinical Chemistry, University of Amesterdam, The Netherlands.

Carnitine palmityl transferase I is the key enzyme in the carnitine dependent transport of long chain fatty acids across the mitochondrial inner membrane and its deficiency results in a decrease rate of fatty acids b-oxidation with decreased energy production. We report two families of five affected patients who are the product of first degree cousin marriage. Two patients presented with typical Reye-like syndrome with unconsciousness, hepatomegaly, hypoglycemia, hyperammonemia and very high liver enzymes with hemophagocytic syndrome and brain abscess in the second patient. Liver biopsy showed steatosis. On screening of the two families, the other three siblings were found to have hepatomegaly. The five siblings showed an acyl carnitine profile with very high free carnitine with almost absent long-chain acyl carnitines , suggestive of CPT-I deficiency. This was confirmed by enzyme analyses in fibroblast cultures. Molecular analysis on cDNA shows 1950 GoA transition resulting in glycine 650 aspartic acid change (G650D) in the protein. These patients were effectively treated with a diet high in carbohydrate, low in long chain fatty acids with medium chain triglycerides. In conclusion, CPT -I deficiency is an important cause of Reye-like syndrome with secondary hemophagocytic syndrome, which may be treated easily with very good results if detected early in life.

Molecular and biochemical diagnosis of lysosomal free sialic acid storage disorders. *D.L. Fitzpatrick¹, R. Kleta¹, R.A. Martin², D.J. Aughton³, M.J. Rivkin⁴, E. Orvisky⁵, M. Huizing¹, D. Krasnewich⁶, W.A. Gahl¹.* 1) Section on Human Biochemical Genetics, HDB, NICHD, NIH, Bethesda, MD; 2) Children's Hospital, Washington University, Saint Louis, MO; 3) William Beaumont Hospital, Royal Oak, MI; 4) Children's Hospital, Harvard Medical School, Boston, MA; 5) NSB, NIMH, NIH; 6) MGB, NHGRI, NIH.

The differential diagnosis of developmental delay in childhood is difficult and challenging. The allelic lysosomal storage disorders Salla disease and infantile free sialic acid storage disease (ISSD) can cause such developmental delay. These patients have mutations in the SLC17A5 gene which codes for the lysosomal transporter sialin, responsible for the egress of the charged sugar, sialic acid (SA), out of lysosomes. We describe 3 North American (non-Finnish) sibships with different degrees of lysosomal free SA storage disease. 5-year old twins had developmental delay, hypotonia, mildly coarse facial features, truncal ataxia, and poor speech and ambulation. The free SA content of fibroblasts was 7.7 ± 3.1 nmol per mg protein (normal 1.1 ± 1.0), and cDNA mutation analysis revealed homozygosity for the typical Salla mutation, R39C. A female infant, normal at 4 weeks of age, had progressive growth retardation, developmental delay, seizures, coarse facies, hepatosplenomegaly, cardiomyopathy and fatal respiratory insufficiency at 33 months of age. Fibroblasts contained 86 ± 30 nmol free SA per mg protein, and the patient was compound heterozygous for a deletion of exon 9 and a 15-bp deletion in exon 6 of sialin. A fourth patient had developmental delay intermediate in severity between that of patients 1,2 and 3. Fibroblasts contained 9.1 ± 1.1 nmol free SA per mg protein, and the patient was compound heterozygous for the Salla mutation and the above mentioned 15-bp deletion. These 3 sibships illustrate that the clinical manifestations of different types of lysosomal free SA storage diseases correlate with biochemical findings (fibroblast free SA content) and with sialin mutations. Thus, the differential diagnosis of postnatal developmental delay should include free SA storage disorders such as ISSD and Salla disease regardless of ethnic background.

The Identification of Different Tissue Isoforms of Glucocerebrosidase in Patients With Gaucher Disease. E.

Orvisky¹, J.M. Walker¹, E. Sidransky¹, B.M. Martin². 1) Section on Molecular Neurogenetics, NIMH, NIH; 2) Laboratory of Neurotoxicology, NIMH, NIH.

Gaucher disease (GD) is an autosomal recessive storage disorder caused by mutations in the gene encoding for the lysosomal enzyme glucocerebrosidase (GC). There are three clinical variants of the disease: type 1, chronic non-neuronopathic; type 2, acute neuronopathic; and type 3, subacute neuronopathic. Genotype-phenotype correlations among the three types are limited. To discriminate between the neuronopathic and non-neuronopathic phenotypes of GD, multiple isoforms of GC have been studied in fibroblasts. Previous studies of glucocerebrosidase have shown that there are four glycosylation sites on the protein. Western blots of fibroblast GC have consistently shown three isoforms with molecular weights of 63, 61, and 59kDa, where the 59kDa form is believed to be the functional GC. We have done a more extensive study on GC in multiple tissues from patients with Gaucher disease by comparing brain, liver, and spleen isoforms of GC in the same patients. Brain GC showed different isoforms than the other tissues analyzed. Westerns performed on samples of brains from normals consistently demonstrated two bands for GC, one at 56kDa and one at 59kDa. Brain samples from patients with Gaucher disease predominantly had the 56kDa form, but were all deficient in the functional 59kDa form. Thus, it is possible that neurologic involvement in GD may correlate with the lack of the functional form of the enzyme in the brain. Tissue extracts were then digested with Peptide-N-Glycosidase F (PNGase) to remove all oligosaccharides. After PNGase digestion, all samples demonstrated only the lowest 56kDa form of glucocerebrosidase regardless of the tissue studied. This form must be minimally glycosylated or unglycosylated and therefore the alternate forms of GC observed in brain are most likely due to alternative or absent glycosylation.

Towards the diagnosis of defects in the biosynthesis of glycosaminoglycans. *N. Leeuw, de¹, A. van Kuppevelt², A. Oosterhof², S. Wopereis³, C.M. Huyben³, R.A. Wevers³.* 1) Human Genetics, University Medical Centre Nijmegen, Nijmegen, The Netherlands; 2) Department of Biochemistry, University of Nijmegen; 3) Institute of Neurology, University Medical Centre Nijmegen.

Glycans (present in glycoproteins and proteoglycans) are complex molecules fulfilling a wide range of activities essential for a variety of biological processes such as morphogenesis, transport and signalling of biomolecules and immune response. Several glycan degradation defects are known and (sub)grouped together in the so-called Storage Diseases. So far, very little is known about defects in the biosynthesis of glycan molecules.

Defective glycan molecules are suspected in a specific category of patients who primarily suffer from bone and skin malformations. Identification of such defective glycans in these patients will facilitate the search of the underlying genetic defect.

In order to be able to investigate whether certain glycosaminoglycans are absent or malformed in patients with bone and / or skin anomalies, we developed an assay with immunofluorescently labelled antibodies that specifically recognise certain carbohydrate moieties of heparan sulphate (HS), one of the glycosaminoglycans.

Preliminary data of the Immuno Fluorescence Assay have shown that five anti-HS antibodies seem to specifically bind to blood cells that are known to express HS on their cell surface. The applicability of this assay is verified by analysing samples and cell lines from several patients who suffer from bone dysplasia due to an identified gene defect. Subsequently, we will analyse blood and urine samples from patients with progeria and / or bone dysplasia (gene defect unknown).

The use of antibodies that specifically recognise the carbohydrate moieties of certain proteoglycans seem to provide an appropriate screening approach to identify aberrant glycan molecules in patients with bone and skin malformations.

Further studies on the Arginase I-deficient mouse. *R.K. Iyer*^{1,5}, *H. Yu*^{3,5}, *R.M. Kern*^{3,5}, *P. Yoo*³, *R.W. Tsoa*³, *W.W. Grody*^{1,2,4,5}, *W.E O'Brien*⁶, *S.D Cederbaum*^{2,3,4,5}. 1) Pathology & Lab Med; 2) Pediatrics; 3) Psychiatry; 4) Human Genetics; 5) Mental Retardation Research Center, David Geffen School of Medicine at UCLA, Los Angeles, CA; 6) Molecular and Human Genetics, Baylor College of Medicine, Houston TX.

Deficiency of hepatic arginase (AI) is characterized (in humans) by progressive mental impairment, growth retardation, spasticity, and punctuated episodes of hyperammonemia. The AI-deficient mouse (Iyer et al, 2002, *Mol Cell Biol*, 22:4491-98) replicates several pathobiological aspects of the human condition, but (unlike humans) dies at day p10-p12 exhibiting severe hyperammonemia and liver failure. Here we report the results of some further comparative studies on pre-symptomatic (p6-p9/10) and symptomatic (p10-12) AI-deficient mice, versus their normal (wildtype or heterozygote) counterparts: (a) GROWTH RATE:- AI-deficient mice were ~15% smaller at birth; in addition, significant and increasing growth retardation was observed in the pre-symptomatic period; (b) PLASMA AMMONIA:- Moderate hyperammonemia was apparent in AI-deficient mice by day p6-p8 and reached symptomatogenic levels by p10-12; (c) PLASMA AMINO ACIDS:- Hyperargininemia, hypoornithinemia and hypoprolinemia, all predictable consequences of lack of AI activity were seen in p6-7 day old AI-deficient mice. Though plasma arginine remained steady at a high level and proline dropped further, a seemingly paradoxical increase in ornithine concentration was observed in symptomatic versus non-symptomatic AI-deficient mice, suggesting the possibility that (unlike other urea cycle disorders) ornithine deficiency may not play a major role in the pathology of this disorder. Glutamate was also increased in symptomatic mice, compared to non-symptomatic AI-deficient and normal mice. SUMMARY:- Like in hyperargininemic patients, growth retardation and hyperammonemia were seen in the AI-deficient mice even before plasma ammonia reached lethal levels. In addition, the increased glutamate levels seen in symptomatic animals could mediate excitotoxic neuronal injury, a pathologic process that may also be implicated in the progressive neurological impairment seen in human patients.

Galactose-1-phosphate uridylyltransferase deficiency causes decreased UDP-hexose concentrations in human galactosemic cells. *K. Lai¹, S.D. Langley¹, F. Khwaja², E.W. Schmitt¹, L.J. Elsas^{1,2}.* 1) Dept Ped, Div Medical Genetics, Emory Univ, Atlanta, GA; 2) The GMB program. Grad Sch of Arts & Sci, Emory Univ, Atlanta, GA.

Previously we reported that stable transfection of human UDP-glucose pyrophosphorylase (hUGP2) rescued galactose-1-phosphate uridylyltransferase (GALT) deficient yeast. Here we test the hypothesis that excess accumulation of galactose-1-phosphate (gal-1-P) in fibroblasts from galactosemic patients inhibits hUGP2 and creates UDP-hexose deficiency. We transfected SV40 immortalized fibroblasts from a galactosemic patient homozygous for the Q188R mutation (GALT deficient) and a control with pCDNA3.0 containing either hUGP2 or hGALT. Stable neomycin-resistant transfectants had hUGP2 or hGALT activity at least 2 fold greater than the background. We quantitated critical metabolites in this evolutionarily conserved pathway in all four cell lines before and after two days in galactose media (5.5mM). Galactosemic cell lines accumulated gal-1-P from 1.2 ± 0.4 to 5.7 ± 0.5 mM ($p < 0.01$) when cultured in D-galactose and ceased to grow. Control and transfected cell lines had about 30% reduction in UDP-glucose (UDP-glc) and UDP-galactose (UDP-gal) concentrations when transferred to D-galactose. Untransfected GALT-deficient cells had the lowest UDP-hexoses and highest gal-1-P in both media. When transfected with hUGP2 or hGALT, GALT-deficient cell lines had a 40-100% increase in UDP-glc and UDP-gal even in D-galactose. Using purified hUGP2 we found that the K_M for glucose-1-phosphate increased from 19.7mM to 1900mM in the presence of 2.5mM gal-1-P. We conclude that gal-1-P is toxic to human cells and that its pathologic mechanism results in reduced cellular content of UDP-hexoses that are essential for human fibroblasts growth and survival.

Variant non-lethal rhizomelic chondrodysplasia punctata with normal plasmalogen and cholesterol biosynthesis.

*N. Shur*¹, *R. Marion*², *A. Shanske*², *E. Hantman*², *C. Vega-Rich*³. 1) Albert Einstein College of Medicine (AECOM), Bronx, NY; 2) Center for Congenital Disorders, Div. of genetics, Dept. of Pediatrics, Children's Hospital at Montefiore (CHAM), AECOM, Bronx, NY; 3) Div. of Neonatology, Dept. of Pediatrics, CHAM, AECOM, Bronx, NY.

The most common form of rhizomelic chondrodysplasia punctata (RCDP) is an autosomal recessively inherited disorder that is diagnosed in the newborn period based on classic clinical, radiologic, and biochemical features. Clinically, affected newborns typically demonstrate severe proximal shortening of all limbs, bilateral cataracts, and a characteristic facial appearance, and radiologically, epiphyseal calcifications, as well as growth failure and mental deficiencies. Biochemically, their red blood cells demonstrate a marked deficiency of plasmalogens, increased plasma concentration of phytanic acid, deficiency of the enzyme dihydroxyacetone phosphate acyltransferase and dihydroxyacetone phosphate acyltransynthase, and normal concentrations of very long chain fatty acids. In the past, variant forms of RCDP have been described in which plasmalogen synthesis has been normal. We report an individual who at birth resembled clinically classic RCDP: features included rhizomelic shortening of the arms and legs, and a skeletal survey demonstrated multiple anomalies with punctate mineralization in the epiphyses of the knees, limbs, hips, and spine. He also had a short neck with nuchal fullness, a barrel shaped chest, and bilateral brachydactyly of the hands with short 2nd and 3rd fingers. Plasmalogen synthesis, LCFA's and phytanic acid were normal. Cholesterol biosynthesis appeared normal, ruling out a milder, X-linked dominant form of chondrodysplasia (CDPX2). Over the course of a ten-month follow-up, the rhizomelia has decreased, but the disproportionate growth of the patient's digits remains striking. He has slight motor delays, but otherwise his development is appropriate for age in contrast to patients with classic RCDP. We reviewed the literature of primary and secondary CDP. Our patient does not resemble previously described cases and may represent another variant of non-lethal RCDP.

Cystinosis in Denmark: Mutation analysis and treatment with cystamine, the disulfide of cysteamine. *F. Skovby¹, R. Kleta², Y. Anikster², R. Christensen¹, W.A. Gahl².* 1) Department of Clinical Genetics, Rigshospitalet, Copenhagen, Denmark; 2) Section on Human Biochemical Genetics, HDB, NICHD, NIH, Bethesda, MD.

Nephropathic cystinosis is an autosomal recessive defect of intracellular cystine transport across the lysosomal membrane. Most patients present as infants with failure to thrive and renal tubular Fanconi syndrome. Untreated, they succumb to renal failure at ~10 years of age. Early, diligent cystine-depleting therapy with a form of cysteamine prevents or delays renal failure and other serious organ dysfunction. Cystinosis results from mutations in the gene CTNS; the most common CTNS mutation is a 57-kb founder deletion thought to arise in Germany ~500 A. D.. We reviewed the clinical course, management, and molecular genetics of 9 affected Danish children diagnosed 1969-2000. Assuming complete ascertainment, the incidence was 1:200,000 live births. Thirteen of 18 CTNS alleles contained the 57-kb deletion. Two of the 9 children, sibs diagnosed with nephropathic cystinosis after age 5, are compound heterozygous for the 57-kb deletion and a novel Alu Y repeat insertion which changes a splice site at the intron 6-exon 7 boundary. Another patient was homozygous for a novel 1007 del G nonsense mutation. Three children with nephropathic cystinosis children never received cystine-depleting therapy and died before age 11 of renal failure. All but one of the remaining patients were treated with oral cystamine, the disulfide of cysteamine, between 8 and 28 months of age and continuing for 8-16 years. All are alive. One received a renal transplant at age 13. The other 3 have glomerular filtration rates of 22, 42, and 98 ml/min/1.73m² at 19, 11, and 10 years of age. Of the 2 sibs with the Alu Y insertion on one allele, one received no cystamine and lost all renal function at age 12. The other received cystamine for 10 years starting at age 8 and went to renal failure at age 18. We conclude that the 57-kb deletion in CTNS is common in Denmark, and that cystamine, which can be prepared as a tasteless liquid for oral use, is an effective alternative to other cystine-depleting agents for treating cystinosis patients.

Functional and structural characterization of disease-causing mutations in α -mannosidosis. *H.M.F. Riise Stensland^{1,2}, G.M. Hansen¹, P. Heikinheimo^{1,3}, O. Nilssen², O.K. Tollersrud¹.* 1) Dept. Medical Biochemistry, Univ.of Tromsø, Tromsø, Norway; 2) Dept. Medical Genetics, Univ. Hospital of Northern Norway, Tromsø, Norway; 3) Dept. Chemistry, Univ.of Tromsø, Tromsø, Norway.

α -Mannosidosis is an autosomal recessive storage disorder caused by deficiency of lysosomal α -mannosidase (MAN2B1, LAMAN). Major symptoms are progressive mental retardation, skeletal changes and immunodeficiency. Previously we reported 26 putative α -mannosidosis causing mutations, of which about two thirds were severe-type mutations, while the remaining were predicted to cause single-amino acid substitutions or small in-frame deletions. To better understand the biochemical consequences of the latter group of mutations, eleven missense mutations and two small in-frame deletions were constructed by site-directed mutagenesis of human LAMAN cDNA, and expressed in transfected COS-cells. Pulse-chase analysis and intracellular localization studies showed that the mutations could be divided into three groups: Group A, containing seven mutations resulting in transport-arrest and accumulation in the endoplasmic reticulum; group B, one mutation leading to lysosomal targeting but abolition of α -mannosidase activity; and group C, five mutations leading to correct targeting and preservation of low, but significant, residual enzymatic activity towards the artificial substrate p-nitrophenyl α -D-mannopyranoside. We are currently expressing LAMAN-variants carrying the group C mutations in CHO-cells to investigate their activities towards natural substrates. To study the biochemical consequences of mutations in the active site, two active site mutants were constructed. Both these mutations fell into group B, showing that active site substitutions are compatible with correct sorting and stability. The recently solved 3-D structure of LAMAN was used to predict the structural consequences of the α -mannosidosis mutations. All five amino acid substitutions in group A are localized outside the active site regions, and are probably important for correct folding of the enzyme. The substitutions in groups B and C involve residues within or close to the active site, and do not seem to disrupt the folding process.

Lysosomal cystine loading increases apoptosis in normal and cystinotic fibroblasts and renal proximal tubule epithelial cells. *M.A. Park, A. Helip-Wooley, J.G. Thoene.* Human Genetics, Tulane Univ, New Orleans, LA.

Nephropathic cystinosis is a lethal disorder of lysosomal cystine storage due to defective lysosomal cystine transport, and culminates in end-stage renal disease by 10 years of age. The mechanism whereby lysosomal cystine causes this multi-systemic disorder is not known. We here report that increased lysosomal cystine causes increased apoptotic rates in both normal and nephropathic cystinotic fibroblasts, and in cultured human renal tubular epithelial cells (RPTE cells), when treated with TNF-alpha and ultraviolet B light, and analyzed by TUNEL, CaspACE, or Annexin V-FITC. Normal fibroblasts cystine-loaded with 0.5mM cystine dimethylester (CDME), and exposed to apoptotic stimuli, show an increase in the average rate of apoptosis from 9.7% \pm 3.2 to 16.8% \pm 3.5 ($p < 0.05$), with a lysosomal cystine increase from < 0.01 to 1.21 nmols cystine per mg protein. Cystinotic fibroblasts cystine-depleted with cysteamine, show a decrease in average apoptosis from 17.0% \pm 4.4 to 4.9% \pm 1.3, ($p < 0.05$), with a decrease in lysosomal cystine from 4.1 to 0.12 nmols cystine per mg protein. Fibroblasts from two cystinotic variants, benign ocular and intermediate cystinosis show apoptosis rates not significantly increased from normal fibroblasts, and averaging only 6.5% and 9.2% respectively. RPTE cells tolerate exposure to 0.25 mM CDME alone for only 6 h and show an apoptotic rate of 43.8%, compared to 5.4% in normal fibroblasts treated with 0.5 mM CDME for 17 h. RPTE cells are also more sensitive to other apoptotic triggers with or without CDME, with a 40.7% average apoptosis rate upon exposure to UV and TNF-alpha (without CDME), compared to an average of 6.7% in normal fibroblasts. We speculate that enhanced apoptosis resulting from lysosomal cystine storage leads to inappropriate cell death, decreased cell numbers in many tissues, and hence, the nephropathic cystinotic phenotype. The variant forms may represent co-segregation of rare allele(s) that confer resistance to apoptosis, moderating the cell loss and causing the milder phenotype.

Use of cDNA Microarrays to Evaluate Molecular Mechanisms Involved in Gray Platelet Syndrome (GPS). *T. Hyman*¹, *M. Huizing*², *Y. Anikster*², *T.C. Falic-Zaccari*³, *W.A. Gahl*². 1) LCCTP, NCI, Bethesda, MD, USA; 2) Section on Human Biochemical Genetics, NICHD, NIH, Bethesda, MD, USA; 3) Division of Medical Genetics, Hospital of Western Galilee-Naharia, Rappaport Faculty of Medicine, Technion, Haifa, Israel.

The gray platelet syndrome (GPS) is a rare congenital bleeding disorder in which thrombocytopenia is associated with increased platelet size and decreased alpha-granule content. We described two siblings with GPS who had characteristic pale blue platelets lacking alpha-granules on electron microscopy. On bone marrow biopsy, one sibling, an 8-year old girl, exhibited mild myelofibrosis and extensive emperipoiesis. We used cDNA microarray technology to investigate changes in gene expression which might reveal the mechanism involved in causing this disease. The expression of approximately 6,500 genes was evaluated in fibroblasts cultured from one of the GPS patients; normal fibroblasts provided the reference standard. Genes that were differentially regulated in the GPS cells were categorized into gene clusters according to their biological function. This analysis revealed significant upregulation of selected biological processes involving the production of cytoskeleton proteins (e.g., fibronectin, thrombospondin 1 and 2, and collagen VI a). These genes, as well as certain genes involved in cell cycle progression, appear to play a role in the pathogenesis of GPS. Indeed, northern blot analyses confirmed that fibronectin, thrombospondin and MMP2 were overexpressed in GPS fibroblasts compared to the control. Moreover, immunocytofluorescence studies revealed robust fibronectin staining in GPS fibroblasts compared to normals. Our findings support the feasibility of using cDNA microarray techniques to detect distinctive and informative differences in gene-expression patterns relevant to GPS. Specifically, our studies suggest that the molecular basis for myelofibrosis in GPS involves upregulation of cytoskeleton proteins.

Hepatic veno-occlusive disease (HVOD) after high-dose chemotherapy and blood cell transplant (BCT): Association with the major hemochromatosis (HFE) mutation C282Y and modification by polymorphisms of the hepatic urea cycle enzyme, carbamyl phosphate synthetase 1 (CPS-1). A. Kallianpur¹, L. Hall³, M. Yadav³, B. Christman¹, R. Dittus¹, J. Haines², M. Summar^{2,3}. 1) Medicine, Vanderbilt Univ. Med. Ctr., Nashville, TN; 2) Mol. Phys. & Biophysics; 3) Pediatrics.

HVOD is a dose-limiting and often fatal toxicity in patients undergoing high-dose chemotherapy and BCT for malignancy. HVOD is a syndrome of increased bilirubin and either liver enlargement or weight gain >5% over baseline, occurring by Day 21 after BCT. The C282Y mutation in the HFE gene is responsible for >85% of cases of hereditary hemochromatosis. C282Y heterozygotes have elevated mean body and liver iron content (LIC). LIC has been associated with post-BCT liver dysfunction. We determined whether carriage of at least one C282Y allele conferred an increased risk of HVOD and early death (< Day 61 post-BCT) in adult BCT patients. A secondary aim was to test for interactions between the C282Y allele and the T1405N SNP of the hepatic urea cycle (HUC) enzyme CPS-1, since HUC-generated nitric oxide (NO) may regulate iron metabolism. Genotyping was successful in 161 of 200 patients after DNA extraction from stored blood and urine, PCR amplification, and SSCP or HPLC (Genomic WAVE) SNP analysis, and scoring by outcome-blinded readers. Relative risk (RR) of HVOD was significantly increased in patients carrying ³ 1 C282Y allele, adjusting for age, sex, chemotherapy regimen, CPS-1 genotype, donor type, and 3 other known HVOD risk factors (RR=3.9 with 95% CI 1.3-12.5). An allelic dose-response effect was seen with RR of HVOD in C282Y heterozygotes of 2.2 (95% CI 0.6-7.8) and RR in homozygotes of 5.8 (95% CI 1.1-29.6). Risk of early death was increased but was not statistically significant (RR=1.69; 95% CI 0.4-8.1). A significant interaction between C282Y and the T1405 form of CPS-1 was noted (p=0.04), consistent with our previous findings that HVOD risk is related to this less efficient enzyme and inversely related to HUC efficiency/NO production. These findings suggest that the C282Y allele is a risk factor for HVOD and that its effect on the liver may be augmented by CPS-1 alleles that lead to diminished HUC function.

Clinical, radiographic, biochemical and genetic delineation of pantothenate kinase associated neurodegeneration.

S.J. Hayflick¹, S.K. Westaway¹, B. Levinson², B. Zhou², M.A. Johnson¹, K.H.L. Ching¹, J. Gitschier². 1) Departments of Molecular and Medical Genetics, Pediatrics and Neurology, Oregon Health & Science University, Portland; 2) the Howard Hughes Medical Institute and Departments of Medicine and Pediatrics, University of California, San Francisco.

The diagnosis of Hallervorden-Spatz syndrome (HSS) is based on dystonia, parkinsonism, pigmentary retinopathy and radiographic evidence of brain iron accumulation. Recently, we discovered that many patients with HSS have mutations in the gene encoding pantothenate kinase 2 (*PANK2*) and designated such patients as having pantothenate kinase associated neurodegeneration (PKAN). We compared specific clinical and radiographic features in patients with PKAN to those in HSS patients lacking defects in *PANK2*. Ninety-eight families with the diagnosis of HSS were stratified by sequencing genomic DNA for *PANK2* mutations and by clinical assessment into early onset, rapidly progressive or later onset, slowly progressive disease. Data were compared for 123 patients from 66 mutation-positive and 32 mutation-negative families. All early onset HSS patients and one-third of later onset patients were found to have *PANK2* mutations. Whereas almost all mutations in later onset patients lead to amino acid changes, early onset disease is characterized by more severe mutations. Later onset patients with *PANK2* mutations more often exhibit prominent speech and psychiatric manifestations compared to either classical patients or the mutation-negative patients. Remarkably, in all PKAN patients, a very specific brain MRI pattern of globus pallidus changes called eye of the tiger was observed. Moreover, these changes were not seen in any mutation-negative patients. Lipoprotein abnormalities have now been demonstrated in patients with PKAN, suggesting aberrant lipid metabolism, which would be consistent with the prediction of a deficiency of coenzyme A due to defective pantothenate kinase.

Arginase I in the Nervous System during Development. *H. Yu^{1,2}, P.K. Yoo^{1,3}, R. Kern^{1,2}, R. Tsoa^{1,3}, W.W. Grody^{1,3,4,5}, S.D. Cederbaum^{1,2,4,5}, R.K. Iyer^{1,3}.* 1) Mental Retardation Res Center; 2) Dept of Psychiatry; 3) Dept of Pathology; 4) Dept of Human Genetics; 5) Dept of Pediatrics; David Geffen School of Medicine at UCLA, Los Angeles, CA.

Arginase I (liver arginase, AI), the fifth enzyme of the urea cycle, catalyzing the hydrolysis of arginine to ornithine and urea, functions primarily to detoxify ammonia as part of the urea cycle. Recently, AI was found in the brain and embryo, and thus may play an important role for synthesizing ornithine, which is a precursor in the synthesis of glutamate and polyamines. In humans, inherited deficiency of AI is characterized clinically by hyperargininemia, growth retardation and progressive neurologic impairment. The purpose of this study is to elucidate the pattern of expression of arginase, ornithine decarboxylase (ODC) and ornithine aminotransferase (OAT) in the nervous system, in order to understand the role of AI in nervous system development with the expectation that this knowledge will help patients suffering from AI deficiency. Arginase, ODC and OAT expression during mouse development was detected by DIG-labeled RNA in situ hybridization. We found that AI was expressed strongly in spinal cord in the early stages of embryonic development. In the peripheral nervous system, AI co-localized with ODC in the dorsal root ganglia of the spinal nerves during embryonic stages whereas neither AI nor ODC were expressed in these tissues during postnatal development. AI was also found in sympathetic ganglia in all stages of development, and co-localized with OAT. This study suggests that AI is important in the developmental nervous system, and may regulate the ornithine supply to influence polyamines which are important in cell growth, and to influence glutamate - a neurotransmitter. The neurologic impairment due to AI deficiency may be explained by the lack of AI activity in the nervous system during development.

Keratopathy of multiple myeloma masquerading as the corneal crystals of ocular cystinosis. *I. Bernardini¹, C.R. Hermos¹, S. Blair², M.I. Kaiser-Kupfer³, R. Kleta¹, W.A. Gahl¹.* 1) Section on Human Biochemical Genetics, HDB, NICHD, NIH, Bethesda, MD; 2) Hematology / Oncology, Riverside Methodist Hospital, Columbus, OH; 3) Ophthalmic Genetics Branch, NEI, NIH.

The isolated finding of corneal crystals observed on slit lamp examination by an experienced ophthalmologist, can make the diagnosis of ocular cystinosis. This variant of cystinosis never manifests with renal or any other systemic involvement. Here we describe a 49 year old woman diagnosed with ocular cystinosis during a routine eye examination 12 years previously. A conjunctival biopsy was reported to support the diagnosis at that time, but leucocyte cystine measurements were not performed. The patient reported photophobia and increased glare for the past 5 years, and mentioned that her serum IgG had been elevated to twice the normal level for the past 12 years. She came to the NIH to participate in an ongoing study of cysteamine eye drops, a medication known to dissolve corneal cystine crystals. When the patient's eyes were examined at the NIH, the crystals looked different from those of ocular cystinosis and appeared in the epithelial and most superficial stromal layers rather than being present throughout the corneal epithelium and the entire stroma. Triplicate leucocyte cystine measurements revealed a completely normal level of 0.04 nmol half cystine per mg of protein (normal, less than 0.2). Blood chemistries revealed an elevated sedimentation rate, hemoglobin was 12.3 g/dL. The serum protein was elevated at 84 g/l; protein electrophoresis showed an elevated gamma-globulin peak, and the IgG level was twice normal at 2820 mg/dl. Blood viscosity was slightly elevated. Urine protein electrophoresis showed also elevated gamma globulins. Bone marrow biopsy confirmed the diagnosis of multiple myeloma. This case illustrates that multiple myeloma can mimic the corneal findings of cystinosis. It also emphasizes the importance of measuring the leucocyte cystine in all patients suspected of having any form of cystinosis to confirm (or to rule out) the diagnosis. The morphology and location of the crystals in the cornea can help distinguish between cystinosis and multiple myeloma.

Natural history of cardiac involvement in hemizygotes Fabry patients. *G. Altarescu¹, D. Moore², R. Schiffmann².* 1) Shaare Zedek Medical Center, Jerusalem Israel; 2) National Institutes of Health Bethesda, MD.

Objective: To determine the natural history of cardiac involvement in Fabry disease and relation of cardiac involvement to constitutive enzyme activity. **Introduction:** Fabry disease, an X-linked lysosomal storage disorder caused by deficiency of alpha-galactosidase A, is characterized by progressive intracellular lysosomal accumulation of glycosphingolipids through body including cardiovascular system. Cardiac manifestations consist of left ventricular hypertrophy (LVH), valvular involvement and cardiac conduction defects. **Material and Methods:** 86 hemizygotes, mean age 32 years were examined by a retrospective historical analysis. Mean alpha-galactosidase A levels was 0.45% of controls. Patients were genotyped. Cardiac function was evaluated by ECG and 2-D Echocardiography (ECHO) every 6 months over 3-17 years. PR, QT intervals (ms) and the septal thickness (mm), left ventricular (LV) free wall thickness (mm) and aortic root (mm) were found to be outside the normal range. Subsequent statistical analysis examined these parameters as indices of cardiac involvement secondary to Fabry disease. Kaplan-Meier (KM) analysis was performed for each of the ECG and ECHO parameters together with subgroup comparison of those patients with <1% residual alpha-galactosidase A activity to those with >1% residual enzyme activity. **Results:** There was no significant subgroup difference between the cardiac parameters measured and the patients genotype or the residual level of alpha-galactosidase A activity. The natural history of the ECG and ECHO parameters overlapped. 25 patients developed LVH and 2 patients developed pulmonary hypertension. One patient had dilated aortic root (6mm) and one moderate aortic stenosis. On ECG most patients fulfilled criteria for LVH, 7 patients had right bundle branch block, one patient first degree AV block and 2 patients atrial fibrillation. **Conclusions:** Progression of cardiac Fabry disease does not depend on residual enzyme activity or genotype suggesting that the heart metabolism is less tolerant to reduction of enzyme activity. Cardiac abnormalities in Fabry disease may be less amendable to treatment with enzyme replacement therapy.

Natural History of the Anderson - Fabry Disease related Cardiomyopathy. *F.A. Baehner¹, C.M. Wiethoff¹, C. Whybra², E. Miebach², M. Beck², C. Kampmann¹.* 1) Pediatric Cardiology, University Children's Hospital, Mainz, Germany; 2) Lysosomal Storage Diseases, University Children's Hospital, Mainz, Germany.

Background: Anderson - Fabry disease (AFD), an X-linked metabolic disorder, causes a progressive accumulation of globotriaosylceramide (Gb3), in a wide variety of tissues, including the development of left ventricular (LV) hypertrophy. We aimed to evaluate onset and progression of the AFD related cardiomyopathy. **Methods and Results:** 119 genetically proven hemi- and heterozygotes aged 0.5 to 70.8 years were echocardiographically evaluated. For both genders, there was a strong correlation between age and LV mass ($F < 38.12$; $P < 0.0001$). All 30 males older than 28 and all 37 females older than 38 years had abnormal LV geometry (wall thickening with small cavity) (3.4% of males, 24.3% of females) or increased LV mass (96.6% of males, 75.7% of females). Mean LV mass indexed to height (normal: $< 50 \text{ g/m}^{2.7}$) in males > 28 yrs was $78 \pm 22 \text{ g/m}^{2.7}$ and in females > 38 yrs $86 \pm 40 \text{ g/m}^{2.7}$. Most common findings were concentric hypertrophy, followed by cardiac remodelling and eccentric hypertrophy. Kaplan Meier estimation of freedom from developing severe cardiomyopathy (mean LV wall thickness ≥ 15 mm) was 39.3 years in males and 50.9 years in females. Repetitive follow up examinations of 35 pts (17 females and 18 males) revealed an increase in mean ventricular wall thickness of 0.98 mm per year. Severe Cardiomyopathy was accompanied by disturbed diastolic and systolic LV function, resulting in reduced cardiac output, and increase in NYHA heart failure functional class. **Interpretation:** The classical Anderson Fabry disease related hypertrophic cardiomyopathy affects both genders equally in terms of severity, but develops at different ages. Female heterozygotes are affected about 10 years later. **Conclusion:** Hypertrophic cardiomyopathy is a common feature in AFD. Close follow up is warranted for both genders, whether hemi- or heterozygous for AFD. This data supports the concept that AFD has X-linked dominant rather than recessive transmission.

Prolidase Deficiency: a molecular, biochemical and morphological study on five cases to investigate the molecular bases of the disease. A. Forlino¹, A. Lupi¹, P. Vaghi², A. Icaro Cornaglia³, E. Campari¹, A. Calligaro³, G. Cetta¹. 1) Dipartimento di Biochimica, University of Pavia, Pavia, Italy; 2) Centro Grandi Strumenti, University of Pavia, Pavia, Italy; 3) Dipartimento di Medicina Sperimentale, University of Pavia, Pavia, Italy.

Mutations in the prolidase gene cause Prolidase Deficiency (PD), a rare recessive disorder characterized mainly by skin lesions, mental retardation and recurrent infections. The mechanisms leading to the phenotype in PD are still poorly understood. We characterized the molecular defect in five PD patients. Direct sequencing of PCR amplified genomic DNA showed a G→A transversion in two siblings leading to a G448R substitution. A G→C transition in one allele of intron 11, causing the skipping of exon 11, was detected in a third proband and this is the first report of a mutation in a splicing donor site of the prolidase gene. A G→A transversion in intron 7 was identified in two unrelated probands and shown to cause multiple alternative spliced transcripts. Long term cultured fibroblasts from these PD patients were used to investigate the biochemical, morphological and ultrastructural changes in affected cells. By light and electron microscopy patients cells appeared swelling with increased cytosolic vacuolation, plasma membrane interruptions, mitochondria swelling and mitochondrial matrix and cristae modifications. The cellular death was evaluated by trypan blue uptake. The percentage of nonviable cells was statistically higher for the mutant than for control cells. JC-1 labelling showed decreased mitochondrial membrane potential. A significant intracellular accumulation of the Gly-Pro dipeptide was revealed by capillary electrophoresis analysis. The composite data provide new insights into PD pathophysiology, suggesting the activation in skin fibroblasts of a necrosis-like cellular death, which could be responsible for the typical skin lesions in this disease.

Molecular analysis and in vitro expression of two novel mutations identified in Italian patients affected by carbonic anhydrase II deficiency. *G. Bonapace*¹, *G. Weber*², *P. Strisciuglio*¹. 1) Dept of Pediatrics, Univ "Magna Graecia" of Catanzaro, Catanzaro, Italy; 2) Dept of Pediatrics University of Milan.

Deficiency of Carbonic anhydrase II (CAII), results in a rare syndrome characterized by osteopetrosis, renal tubular acidosis and cerebral calcification, inherited as an autosomal recessive trait. Previously (1) we reported in three Italian patients, two novel mutations: the IVS6nt1, associated to a mild phenotype without mental retardation, and Del 164 C associated to mental retardation, cerebral calcification and frequent fractures. We here describe two novel mutations recently identified. The first was a Gt insertion at the codon 10 in exon 6 of CAII gene (601insgt-stop) present in two brothers coming from Naples, characterized by absence of enzymatic activity, the second was a transition G-A at nucleotide 352 in exon 3 (352G-A stop) present in the proband coming from Lombardia, northern Italy associated to a quite residual enzymatic activity. The last mutation was confirmed by restriction analysis for the appearance of a new BfaI site. The expression in E Coli BL21DE, of two of the human cDNA containing the novel mutations, revealed for 352G-A stop mutation, absence of activity and a minimal residual activity for 601insgt stop mutation, according with their location. In fact while the 352G-A mutation introduces an early stop codon into exon 3, altering the enzymes catalytic domain, the 601 insgt stop mutation, resides in exon 6, allowing a more complete protein translation that could account for the minimal residual activity. Strikingly the expression data seem not in agree with the clinical findings of our patients having the 352G-A stop mutation a phenotype milder than the 602insgt stop mutation. We believe the minimal residual activity observed in our patient, could reflect some postranslational modification not obviously valuable in E. Coli expression system. In conclusion our data confirm the molecular heterogeneity of CAII deficiency in Italy, and suggest that in this syndrome, also the postranslational modification have to be evaluated to perform a correct genotype-phenotype correlation 1) P.Hu. et al Hum. Assessment of Antioxidant Status in Wilson disease children:Effect of Vitamin E and Zinc supplementation. *G. Kaur¹, R. Prasad², B.R. Thapa³, S. Kumar²*. 1) Dept of Physiology, Prayas Building,Sec-38, GMCH, Chandigarh, India; 2) Dept of Biochemistry,PGIMER, Sector-12,Chandigarh-India; 3) Dept. Of Gastroenterology,PGIMER, Sector-12, Chandigarh-India.

Wilson disease is an autosomal recessive disorder of copper metabolism. However, copper is an essential component of many enzymes, it is only required in trace quantities and is toxic in large amount due to production of hydroxyl free radicals by Fenton type of mechanism. Therefore in the present study antioxidant status was assessed by measuring antioxidant enzymes and lipid peroxidation. The supplementation of vitamin E and Zinc was also evaluated. The antioxidant enzymes like catalase, SOD, Glutathione peroxidase activities were significantly diminished in Wilson disease patient as compared to normal children of the matched age group. GSH which is a prominent scavenger of copper was significantly reduced in Wilson disease patients. Decrease in antioxidant enzymes and GSH, resulted in increase lipid peroxidation of erythrocyte membrane which was assessed by measuring MDA. Interestingly supplementation to Wilson disease patients of Vitamin E and Zinc for three months restored the antioxidant status, which was again assessed by measuring antioxidant enzymes and lipid peroxidation. In conclusion, copper influences the anti oxidant status in Wilson disease, which is normalised by supplementation of Vitamin E and Zinc.

GenotypePhenotype Analysis of American Patients with Congenital Disorders of Glycosylation-IA (CDG-1A). *D. Krasnewich¹, E. Orvisky², M. LaMarca², D. Andrews², N. Tayebi², O. Goker-Alpan², E. Sidransky².* 1) Medical Genetics Branch, NHGRI/NIH, Bethesda, MD; 2) Section of Molecular Neurogenetics, NIMH/NIH, Bethesda, MD.

CDG are a group of metabolic disorders resulting from the defective synthesis of N-linked glycans. Eight types of CDG have been defined with distinct enzyme defects and genes; the most common is CDG-1A. CDG-1A is caused by the deficiency of phosphomannomutase (PMM) resulting from mutations in the gene, PMM2. The genotypes and phenotypes of 23 patients with CDG-1A, including 3 sib pairs were studied. 90% of the mutant alleles were identified including 14 different mutations in 20 probands. As expected from other reports, R141H/F119L was the most common genotype; no homozygous genotypes were identified. PMM was assayed in lymphoblasts or fibroblasts from patients by HPLC. PMM enzyme activities ranged from 0-18% of control. Children are most commonly ascertained during the workup for failure to thrive (FTT), developmental delay, elevated liver transaminases, coagulopathy or cerebellar hypoplasia. Children with the most severe clinical presentations of CDG-1A (3/23) die in infancy from medical sequelae of FTT, hypoalbuminemia and intractable fluid imbalance. Other patients have a milder course of developmental delay, ataxia and slow growth. However, when comparing the clinical course of these subjects there was no apparent correlation between enzyme activity, genotype and phenotype. For example, 2 children sharing genotype, R141H/V231M, had different PMM activities and dramatically different clinical courses. The first child, with less than 1% of control enzyme activity, died in infancy while the second, with 13% of control, had a more typical course with hypotonia, FTT and seizures. Similarly, 2 affected individuals with genotype R141H/F119L also had discordant phenotypes. Surprisingly, the child with higher PMM activity, 5% of control values, had a catastrophic newborn course, while the child with 1% of control activity had moderate developmental delay and FTT. Clearly, other factors, including environmental and genetic modifiers, may contribute to the clinical phenotype in this complex disorder.

Growth Retardation in Children and Adolescents with Type B Niemann-Pick Disease. *M.P. Wasserstein, A.E. Larkin, R.B. Glass, R.J. Desnick, E.H. Schuchman, M.M. McGovern.* Mount Sinai School of Medicine, NY, NY.

Types A and B Niemann-Pick disease (NPD) are rare inherited lysosomal storage disorders caused by deficient activity of acid sphingomyelinase. Type A NPD is characterized by failure to thrive, severe neurologic disease, hepatosplenomegaly, and death in infancy. In contrast, patients with type B NPD have multi-organ involvement, including hepatosplenomegaly, hyperlipidemia, and progressive infiltrative pulmonary disease with sparing of the nervous system. The phenotypic spectrum of type B NPD ranges from severe disease with death in childhood to a milder disease in adults with hepatosplenomegaly. Although failure to thrive is a recognized feature of type A NPD, growth parameters have not been well described in children with type B NPD. We therefore performed a cross-sectional analysis of growth in 23 children and adolescents with type B NPD. Anthropometric parameters were compared with bone age, organomegaly, serum levels of insulin-like growth factor-1 (IGF-1), and genotype. Height was at or below the 5th percentile in 39% of all subjects. The mean z score for height was 1.24, corresponding to the 29th percentile. Weight was at or below the 5th percentile in 21% of subjects. The mean z score for weight was -0.75, corresponding to the 34th percentile. The mean bone age delay, measured as bone age minus chronological age, was 2.57 years. The mean liver volume was 2.07 times normal for weight, and the mean spleen volume was 14 times normal for weight. Serum IGF-1 was below the 2nd percentile for age and sex in 7 of the 10 patients in whom it was determined, and correlated with short stature. When considering genotype, striking differences were found between patients who were homozygous for the most common allele, delR608, vs. patients with all other genotypes. The delR608 homozygotes were of normal height and weight, had less organomegaly, less bone age delay, and normal serum IGF-1 levels. These findings suggest that 1) abnormal linear growth associated with delayed skeletal maturity is common in children and adolescents with type B NPD, and 2) homozygosity for the delR608 allele may be associated with a milder phenotype.

Biotin availability regulates the expression of enzymes involved in its utilization and recycling in human cells. *D. Pacheco-Alvarez*¹, *S. Solorzano-Vargas*¹, *A. Velazquez*², *J. Zemleni*³, *A. Leon-Del-Rio*¹. 1) Department of Molecular Biology, UNAM, Mexico D.F., Mexico, D.F., Mexico; 2) Department of Genomic Medicine and Toxicology; 3) Department of Nutritional Genetics, University of Nebraska-Lincoln.

In human cells biotin is used as cofactor of enzymes involved in carboxylation reactions. Biotinylation of these enzymes is catalyzed by holocarboxylase synthetase (HCS). Recently, we showed that biotin and HCS are required to maintain the mRNA levels of HCS and of biotin-dependent carboxylases genes in human cells. In this work we show the effect of biotin availability on the mRNA levels of the sodium dependent multivitamin transporter (SMVT) which is responsible for the vitamin uptake in humans. We present evidence of a correlation between SMVT expression and the mRNA levels of enzymes involved in biotin utilization in human cells. Our results showed that biotin deficiency in human hepatocytes and fibroblasts results in a 70 % reduction on both the mRNA levels and protein amount of SMVT. Stimulation of biotin deficient cells with biotin or cGMP restored the SMVT mRNA levels to within normal values after 24 hr. Similar effects on mRNA levels were observed for the genes encoding HCS and pyruvate carboxylase (PC). We suggest that biotin deficiency results in the downregulation of the expression of enzymes such as HCS, PC and SMVT in peripheral tissues to allow a continuous supply of biotin to the brain. This hypothesis is confirmed by studying the expression of all these genes in an animal model for biotin deficiency. In these animals, biotin deficiency resulted in a decrease in the mRNA levels of HCS, SMVT and PC in liver, kidney and muscle. However, mRNA levels of all these enzymes were not affected in brain by biotin deficiency. The mechanism for biotin utilization reported here is impaired in the disease multiple carboxylase deficiency and this may cause some of the symptoms observed in patients. The mechanism proposed for biotin utilization is very similar to the well known mechanism of glucose utilization in muscle and brain during fasting.

Insights into obesity and glucose homeostasis from study of Angelman syndrome mouse models. *R.D. Nicholls¹, Y. Qi¹, D.J. Driscoll², M. Dhar³, R.S. Ahima¹*. 1) University of Pennsylvania, Philadelphia, PA; 2) University of Florida, Gainesville, FL; 3) University of Tennessee, Knoxville, TN.

Angelman syndrome (AS) patients have genetic defects in chromosome 15q11-q13, with neurological disease due to loss of maternal-only imprinted expression of the *UBE3A* gene in some brain regions. AS subjects in several molecular subclasses have obesity, with a body mass index in the 80th-100th percentile for age. Similarly, an AS mouse model with a chromosome deletion and mice with maternally-inherited, radiation-induced deletions of the *Atp10c* gene have obesity by 4-6 months (mo) of age. We have performed physiological and metabolic studies of AS mice to gain insight into the pathophysiological basis of obesity in AS. When AS (CD-1) deletion mice fed a standard low (4%) fat chow diet were placed on a high (45%) fat diet, within 4 weeks (wks) they became obese compared to similarly treated wildtype (WT) littermates [12 wks, AS=31.1+/-0.4 g vs. WT=29.3+/-1.8 g, p=0.506; 20 wks, AS=46.8+/-1.9 g vs. WT=35.5+/-1.5 g, p=0.012]. AS mice of normal weight at 3 mo show mild glucose intolerance, with a glucose level 30 min after an i.p. injection of 20% glucose (2g/kg) of 196+/-2.3 mg/dl vs. WT (156+/-12.7 mg/dl; p=0.036). After a 4 wk high fat diet, AS mice have significant glucose intolerance (30 min, AS=423.5+/-25.2 mg/dl vs. WT=261+/-33 mg/dl, p=0.096; 60 min, AS=221+/-14.9 mg/dl vs. WT=174.5+/-7.5 mg/dl, p=0.041). The weight gain in AS mice on a high fat diet was not dependent on increased food intake (AS=2.5+/-0.1 g vs. WT=2.5+/-0 g, p=0.678); in contrast, indirect calorimetry revealed a lower oxygen consumption (AS=2051+/-50 ml/kg/h vs. WT=2365+/-71 ml/kg/h, p=0.003). Therefore, the loss of *Atp10c* function may predispose to obesity by lowering energy expenditure. Similar studies of AS and WT mice on several genetic backgrounds are ongoing to give insight into the natural history of glucose impairment in this mouse model. Studies are also underway on *Atp10c* imprinting, expression and function, putatively in some aspect of lipid translocation. This work will further an understanding of the genetic control of glucose homeostasis and obesity in animal models and the human population.

Energy metabolism and glucose homeostasis in a mouse model of Prader-Willi syndrome. *M. Stefan*¹, *H. Ji*², *S. Frayo*³, *H.R. Patel*¹, *D.E. Cummings*³, *R.S. Ahima*¹, *M.I. Friedman*², *R.D. Nicholls*¹. 1) University of Pennsylvania, Philadelphia, PA; 2) Monell Chemical Senses Center, Philadelphia, PA; 3) University of Washington, Seattle, WA.

Prader-Willi syndrome (PWS) subjects have neonatal failure-to-thrive and hypotonia, with hyperphagia and obesity starting in early childhood, short stature, abnormal fat and muscle composition, hypogonadism and abnormal behavior. PWS is caused by loss of function of several paternally expressed, imprinted genes in a 1.5 Mb region of chromosome 15q11-q13. Candidate genes include 5 protein-coding genes and 5 classes of snoRNAs, many of which appear to have regulatory function and may regulate genetic pathways leading to the clinical phenotype (e.g., GH and IGF1 deficiency). Mouse models of PWS recapitulate the neonatal phenotype with severe failure-to-thrive and survival for 1 week only. The basis of PWS is not known, and we show here that a mouse model has a widespread metabolic dysfunction. Abnormalities in PWS *vs.* wildtype (WT) pups include severe hypoglycemia, low insulin levels and high liver glycogen. Oxygen consumption and heat, measured by indirect calorimetry, were markedly reduced in PWS mice. Although there were no differences in liver ATP for postnatal day 1 (P1) between PWS and WT mice (0.990 +/- 0.66 *vs.* 0.89 +/- 0.55 umol/g; n=5-7; p=0.18), liver ATP was significantly higher in P2 PWS mice (1.34 +/- 0.10 *vs.* WT, 0.84 +/- 0.003 umol/g; n=5-8; p<0.0001) as well as for P3-P4 pups. Liver and blood ketones were significantly higher in P1-P4 PWS *vs.* WT mice while circulating free fatty acids and triglycerides were lower. PWS (P1) mice had higher plasma ghrelin levels than WT mice (2919 *vs.* 2316 pg/ml, n = 15-17, p=0.017), suggesting abnormal regulation of this orexigenic hormone. Our data suggest that PWS mice have abnormal energy metabolism, possibly caused by accelerated fat oxidation despite severe deficits in glucose and fat fuel supplies. Additional studies are ongoing with microarray technology to examine the global gene expression patterns in liver and brain of PWS and WT mice. This approach will define genetic pathways leading from the imprinted genes to the metabolic changes in PWS.

Adenine phosphoribosyltransferase deficiency and recurrent nephrolithiasis. *L. Deng¹, L. Liang¹, R. Chiarle², P. Barocelli³, P.F. Celle², C. Salerno⁴, H.A. Simmonds⁵, L. Fairbanks⁵, J.A. Tischfield¹, A. Sahota¹.* 1) Dept. of Genetics, Rutgers Univ., Piscataway, NJ; 2) Dept. Anatomic Pathology, Univ. Turin, Italy; 3) Pediatric Unit, Chivasso Hospital, Italy; 4) Clinical Biochem., La Sapienza Univ., Rome, Italy; 5) Purine Research Unit, Guys Hospital, London, UK.

Adenine phosphoribosyltransferase (APRT) deficiency results in 2,8-dihydroxyadenine (DHA) nephrolithiasis and in some cases renal failure. We examined the mutational basis of APRT deficiency in a 45-year-old patient of Italian origin who passed crystals and stones, initially thought to be made-up of urate, between ages 4-7. The left kidney was described as hydronephrotic but the right kidney was normal. Radioisotope studies at age 14 showed severely impaired renal function, but follow-up studies at age 34 did not demonstrate significant changes. A large stone (identified as >90% DHA) was present in the left kidney but the right kidney was again normal. The patient was placed on a low purine diet and high water intake. He remained asymptomatic until age 44, when he developed anemia and polyuria, and a stone was present in the right kidney. The patient had no detectable APRT activity in erythrocytes, and low levels of DHA were present in the urine and serum. The five exons and flanking regions of APRT were amplified by PCR and sequenced. A novel A-to-G transition was identified at the intron 2 splice acceptor site (AG-to-GG). The parents are first cousins and they were both heterozygous for the mutation, confirming that the patient is homozygous deficient. This was verified by Stu I digestion of PCR-amplified DNA spanning exon 3. The transition alters the reading frame downstream of codon 62 and is expected to abolish enzyme activity. The patient is on allopurinol and dialysis, waiting for a transplant. APRT deficiency was discovered nearly thirty years ago, and a variety of methods are available for its rapid diagnosis. However, as this case illustrates, APRT deficiency continues to be unrecognized or untreated, possibly due to the asymptomatic nature of the disease and the long intervals between stone episodes in some patients. Supported by NIH grant DK 38185.

Sibling phenotype concordance in classical infantile pompe disease. *W.E. Smith*¹, *J.A. Sullivan*², *P.S. Kishnani*², *Y-T. Chen*², *D. Corzo*³, *G.F. Cox*³. 1) Barbara Bush Children's Hospital, Maine Medical Center, Portland, ME; 2) Duke University Medical Center, Durham, NC; 3) Genzyme Corporation, Cambridge, MA.

Background: Glycogen storage disease, type II, includes severe (classical infantile, Pompe disease), moderate (non-typical infantile and juvenile), and mild (adult) forms that generally correlate with the degree of acid--glucosidase deficiency. Sibling phenotype discordance has been reported for later-onset forms of glycogen storage disease, type II, but has not been studied in classical infantile disease.

Methods: The literature was reviewed for affected sibships in which at least one sibling (the proband) had clinical and either histologic or biochemical features consistent with classical infantile Pompe disease. Age of onset, age of death, and clinical course were compared between probands and affected siblings.

Results: From 1930 to 1986, 14 case reports described 12 such families with a total of 29 affected infants. There were 10 probands and 19 affected siblings. The average age at onset of symptoms for all affected infants was 2.7 months (STD 1.5), 2.4 months (STD 1.4) for probands, and 3.0 months (STD 1.6) for siblings. The average age at death for all affected infants was 5.6 months (STD 2.6), 6.8 months (STD 3.1) for probands, and 5.0 months (STD 2.2) for siblings. The average length of disease course for all affected infants was 3.3 months (STD 2.5), 4.5 months (STD 2.9) for probands, and 2.5 months (STD 1.8) for siblings. Probands and siblings showed similar ages of onset and death, clinical symptoms, and causes of death that reflect the characteristic cardiac and respiratory compromise.

Conclusions: Unlike later-onset forms of glycogen storage disease, type II, there appears to be little to no phenotypic variation, especially in terms of lifespan, among siblings with classical infantile Pompe disease.

Short Tandem Repeat Polymorphism at Phenylalanine Hydroxylase Locus and its Application to Prenatal Diagnosis and Carrier Detection of Phenylketonuria in the Iranian Population. *N. Hoseinpur, Kh. Anisi, S.M. Seifati, Z. Khazae-Koohpar, S.M. Hosseini-Mazinani.* Medical Genetics, National Research Center for Genetic Engineering and Biotechnology, Tehran, Iran.

A polymorphic short tandem repeat (STR) marker at phenylalanine hydroxylase locus shows an informativity of 80 percent in prenatal diagnosis and carrier detection of phenylketonuria (PKU) in European PKU kindreds and 73 percent in Chinese PKU kindreds. To investigate the usefulness of this marker in carrier detection and prenatal diagnosis of phenylketonuria in Iranian population, allelic distribution of STR polymorphism was studied in 10 Iranian PKU families and segregation analysis of this polymorphism was performed for 6 siblings of PKU patients. The STR fragments were amplified by PCR and alleles were separated by acrylamide gel electrophoresis. In 8 families (80% of the families), distribution of STR alleles was deemed to be informative. Segregation analysis of STR alleles yielded informative results in all 6 cases and the carrier status could be determined. Our findings indicate a high level of informativity for this marker in carrier detection and prenatal diagnosis in Iranian PKU families. Our results are comparable to those obtained in European Caucasian and Oriental populations.

The Association of Gaucher Disease and Parkinsonism. *J.M. Walker¹, N. Tayebi¹, M. Hanson², B.K. Stubblefield¹, E. Sidransky¹.* 1) Sec on Molecular Neurogenetics, National Institute of Mental Health, Bethesda, MD; 2) Lab of Neurogenetics, NIA.

Gaucher disease, the inherited deficiency of glucocerebrosidase, presents with many diverse phenotypes including a rare group of patients who develop parkinsonian manifestations. While the basis for this association is unknown, patients with this atypical Gaucher phenotype often have early onset, treatment refractory parkinsonism but few Gaucher related symptoms. Mutation analysis of fifteen such patients revealed no shared genotype, although many carried at least one allele with mutation N370S. No mutations in the genes for alpha synuclein or parkin were identified. Of note, several of the probands had family members with parkinsonism but without Gaucher disease. Post mortem studies performed on one of the patients demonstrated diffuse Lewy body inclusions in the hippocampus, substantia nigra, pyramidal neurons and midbrain structures, but not in the cortex. The concurrence of Gaucher disease and parkinsonism, both in these patients and in others in the literature and the unusual neuropathological findings suggest a shared pathway, modifier or other genetic etiology for the two phenotypes. To further explore this association, the gene for glucocerebrosidase is being examined in a large series of probands with early-onset Parkinson disease, but without known Gaucher disease. Exons 8-11 of glucocerebrosidase have been sequenced in 65 individuals and two alterations, E326K and T369M have been identified, on each allele. Studies of this association may yield valuable insights into the neuropathophysiology of both Gaucher disease and parkinsonism.

Identification of the mouse buff (*bf*) gene, a candidate for human Hermansky-Pudlak syndrome (HPS). *N. Oiso*¹, *T. Suzuki*¹, *E.K. Novak*², *R.T. Swank*², *R.A. Spritz*¹. 1) Human Med Genetics, Univ Colorado HSC, Denver, CO; 2) Mol Cell Biol, Roswell Park Canc Inst, Buffalo, NY.

Hermansky-Pudlak syndrome (HPS) is an autosomal recessive disorder characterized by albinism, bleeding, and lysosomal storage, with frequent fatal complications. In mouse, more than 15 loci are associated with mutant phenotypes similar to human HPS. We have mapped and positionally cloned one of these loci, buff (*bf*), characterized by reduced coat coloration and hypopigmented melanocytes with a reduced number of melanized melanosomes, and by reduced platelet aggregation.

The mouse *bf* locus is located at 64 cM on chromosome 5. Within the *bf* genetic interval we identified a strong biological positional candidate, *Vps33a*, a mammalian homologue to the yeast vacuolar protein sorting (Vps) mutant *Vps33*. *Vps33* belongs to the yeast class C Vps protein complex, composed of Vps11, Vps16 and Vps18 and involved in the regulation of vacuolar SNARE pairing and vesicle docking/fusion.

DNA sequence analysis of *Vps33a* in *bf*-mutant mice identified a missense substitution, D251E (GAT®GAG), not present in the C57BL/6J background strain. The D251 residue has been absolutely conserved throughout evolution, strongly suggesting that the D251E substitution is pathologic. We recapitulated the D251E mutation in mouse *Vps33a* cDNA, and stably transformed *bf*-mutant melanocytes, whose abnormal melanosomal phenotype was complemented by stable transformation with wild-type *Vps33a* cDNA, but not by the D251E cDNA or by empty vector. These results confirm that the D251E substitution is pathologic, and that *Vps33a* is thus the murine *bf* locus.

To determine whether human *VPS33A* is a major HPS locus, we screened for mutations in 24 HPS patients who lacked mutations in the *HPS1*, *HPS2*, *HPS3*, *HPS4*, or another HPS gene. One patient was heterozygous for a novel substitution, I256L; however, we did not find any other mutation in this patient and conclude that this substitution is a rare polymorphism.

Fabry Disease: Unrecognized ESRD Patients and Effectiveness of Enzyme Replacement on Renal Pathology and Function. *R.J. Desnick.* Dept Human Genetics, Department of Human Genetics, Mount Sinai School Medicine, New York, NY.

Classical Fabry disease (FD), α -galactosidase A deficiency (α -gal A), is an X-linked lysosomal storage disease that leads to end-stage renal disease (ESRD) in the third to fifth decades of life. In affected males, the progressive accumulation of glycosphingolipid substrates, predominantly globotriaosylceramide (GL-3), in the plasma and in lysosomes of blood vessels and other tissues leads to onset of angiokeratoma, hypohydrosis, acroparesthesias, corneal dystrophy in childhood with vascular disease of the heart, brain, and kidney (ESRD) causing early demise in adulthood. Recently, enzyme replacement therapy (ERT) was shown to be safe and efficacious in a double-blind randomized control Phase 3 study (*New Engl. J. Med.* 345: 9-16, 2001). Results of the Phase 3 extension trial demonstrated GL-3 clearance in renal endothelial, mesangial and interstitial cells with reduced GL-3 in podocytes and tubular epithelium. These findings emphasize the importance of identifying underdiagnosed affected males with ESRD, since later complications include cardiac and cerebro-vascular disease. To investigate the possibility that unrecognized ESRD patients undergoing chronic dialysis have FD, independent studies were conducted in Japanese, Italian, and American centers to identify such patients by screening for deficient α -gal A in plasma and/or leukocytes. In Japan, 6 of 514 males (1.2%), in Italy 18 of 1522 males (1.2%), and in the United States, 9 of 1903 (2.1%) males on dialysis (typically diagnosed chronic glomerular sclerosis) had FD. These ESRD patients lacked angiokeratoma, acroparesthesias, hypohydrosis, and/or corneal changes, precluding their earlier diagnosis of FD. These studies indicate that 1-2% of ESRD patients may be undiagnosed FD renal variants who would benefit from ERT, which can be accomplished during dialysis.

Fabry disease in Europe: update from FOS — Fabry Outcome Survey. A. Mehta¹, M. Beck², J. Ahlmen³, T. Cox⁴, F. Dehout⁵, J-O. Johansson³, A. García de Lorenzo⁶, K. MacDermot¹, R. Ricci⁷, M. Ries², G. Sunder-Plassmann⁸, U. Widmer⁹. 1) Royal Free Hospital, London, UK; 2) University of Mainz, Mainz, Germany; 3) Sahlgrenska University Hospital, Göteborg, Sweden; 4) University of Cambridge, Cambridge, UK; 5) CHU, Charleroi, Belgium; 6) Formación Médica Continuada Hospital Universitario La Paz, Madrid, Spain; 7) Università Cattolica del Sacro Cuore, Rome, Italy; 8) University of Vienna, Vienna, Austria; 9) University Hospital, Zurich, Switzerland.

Introduction: Fabry disease is a lysosomal storage disorder due to deficiency of the enzyme α -galactosidase A. Enzyme replacement therapy with agalsidase alfa has recently been shown to have significant clinical benefits. FOS—Fabry Outcome Survey—has therefore been established to follow the long-term effects of treatment, and currently contains data on nearly 200 patients (>33% female).

Methods: Data on the baseline characteristics of patients in FOS were analysed.

Results: Age at entry into FOS ranged from 9 months to 71 years. For males the diagnosis of Fabry disease was most frequently first suspected by nephrologists or dermatologists, whereas affected family members were most likely to be the first to suspect Fabry disease in females. Misdiagnosis was common, and the mean age of diagnosis was 25 years in males and 37 in females. The most common signs and symptoms in both sexes were neurological, cardiac and dermatological, and the number of organs affected increased with age. No patient had only cardiac involvement. Proteinuria was present in 52 and 39% of males and females, respectively. Mean age at start of agalsidase alfa treatment was 35 and 44 years in males and females, respectively.

Conclusions: There is a clear need for increased awareness of Fabry disease, to allow early diagnosis and treatment. It is also clear that many heterozygous women are affected by the disease.

Coenzyme Q-responsive Leigh encephalopathy in two sisters. *I. Maystadt¹, F. Trijbels², S. DiMauro³, P.J. Sindelar⁴, O. Musumeci³, A. Janssen², X. Delberghe⁵, J.J. Martin⁶, L. Van Maldergem¹.* 1) Ctr Human Genetics, Inst Pathology and Genetics, Loverval, Belgium; 2) Ctr Mitochondrial Disorders, Clinical Genetics Ctr, University of Nijmegen, The Netherlands; 3) Columbia University, College of Physicians and Surgeons, Dpt of Neurology, New York, USA; 4) Dpt Biochemistry and Biophysics, Stockholm University, Stockholm, Sweden; 5) Institut Medicopedagogique Montfort, Herseaux, Belgium; 6) Dpt of Neuropathology, Born-Bunge Foundation, University of Antwerp, Antwerp, Belgium.

A 31-year-old woman had encephalopathy, growth retardation, infantilism, ataxia, deafness, lactic acidosis and increased signals of caudate and putamen on brain MRI. Muscle biochemistry showed succinate:cytochrome c oxidoreductase (complex II-III) deficiency. Both clinical and biochemical abnormalities improved remarkably with CoQ10 supplementation. Clinically, on 300 mg CoQ10/day, she resumed walking, gained weight, underwent puberty, and grew 20 centimeters between 24 and 29 years of age. CoQ10 was markedly decreased in CSF, muscle, lymphoblasts, and fibroblasts, suggesting the diagnosis of primary CoQ10 deficiency. An older sister has similar clinical course and biochemical abnormalities. These findings suggest that CoQ10 deficiency can present as adult Leigh syndrome.

Lessons learned from an attempt to rescue the phenotype in acid alpha-glucosidase knockout mice. *N. Raben, T. Jatkar, A. Lee, P. Plotz.* NIAMS, ARB, NIH, Bethesda, MD.

Deficiency of acid alpha-glucosidase (GSDII, Pompe disease) results in generalized deposition of lysosomal glycogen and manifests as myopathy and fatal cardiomyopathy. A knockout mouse model (GAA^{-/-}) resembles the most severe human infantile form of the disease. To rescue the phenotype of ^{-/-} mice, we have made transgenic lines expressing different levels of human GAA cDNA (hGAA) in skeletal muscle or liver of these mice by using a tetracycline-controllable system. The system allowed us to demonstrate the advantage of liver-mediated gene transfer for secretion and systemic delivery of the enzyme and address the issue of reversibility of the disease by turning the transgene on at different stages of the disease progression. Although many lysosomal disorders are corrected by 1-2% of normal level of enzyme activity, it has been generally accepted that 20-30% of normal GAA activity, provided by gene or enzyme replacement therapy, would be required to reverse the myopathy and cardiomyopathy in Pompe disease. We have demonstrated that the levels of 20-30% of normal enzyme activity are indeed sufficient to clear glycogen in cardiac muscle of young (2 months of age) ^{-/-} mice, but not in older (6 months of age) mice with advanced pathology and a considerably higher glycogen load. Thus, at later stages of disease progression, the required therapeutic level of enzyme activity may be much higher than previously expected. Skeletal muscle a major organ affected in both infantile and late-onset forms without cardiac involvement has proved to be a much greater challenge. By contrast with the outcome in cardiac muscle, the levels of 22-38% wild type were far from sufficient to clear glycogen completely in skeletal muscle resulting in only 43-46% glycogen reduction. Furthermore, induction of hGAA expression in young ^{-/-} mice to the levels greatly exceeding wild type values did not result in full phenotypic correction, and some muscle fibers showed little or no glycogen clearance. The results emphasize the importance of early intervention and point to problems ahead in the first attempts to treat a muscle disorder with enzyme replacement therapy.

A Nova Scotia (NS) Kindred with Fabry Disease (FD). *M. West*¹, *S. Dyack*², *C. Riddell*³, *K. Lemoine*¹, *C. Camfield*⁴, *P. Camfield*⁴. 1) Departments of Medicine; 2) Medical Genetics; 3) Pathology; 4) Pediatrics, Dalhousie University, Halifax, Nova Scotia, Canada.

We describe a kindred in NS with classic FD and a uniform genotype. All records for all FD patients in NS were retrospectively reviewed. This kindred of 948 in 14 generations (100 heterozygotes and 65 hemizygotes) arose with a woman of German parentage born in 1799 on Tancook Island off the southeast coast of NS. Diagnosis of FD was based on a-galactosidase A activity, DNA mutational analysis and clinical features. All NS FD patients are of this kindred based on pedigree and/or DNA mutational analysis with a missense mutation A143P in exon 3. Almost all live within 100 miles of Tancook Island consistent with a founder effect. There are 4 smaller kindreds of Fabry disease in NS of 72 individuals, including 9 hemizygotes and 18 heterozygotes. While unrelated by pedigree to the largest kindred of 876, the 4 smaller kindreds are uniform in terms of classic phenotype, A143P mutation and geographic distribution. In 2000 there were 36 heterozygotes and 27 hemizygotes alive, total 63, from all 5 NS kindreds. Three males (ages 25-48 years) are alive with renal transplants; two have cardiomyopathy and cerebrovascular disease. Another male (age 48 years) is on hemodialysis awaiting a renal transplant. All four are receiving enzyme replacement therapy (ERT) with a-galactosidase A. Another 7 males and 1 female are enrolled in clinical trials of ERT. ERT was well tolerated by all. The details of this kindred will be displayed. This is one of the largest FD kindreds in the world and is an important resource for ongoing study because of its size and uniform genotype.

Osteopontin and kidney stone disease. *H.J. Tinkel-Vernon¹, C. Osborne¹, H.A. Simmonds², M. Yang¹, B.J. Zerlanko¹, S. Rittling¹, D.T. Denhardt³, A. Sahota¹, J.A. Tischfield¹.* 1) Dept Genetics, Rutgers Univ, Piscataway, NJ; 2) Purine Research Unit, Guy's Hospital, London, UK; 3) Dept of Cell Biology and Neuroscience, Rutgers Univ, Piscataway, NJ.

Osteopontin (OPN) has multiple functions in the kidney, including inhibition of stone formation and propagation of inflammation via macrophage attraction. We created *Opn/Aprt* double knockout mice to delineate the role of OPN in renal stone disease. *Aprt*^{-/-} mice develop 2,8-dihydroxyadenine (DHA) nephrolithiasis similarly to patients with adenine phosphoribosyltransferase (APRT) deficiency. This is due to the conversion of adenine (A) to DHA by xanthine dehydrogenase (XDH), which converts hypoxanthine (H)/xanthine (X) to uric acid (UA). *Opn*^{-/-} mice show normal renal histology. The lack of spontaneous renal deposition of lithogenic substances in *OPN*^{-/-} mice suggests that OPN may not have a protective role *in vivo* in the absence of additional renal insult. The *Opn*^{-/-}*Aprt*^{-/-} mice allow us to study the role of OPN in renal stone disease. Pooled urine was collected from 3-4 *Aprt* and *Opn/Aprt* mice at 1-3 months old and analyzed for purines, creatinine, and other metabolites by reverse phase HPLC. The levels of total purines (TP = A, DHA, H, X, UA), oxypurines (OP = H, X, UA), and total adenines (TA = A, DHA) were normalized to creatinine (mmol/mmol). TP excretion in the *Aprt* and *Opn/Aprt* mice was comparable (0.650 v 0.648), but the *Aprt* mice excreted more TA (0.416 v 0.266). The OP/TP, TA/TP, DHA/TA ratios in the *Aprt*^{-/-} mice were 0.36, 0.64, and 0.75, respectively. The ratios in the *Opn/Aprt* mice were 0.59, 0.41, and 0.58. These data show less conversion of A to DHA in the double knockout mice, which is also reflected in the increased OP content, mainly UA. The shift towards a more normal urine purine profile in the *Opn*^{-/-}*Aprt*^{-/-} mice may be due to less macrophage infiltration, and hence less injury at the sites of DHA deposition. Release of XDH by macrophages may contribute to the conversion of A to DHA in *Aprt*^{-/-} mice. Therefore, OPN may promote injury in DHA-induced stone disease via increased inflammation. Histopathological studies are in progress. Supported by NIH grant DK38185.

Molecular characterization of a large genomic deletion including a part of the HPRT gene responsible for the Lesch-Nyhan syndrome. *Y. Yamada*¹, *N. Nomura*¹, *K. Yamada*¹, *N. Igarashi*², *N. Wakamatsu*¹. 1) Dept Genetics, Inst Dev Res, Aichi Human Service Ctr, Kasugai Aichi, Japan; 2) Toyama Centrl Hosp, Toyama, Japan.

Inherited mutations of a purine salvage enzyme, hypoxanthine guanine phosphoribosyltransferase (HPRT, MIM308000), give rise to Lesch-Nyhan syndrome (MIM 300323) or HPRT-related gout (MIM 300323). We have identified a number of such HPRT mutations in the patients manifesting different clinical phenotypes, by analyses of all nine HPRT exons from the genomic DNA and reverse transcribed mRNA using polymerase chain reaction (PCR) technique coupled with direct sequencing. In a typical Lesch-Nyhan patient deficient in HPRT mRNA, we identified a large genomic deletion (~15 kb) including the promoter region and the whole of exon 1. PCR amplification from the patient's genomic DNA showed lacking of HPRT exon 1, and RT-PCR analysis demonstrated deficiency of HPRT mRNA. In exons 2 to 9 of the gene from this patient, no mutations were found. Southern analysis using *Eco* RI and *Pvu* II digested genomic DNAs revealed a more than 13-kb deletion and we could identify by PCR methods the mutant gene deleted about 15 kb upstream from the HPRT intron 1, referring to the nucleotide sequences of the HPRT gene locus (M 26434) and a Bac clone AL590875 containing the HPRT gene. Furthermore, we carried out a family study by PCR amplification of normal and mutant genes. The mother was diagnosed as a heterozygous carrier, but the grandmother was negative and the sister had not inherited the mutant gene. Thus, the deletion mutation was a *de novo* event that had occurred either in germ cells of the grandmother or grandfather, or in the mother during the early phase of fetal development.

Molecular studies of CPS I gene: determination of genomic organization and mutation detection. *S. Funghini, M.A. Donati, E. Pasquini, E. Zammarchi, A. Morrone.* Dep. of Pediatrics, University of Florence, Florence, Italy.

Carbamyl Phosphate Synthetase I (CPS I) deficiency (CPSD) is a rare autosomal recessive urea cycle disorder usually characterized by potentially lethal neonatal hyperammonemia. Based on the age of onset, clinical symptoms and partial residual enzymatic activity, two distinct CPSD clinical phenotypes can be identified: neonatal and late-onset. The structural gene of CPS I has been mapped in the long arm of chromosome 2 at q35. The large (5215 bp) CPSI-cDNA expressed only in liver and epithelial cells of intestinal mucosa has been cloned. So far only a few genetic lesions have been described, while a lot of discrepancies have been reported between the CPSI cDNA cloned by two different groups. Up to now the CPSI genomic organization was unknown. Taking advantages of the phylogenetic lineage between the CPSI gene of *Homo sapiens* and *Rattus Norvegicus* we determine the intron-exon organization of the human CPS I gene. Starting from the ATG, the CPS I gene is organized in 38 exons spanning from 200 to 500 bp. The full-length cDNA sequences from different tissues didn't show any discrepancies, consequently any of these tissues can be used to identify the genetic lesions in the CPS I gene. We also report the molecular studies of an Italian patient affected by CPSD. Two new genetic lesions c1370T>G and c2429A>G that lead to the new V457G and Q810R amino acid substitutions were detected in the patients CPS I DNA isolated from peripheral blood lymphocytes. In addition we have detected the presence of numerous polymorphisms on the patients DNA at heterozygous level. The polymorphic discrepancies come out from the two different CPSI cDNA cloned by two different groups. These findings lead us to believe that our patient descends from two different ancestral backgrounds. The characterization of the intron-exon organization and of genetic lesions in CPSD patients will allow us to offer better genetic counselling and prenatal diagnosis.

Phenotypic characterization and functional consequences of a mutation (ORNT1-T32R) in the human mitochondrial ornithine transporter. *J.A. Camacho¹, R. Mardach², N. Rioseco¹, S. Cress², S. Cedarbaum³.* 1) Human Genetics, OUHSC, Oklahoma City, OK; 2) Medical Genetics, Kaiser Permanente, Los Angeles, CA; 3) MRRC, UCLA, Los Angeles, CA.

Human ORNT1 is the gene defective in the hyperornithinemia-hyperammonemia-homocitrullinemia (HHH) syndrome. Clinical features may include developmental delay, ataxia, coagulation abnormalities and a cognitive function that varies from low normal intelligence to severe retardation. We studied two families of Mexican descent (probands HHH13 & HHH15) that have a mild but variable phenotype. HHH13: The older sibling (18 y/o) was initially diagnosed at the age of 9 during an evaluation for poor school performance. Currently, three symptomatic brothers are in special education classes; psychometric evaluation revealed an IQ of 76 and 80 in the two youngest and 70 in the oldest. HHH15: The youngest sibling (6 y/o) was diagnosed at the age of 3 during an evaluation for gastroenteritis which demonstrated abnormal liver enzymes and coagulation studies, hypoglycemia, mild hyperammonemia and significant hyperornithinemia. His sister was subsequently diagnosed at age 13. Psychometric testing revealed an IQ of 79 in both children who are doing well in school. Analysis of the ORNT1 gene revealed a T32R mutation in both families that was not observed in 128 control alleles. We transfected cultured HHH fibroblasts with an Nmyc-tagged ORNT1-T32R construct and assayed for its ability to restore ornithine metabolism. Relative to the wild-type ORNT1 allele (3-fold baseline activity), the ORNT1-T32R allele is a decrease of function mutation (1.5-fold) with a normal mitochondrial targeting pattern. Interestingly, ORNT2 analysis demonstrated that both HHH15 siblings are heterozygous for an ORNT2-Gly181 allele that is a gain of function polymorphism when compared to the wild-type ORNT2-Val181 allele. These observations suggest that the milder phenotype of these five HHH patients may, in part, be attributed to the partial retention of ornithine transport activity exhibited by the ORNT1-T32R allele. However, ORNT2 and other unknown factors may also play a role in the phenotypic variability of HHH patients.

Expression and characterization of recombinant uroporphyrinogen III synthase mutations causing congenital erythropoietic porphyria.. *L.F. Cunha, D.F. Bishop, R.J. Desnick.* Human Genetics, Mount Sinai School of Medicine, New York, NY.

The markedly deficient (but not absent) activity of uroporphyrinogen III synthase (UROS) results in congenital erythropoietic porphyria (CEP), an autosomal recessive disorder with marked phenotypic heterogeneity. Previously, genotype/phenotype assessments were based on UROS activity in unpurified lysates from a bacterial expression system that generates low amounts of the recombinant enzyme. To characterize the mutations, a new fusion protein expression system was used to obtain high yields of soluble UROS allowing rapid purification to homogeneity by affinity and conventional chromatography. Wild-type and mutant human UROS were expressed in the pSUMO vector as a fusion protein with the 14 kDa Small Ubiquitin-related MOdifier peptide (SUMO). Characterization of the mutations expressed in this system demonstrated the reduced specific activity of purified UROS and/or reduced yield of the mutant proteins. For example, purified UROS with the C73R mutation (one of the most severe phenotypes) had significant residual activity, but yielded less than 2% of wild-type protein. Likely protein miss-folding and/or protease instability additionally contributes to the residual activities in vivo. This rapid high-efficiency purification system will facilitate genotype / phenotype studies and guide efforts such as utilization of small molecule chaperones in studies of potential therapies.

A point mutation in metaxin 1 is associated with the N370S mutation in Gaucher disease. *M.E. LaMarca, N. Tayebi, E. Sidransky.* Clinical Neurogenetics, NIMH/NHGRI, NIH, Bethesda, MD.

The region of chromosome 1q21 encompassing the human glucocerebrosidase gene (GBA) is particularly gene rich, with 7 genes and 2 pseudogenes located within 85 kb. Metaxin 1 (MTX1), a novel gene believed to encode a part of the preprotein import complex of the mitochondrial membrane, is a convergently transcribed gene contiguous to the 3' end of the GBA pseudogene. A metaxin pseudogene is located in the 16 kb region between GBA and its pseudogene. To investigate whether alterations in the MTX1 gene could be associated with atypical presentations of Gaucher disease, the MTX1 gene was sequenced in patients with Gaucher and parkinsonian manifestations. A T>C point mutation in exon 7 of MTX1 leading to the amino acid change F202L was detected in 6 of 8 patients. It was noted that the MTX1 F202L mutation occurred only in those patients with an N370S allele in GBA, and was homozygous in the 2 patients who were homozygous for N370S. DNA from normal controls and from additional patients with Gaucher disease was screened to determine the frequency of the MTX1 F202L mutation. Using PCR amplification and direct sequencing of exon 7 of MTX1, 152 alleles from control individuals (72 Ashkenazi and 80 non-Ashkenazi) were screened for the MTX1 F202L mutation. Seven alleles (4.6%) were identified with MTX1 F202L, but none of the 7 had the GBA N370S. However, 16 GBA N370S homozygotes were all found to be MTX1 F202L homozygotes. Moreover, 27 non-Jewish patients with type 1 Gaucher disease who were N370S heterozygotes were also found to carry one allele with the MTX1 F202L mutation. Eight patients with type 3 Gaucher disease (without N370S) all lacked the MTX1 F202L mutation. The functional consequences of the MTX1 F202L alteration and its possible relationship to Gaucher disease remain to be elucidated. While the F202L in metaxin 1 may be a polymorphism, it does appear to be closely associated with the N370S mutation in glucocerebrosidase, and may be useful in tracing the evolution of the N370S allele.

Mutations in the 3' region of *DHCR7* and failure to normalize plasma cholesterol correlate with need for tube feeding in Smith-Lemli-Opitz syndrome. *L.S. Merkens*¹, *W.E. Connor*², *K.P. Battaile*¹, *C.L. Maslen*², *L.M. Linck*¹, *D. Lin*², *D. Flavell*², *R.D. Steiner*^{1,3}. 1) Pediatrics; 2) Medicine; 3) Mole&Med Genetics, Oregon Health & Sci Univ, Portland, OR.

Smith-Lemli-Opitz syndrome (SLOS) is an autosomal recessive condition caused by mutations in the gene encoding the final enzyme in cholesterol synthesis, 7-dehydrocholesterol D⁷reductase (*DHCR7*). Low cholesterol and high 7-dehydrocholesterol (7DHC) concentrations contribute to the pathogenesis. We studied whether dietary cholesterol (egg yolk) supplementation would increase cholesterol and decrease 7DHC plasma concentrations. 16 subjects with SLOS were enrolled. Feeding difficulties are common in both human SLOS and in the SLOS mouse models. 7 of the 16 subjects in the study were unable to take adequate caloric intake orally and required tube feeding. We identified mutations in *DHCR7* in 15 of the subjects and measured plasma sterols at baseline (after ≥ 3 wk of an essentially cholesterol-free diet) and after ≥ 6 months of cholesterol supplementation. Plasma cholesterol increased significantly in response to supplementation. The 9 subjects who were orally fed had significantly higher plasma cholesterol at baseline and after supplementation (83 and 126mg/dl, means) vs. subjects who were tube fed (50 and 74mg/dl) $P < .001$. After supplementation 8 of the orally fed subjects had cholesterol concentrations above 100mg/dl. Only 1 of the tube fed subjects had plasma cholesterol that was above this limit. 7DHC concentrations were significantly lower at baseline and after supplementation in orally fed subjects (6.9 and 5.2mg/dl) vs. tube fed subjects (11.8 and 12.1mg/dl) $P < .002$. Even 5mg/dl, is 500 times greater than normal (0.01mg/dl). None of the orally fed subjects, but 5 of the 7 tube fed subjects had at least one missense mutation in the 3' region of *DHCR7*, which altered an amino acid within the last 65 amino acids. Mutations in the 3' region of *DHCR7* may predispose to feeding difficulties. Therapies in addition to cholesterol supplementation may be necessary to normalize the concentration of plasma (and tissue) sterols, particularly in tube fed patients.

Comparison of Baseline Clinical Characteristics Between Patients (pts) with Type I Gaucher Disease (GD) with Multi-point Genotype Mutations and Pts with More Common Genotype Mutations: A Report from the Gaucher Registry. *P. Kaplan, H. Andersson, J. Charrow, E. Kolodny, P. Mistry, G. Pastores, B. Rosenbloom, C.R. Scott, R. Wappner, N. Weinreb, A. Prakash-Cheng.* ICGG, Cambridge, MA.

Multi-point mutations [mpm] (L444P+A456P+V460V; D409H+L444P+A456P+V460V) in the glucocerebrosidase gene are generally associated with more severe Type I GD. This GR report compares baseline clinical characteristics of Type I GD pts with a mpm to pts with the 3 commonest genotypes. All Type I pts with reported genotypes and baseline clinical characteristics were summarized. Baseline is the value closest to 1st infusion for pts receiving Enzyme Replacement Therapy [ERT] or most recent value for pts Not on ERT. Among 1518 pts with genotype data in January 2002, the commonest genotypes were N370S/N370S (34%), N370S/L444P (17%), and N370S/84GG (11%). 2% of 1518 patients reported a mpm. Pts with unknown/rare alleles were not included in this summary. The proportions of pts in each genotype group with total splenectomy at baseline were 13% in N370S/N370S, 21% in N370S/L444P, 31% in N370S/84GG, and 21% in multi-point genotype mutations. Mean baseline hemoglobin (g/dL) was 12.2 in N370S/N370S, 11.7 in N370S/L444P, 11.6 in N370S/84GG, and 11.2 in multi-point genotype mutation. Mean baseline platelets ($\times 10^3/\text{mm}^3$) was 124 in N370S/N370S, 125 in N370S/L444P, 154 in N370S/84GG, and 129 in multi-point genotype mutation. Mean baseline liver volume [multiples of normal (MN)] was 1.4 in N370S/N370S, 1.7 in N370S/L444P, 2.2 in N370S/84GG, and 1.8 in multi-point genotype mutation. Mean baseline spleen volume (MN) was 10.4 in N370S/N370S, 16.3 in N370S/L444P, 20.1 in N370S/84GG, and 15.9 in multi-point genotype mutation.

Conclusion: The baseline clinical characteristics of Type I pts with a multi-point genotype mutation are comparable to Type I pts with the N370S/N370S, N370S/L444P, and N370S/84GG mutations. Although mean baseline clinical values among these 4 groups of pts are comparable, variation among individual results suggests that genotype cannot be used as the single indicator of disease severity and that the relationship between genotype and phenotype in GD is not fully understood.

Clinical findings in MCAD patients heterozygous for the common mutation identified by MS/MS newborn screening. *S.E. McCandless¹, D. Millington², B.S. Andresen³, N. Gregersen³, J. Muenzer¹, D.M. Frazier¹.* 1) Depts of Pediatrics & Genetics, Univ North Carolina, Chapel Hill, NC; 2) Dept of Pediatrics, Duke Univ, Durham, NC; 3) Faculty of Health Sciences, Århus Univ, Århus, Denmark.

Through May 2002, North Carolina has identified 41 individuals with medium chain acyl-CoA dehydrogenase (MCAD) deficiency from 557,720 MS/MS newborn screening (NBS) samples. Accumulation of diagnostic acylcarnitines (AC) in plasma or acylglycines in urine confirmed affected status. Of the 41, 30 (71%) are homozygous for the common G985A mutation. Eleven individuals have one or no copies of the common mutation. One African-American male has no recognizable mutation found after sequencing the coding portion of the gene. He had classic biochemical findings in the newborn period (plasma AC8 and AC8/AC10 ratio both markedly elevated and diagnostic acylglycines in the urine). Ten presumed compound heterozygotes were found to have at least one copy of the common mutation. The second mutation has been identified in seven; three individuals are still being studied. All 10 were confirmed by plasma acylcarnitine profile collected at 2 to 25 days of age. Urine organic acids at various times were diagnostic in 6, and suggestive in 3, of 9 tested. No compound heterozygote had low plasma free carnitine concentrations prior to treatment with supplemental carnitine compared to 3/23 among the homozygotes tested. Significant differences in initial metabolic measures between compound heterozygotes and homozygotes include (95% C.I.): NBS AC8 to AC10 ratio 6.0 (3.6-8.4) vs. 10.2 (9.2-11.2), plasma AC8 1.86 (0.83-2.89) mmol/L vs. 3.91 (3.24-4.59), and plasma AC8 to AC10 ratio 5.6 (3.3-7.9) vs. 11.6 (9.9-13.4). No compound heterozygote had neonatal hypoglycemia (compared to 1/30 of the homozygotes). There have been no episodes of documented hypoglycemia in the compound heterozygotes, but several admissions for persistent vomiting. Clinical outcomes have been excellent for both groups to date, with no deaths or individuals with developmental delay. In spite of differences in metabolite profiles, we are not able to identify a significant difference in the clinical course between the two groups when on treatment.

A new approach for positional cloning using cDNA clones: The discovery of *HPS3* and *OPA3*. Y. Anikster^{1, 2}, M. Huizing², R. Kleta², P.D. Anderson², W.A. Gahl². 1) Metabolic Disease Unit, Pediatrics, Chaim Sheba Medical Center, Tel- Hashomer, Israel; 2) Section on Human Biochemical Genetics, NICHD, NIH, Bethesda, Maryland.

Linkage analysis for central Puerto Rican Hermansky-Pudlak syndrome (HPS) patients and for Iraqi-Jewish 3-methylglutaconic aciduria (MGA) patients identified the general locations for the genes causing these disorders. Traditionally, this localization would be followed by gDNA sequencing of candidate genes in the region. We have successfully used an alternative approach. PCR amplification was attempted for each candidate gene using cDNA from patient and control fibroblasts.

For HPS, three cDNA clones with unknown function served as candidate genes. For one of them, we were unable to amplify patient cDNA, but could amplify control cDNA. We next checked for the presence of an mRNA transcript on a northern blot and found none. We concluded, correctly, that this cDNA was the *HPS3* gene. For MGA, we identified four candidate genes. Two were not expressed in fibroblasts, and their genomic DNA was sequenced. The third and fourth were expressed in fibroblasts from controls, but one was not expressed in patients. This gene was identified as *OPA3*.

In *HPS3* the central Puerto Rican mutation was a 3904-bp deletion, and in *OPA3*, the mutation involved a splice site. Since approximately 30% of human gene mutations result in reduced mRNA expression, our approach can often be effective, and is more efficient than extensive sequencing.

In addition to its use for positional cloning, demonstrating absent expression is helpful in identifying genes mutated in certain syndromes. We used this method to rule out *MYO5A* mutations and rule in *RAB27A* mutations in a specific case of Griscelli syndrome.

3-Methylglutaconic aciduria type III in a non Iraqi-Jewish patient. A. Jeong¹, M. Lalor¹, P.D. Anderson¹, R. Kleta¹, F. Skovby², M. Huizing¹, W.A. Gahl¹, Y. Anikster^{1,3}. 1) Section on Human Biochemical Genetics, HDB, NICHD, NIH, Bethesda, MD; 2) Department of Clinical Genetics, Rigshospitalet, Copenhagen, Denmark; 3) Sheba Medical Center, Tel Hashomer, Israel.

Based on clinical and molecular findings, 3-methylglutaconic aciduria (MGA) has been divided into four different disease categories: type I (3-methylglutaconyl-CoA hydratase deficiency), type II (Barth syndrome), type III (Costeff Optic Atrophy syndrome), and type IV (unclassified). MGA type III is a neurophthalmologic syndrome consisting of early (infantile) bilateral optic atrophy, ataxia and mild spasticity. The urinary excretions of 3-methylglutaconic and 3-methylglutaric acids are elevated in type III MGA. The presence of the disorder in an Iraqi-Jewish genetic isolate led to mapping of the OPA3 gene to chromosome 19q13.2-q13.3, followed by isolation of the gene itself. OPA3 consists of two exons and codes for a peptide of 179 amino acids. Iraqi-Jewish patients with type III MGA are homozygous for a splice site founder mutation in OPA3 (IVS1-1G>C) that abolishes mRNA expression in fibroblasts. To date, MGA type III has been assigned only to patients of Iraqi-Jewish ancestry. Our patient is a 14-year old boy whose Kurdish-Turkish parents are first cousins. Dysmorphic features were never noted. The patient walked at 11 months but the gait was unsteady at 16 months. CT of the brain was normal. Organic acid analysis of the urine revealed elevated 3-methylglutaconic acid and 3-methylglutaric acid. Major motor milestones were reached in spite of non-progressive ataxia, mild hypotonia and hypermobility. A brain magnetic resonance image revealed atrophy of the optic nerves, in both their retrobulbar and intracranial pathways. There was no cardiomyopathy, and the peripheral blood smear was normal. In this patient, previously assigned to the MGA type IV group, we found an in-frame 18 bp deletion in exon 2 of OPA3 (320-337del) leading to a shortened protein of 173 amino acids. We conclude that type III MGA also occurs in patients of non Iraqi-Jewish ancestry, and should be considered in patients with type IV MGA who have infantile optic atrophy and ataxia.

Mutations in the FTCD gene causing glutamate formiminotransferase deficiency. *D.S. Rosenblatt*^{1,2,3,4}, *J.F. Hilton*³, *K. Christensen*⁵, *T.J. Hudson*^{1,2,6}, *B.A. Raby*^{2,6}, *X. Estivill*⁷, *S. de la Luna*⁷, *R.E. MacKenzie*⁵. 1) Departments of Human Genetics; 2) Medicine; 3) Biology; 4) Pediatrics; 5) Biochemistry, McGill University, Montreal, Quebec, Canada; 6) Montreal Genome Centre; 7) Genomics Regulation Center, Barcelona, Spain.

Glutamate formiminotransferase deficiency (GFTD) (OMIM 229100) is an autosomal recessive inborn error of folate metabolism. A severe phenotype includes high levels of formiminoglutamate (FIGLU) excretion, megaloblastic anemia and developmental delay. A milder phenotype is characterized by even higher levels of FIGLU excretion but only mild developmental delay. Human formiminotransferase-cyclodeaminase consists of a tetramer of dimers, with dimerization essential for both formiminotransferase (FT) and cyclodeaminase (CD) activity. The human FTCD gene consists of 15 exons and is located on 21q22.3. Genomic DNA was isolated from 3 patients with suspected GFTD and each of the FTCD exons was amplified by PCR followed by direct sequencing. Cell lines from two siblings were heterozygous for mutations c457C®T and c940G®C. The c457C®T mutation changes a conserved arginine to a cysteine (R135C) in a loop involved in the binding of tetrahydrofolate to the FT enzyme domain. The c940G®C mutation converts an arginine to a proline (R299P) in a helix essential for dimerization of the FT domain. The third patient was either homozygous or hemizygous for a c1033insG mutation. All three mutations were absent in 200 control alleles. The c457C®T (R135C) and c940G®C (R299P) mutations were introduced into an expression vector containing the porcine FT domain with a C-terminal six histidine tag using overlap PCR. The proteins were expressed in *E. coli* (BL21DE3) and purified using a NiNTA column. Assays of R135C and R299P showed 61% and 57% of wild type activity respectively. A western blot of the expressed crude extract of the c1033insG mutations showed that the protein was truncated, completely lacking the CD domain. Assay of the crude extract for FT activity showed that the truncated protein was active. These findings represent the first demonstration that mutations in the human FTCD gene underlie GFTD.

Characterization of the normal cDNA for the canine *N*-acetyl- α -D-glucosaminidase gene, the gene defective in mucopolysaccharidosis IIIB. *N.M. Ellinwood*¹, *P.S. Henthorn*², *U. Giger*², *M.E. Haskins*¹. 1) Dept Pathobiology, Univ Pennsylvania, Philadelphia, PA; 2) Dept Clinical Studies, Univ Pennsylvania, Philadelphia, PA.

Mucopolysaccharidosis (MPS) III is a severe neuropathic lysosomal storage disease involving a failure of normal heparan sulfate catabolism. A canine form of MPS IIIB has been identified in Schipperke dogs, and we report herein on the normal cDNA for the canine *N*-acetyl- α -D-glucosaminidase (NAGLU) gene.

Canine MPS IIIB, characterized by deficient NAGLU activity, results in severe neuropathic disease, with clinical signs of diffuse cerebellar disease becoming evident in affected dogs as young adults. As a first step in defining the genetic basis of this disease model we isolated the normal canine NAGLU cDNA. The sequence extended from position -7 from the first ATG (in the context of a strong initiator site from -3 to +4), to the polyadenylation signal. The open reading frame of 2244 nucleotides bears substantial identity to human (87%) and mouse (84%) NAGLU sequences. The predicted protein comprises 747 amino acids, again with considerable identity to the human (83%) and mouse (79%) proteins. The amino terminus contains a stretch of 23 hydrophobic amino acids consistent with a signal peptide. The predicted mature protein, minus any possible carbohydrate residues, comprises a protein of 724 amino acids with a mass of 81.2 kDa.

The identification of the normal canine NAGLU sequence will allow for the identification of the disease causing mutation, and hence development of DNA based diagnostic, to be used to manage a research colony, and to help identify carrier animals in the pedigreed Schipperke dog population. The normal cDNA will also prove useful in developing this model as a means to evaluate enzyme replacement and gene therapies. A breeding colony of 6 dogs has been produced and the first carrier-by-carrier matings are under way. This colony will allow for the assessment of the pathogenesis of and therapy for MPS IIIB. Supported by NIH Grants RR02512 and RR007063 and a grant from The National MPS Society.

Renal Involvement in Gaucher Disease: Pathogenesis and Natural History. *O. Goker-Alpan*¹, *N. Tayebi*¹, *P.S. Kishani*², *H. Rosenbaum*³, *D. Rubinger*⁴, *E. Sidransky*¹. 1) NIMH/NIH, Bethesda, MD; 2) Duke University, Durham, NC; 3) Rambam Medical Center, Haifa, Israel; 4) Hadassah University, Jerusalem, Israel.

Gaucher disease (GD) is characterized by multi-organ involvement due to the accumulation of glucocerebroside in the cells of the monocyte-macrophage system. While hematopoietic, skeletal and hepatic involvement is frequently encountered, renal disease has been considered rare. To determine the incidence and nature of kidney involvement and to further investigate the pathogenesis of kidney disease in GD, we examined clinical and molecular data of 135 patients and identified 8 patients with renal involvement. Overall, 6% of our patient population had kidney involvement. There was no single common genotype nor pathological diagnosis shared among the 8 patients. The kidney disease did not correlate with the severity of GD or the patients genotype. Proteinuria was the most common presenting symptom (7/8). In the majority it was in the range encountered in nephrotic syndrome (4/7). There were two major presentations: isolated proteinuria (3/8) and proteinuria associated with immune activation (3/8). The course of the patients with isolated proteinuria was benign. However the three patients with immune mediated renal disease developed renal failure and one died of end stage renal disease. Two biopsy specimens, one from a patient with isolated proteinuria and the other with end stage renal disease with decreased complement levels were analyzed by light microscopy, EM and immunofluorescent studies. The light microscopy and EM failed to detect any Gaucher cells in the first patient. However on immunofluorescent studies there was no staining for glucocerebrosidase (GC) in the glomeruli, suggesting GC deficiency might have altered glomerular permeability and cause proteinuria. In the second patient, Gaucher cells were detected in the glomeruli on EM. In this patient, the release of cytokines from macrophages primed with glucocerebroside might have triggered a cascade of immune responses, causing irreversible renal damage. These two cases illustrate that there may be different mechanisms involved in pathogenesis of kidney disease in GD.

Enzyme replacement therapy in Japanese Fabry disease patients. *Y. Eto¹, T. Ohashi¹, Y. Utsunomiya¹, M. Fujiwara¹, A. Mizuno², K. Inui³, N. Sakai³, T. Kitagawa⁴, Y. Suzuki⁵, S. Mochizuki¹, M. Kawakami¹, T. Hosoya¹, M. Owada⁴, H. Sakuraba⁶, H. Saito⁷.* 1) Tokyo Jikei Univ Sch Med; 2) Chubu Nat'l Hosp; 3) Osaka Univ Sch Med; 4) Nihon Univ; 5) Int'l Univ Health and Welfare; 6) Tokyo Metro Inst Med Sci; 7) Nat'l Childrens Hosp.

Fabry disease (Galactosidase A deficiency) is an X-linked hereditary disorder that leads to the pathologic accumulation of globotriaosylceramide (GL-3) in cellular lysosomes, particularly in the vascular endothelium of the kidney, heart, and brain. This results in premature death due to the failure of these organ systems. The results of a Phase 3 clinical trial with recombinant human α -galactosidase (r-haGAL, Fabrazyme®, Genzyme Corp) in Fabry disease patients showed safe and effective clearance of GL-3 from the capillary endothelial cells of the kidney, heart, and skin. Here we report the results of an open-label phase 2 study of Fabrazyme therapy in 13 male Japanese Fabry patients. Endpoints included GL-3 clearance from kidney and skin vasculature measured by light microscopy (LM) and ELISA, and Quality of Life improvement. Patients were 16-34 years of age (mean 26.6) and were treated bi-weekly with 1 mg/kg of Fabrazyme for 20 wks. At 20 wks, 12/13 (92%) patients achieved reduction of GL-3 accumulation in both kidney and skin capillary endothelial cells to normal or near-normal levels ($p < 0.001$). Median kidney and plasma GL-3 levels decreased by 51.9% ($p = 0.003$) and 100% ($p < 0.001$) respectively, as measured by ELISA; renal function remained normal based on serum creatine levels and creatinine clearance. Fabry pain and quality of life were measured with the Short Form McGill Pain and SF-36 Health Survey questionnaires, respectively and improvement over baseline was observed in multiple categories. Related adverse events were mostly infusion-associated (fever and rigors). As expected, IgG antibody formation was observed in 11/13 (85%) patients, but resulted in no effect on treatment response. No IgE antibody formation was detected. The results suggest that treatment with r-hGAL is safe and effective in Japanese patients with Fabry disease.

Effective enzyme replacement therapy of murine galactosialidosis using insect cell-expressed PPCA and neuraminidase. *E.J. Bonten, J.N. Toy, L. Mann, J. Knowles, H. Hu, A. d'Azzo.* Department of Genetics, St Jude Child Res Hosp, Memphis, TN.

Galactosialidosis (GS) belongs to the type of lysosomal storage disorders (LSDs) which affects primarily cells of the reticuloendothelial system. The disease is caused by a defect in protective protein/cathepsin A (PPCA) that results in the secondary deficiency of neuraminidase (NEU1) and b-galactosidase. Early onset patients present with both somatic manifestations and neurodegeneration while late infantile/juvenile patients have only a systemic disease. These patients, as many other non-neuropathic LSD patients, could benefit from enzyme replacement therapy (ERT) if the therapeutic protein is poised for receptor-mediated uptake by affected cells. Enzymes produced in insect cells naturally expose core-type mannose residues and are specifically internalized by macrophages and other cell types via the mannose receptor. These recombinant enzymes could, therefore, be used for ERT in lysosomal diseases with a primary involvement of macrophages. We used the mouse model of GS to test this hypothesis. Cultured GS-macrophages effectively internalized both insect cell-produced PPCA and Neu1, restoring their catalytic activities up to 60-fold the control values. Internalization occurred via the mannose receptor and was inhibited by mannan, a competitive substrate for this receptor. Short term treatment of young GS mice by intravenous administration of a mixture of both enzymes led to full restoration of catalytic activities in visceral organs, and almost complete resolution of lysosomal storage in kidney, liver, and spleen. The injected enzymes were detected by Western blotting or by immunohistochemistry in the liver, spleen, kidney, skeletal muscle, heart, adrenal gland, and choroid plexus. The results of these studies suggest that the use of a BV-produced recombinant enzyme alone or combined with other therapeutic means could afford amelioration of the systemic phenotype in non-neuropathic GS patients, and other LSDs affecting primarily the reticuloendothelial system. (Supported by NIH grants DK52025 and GM60950).

Patients Affected With Fabry Disease Have An Increased Incidence of Progressive Hearing Loss and Sudden Deafness: A Study of Twenty-Two Hemizygous Male Patients. *D.P. Germain¹, P. Avan², A. Chassaing¹, P. Bonfils².*
1) Dept Genetics, European Hospital Georges Pompidou, Paris, France; 2) Auditory Research Laboratory, European Hospital Georges Pompidou, Paris, France.

Objective: Fabry disease (FD, OMIM 301500) is an X-linked inborn error of glycosphingolipid metabolism due to the deficient activity of alpha-galactosidase A, a lysosomal enzyme. While the progressive systemic deposition of uncleaved glycosphingolipids throughout the body is known to have protean clinical manifestations, few data are available regarding the cochlear involvement. **Methods:** We non-invasively investigated cochlear functions in 22 consecutive hemizygous males (age 19-64 years, mean 39) affected with classic FD. Conventional audiometry, tympanometry, ABR audiometry, otoacoustic emissions were performed in all patients, together with medical history record and physical examination as part of an exhaustive baseline evaluation prior to enzyme replacement therapy. **Results:** A total of 12 patients (54.5%) with classic FD were found to have abnormal audition. Five patients had progressive hearing loss and seven patients (32%) experienced sudden deafness. In addition, a hearing loss on high-tone frequencies was found in 7 out the 10 remaining patients without clinically significant deafness, despite their young age at time of examination. The incidence of hearing loss appeared significantly increased in FD patients with kidney failure ($P < 0.01$) or cerebrovascular lesions ($P < 0.01$), whereas there was no correlation with left ventricular hypertrophy. In addition, tinnitus aurium was found in six patients (27%). **Conclusion:** This is the first evidence of a high incidence of both progressive hearing loss and sudden deafness in a cohort of male patients affected with classic Fabry disease. The exact pathophysiologic mechanism of the cochlear involvement deserves further studies.

Making the diagnosis of cystinosis. *W.A. Gahl, I. Bernardini, C.R. Hermos, R. Kleta.* Section on Human Biochemical Genetics, HDB, NICHD, NIH, Bethesda, MD.

Nephropathic cystinosis is an autosomal recessive disorder due to deficient transport of free cystine out of lysosomes. Cystine accumulation causes renal tubular Fanconi syndrome (FS) in infancy, glomerular failure by 10 years of age, and other systemic complications. Early diagnosis is critical, because an effective therapy is available. Oral cysteamine, given every 6 hours at doses of 1.3-1.95 g/m² of free base or 60-90 mg/kg per day, delays or prevents renal deterioration and enhances growth if begun in the first 2 years of life. Recent experience with NIH patients points to possible pitfalls in the diagnosis of cystinosis. First, cystinosis patients can have significant proteinuria, and this finding should not militate against the diagnosis. FS is widely recognized to consist of impaired proximal tubular functions, e. g., reabsorption of glucose, phosphate, bicarbonate, and amino acids, the latter providing the most sensitive parameter for detecting the FS. However, protein reabsorption is also compromised in FS. Normally, albumin is filtered but nearly completely reabsorbed by the proximal tubule. When cystinosis impairs reabsorption, a significant tubular proteinuria can occur. Glomerular and tubular proteinuria can be distinguished by urine protein electrophoresis, and this can prevent unnecessary kidney biopsies. Second, corneal cystine crystals may be absent from cystinosis patients prior to one year of age, but are present in all affected individuals after 16 months of age. This slit lamp finding can make the diagnosis if noted by an experienced ophthalmologist. Third, leucocyte cystine measurements provide the gold standard for diagnosing cystinosis. Normal values are less than 0.2 nmol half-cystine/mg protein, and cystinosis values are ~3-20. For cystine determinations, the cystine binding protein assay is superior to standard amino acid analysis. Because artifacts underestimate cystine concentrations, any values above 0.2 should raise suspicion of cystinosis. These artifacts include increasing the protein denominator by red cell contamination or isolating lymphocytes (which store only 3-5 fold normal cystine in cystinosis) instead of polymorphonuclear leucocytes (which store 50-100 fold normal).

Characterization of the Functional Disability in Patients with Late Onset Glycogen Storage Disease type II (GSD II) Using a Modified Version of the Pediatric Evaluation of Disability Inventory (PEDI). *S.M. Haley¹, M.A.*

Fragala¹, A. Skrinar², E. Ponce². 1) Sargent College of Health and Rehabilitation Sciences, Boston University, Boston, MA; 2) Genzyme Corporation, Cambridge, MA.

GSD II is caused by deficiency of the lysosomal enzyme acid alpha glucosidase. Late onset GSD II presents as a progressive disease of the trunk, limb girdle, and respiratory muscles. The goal of this study is to characterize the functional status of patients with late onset GSD II using a GSD-II specific functional outcome measure. **Methods:** The PEDI is a standardized instrument developed to assess the functional self-care and mobility skills of children 6 months to 7.5 years of age. For this study, the PEDI was revised to include less challenging head, trunk and upper extremity items for children with severe functional loss and more challenging gross motor items for children with milder symptoms. Telephone interviews were done by parent proxy on a convenience sample of 30 patients (mean age 7.7 5.6 years; range 0.4-22.1). The sample was predominantly male (76.7%) and Caucasian (86.7%) originating from the U.S. (24), Canada (2), Germany (1), Spain (1), England (1), and Denmark (1). One parent required a translator to respond to the English survey. **Results:** Two-thirds of the sample was non-ambulatory and an additional 10% was able to ambulate only with assistance of a device. 2 out of 30 patients were able to participate in age-expected sports/school activities. 3 out of 30 patients had severe motor loss and could accomplish only a few head control items in supine. One-half of the children used a ventilator during the day, and only 23% of the school-age children attended school. Although the average chronological age of the sample was 7.7 years, the actual average age performance was 2.4 years (range 0.5-4.6) for self-care skills and 1.4 years (range 0.4-7.5) for mobility skills. **Conclusion:** Patients with late onset GSD II presented with heterogeneous functional profiles, although most had severe functional self-care and motor losses. These findings provide a rationale for the modification of instruments to capture the wide range of functional skills observed in patients with late onset GSD II.

Cystinosis due to a CTNS deletion having breakpoints within Alu repeats. *R. Kleta, D.L. Fitzpatrick, M. Rausche, C. Lucero, C.R. Hermos, Y. Anikster, I. Bernardini, W.A. Gahl.* Section on Human Biochemical Genetics, HDB, NICHD, NIH, Bethesda, MD.

Cystinosis is an autosomal recessive disease with intralysosomal cystine accumulation leading to kidney failure within the first decade of life and several nonrenal complications if a renal transplant is performed. The gene CTNS, mutated in cystinosis, codes for the protein cystinosin, which contains 367 amino acids and 7 transmembrane domains. Cystinosin is the lysosomal cystine carrier defective in cystinosis. The disorder occurs in all ethnic groups and, to date, 56 different CTNS mutations have been described, including promoter, missense, nonsense, deletion, insertion, and splice site mutations. The genomic area covering the CTNS gene consists of ~25 kb and 12 exons. A 200,237-bp region encompassing CTNS consists of ~42% repetitive elements, of which 30 % are Alu-like repeats. Such repeats have been implicated as the cause of mutations, via homologous recombination, in hereditary disease. The most prevalent CTNS mutation is a 57,257 bp deletion removing exons 1 to 10, the promoter region and an adjacent gene of unknown function called CARKL. The breakpoints of this deletion, in exon 10 and ~45-kb upstream of the CTNS start codon, are unrelated to repetitive elements. We investigated a 20-year old Mexican patient with classical nephropathic cystinosis who was heterozygous for the 57-kb deletion. We could not obtain a PCR product using his genomic DNA and primers in exons 4 and 5, pointing to another large deletion in the patient's second allele. In fact, it was extremely difficult to obtain any PCR products within this highly repetitive region. By sequential PCR amplification between exons 3 and 6, we eventually defined both breakpoints within two separate Alu repeat regions of 290 bp and 279 bp. The breakpoints match exactly the beginning of a new motif within the two Alu repeats, which exhibits 87% homology. This previously undocumented deletion encompasses 6114 bp between intron 3 and intron 5 of CTNS. Our patient's mutation represents the third largest CTNS deletion known and the first Alu repeat-based deletion in CTNS.

Mutation analysis and X-inactivation studies in the α -galactosidase A gene. *A. Morrone*¹, *C. Cavicchi*¹, *T. Bardelli*¹, *D. Antuzzi*², *D. Rigante*², *R. Parini*³, *M. Di Rocco*⁴, *S. Feriozzi*⁵, *O. Gabrielli*⁶, *R. Barone*⁷, *M. Aricò*⁸, *R. Ricci*², *E. Zammarchi*¹. 1) Dept Pediatrics, Univ Florence; 2) Catholic Univ, Rome; 3) ICP Hosp, Milan; 4) Gaslini Inst, Genova; 5) Belcolle Hosp, Viterbo; 6) Ped Clinic, Ancona; 7) Dept Ped, Catania; 8) Dept Dermatology, Palermo, Italy.

Fabry disease is an X-linked lysosomal storage disorder due to a deficiency of the enzyme α -galactosidase A (GLA). It is a multisystemic disease characterized by renal failure and angiokeratoma. Heterozygous females can be asymptomatic or clinically affected. Up to now more than 200 mutations have been identified in the GLA gene, mapped on Xq22. We report the molecular studies of 14 Italian Fabry male patients affected by the classic form of the disease and 7 carriers from 11 unrelated families. Four new (L167P, c617-618delTT, c126-127insCATG, c946delG) and seven known (P40L, R227Q, W236C, C378Y, R220X, Y356X, IVS3+1G>A) mutations were identified in the patients' GLA gene. An aberrant GLA transcript c486-547del62bp, that leads to an early stop codon, was detected in a male patient carrying the IVS3+1G>A splicing defect. These results confirm the molecular heterogeneity also in the Italian Fabry patients. We also report X-inactivation studies on 7 carriers with a positive family history for Fabry disease in males. Four females showed a random X-inactivation pattern and three were skewed. One of the skewed females was a manifesting carrier with angiokeratoma. The other two skewed carriers were two sisters and only one was a manifesting carrier. In these sisters the skewed X-inactivation pattern in favour of the mutant allele was detected in the manifesting carrier, while a skewed pattern in favour of the wild type allele was detected in the other. In these carriers the X-inactivation studies suggest a correlation between clinical manifestations and the skewing of X-inactivation. It is important to emphasize the characterization of Fabry patients genotype with the aim of a genotype/phenotype correlation and the carrier status assignment. We would like to point out the importance of X-inactivation studies that could be helpful in predicting the carriers' phenotype and give useful indications for therapeutic management.

Genes required for cholesterol biosynthesis and lysosomal function are upregulated over time in response to sucrose-induced vacuolation in normal fibroblasts. A. Helip Wooley, J.G. Thoene. Human Genetics, Tulane Univ Sch Medicine, New Orleans, LA.

Normal human fibroblasts cultured in the presence of 100 mM sucrose form lysosome-derived vacuoles via pinocytic uptake and storage of sucrose, due to the absence of invertase in these cells. The protein synthesis inhibitor cycloheximide significantly decreased apparent vacuolation, observed by phase microscopy and ^{14}C -sucrose uptake and storage, in a time and concentration dependent manner. 50 mM cycloheximide decreased ^{14}C -sucrose uptake by 36%; at 48 h, $P < 0.004$. Changes in gene expression following 24 hours of sucrose induced-vacuolation were examined in triplicate using the Affymetrix HGU95A microarray. Thirty-seven genes were increased an average of 2-fold or greater, relative to matched controls including cholesterol biosynthesis and metabolism genes (mevalonate pyrophosphate decarboxylase (MPD) (16.8 fold \pm 13), delta7-sterol reductase (2.7 \pm 0.8), LDL receptor (3.0 \pm 0.3) and 3-HMG-CoA reductase (2.0 \pm 0.1)), lysosome related genes (neuraminidase (2.4 \pm 0.4), CLN3 (gene for Juvenile Batters disease) (2.2 \pm 0.8) and CLC-7 a lysosomal chloride channel (2.0 \pm 0.5)), and a protein (Rab7L1) with 30% homology to the small GTP-binding protein Rab7, implicated in late endosome and lysosome fusion (2.1 \pm 0.4). Gene expression was also examined by microarray following 12, 24, 72 or 120 hours of sucrose exposure and compared to both time 0 control and matched time controls. The majority of increased genes, including those mentioned above, demonstrated little or no change at 12 hours but were increased by 24 hours and at all timepoints thereafter. These changes were generally greater when compared to the T_0 control but were similar to time matched control results. This is illustrated by MPD which increased 0, 13, 16 and 17 fold at 12, 24, 72 and 120 hours versus T_0 and 1.4, 13, 13, and 4 fold versus time matched controls. These findings suggest that cellular mechanisms exist to detect perturbations in lysosomal physiology and respond by upregulating pathways necessary to accommodate these changes.

Experience with Safety Surveillance Programs for Diseases Requiring Enzyme Replacement Therapy. *M.J. Motta, R.D. Cintron.* Medical Affairs, Genzyme Corporation, Cambridge, MA.

Lysosomal storage disorders are caused by deficiency of catabolic enzymes leading to the accumulation of substrates within the lysosomes and causing function impairment. With the development of enzyme replacement therapy (ERT) an established safety surveillance program is essential to provide careful and timely medical review of reported adverse events (AEs). A proactive method to monitor antibody formation is also critical. **Methods:** Approximately 4,000 patients worldwide currently receive ERT for Gaucher, Fabry, MPS-I and GSD-II. AEs information is collected in the United States following FDA guidelines detailed in 21CFR 312.32 (clinical trials) and 21CFR 314.80 (post-marketing). Clinically significant changes observed in ophthalmic tests, echocardiograms, EKGs and routine blood chemistries among others are recorded and analysed. Patient sera are regularly monitored for antibody formation and to study immunologic tolerance over time. **Results:** Observed AEs generally fall within three main groups: infusion site reactions, immune-mediated reactions, and events secondary to the nature of the disease. Infusion site reactions are primarily local swelling/irritation and are often due to extravasation. Immune-mediated reactions often correlate with the development of antibodies to the exogenous protein. In this group of patients, infusion-associated reactions are possible, often predictable, found to be a function of protein load, and influenced by the rate of infusion. AEs secondary to the nature of the disease vary within the different LSDs. Factors affecting the nature and frequency of the latter include type, extent, and severity of the organ(s) involvement. **Conclusions:** Safety surveillance provides vital information on ERT and continuous information on the nature of the disease being treated. Infusion-associated reactions can be managed with conservative measures. The development of antibodies to exogenous proteins is anticipated in patients with little or no endogenous enzyme activity and does not preclude the safe continuation of ERT. In protein-based recombinant products, the extent and overall effect of immunogenicity remains an open question.

Neurologic complications of female and male patients with Fabry disease. *R.J. Hopkin^{1,3}, F.J. Samaha^{2,3}, H. Zhao¹, L. Bailey^{1,3}, G.A. Grabowski^{1,3}.* 1) Dept Human Genetics, Cincinnati Children's Hosp, Cincinnati, OH; 2) Dept Neurology, Cincinnati Children's Hosp; 3) Lysosomal Disease Center, Cincinnati Children's Hosp.

Fabry disease is an X-linked lysosomal storage disease caused by a deficiency in agalactosidase A. Twenty-three hetero- or hemi-zygotes (ages 20-61) were evaluated for CNS involvement using history, clinical examination, and CNS MRI. The most common abnormalities reported are summarized in the table. The vertigo and head aches were quite severe leading to hospitalizations and/or job loss for several participants. Hyperacusis was more common in heterozygotes than hemizygotes. Psychiatric diagnoses included schizophrenia (1 female, 2 male), antisocial behaviors (3 female, 3 male), and depression (4 female, 4 male). Although neurologic complications have previously been reported in Fabry disease, these findings are surprising since the age at onset was earlier than previously reported (teens for several participants). The frequency of complications was extremely high (90 percent had at least one clinically significant CNS complication). The equal frequency and severity of neurologic complications in hetero- and hemi-zygotes is surprising and significant. These findings have important implications in planning for and monitoring treatment needs of individuals with Fabry disease. The availability of enzyme therapy for Fabry disease provides added impetus to further delineate the spectrum of this disease especially in heterozygotes.

Report of the Fabry International Research Exchange (FIRE) Registry. *R.D. Steiner¹, C. Feist¹, T. Clemons² for the FIRE Registry Group.* 1) Oregon Hlth Sci U, Portland, OR; 2) EMMES, Rockville, MD.

Fabry disease is an x-linked glycosphingolipid storage disorder caused by deficient activity of the lysosomal enzyme α -galactosidase A. Globotriaoslyceramide (Gb3), the substrate for this enzyme, progressively accumulates in cells and tissues of affected patients causing pathology. The FIRE Registry collates data on the natural history of Fabry disease and response to therapy. As of 6/02, 68 patients (39 males (m) and 29 females (f)) have been enrolled at 17 centers across the US and overseas. The mean age of m = 32 ± 13 years(y), and f = 39 ± 17 y. Most (85%) were Caucasian. One m had received enzyme replacement therapy. The majority (54%) of m were diagnosed by mutation analysis, while many of the f (59%) were diagnosed by having an affected m first degree relative with the diagnosis confirmed by genotyping. The mean age of onset of Fabry symptoms was 9 ± 6 y in m and 16 ± 16 y in f. The mean age of diagnosis was 18 ± 12 y in m and 27 ± 17 y in f. The prevalence in m and f of the following signs and symptoms were: tinnitus (m-33%, f-30%); vertigo (m-22%, f-22%); hearing loss (m-28%, f-22%); angiokeratoma (m-72%, f-37%); corneal pathology (m-61%, f-41%); and pain (m-67%, f-52%). The prevalence of organ involvement was: stroke (m-11%, f-4%); proteinuria (m-28%, f-41%); renal insufficiency (m-22%, f-7%); HTN (m-17%, f-11%) and cardiomyopathy (m-6%, f-11%). Analysis of the occurrence of signs/symptoms by age and gender revealed that the earliest signs/symptoms in m were angiokeratomas, corneal pathology and neuropathic pain, while in f, corneal pathology and pain were the most common presenting signs/symptoms with angiokeratomas not reported in f until >25y. Proteinuria was common in m and f >25y, while renal insufficiency and cardiomyopathy were not reported until >35y in m and >44y in f. F with Fabry disease appear to have many if not all of the signs/symptoms seen in m, but typically present and are diagnosed almost 10y later than m. Organ involvement manifests approximately 10y later in f as well. In contrast to previous characterizations of Fabry as X-linked recessive, most, if not all women with a Fabry gene mutation exhibit signs or symptoms of disease.

A biochemical and histological mouse model for aggressive Gaucher disease. *B.M. Quinn¹, Y. Sun¹, D.P. Witte², G.A. Grabowski¹*. 1) Human Genetics; 2) Pediatric Pathology, Children's Hosp Medical Ctr , Cincinnati, OH.

Gaucher disease, an autosomal recessive trait, results from deficiency of the activity of the lysosomal enzyme acid b-glucosidase (BGC). This leads to the accumulation of glucosylceramide within the lysosomes of Gaucher storage cells contained in several organs, mainly the spleen and liver. Mice homozygous for V394L mutation of BGC showed < 20% of WT activity *in vitro* but no phenotype out to > 13 months. In humans Gaucher like disease also results from mutations in saposin C, an activator of BGC. Mice with a homozygous knock out of the saposin C precursor, prosaposin, die of neurological complications within one month. These mice can be rescued with a prosaposin transgene (PS-TG) driven by the low level general promoter for 3-phosphoglycerate kinase. This rescue leads to fertile mice with greatly delayed neurological complications and lifespans > 7 months. The visceral organs accumulate glycosphingolipids but appear histologically normal though out their lives. The combination of prosaposin knockout, the PS-TG and V394L homozygosity results in mice with considerable numbers of Gaucher storage cells in the spleen, liver and lungs by two months of age. Electron microscopy shows these cells to contain the characteristic braided structure of stored glucosylceramide. Lipid analysis by TLC confirmed accumulation of glucosylceramide in these tissues. These mice also manifest CNS clinical abnormalities. This represents a viable mouse model of aggressive visceral Gaucher disease associated with CNS deterioration and should be a useful therapeutic model.

Activation mechanism of saposin B. *M. Wang, X. Qi.* Dept Human Genetics, Children's Hosp Medical Ctr, Cincinnati, OH.

Saposin B is an activator for enzymatic hydrolysis of sulphatide by arylsulfatase A in lysosomes. Deficiencies of saposin B have been shown to result in metachromatic leucodystrophy. Some investigations have shown that unlike saposin C, saposin B activates the enzyme by interacting with substrate in lipid bilayers. In order to study the activation mechanism of saposin B, an in vitro detergent free activation assay and a fluorescent resonance energy transfer (FRET) system were exploited to measure the activation function of saposin B and interaction mechanism between saposin B and cerebroside sulfate. To clarify that the interaction between saposin B and cerebroside sulfate is related to the activation function of saposin B, three mutants (Y50A, Y54A, I8R) with different secondary structure as determined by circular dichroism spectroscopy were generated and produced. The circular dichroism spectra of mutant Y50A is same as the wild-type saposin B. According to the product amount in the in vitro assay analyzed on TLC, the activation of the Y50A mutant was the same as the wild type saposin B. The activation of the Y54A mutant was half of the wild type saposin B. The I8R mutant lost nearly all of its activation function. The rearranging tendency of cerebroside sulfate on the lipid bilayer was detected by the degree of the decreased intensity of fluorescent resonance energy transfer. The fluorescent intensity of the energy transfer between Dansyl-PS (1,2-Dioleoyl-sn-Glycero-3-Phospho-L-Serine-N-(5-dimethylamino-1-naphthalenesulfonyl)(Dansyl)) and LRh-CS (Lissamin-Rhodamin labeled Cerebroside Sulfate) was the wide-type Y50A < Y54A < I8R. The I8R showed no decrease in the intensity of fluorescent resonance energy transfer. The above results indicated that the FRET changes affected by saposin Bs were correlated with the activation function of saposin Bs. This suggested that the functionality of saposin B could be accomplishing by rearranging cerebroside sulfate on the lipid bilayer.

ER Stress-Mediated Apoptosis in the CNS of the GM1 Gangliosidosis Murine Model. *A. Tessitore, M. Del Pilar Martin, A. d'Azzo.* Genetics, St. Jude Child Res Hosp, Memphis, TN.

GM1 gangliosidosis is a lysosomal glycolipid storage disease caused by deficiency of the acid beta-galactosidase. The early infantile form of the disease is characterized by generalized central nervous system involvement, and is fatal in infancy. The mouse model of GM1 gangliosidosis develops features, which resemble the severe human condition, resulting in rapid progressive neurodegenerative symptoms, associated with neuronal cell death. Recent findings have suggested that activation of an endoplasmic reticulum (ER) stress response may be involved in the pathogenesis of neuronal cell injury in acute and chronic diseases of the brain. Conditions that alter the ER environment induce highly conserved cell stress responses, which include the transcriptional induction, translational attenuation, and degradation of unfolded proteins. In contrast, excessive and/or prolonged ER stress results in apoptosis. We found that activation of an ER stress-induced apoptotic pathway may contribute to the pathology of GM1 gangliosidosis. Increased mRNA levels of the stress-inducible transcription factor CHOP (C/EBP homologous protein) were detected in spinal cord samples from 5- to 8-month old GM1 gangliosidosis mice. In addition, mRNA levels of the ER resident protein GRP78 (78kD glucose-regulated protein) were inversely regulated during the course of the disease compared to CHOP. We also demonstrated transcriptional induction of caspase-12, a caspase family member predominantly localized in the ER and shown to be exclusively activated in ER stress-mediated cell death. The mRNA results were confirmed by immunoprecipitation and Western blot analysis of the caspase-12 protein. Together, the coordinate induction of CHOP and caspase-12 and the presence of apoptotic cells in spinal cord samples point to the activation of ER-stress apoptotic pathway in the CNS of GM1-gangliosidosis mice that might contribute to neurodegeneration. However, the mechanisms by which beta-galactosidase deficiency followed by massive lysosomal accumulation of GM1-ganglioside activate or render cells susceptible to ER stress cell death remain to be elucidated. (Supported by NIH grant DK52025).

Predictors of verbal dyspraxia in galactosemia. *L.J. Elsas II, A.L. Webb, R.H. Singh, M.J. Kennedy.* Division of Medical Genetics, Emory Univ School of Medicine, Atlanta, GA.

Classical galactosemia is an autosomal recessive disorder resulting from deficient galactose-1-phosphate-uridyl transferase (GALT). Verbal dyspraxia is one unexpected outcome of treated children with galactosemia. In this study, we validated a 2-hour breath test and evaluated four additional potential biochemical risk factors for verbal dyspraxia: mean RBC galactose-1-phosphate, highest RBC galactose-1-phosphate, mean urinary galactitol, and erythrocyte GALT activity, for their predictive value among a galactosemic population.

Thirteen controls and 42 patients with galactosemia took an oral bolus of ^{13}C -galactose and their breath was collected at 0, 90, 100, 110, and 120 minutes. The rate and cumulative percent dose (CUMPCD) of $^{13}\text{CO}_2$ in expired air was determined by dual isotope mass spectrometry at each time point. Twenty-eight of the 42 patients with galactosemia had <5% CUMPCD ("severe") and 14 had >5% CUMPCD ("variant"). Mutant hGALT alleles in the "severe" category were Q188R, K285N, D5kb, Y209C, V151A, and in the "variant" group were S135L, L189R, T138M, and D113N. A subset of 24 patients underwent formal speech evaluation; 15 (63%) had verbal dyspraxia. Those with dyspraxia had significantly lower CUMPCD values ($2.84 \pm 5.76\%$ vs $11.51 \pm 7.67\%$; $p < 0.008$), significantly higher mean erythrocyte galactose-1-phosphate (3.38 ± 0.922 mg/dL vs. 1.92 ± 1.28 mg/dL; $p = 0.019$) and mean urinary galactitol levels (192.4 ± 75.8 mmol/mol creatinine vs. 122.0 ± 56.4 ; $p = 0.048$) than those with normal speech. CUMPCD values below 5%, mean erythrocyte galactose-1-phosphate levels above 2.7 mg/dl and mean urinary galactitol levels above 135 mmol/mol creatinine were strongly associated with dyspraxic outcome with odds ratios of 21, 13, and 5, respectively.

We conclude that measurement of total body oxidation of galactose to CO_2 in a breath test is the most significant, sensitive, and specific predictor for dyspraxia among the abnormal biochemical parameters found in patients with galactosemia.

Remarkable recovery in adult-onset leigh syndrome with partial cytochrome *c* oxidase deficiency. P.C.

Goldenberg¹, R. Steiner¹, L. Merkens¹, T. Dunaway¹, R. Egan², E. Zimmerman¹, G. Nesbit¹, B. Robinson³, N. Kennaway¹. 1) Oregon Health & Science Univ., Portland, OR; 2) Casey Eye Inst., Portland, OR; 3) Hospital for Sick Children, Toronto, Ontario.

Leigh syndrome (LS) is a heterogeneous disorder, usually due to a defect in energy metabolism. Symptoms typically commence in infancy or childhood. Progressive deterioration is the norm. We describe a 22-year old woman with acute presentation of LS and partial cytochrome *c* oxidase (COX) deficiency with dramatic clinical and neuroradiologic improvement following an acute encephalopathic episode.

The patient developed progressive spastic paraparesis one week following a febrile gastrointestinal illness. Over the next month, she developed complete aphonia, near quadriplegia, retinopathy and sensorimotor axonal polyneuropathy. Blood and CSF lactates were elevated. Vitamin and coenzyme Q therapy was instituted. MRI was normal at the onset of illness but later showed neurodegeneration in the basal ganglia. MRS showed increased lactate doublet and reduced N-acetylaspartate (NAA) in these areas.

Over the next five months the patient recovered muscle strength, sensation, the ability to ambulate with a cane, and spoke with only subtle dysarthria. Retinopathy continued. MRI showed decreased high signal intensity, with decreased lactate doublet and increased NAA on MRS.

COX activity was 48% and 58% of control mean in muscle mitochondria ($p < .05$) and skin fibroblasts respectively. All other respiratory chain activities and PDH were normal, ruling out other major causes of LS. Surf1 levels were normal. Sequencing of the three mtDNA-encoded COX subunits revealed no pathogenic mutations.

This is the first report of significant recovery in a patient with COX deficiency who met accepted criteria for LS. Her remarkable clinical improvement correlated with improvement of MRI and MRS.

The new mutation G105E in the OTC gene causes an acute onset in a man affected by ornithine transcarbamylase deficiency. *S. Bisanzi¹, A. Morrone¹, N. Gentiloni Silveri², M. Di Lillo², R. Ricci², D. Antuzzi², E. Zammarchi¹.* 1) Department of Pediatrics, University of Florence; 2) Catholic University, Rome, Italy.

Ornithine transcarbamylase deficiency (OTCD) is the most frequent urea cycle disorder, inherited as an X-linked trait. The OTCD phenotype is heterogeneous, ranging from neonatal onset hyperammonemic coma to asymptomatic adult. Here we report a 21 year old man with acute onset OTCD. He started complaining about abdominal pain and vomiting after a meal of fresh salmon and pasta, and he appeared a little disoriented. In the following few hours his symptoms were getting worse and he began to feel drowsy. Laboratory finding showed hyperammonemia and increased transaminases. Three days afterwards coma occurred. OTCD was suspected and sodium benzoate and bioarginine therapy was initiated. The patients ammonia blood level normalised but after 24 hours he went into a deep coma and he died after ten days. Direct DNA sequencing of the patient's OTC gene led to the identification of the transition c.314G>A that leads to the new amino acid change G105E. This mutation occurred in an evolutionary invariant residue, located in the polar domain of the OTC protein, and is likely to be important in the assembly of the trimer. It can be hypothesised that the G105E mutation could interfere with forming the active site. The late onset in this patient and the finding that his maternal grandfather is a hemizygous healthy carrier suggest that this mutation causes a partially functional protein (residual enzymatic activity 10%), although occurring in a conserved amino acid. It can be assumed that environmental factors provoke significant catabolic events able to upset the patients homeostasis and destabilize the protein complex interfering with residual OTC activity. In the patients mother the assay for X-inactivation showed a skewed pattern in favour of the mutant paternal X-chromosome. This pattern seems to contradict her asymptomatic carrier status and the negative allopurinol loading test, but it supports the hypothesis that phenotypic presentation can be caused by a combination of genetic and environmental factors.

Hermansky-Pudlak syndrome type-4 (HPS-4): Clinical and molecular characteristics. *P.D. Anderson, M. Huizing, M. Lynch, W.A. Gahl.* Heritable Disorders Branch, NICHD, NIH, Bethesda, Maryland.

Hermansky-Pudlak syndrome (HPS) is a rare disorder of vesicle formation characterized by oculocutaneous albinism, a bleeding diathesis due to storage-pool-deficient platelets, and in some patients lysosomal accumulation of ceroid lipofuscin. The disorder exhibits considerable locus heterogeneity; four genes in humans are now associated with HPS, and there are at least 14 mouse models with an HPS phenotype of reduced coat color, storage-pool-deficient platelets, and variable lysosomal dysfunction. The human homologue of the *light ear* mouse locus was recently identified as the fourth HPS-causing gene. We performed an extensive study on 23 unassigned HPS patients (not having HPS-1, HPS-2, or HPS-3 disease) to further characterize HPS-4 disease on clinical and molecular bases.

We identified the genomic organization of *HPS4*, including intron/exon boundaries, and found that the *HPS4* gene, located on chromosome 22q11.2-q12.2, produces at least two alternatively spliced mRNA transcripts which differ at their 5' ends. Using SSCP, we determined that 8 of our 23 at-risk patients had HPS-4. In the process, we identified 5 different *HPS4* mutations, including 1 frameshift and 4 nonsense mutations. Three alleles in 2 patients contained the previously reported Q698insAAGCA frameshift, and 1 patient was homozygous for the previously reported Q631X nonsense mutation. Four alleles in 3 patients contained the novel mutation R217X, and 2 siblings were compound heterozygotes for the novel mutations E138X and E222X. We also characterized the clinical phenotype of HPS-4 disease, demonstrating iris transillumination and absent platelet dense bodies. In addition, patients with mutations in *HPS4* appear to be at risk for developing pulmonary fibrosis and granulomatous colitis; the relatively severe HPS-4 phenotype is similar to that of HPS-1. In fact, melanocytes from the *HPS4*-deficient light ear mouse are not only deficient in the HPS4 protein, but also lack the HPS1 protein. This points to a possible interaction of the two proteins, as well as their functioning in the same pathway. It also explains the similar phenotypes of HPS-1 and HPS-4 patients.

Short-Chain Acyl-Coenzyme A Dehydrogenase Deficiency: Expanding the Phenotype. *E.A. Crombez¹, M. Fox¹, N. Gregersen², E. Vilain^{1,3}.* 1) Pediatrics, UCLA Medical Center, Los Angeles, CA; 2) Molecular Medicine, Aarhus University Hospital, Denmark; 3) Human Genetics, UCLA Medical Center, Los Angeles, CA.

Short-chain acyl-coenzyme A dehydrogenase [SCAD] is found in the mitochondrial matrix and is involved in the beta-oxidation of saturated fatty acids. SCAD deficiency, once thought of as rare, is becoming increasingly more often diagnosed. SCAD deficiency typically presents in the neonatal or newborn period with metabolic acidosis, failure to thrive, developmental delay, and seizures. There are only nineteen reported cases confirmed by enzyme assay in cultured skin fibroblasts. Here, we present two additional cases of confirmed SCAD deficiency that expand the clinical phenotype. Both patients presented in the newborn period with respiratory distress and dysmorphic features. Both patients later developed cyclic vomiting. In addition, the first patient had: hypotonia, low set ears, high arched palate, broad nasal bridge, pectus excavatum, symmetrical hand anomalies, and malformed feet. The second patient had: facial asymmetry, deformation of the limbs with contractures, adducted thumbs, a defect of the abdominal wall, bilateral cryptorchidism, bilateral hip dislocations, and soft tissue webbing in the upper extremities. Laboratory evaluation in both patients revealed elevated ethylmalonic and methylsuccinic acid in the urine. Acylcarnitine profile showed elevated C4 compounds. In the first patient DNA analysis revealed the patient to be homozygous for the SCAD gene mutation 319C>T which changes the amino acid arginine to cysteine. In the second patient DNA analysis revealed the patient to be homozygous for the SCAD gene variation 625G>A which results in a glycine to serine amino acid change. These are both known susceptibility SCAD gene variations. The diagnosis of SCAD deficiency was confirmed by enzyme assay in cultured skin fibroblasts in both patients. We conclude that SCAD deficiency may present with congenital anomalies and that SCAD may play an important role during development. This expansion of the clinical phenotype of SCAD deficiency will also help identify new patients with this disorder.

Loss of vision in MPS VI is a consequence of increased intracranial pressure. *J.T. Goodrich¹, P. Harmatz², P.A. Levy¹, R.W. Marion¹.* 1) Children's Hospital at Montefiore/ A. Einstein Col of Med, Bronx, NY; 2) Oakland Childrens' Hospital, Oakland, CA.

Caused by a deficiency of N-acetylgalactosamine 4-sulfatase, Maroteaux-Lamy syndrome (MPS VI) is a rare, progressive autosomal recessively inherited disorder. Of the many clinical features associated with MPS VI, the sudden onset of permanent vision loss is one of the most devastating. The cause of this vision loss is not fully understood: theories include the effect of chronically increased intracranial pressure (IICP) and infiltration of the optic nerve with GAGs. We are currently following three patients with MPS VI who are blind. The youngest of these patients, KG, was diagnosed with MPS VI at birth, because of a positive family history. At 4 years of age, he presented with nystagmus; over the course of the next three weeks, he lost all vision in both eyes. Examinations by an ophthalmologist and neuro-ophthalmologist failed to identify papilledema or any other significant ocular pathology. A CT scan and MRI showed findings consistent with MPS VI, but no apparent signs of IICP were seen. A lumbar puncture performed under general anesthesia revealed a markedly elevated opening pressure (>500 mm H₂O). Based on this finding, a ventriculoperitoneal shunt was placed. Following the procedure, KG has regained some vision. Although no cure for MPS VI exists, one of us (PH), in collaboration with BioMarin, is currently involved in an enzyme replacement trial using Aryplase (TM), a specific form of recombinant N-acetylgalactosamine 4-sulfatase. With a possible treatment close at hand, attempts to prevent patients from developing the most disabling manifestations of this condition are of the utmost importance. Our experience strongly suggests that blindness in MPS VI is caused by IICP that may not be detectable using standard exams and imaging studies. Patients with this condition require lumbar puncture for correct diagnosis. We urge that this course of action be taken in any patient with MPS VI showing signs or symptoms of IICP, even when exams and imaging studies reveal "normal" findings.

Aromatic L-aminoacid decarboxylase (AADC) deficiency: Unusual neonatal presentation and new findings in organic acid analysis (OA). *J.E. Abdenur¹, N.G. Abeling², A.C. van Cruchten², N. Specola¹, L. Jorge¹, A.B. Schenone¹, N.A. Chamoles¹.* 1) FESEN, Buenos Aires, Argentina; 2) Academic Medical Center, University of Amsterdam, The Netherlands.

AADC deficiency is a rare neurotransmitter defect leading to a combined deficiency of catecholamines and serotonin. Patients are usually detected in infancy due to developmental delay, hypotonia and extrapyramidal movements. The diagnosis is based on abnormal neurotransmitter pattern in CSF and reduced AADC activity in plasma. An elevation of vanillic acid (VLA) has been described in a few patients as the only abnormality detected in OA. We report a new patient who presented in the neonatal period with lethargy, hypotonia, metabolic acidosis and recurrent hypoglycemia. An inborn error of intermediate metabolism was suspected. Ammonia, lactic acid and acylcarinitines were normal and urine OA (GC/MS) showed a small increase of vanillic acid. The presumptive diagnosis of AADC deficiency was established. The patient was lost to follow-up until the age of 8 months, when he presented with dystonia, abnormal movements, oculogyric crises and hypothermia. Samples of CSF, plasma and urine were obtained at that time. Repeat OA showed not only increased levels of VLA, but also increased vanilpyruvic (VPA), acetyl-vanilalanine (AVA) and N-acetyl-tyrosine (NAT). No significant differences were found with and without ethoximation. Neurotransmitter analysis in CSF showed a marked increase of vanilalanine (1,200 nmol/l, nl up to 100) with decreased levels of 5-hydroxy-indolacetic acid (5 nmol/l, normal 152-462), homovanillic acid (83 nmol/l, normal 302-845) and methoxy-hydroxy-phenyl-glycol (5 nmol/l, normal 51-112). AADC activity in plasma was nearly undetectable. As reported in other patients, the urinary profile of biogenic amines was consistent with the production of dopamine in the kidney. We postulate that that VPA and AVA could originate from vanilalanine (through a transaminase and an acetylase respectively), while NAT could originate from tyrosine through an AA acetylase. This report expands the clinical presentation of AADC deficiency and adds new markers of the disease for OA analysis.

Cloning and Characterization of the Human N-acetylglutamate Synthase Gene. *L.M. Caldovic¹, H. Morizono¹, R. Gallegos², M.H. Malamy², M. Tuchman¹*. 1) Center for Genetic Medicine, CNMC, Washington, DC; 2) Department of Microbiology, Tufts University, Boston, MA.

N-acetylglutamate synthase (NAGS, E.C. 2.3.1.1) is a mitochondrial enzyme that catalyzes the formation of the N-acetylglutamate (NAG) from glutamate and acetyl-CoA. NAG is an essential allosteric activator of carbamylphosphate synthetase I (CPSI), the first enzyme of the urea cycle. NAGS is thought to regulate ureagenesis by producing variable amounts of NAG, thus modulating CPSI catalytic activity. Moreover, inherited deficiencies in NAGS have been associated with hyperammonemia, presumably due to the loss of CPSI activity. The gene encoding human NAGS was identified and cloned based on its similarity to mouse NAGS which we cloned previously. The human gene was cloned from a liver cDNA library and the open ORF is 85% identical to mouse NAGS. The deduced amino acid sequence contains a putative mitochondrial targeting signal of approximately 50 amino acids at the N-terminus. The cDNA sequence complements an *argA* (NAGS deficient) *E. coli* strain, confirming that it indeed has NAGS catalytic activity. The NAGS cDNA was aligned to the human genome draft sequence to identify the intron/exon boundaries and to determine its chromosomal location. The gene has 7 exons, is approximately 4kb long and maps to chromosome 17 band q21.31. Primers were designed to amplify all NAGS exons and their flanking sequences from genomic DNA of patients with possible NAGS deficiency. These patients have hyperammonemia with the clinical and biochemical characteristics of CPSI deficiency, but show normal CPSI enzyme activity in the liver. We are currently screening these patients for mutations in the NAGS gene. Northern blot analysis was used to examine the size and expression pattern of the NAGS transcript. The gene is expressed in the liver and intestine as a 2.3 kb message. We are currently overexpressing His-tagged versions of the NAGS preprotein and putative mature protein in *E. coli* and purifying them using a nickel affinity column. The purified proteins will be used for biochemical characterization and determination of 3-D structure.

Program Nr: 1484 from 2002 ASHG Annual Meeting

EUROGLYCAN: A systematic approach towards the understanding, diagnosis and treatment of CDG, a novel group of inborn metabolic disorders caused by defects of glycosylation. *M. Aebi¹, E.G. Berger¹, P. Briones¹, K. von Figura¹, T. Hennet¹, J. Jaeken¹, C. Körner¹, G. Matthijs^{1,2}, E. Van Schaftingen¹, M.A. Vilaseca¹, R. Wevers¹, B. Winchester¹.* 1) Participants of the EUROGLYCAN Network; 2) Co-ordinator (Center for Human Genetics, University of Leuven, Leuven, Belgium).

EUROGLYCAN is a European network for basic and clinical research into congenital disorders of glycosylation (CDG), a rapidly expanding group of metabolic diseases.

The major aims are to 1) promote early diagnosis by offering free diagnostic work-up of new cases; 2) collate patient information, useful for the identification of novel types; 3) raise awareness; and 4) establish a patient group large enough for systematic investigations and clinical trials. To fulfil these aims, a database was created that is maintained by the reference centre (<http://www.kuleuven.ac.be/med/cdg>). National referral centres have been established for the recruitment of patient samples. These centres offer first-line diagnostic services, and provide an interface between the network and the referring clinician. Unsolved cases are dispatched by the reference centre to the expert laboratories within the network for systematic analysis. Up to date, the partners of the network were involved in the identification and elucidation of 10 of the 11 known types of CDG-I and CDG-II, and a plethora of unsolved cases are under investigation.

The ultimate goal of the network is to put a precise diagnosis on all cases of CDG, to promote fundamental research in the field and to extend the diagnostic and therapeutic tools.

The project is funded by grant QLG1-CT2000-00047 of the European Commission.

Acute severe metabolic decompensation in Maple Syrup Disease can be optimally treated without dialysis by utilizing high caloric nutrition containing branched chain-free amino acids: 11 year experience with 52 episodes.

J. Ganesh, G.T. Berry, R.P. Deering, M.J. Palmieri, P. Kaplan. Department of Biochemical Genetics, Children's Hospital of Phila., Philadelphia, PA.

The goal of therapy in acutely ill patients with Maple Syrup Urine Disease (MSUD) is rapid reduction of plasma branched chain amino acid (BCAA) and ketoacid levels, and resolution of acute signs and symptoms of metabolic decompensation. We assessed the efficacy of primary nutritional therapy with parenteral and/or enteral BCAA-free solution or formula in 52 treatment episodes in 15 patients with acute decompensation of MSUD. Patients were multi-ethnic with ages ranging from 6 days to 14.5 years with 4 episodes involving neonates. Patients experienced acute onset of one or more of the following at presentation: lethargy, coma, seizures, ataxia, emesis or ketoacidosis. Pre-treatment leucine levels were $> 800\text{mmol/L}$ (range 801-3944; mean 1404.82). In addition to nutritional therapy, correction of acidosis, supplementation with valine and/or isoleucine (to correct deficiencies and promote protein accretion), and insulin therapy (to overcome insulin resistant states) were instituted as needed. Dialysis was not performed during any of these episodes. In each episode there was a resolution of acute signs and symptoms of decompensation and ketoacidosis. Plasma leucine levels were reduced to $<500\text{ mmol/L}$ by 72 hr in 42 episodes, and by 120 hr after starting treatment in all episodes. No therapy-related complications were encountered. Conclusions: BCAA-restricted parenteral and/or enteral nutrition therapy can effectively improve the clinical and laboratory abnormalities in the majority of patients with MSUD with metabolic decompensation by reducing plasma BCAA levels, and inducing protein accretion and promoting an anabolic state. The need for dialysis, which is effective but invasive and often associated with complications, was obviated in this cohort.

Improved molecular diagnosis of Canavan Disease by multiplex ligation-dependent probe amplification (MLPA) and sequence analysis: identification of novel mutations. A. Errami^{1,2}, G.S. Salomons³, S.J.M. van Dooren³, J.J.P. Gille¹, G. Pals¹, J.P. Schouten², O. Elpeleg⁴, C. Jakobs¹. 1) Clinical Genetics, VU University Medical Center, Amsterdam, Netherlands; 2) MRC-Holland, Amsterdam, Netherlands; 3) Clinical Chemistry, VU University Medical Center, Amsterdam, Netherlands; 4) Metabolic Disease Unit, Shaare-Zedek Medical Center, Jerusalem, Israel.

Canavan disease, an autosomal recessive neurodegenerative disorder, affecting cerebral white matter, is caused by a deficiency of aspartoacylase (ASPA; MIM 271900). The biochemical hallmark is an increased level of N-acetylaspartic acid in body fluids. The identification of the molecular basis for this defect is of pivotal importance for prenatal diagnosis and carrier detection. We have set up the molecular analysis for Canavan disease not only by sequence analysis at the DNA and RNA level, but also developed a multiplex ligation-dependent probe amplification (MLPA) test. This test allows the identification of deletions or duplications of one or more exons of the ASPA gene. Methods: A BLAST (www.ncbi.nlm.nih.gov/) search with the ASPA mRNA (Genbank: AC025125) against the htgs database identified a contig that contained the almost complete ASPA gene (Genbank: NM_000049). We designed PCR primers for all 6 exons. Purified PCR products were directly sequenced and aligned with the ASPA gene. Furthermore, for the MLPA test we designed and synthesized probes specific for each of the exons. After ligation, which depends on the presence of target sequences in the DNA sample, the probes were amplified by PCR. The PCR fragments were analyzed by capillary electrophoresis. Results: In 11 unrelated patients we identified two mutant alleles per patient, including 3 deletions that comprises one or more exons of the ASPA gene and four other novel mutations. In conclusion: DNA based sequence analysis of the ASPA gene allows the identification of mutations that remained undetected by RNA based sequence analysis. The MLPA test proved the presence of deletions. Furthermore homozygosity could be confirmed by this new method.

Orthotopic Liver Transplantation (OLT) in Ornithine Transcarbamylase Deficiency (OTCD) carriers. M.J.

*Dasouki*¹, *J. DANIEL*¹, *L. LOWE*¹, *W. ANDREWS*¹, *M. TUCHMAN*². 1) Sect Medical Gen & Molec Med, Children's Mercy Hosp, Kansas City, MO; 2) Children's National Medical Center.

OTCD is the most common inherited urea cycle disorder. The gene is X-linked causing fatal hyperammonemia in affected males and widely variable clinical severity in female carriers. Despite protein restriction and the use of sodium benzoate and phenylbutyrate, such patients continue to experience recurrent attacks of severe hyperammonemia associated with significant morbidity and mortality. OLT is the only currently available curative procedure as it corrects hyperammonemia, halts progress of disease and improves quality of life. The neurological outcome after transplantation correlates closely with the status prior to transplantation. The decision to perform definitive OLT in carrier females is still controversial and depends on several factors including: phenotypic severity, failure of medical therapy, availability of expertise in the management of acute hyperammonemia, and social factors. Here, we report on two unrelated symptomatic OTCD female carriers corrected with OLT at 14-years of age. Patient 1 (African American) with OTCD diagnosed at 7-years of age. Her OTC enzyme activity was low at 1.3 umol/gm liver/min(80.6+/-5.5). She carried a deleterious OTC mutation (G195R) in exon 6. Patient 2 (caucasian) was diagnosed at 10 years of age. Her OTC enzyme activity was also reduced at 304 umol/gm liver/hr(1500-9000). Using SSCP analysis, no OTC-DNA mutation was found. During acute hyperammonemia, H-MRS of the brain showed elevated glutamine and decreased choline and myoinositol. Basal ganglia calcification in addition to focal seizure activity developed in patient 2. Post-operative immune suppression regimen (prednisone, mycophenolate mofetil, FK506) was well tolerated. Patient 1 underwent biliary reconstruction due to a bile leak. At 6 months post OLT, their hyperammonemia is corrected and neurological status stabilized. No recurrence of seizure activity (patient 2) was reported. We suggest that clear guidelines regarding indications for OLT in OTCD carrier females be developed to avoid the significant morbidity and mortality seen in this metabolic disorder.

Post-partum "psychosis" in mild argininosuccinate synthetase deficiency. *G.M. Enns¹, W.E. O'Brien², K. Kobayashi³, H. Shinzawa⁴, K. Hart¹, H.Z. Gao³, A. Tabata³, T. Saheki³.* 1) Dept Ped, Div Medical Genetics, Stanford Univ, Stanford, CA; 2) Dept Mol Hum Genet, Baylor College of Medicine, Houston, TX; 3) Dept Biochemistry, Kagoshima Univ, Kagoshima, Japan; 4) Dept Internal Med, Public Okitama General Hospital, Yamagata, Japan.

Although underlying ornithine transcarbamylase (OTC) deficiency may be unmasked for the first time after childbirth, reports of other urea cycle disorders presenting for the first time in the post-partum period are rare. We describe two patients, without a past history suggestive of a metabolic disorder, who were diagnosed with argininosuccinate synthetase (AS) deficiency after experiencing neurologic complications post-partum. Patient 1 developed speech and gait abnormalities, which resolved spontaneously, after the birth of her first child. She had memory loss and aggressive behavior and was placed in a psychiatric ward for "post-partum depression/psychosis" after the birth of her second child. She progressed to a coma and was diagnosed with acute fatty liver of pregnancy (AFLP) when mild hyperammonemia ($\text{NH}_3=95\text{mM}$) was found. Post-partum confusion, lethargy, and hyperammonemia ($\text{NH}_3=433\text{mM}$) were present after her third pregnancy. She was again initially diagnosed as having AFLP. Metabolic investigations were performed at that time and showed elevated citrulline. Argininosuccinate lyase activity was normal. Fibroblast AS activity was undetectable and a ^{14}C -citrulline/ ^3H -leucine incorporation assay confirmed the enzymatic defect. She was found to have two novel mutations in the AS gene present in a compound heterozygous state in exon 13 (K310R, delG892). Patient 2 had hyperammonemia at age 25 years at the start of breast feeding following delivery and has been reported previously (Am J Hum Genet 55:1103). DNA analysis detected both mutations in the AS gene (A118T, ins37b/Exons 15 and 16). Urea cycle disorders other than OTC deficiency may present for the first time with neurologic and psychiatric symptoms post-partum and may be an underappreciated cause of such complications. We recommend obtaining metabolic labs immediately in any woman with neurologic or severe psychiatric symptoms in the post-partum period.

Thiamine-responsive pyruvate dehydrogenase deficiency in two patients caused by a point mutation (F205L and L216F) within the thiamine pyrophosphate binding region. *E. Naito¹, M. Ito¹, I. Yokota¹, T. Saijo¹, J. Matsuda¹, Y. Ogawa¹, S. Kitamura¹, E. Takada², Y. Horii³, Y. Kuroda¹.* 1) Department of Pediatrics, School of Medicine, University of Tokushima, Tokushima, Japan; 2) Department of Pediatrics, Saitama Medical Center, Saitama Medical School, Saitama, Japan; 3) Department of Pediatrics, Yamashiro Hospital, Kyoto, Japan.

The human pyruvate dehydrogenase complex (PDHC) catalyzes the thiamine-dependent decarboxylation of pyruvate. Thiamine treatment is very effective for some patients with PDHC deficiency. Among these patients, five mutations of the pyruvate dehydrogenase (E1) α subunit have been published previously: H44R, R88S, G89S, R263G, and V389fs. All five mutations are in a region outside the thiamine pyrophosphate (TPP)-binding region of the E1 α subunit. We report the biochemical and molecular analysis of two patients with clinically thiamine-responsive lactic acidemia. The PDHC activity was assayed using two different concentrations of TPP. These two patients displayed very low PDHC activity in the presence of a low (1×10^{-4} mM) TPP concentration, but their PDHC activity significantly increased at a high (0.4 mM) TPP concentration. Especially, the PDHC activity of patient 2 increased to within the normal range. Therefore, in order to diagnose this type of thiamine-responsive PDHC deficiency and to prevent a diagnostic error, it is necessary to measure the activity of PDHC in the presence of a low (1×10^{-4} mM) as well as a high TPP concentration. Thus the PDHC deficiency in these two patients was due to a decreased affinity of PDHC for TPP. Treatment of both patients with thiamine resulted in a reduction in the serum lactate concentration and clinical improvement, suggesting that these two patients have a thiamine-responsive PDHC deficiency. The DNA sequence of these two male patients' X-linked E1 α subunit revealed a point mutation (F205L and L216F) within the TPP-binding region in exon 7.

A transgenic neuronal cell model for maple syrup urine disease. *A.L. Kasinski, D.J. Danner.* Department of Human Genetics, Emory University School of Medicine, Atlanta, GA.

Maple syrup urine disease [MSUD] is an autosomal recessive inherited metabolic disorder characterized by an extreme rise of the branched-chain amino acids [BCAAs] and their corresponding ketoacids in body tissues and fluids. Mutations in the gene for one of three of the branched-chain α -ketoacid dehydrogenase [BCKD] proteins are causative of MSUD. Transamination by branched-chain amino transferases plays an important role in nitrogen shuttling and metabolism of the excitatory neurotransmitter glutamate in the brain. Excitotoxicity is a contributing element in the neuropathy of MSUD, which may explain the convulsions and cerebral edema characteristic of these patients. To investigate the mechanism for toxicity, we prepared an artificially tet-on regulated transgenic neuronal cell model that over-expresses the murine BCKD-kinase in PC12 cells. BCKD-kinase activity results in inhibition of BCKD. Southern blots verified the presence of transgene in clonally selected cells. The cloned cells retained the ability to respond to nerve growth factor. Addition of doxycycline [DOX] increased BCKD-kinase expression with a concomitant increase in phosphorylated E1 α and a marked decrease in activity-state of BCKD. Preliminary studies show an increase in cell death in doxycycline induced clones when the cells are treated with BCAA and/or branched-chain ketoacid derivatives. The mechanisms for cell death are being investigated to provide a better understanding of the neuropathology seen in MSUD.

Arginase induction by sodium phenylbutyrate in mouse tissues and human cell lines. *R.M. Kern¹, Z. Yang³, P.S. Kim³, W.W. Grody^{1, 3, 4, 5}, S.D. Cederbaum^{1, 2, 4, 5}, R.K. Iyer^{1, 3}.* 1) Mental Retardation Research Center; 2) Depts. of Psychiatry; 3) Pathology; 4) Human Genetics; 5) Pediatrics, David Geffen School of Medicine at UCLA, Los Angeles, CA.

Hyperargininemia is a urea cycle metabolic disorder caused by genetic mutations in arginase I (AI) resulting in elevated blood arginine and ammonia levels. Sodium phenylacetate and its precursor sodium phenylbutyrate (NaPB) have been used to lower ammonia, conjugating glutamine to produce phenylacetylglutamine which is excreted in urine. The elevated arginine levels induce the second arginase (AII) in patient kidney and kidney tissue culture. It has been shown that NaPB increases expression of some target genes and we tested for arginase induction.

Eight 9 week old male mice fed on chow containing 7.5 gm NaPB/kg rodent chow and drank water with 10 gm NaPB/liter, and four control mice had a normal diet. After one week all mice were sacrificed. The arginase specific activities for control and NaPB mice respectively were 38.2 and 59.4 U/mg in liver, 0.33 and 0.42 U/mg in kidney, and 0.29 and 1.19 U/mg in brain. Immunoprecipitation of arginase in each tissue with AI and AII antibodies showed the activity induced by NaPB is mostly AI. AII may also be induced but not as significantly. AI accounts for the four-fold increased activity in brain.

In some cell lines, NaPB increased arginase activity up to 5 fold depending on dose (1-5 mM) and exposure time (2-5 days); control and NaPB activities respectively are: erythroleukemia, HEL, 0.06 and 0.31 U/mg, and K562, 0.46 and 1.74 U/mg; embryonic kidney, HEK293, 1.98 and 3.58 U/mg; breast adenocarcinoma, MDA-MB-468, 1.11 and 4.06 U/mg; and prostate adenocarcinoma, PC-3, 0.55 and 3.20 U/mg. In MDA-MB-468 and HEK most, but not all, of the induced activity is AI.

These studies suggest that NaPB may induce AI when used to treat urea cycle disorders. It is relatively less useful in AI deficiency, although it could have some effect in those with missense mutations. It is tempting to speculate that the induction in brain particularly may be due to the glutamine depletion that occurs with the NaPB administration.

The frequency of short-chain acyl-CoA dehydrogenase (SCAD) gene variants in the U.S. population and correlation with the C4-acylcarnitine (C4-AC) concentration in newborn blood spots. *D. Matern, A. Tauscher, K. Kruckeberg, P. Rinaldo, N. Nagan.* Division of Laboratory Genetics, Mayo Clinic, Rochester, MN.

SCAD deficiency is clinically heterogeneous with patients described as being basically asymptomatic while others had fatal outcomes. Two SCAD gene variants (511C>T; 625G>A) are known. While they cause non-conserved amino acid substitutions that alter the structural and catalytic enzymatic properties, they are neither true disease causing mutations nor polymorphisms but mutations that confer disease susceptibility. Previous studies found these gene variants to be common in the Northern European population (*Pediatr Res* 2001;49:18-23). We aimed to determine the frequency of these variants in the U.S. population and whether their presence correlates with elevated C4-AC concentrations in newborn blood spots. Methods: DNA was purified from blood spots collected prospectively from 612 newborns. The presence of SCAD gene variants was determined using LightCycler technology. C4-AC concentrations in each blood spot were measured by tandem mass spectrometry. Results: 5.2% of all newborns were homozygous for 625G>A, 35.1% were heterozygous and 59.7% were wild type homozygous for this variant. With respect to the 511C>T variant, 93.4% of the newborns were wild-type, 0.1% homozygous and 6.5% heterozygous. 7.4% of the study population were homozygous or compound heterozygous for these variants. The percentage of newborns homozygous for 625A differed among Hispanics (12%) and African-Americans (2%) compared to the predominantly white study population (6%). C4-AC concentrations in newborn blood spots correlated ($p<0.001$) with homozygosity for the 625A variant. Discussion: The frequency of the 625G>A SCAD gene variant was found to be more frequent than 511C>T. While homozygosity for 625G>A correlates with higher C4-AC concentrations than observed in the wild type population, none of the observed genotypes causes C4-AC concentrations strongly suggestive of SCAD deficiency. To further elucidate the clinical significance of these findings, newborn screening blood spots of patients with genotypes involving only these gene variants and biochemically confirmed SCAD deficiency should be analyzed.

Genotype Determinants of Phenotype in Erythropoietic Protoporphyria. *H. Risheg, F. Chen, J.R. Bloomer.*
University of Alabama at Birmingham, Birmingham, AL.

Excessive accumulation of protoporphyrin in erythropoietic protoporphyria (EPP) results from a deficiency in the activity of ferrochelatase (FECH), which catalyzes the final step in heme biosynthesis. This causes the clinical manifestations of EPP, lifelong photosensitivity and in some, liver disease necessitating transplantation. FECH DNA analysis from our lab showed 38 EPP individuals from 24 families to be heterozygous for a variety of FECH mutations, which did not satisfactorily explain phenotype. It was also shown that an intron polymorphism (IVS3-48c) in the FECH gene was associated with frequent formation of aberrantly spliced FECH mRNA, which was rapidly degraded (Gouya et al, Nat Genet 30:2002). **AIM:** Define further the genotype-phenotype relationship in EPP, focusing on the role of this polymorphism. **METHODS AND RESULTS:** The IVS3-48c was examined by sequencing of intron 3 and correlated with disease severity. This revealed 93% of 30 symptomatic individuals with FECH mutations (30 photosensitive; 14 with liver disease) to be heterozygous for the IVS3-48c, whereas 8 asymptomatic individuals with FECH mutations were homozygous for the predominant IVS3-48t polymorphism. Two of 40 controls (5%) were heterozygous for the IVS3-48c. Haplotype analysis was used to trace the mutant and non-mutant FECH alleles in families with asymptomatic and symptomatic individuals. Allele specific oligonucleotides were used to assess the level of normal FECH mRNA by relative quantitative RT-PCR. Results showed symptomatic family members to share the same haplotype for the non-mutant FECH allele, containing the IVS3-48c. Conversely, asymptomatic family members carried the IVS3-48t in their non-mutant allele. Levels of normal FECH mRNA were significantly lower in cultured lymphoblasts of individuals with the IVS3-48c. **CONCLUSIONS:** Symptomatic disease in most EPP patients is explained by the inheritance of a mutation in one FECH allele which causes a structural alteration in the FECH protein that abolishes enzyme activity, together with a low expressing non-mutant FECH allele which is caused by the IVS3-48c. The findings have significant implications for counseling in EPP, and are relevant in other disorders with variable disease expression.

The mtDNA G-A mutation at nt 13513, previously reported in MELAS syndrome, is a frequent cause of Leigh disease. *M. CHOL*¹, *S. LEBON*¹, *P. BENIT*¹, *D. CHRETIEN*¹, *P. DE LONLAY*¹, *V. CORMIER*^{1,2}, *P. RUSTIN*¹, *A. ROTIG*¹, *A. MUNNICH*^{1,2}. 1) INSERM U393, Hopital Necker, Paris, France; 2) Departement de Genetique, Hopital Necker, Paris, France.

Leigh syndrome is characterized by subacute necrotizing encephalomyopathy and is often associated with mitochondrial respiratory chain deficiency. This disease is genetically heterogeneous, as mutations in both mitochondrial (mt) and nuclear genes have been reported in various patients. Here we report on three patients presenting Leigh syndrome associated with a complex I deficiency and harboring a G13513A transition in mtDNA ND5 gene. This mutation was found to be heteroplasmic in all tissues tested, a high percentage of mutant mtDNA being observed in muscle DNA. The asymptomatic maternal relatives presented lower levels of G13513A mutant mtDNA in blood leukocytes. This mutation affects an evolutionary conserved amino acid (D393N). These results suggest that the G13513A transition is likely to be pathogenic. Moreover, this mutation has been previously reported in patients with MELAS or LHON/MELAS syndrome, again demonstrating the phenotypic heterogeneity of mitochondrial DNA mutations. Interestingly, the G13513A mutation seems to represent a frequent cause of Leigh disease as it was found in 21% (3/14) of our patients presenting with Leigh syndrome and complex I deficiency. We therefore suggest that the G13513A mutation in the mtDNA ND5 gene should be systematically screened in Leigh patients and their relatives for molecular diagnosis and genetic counseling.

Mistargeting of mitochondrial NDUFV2 mRNA results in complex I deficiency and causes early onset hypertrophic cardiomyopathy. P. BENIT¹, R. BEUGNOT², D. CHRETIEN¹, P. de LONLAY¹, JP. ISSARTEL², S. KERSCHER³, P. RUSTIN¹, A. MUNNICH¹, A. ROTIG¹, M. CORRAL-DEBRINSKI⁴. 1) Dept Genetics, INSERM U393, Hosp Necker, Paris, France; 2) CEA-DBMS, CEA Grenoble, 17 rue des Martyrs, 38054 Grenoble, Cedex 9, France; 3) Universitätsklinikum Frankfurt, Institut für Biochemie I, ZBC, Theodor-Stern-Kai 7, 60590 Frankfurt am Main, Germany; 4) CNRS URA 1302, Ecole Normale Supérieure, 46 rue d'Ulm, 7505 Paris, France.

Most of the mitochondrial proteins are encoded by nuclear genes, synthesized in the cytosol with a N-terminal mitochondrial targeting signal, which is subsequently cleaved within the mitochondria to give rise to the mature form of the protein. However, a number of mitochondrial proteins are co-translationally imported. Here we show that NDUFV2 mRNAs, which encodes a respiratory chain complex I subunit, as well as several mRNAs encoding mitochondrial proteins, are clustered around the mitochondria in human cultured skin fibroblasts and/or HeLa cells, suggesting a co-translation translocation of these proteins. Studying nuclear genes encoding complex I subunits in a cohort of 42 patients with complex I deficiency, we identified a deletion of NDUFV2 exon 2 in two patients presenting an early onset hypertrophic cardiomyopathy. The deletion of exon 2 which encodes the Ndufv2 targeting sequence resulted in a roughly 50% reduction of the Ndufv2 protein in patient's fibroblast mitochondria compared to control. Accordingly, a 50% decrease of complex I activity was detected in patient's skeletal muscle, heart and fibroblasts. Decreased protein content in patient fibroblasts correlated with an abnormal sub-cellular localization of NDUFV2 mRNAs which were present in free-polysomes rather than in mitochondria-bound polysomes. The quantitative comparison of residual NDUFV2 mRNA bound to mitochondria, residual amount of mitochondrial Ndufv2 protein, and residual enzyme activity indicate that mistargeting of NDUFV2 mRNA probably accounts for complex I deficiency. This suggests that abnormal mRNA distribution could represent a novel mechanism of complex I deficiency in human.

Cell complementation using Genebridge 4 human-rodent hybrids for physical mapping of mitochondrial respiratory chain deficiency genes. *P. de Lonlay*¹, *C. Mugnier*², *D. Sanlaville*³, *V. Geromel*¹, *P. Benit*¹, *D. Chretien*¹, *N. Kadhom*¹, *K. Chantrel*¹, *S. Saker*⁴, *G. Gyapay*⁴, *S. Romana*³, *A. Munnich*¹, *P. Rustin*¹, *A. Rotig*¹. 1) INSERM U393, Hosp Necker-Enfants Malades, Paris Cedex, France; 2) Service Informatique, Hosp Necker-Enfants Malades, Paris Cedex, France; 3) Service de Cytogenetique, Hopital Necker-Enfants Malades, Paris; 4) Genethon, Evry, France.

Mapping and identification of genes responsible for mitochondrial disorders is a difficult endeavour due to the large number of genes either encoding subunits of the respiratory chain (RC) or involved in respiratory chain assembly. We have developed a functional complementation approach for mapping mitochondrial disease genes by combining the use of a highly selective medium for respiratory-competent cells and microcell-mediated transfer of human genetic material in RC-deficient fibroblasts. We first showed that the absence of any ose in the culture medium resulted in a rapid death of RC-deficient fibroblasts. This highly selective medium could therefore be used to rapidly screen for restoration of RC capacity by genetic transfer. Four cell lines of patients with complex I, II or I+IV deficiency were fused with microcells prepared from human:rodent Genebridge 4 panel of whole genome radiation hybrids allowing to map the disease-causing genes to Xq22, 12p12, 21pter and 7p22. These candidate regions were therefore limited to 4 to 30 Mb. This approach allowed us to physically map the disease gene in four sporadic cases. These genetic intervals are similar to that obtained by genetic linkage analyse in large informative families.

Mitochondrial localization of PANK2 and discovery of a common polymorphism that prevents it. *M.A. Johnson¹, Y.M. Kuo², S.K. Westaway¹, S.M. Parker¹, J. Gitschier², S.J. Hayflick¹*. 1) Departments of Molecular and Medical Genetics, Pediatrics and Neurology, School of Medicine, Oregon Health & Science University, Portland, OR; 2) Howard Hughes Medical Institute and Departments of Medicine and Pediatrics, University of California, San Francisco, CA.

Recently we reported that mutations in *PANK2*, one of the four human pantothenate kinase genes, causes pantothenate kinase associated neurodegeneration (PKAN, formerly Hallervorden-Spatz syndrome). Though only cytosolic pantothenate kinase enzymatic activity has been described previously, a mitochondrial targeting sequence (MTS) is uniquely predicted at the amino-terminus of *PANK2*. We transfected full-length human *PANK2* cDNA bearing a carboxy-terminal *myc* tag and observed mitochondrial localization of *PANK2* by immunofluorescence. Immunohistochemistry with antibodies against *PANK2* confirmed localization of the endogenous protein to mitochondria. Mitochondrial localization provides insight into why defects in *PANK2*, expressed ubiquitously, lead specifically to neurodegeneration.

Interestingly, *PANK2* begins with an unconventional CTG translation initiation codon, and we observed that 4% of control chromosomes harbor a CAG codon variant. *In vitro* mutation of the CTG codon to CAG led to cytosolic localization of *PANK2* in transfection experiments, presumably due to use of the methionine initiation codon in the middle of the MTS. This observation suggests that the CAG polymorphism has a likely functional consequence of improper *PANK2* localization. We are currently asking whether this sequence variation may represent a susceptibility allele to common neurodegenerative disorders like Parkinson disease or isolated pigmentary retinopathy.

Mitochondrial porin deficient mice: a murine model of Mendelian respiratory chain defects and encephalopathy.

F. Scaglia¹, Z-J. Cai¹, K. Anflous¹, M. Levy², J.D. Sweatt², W.J. Craigen¹. 1) Department of Molecular & Human Genetics; 2) Division of Neuroscience, Baylor College of Medicine, Houston, TX.

Voltage dependent anion channels (VDACs; porins) are the main pathways for metabolites across the mitochondrial outer membrane and may constitute one component of the permeability transition pore that opens in response to apoptotic signals. Mammals have four VDAC isoforms encoded by three separate genes, each with different electrophysiological behavior. VDAC1(-/-), VDAC3(-/-) and VDAC1/3(-/-) mice have been generated and exhibit abnormalities in spatial and associative learning that resemble the neurological deficits seen in patients with respiratory chain defects. These learning deficits are accompanied by abnormalities of hippocampal synaptic plasticity. Since mitochondrial enzyme assays in skeletal muscle of VDAC1(-/-) animals demonstrate a reduction in cytochrome c oxidase (COX) activity, we sought to determine whether brain tissue from VDAC(-/-) mice exhibits any respiratory chain (RC) defect that could be correlated with cognitive deficits. Mitochondrial RC enzyme assays of brain mitochondria of VDAC1(-/-), VDAC3(-/-) and VDAC1/3(-/-) reveal significant RC defects. There is a marked increase in citrate synthase activity in VDAC1 and VDAC1/3 (-/-) mice, with partial deficiencies of complex I, II, III and IV activity. In the brain mitochondria of VDAC3(-/-) mice there is a marked decrease in COX activity but normal citrate synthase activity. We postulate that the observed RC defects in VDAC deficient mice could be secondary to increased reactive oxygen species or the defective synthesis or assembly of cytochrome c oxidase subunits. Preliminary data suggest that in VDAC1/3(-/-) mice there is an increase in oxidative modification of proteins by reactive oxygen species when compared to wildtype mice and reduced expression of RC proteins in VDAC1(-/-) mice. In summary, VDAC deficient mice exhibit neurological and biochemical deficits seen in patients with RC defects. These data point to a role for VDAC in the modulation of the mitochondrial respiratory chain and we speculate that it is related to abnormal mitochondrial calcium homeostasis and altered gene expression.

Mitochondrial DNA depletion associated with methylmalonic aciduria, and deficiency of 3-methylcrotonyl CoA and propionyl CoA carboxylase. A new disorder of generalized mitochondrial dysfunction? *S. Yano¹, K. Moseley¹, A. Guedalia¹, L. Li¹, J. Lee¹, T.P. Le², R.G. Boles¹.* 1) Div Medical Genetics, Childrens Hospital Los Angeles, Los Angeles, CA; 2) Biochemical Genetics, Pediatrics, University of California San Diego, San Diego, CA.

Mitochondrial DNA (mtDNA) depletion, referring simply to a low mtDNA copy number, is highly heterogenous in terms of associated phenotype (Leigh disease, Alpers syndrome, cardiomyopathy, etc.) and causal genotype (deficiencies of deoxyguanosine kinase, gamma-polymerase, etc.). We report two very similar cases (Pt.1, a 3 y-old Hispanic male; Pt. 2, an unrelated 2 y-old Hispanic female) with mtDNA depletion who were both diagnosed at 5 months of age with failure to thrive, developmental delay, hypotonia, and metabolic acidosis. A diagnosis of methylmalonic aciduria was initially raised in both based upon substantial elevations in urine methylmalonate, 3OHpropionate and methylcitrate by GC/MS, and plasma propionyl- and methylmalonyl-carnitines by MS-MS. Additional elevations found at least once in both children included 3 OHpropionate, 3OHisovalerate, methylmalonate, fumarate, glutarate, malate, pyruvate, 2OHglutarate, isocitrate, citrate, methylcitrate and 2-oxoglutarate. Assay in cultured skin fibroblasts revealed low propionyl CoA and methylcrotonyl CoA carboxylase activities with normal pyruvate carboxylase activity, again in both children. Quadriceps muscle showed focal mitochondrial accumulation and partial complex IV deficiency in patient 1, and abnormal mitochondrial structures with prominent concentric forms and partial deficiencies in complexes I, II/III, and IV in patient 2. Quantitative Southern blot analysis in muscle tissue revealed mtDNA depletion of 24% (Pt1) and 39% (Pt2) to normal controls. Our two patients have multiple mitochondrial dysfunction including defects in mtDNA synthesis/maintenance, and deficiencies in two carboxylases. To our knowledge, there is no obvious connection between the defective pathways in our cases, such as a common co-factor. The primary defect could involve mitochondrial import, biogenesis or membrane integrity, and studies are ongoing to address these possibilities.

Preliminary characterization of a mouse model of diastrophic dysplasia. A. Rossi¹, C. Tiveron², R. Piazza¹, A. Superti-Furga³, L. Tatangelo², S. Della Torre¹, A. Forlino¹, G. Cetta¹. 1) Department of Biochemistry, University of Pavia, Pavia, Italy; 2) Centro Ricerca Sperimentale, Istituto Regina Elena, Rome, Italy; 3) Department of Pediatrics, University of Zurich, Switzerland.

Mutations in the diastrophic dysplasia sulfate transporter (DTDST) gene (SLC26A2) have been associated with a family of recessive chondrodysplasias including, in order of increasing severity, a mild form of multiple epiphyseal dysplasia, diastrophic dysplasia (DTD), atelosteogenesis type 2 and achondrogenesis 1B. The gene encodes for a widely distributed sulfate-chloride antiporter of the cell membrane whose function is crucial for the uptake of inorganic sulfate which is needed for proteoglycan (PG) sulfation. A correlation between the nature of the mutations, the residual function of the sulfate transporter, the degree of PG sulfation and the different clinical phenotypes have been traced. However, to better understand the pathogenetic mechanisms and to explore possible therapeutic avenues a mouse model would be useful. Using homologous recombination in embryonic stem cells (ES AB1 were kindly provided by Dr. A. Bradley, Houston), we have generated a transgenic mouse homozygous for the *ddtst* mutation A386V that we had identified in a patient with classical diastrophic dysplasia (Rossi et al. Hum. Mutat. 17, 159-171, 2001). The neomycine resistance gene in intron 2 was flanked by loxP sequences for possible excision by Cre recombinase.

By clinical inspection, radiography and differential staining of whole mice with Alizarin Red S and Alcian blue, transgenics that are heterozygous for the A386V substitution are phenotypically normal. In contrast, homozygotes grow slowly with an overall shorter skeletal system and reduced body weight compared to normal litter mates. Their movements are impaired, and they show severe thoracic kyphosis and hip dysplasia. Thus, the human DTD mutation introduced in the murine *ddtst* locus produces a skeletal and connective tissue phenotype very reminiscent of human diastrophic dysplasia. Minimal transcript level changes in cerebellum of a mouse genetic model for Down syndrome. *R.H. Reeves¹, N.G. Saran¹, J. Natale², M. Pletcher¹*. 1) Dept Physiology, P202, Johns Hopkins Univ Sch Med, Baltimore, MD; 2) Children's Hospital, Washington D.C.

Trisomy 21 results in Down Syndrome (DS), the most common genetic cause of mental retardation. Cerebellar volume is disproportionately reduced in the DS brain. Ts65Dn (Ts) mice are at dosage imbalance for about half of the genes on Chr21. They demonstrate significant reduction in cerebellar volume, and histological analysis identified specific changes that correctly predicted alterations in the DS brain (Baxter et al., 2000). These changes are dosage sensitive, with milder affects in the Ts1 mouse which has fewer Chr21-homologous genes at dosage imbalance (see L. Olson et al.).

We compared transcript profiles in 5 Ts mice to those in 5 euploid (Eu) littermates in duplicate on Affymetrix U74A chips (20 hybridizations total). Those probes with a high proportion of "absent" calls were eliminated. The CLUSTER program sorted all experiments (Eisen et al. 1998); we analysed the three (12 chips) in which all duplicates were most closely matched. The resulting trees grouped Ts separately from Eu mice, i.e., gene expression profiles discriminated between the two groups. No one functional category of genes was evident among these. Only 25 of 6601 probes varied by 2-fold or more in either direction, and only 171 (2.6%) showed a 1.5-fold change, half increased and half decreased; nine of the 18 human Chr21 homologs on the chip increased 1.5-fold. 97% were essentially unchanged in transcript level.

The predominant cell type in the cerebellum is the granule cell (gc) neuron - indeed, gc represent 50% of all neurons in the adult brain - thus, we essentially measured gc transcript levels. Despite significant changes in granule cell number and the architecture of the internal granule layer, only subtle differences in expression distinguish Ts from Eu neurons. At the transcript level, those neurons that survive to adulthood are relatively normal, and the gene dosage effects of trisomy may be more pronounced in the developmental processes that produce the adult structure.

Membrane regulation in dysferlin deficiency: Evidence for disrupted membrane signaling and altered remodeling through expression profiling. *D.A. Rao^{1,2}, E. Veszelyovszky¹, P.H. Plotz², E.P. Hoffman¹*. 1) Center for Genetic Medicine Research, Children's National Medical Center, Washington, DC; 2) Arthritis and Rheumatism Branch, National Institute of Arthritis and Musculoskeletal and Skin Diseases, NIH, Bethesda, MD.

Deficiency of dysferlin, a skeletal muscle plasma membrane protein, causes two recessively inherited myopathies: Limb Girdle Muscular Dystrophy type 2B and Miyoshi Myopathy, a distal myopathy. Both clinical presentations involve slowly progressive muscle weakness with onset in the late teens, and either presentation can result from the same mutation in dysferlin. Dysferlin shares significant homology with *C. elegans* factor FER-1, a protein required for worm sperm vesicle fusion, indicating a role for dysferlin in membrane fusion events, and EM analysis of human dysferlin-deficient muscle reveals numerous membrane abnormalities, including accumulation of subsarcolemmal vesicles. In this study, we used expression profiling to examine the secondary downstream effects of a primary deficiency in dysferlin. We used Affymetrix U95A and MuscleChip microarrays to generate 14 expression profiles from 5 patients with dysferlin deficiency. By comparing these profiles to profiles of normal muscle (22) and of muscle from patients with Duchenne Muscular Dystrophy (26) using both Affymetrix and GeneSpring software (Welch t-tests, $p < 0.05$), we isolated 121 genes with dysregulation specific to dysferlin deficiency. Seventeen of these genes are involved in membrane regulation, with nine genes known to participate directly in the regulation of vesicle formation or trafficking, including RAD, Rab5C, MLL septin-like fusion, and arfaptin1. We have confirmed altered expression of both vesicle trafficking proteins as well as membrane signaling molecules by QMF-RT-PCR and immunohistochemistry, and have observed altered plasma membrane expression and/or localization of a number of proteins important for membrane signaling and stability. Integration of these expression changes into biochemical pathways will reveal cascades driving myofiber pathogenesis in dysferlin deficiency and promote understanding of dysferlin function at the membrane.

Mutation Screening of the Mitochondrial Genome using Denaturing High-Performance Liquid

Chromatography. *J. Christodoulou*^{1,2}, *A. Biggin*¹, *D.R. Thorburn*³, *B. Bennetts*^{1,2}. 1) Western Sydney Genetics Program, Children's Hospital, Westmead, NSW, Australia; 2) Dept of Pediatrics & Child Health, University of Sydney, NSW, Australia; 3) Murdoch Children's Research Institute, Melbourne, Vic, Australia.

Over 170 disease-causing mutations of the mitochondrial genome have now been identified, and the list continues to grow. The diverse clinical presentations do not often provide pointers that the primary defects might involve mitochondrial DNA (mtDNA). As pathogenic mtDNA mutations are mostly heteroplasmic, denaturing high-performance liquid chromatography (DHPLC) could be used to detect these heteroplasmic species and therefore act as a rapid screening test for mtDNA mutations.

The entire mitochondrial genome was amplified by PCR in 40 overlapping regions. In addition, known mtDNA mutants were constructed for each of these regions using a PCR-based site-directed mutagenesis approach. These mutants were used as positive controls and showed a detection limit of 3-10% heteroplasmy (depending on the specific mutation) compared to 40% for conventional sequencing. To further validate the screening test, mtDNA from 17 patients covering 7 different mutations were used to compare mutation detection by DHPLC and conventional sequencing. DHPLC had a sensitivity (probability that the test was positive if a mutation was present) of 88% compared to 82% for sequencing. This increased to 100% sensitivity for DHPLC when excluding the 8993T>G mutation.

DHPLC analysis is therefore a sensitive, rapid and cost-effective method to screen for mutations in the mitochondrial genome.

A new mutation of the apolipoprotein B gene originates the apo B32,4 truncated protein. *O. Guardamagna¹, E. Bugianesi², R. Bonardi², V. Molini¹, C. Bondone¹, A. Bobbio¹, P. Tarugi³.* 1) Dip.di Scienze Pediatriche e dell'Adolescenza; 2) Dip. dell'Apparato Digerente e della Nutrizione-Universita' di Torino; 3) Dipartimento di Scienze Biomediche,Universita' di Modena,Italia.

Background: Familial hypoblipoproteinemia (FHBL) is an autosomal codominant hypocholesterolemia disorder which prevalence is 1:500/1:3000 in western countries. The clinical phenotype is heterogeneous and homozygous patients present malabsorption and neurological degeneration, while heterozygous ones show a milder phenotype. A relationship between heterozygous FHBL and liver steatosis has been demonstrated. The basic defect relies on the apolipoprotein B (apoB) gene mutation. **Aim of the study** consists in correlating an apoB gene mutation with an unexplained steatohepatitis. **Methods:** A 63yrs old patient being affected from steatohepatitis since adulthood was investigated for FCHL. Total cholesterol and triglycerides were analyzed by standard kit, apoB by immunoturbidimetric method. Plasma lipoproteins were separated by ultracentrifugation and apoB analyzed by immunoblotting and electrophoresed on polyacrylamide gel. The apoB gene mutation detection was performed by PCR amplification of the 5' of the exon 26 and sequenced using the Sequencing System (Promega Co., Madison). **Results:** The conclusive diagnosis of FHBL was based on the apoB gene mutation detection. This is a two base (AG) deletion at codon 1464 causing a stop codon (TAA) at position 1470. This mutation was detected for the first time in this patient who carries an apoB truncated protein which size corresponds to 32,4% of the normal apoB 100. **Conclusions:** A new truncated protein and gene mutation related to liver steatohepatitis have been detected. Although a number of apoB gene mutations were previously recognized correlations between apoB and this phenotype is poorly known and possibly misdiagnosed. Furthermore liver steatosis could represent the initial step evolving to steatohepatitis, as the present case demonstrated, to cirrhosis and hepatocarcinoma.

Thiamine responsive megaloblastic anemia presenting as microcytic anaemia: an unusual case with novel mutations. *A.S. Feigenbaum¹, S. Hewson¹, D. Wherret², J. Doyle³, J.S. Wray⁴, B.D. Gelb⁵.* 1) Dept Genetics and Paediatrics; 2) Div of Endocrinology; 3) Div of Haematology/Oncology, Hospital for Sick Children and University of Toronto, ON, Canada; 4) Program in Human Genetics, McMaster University Medical Centre, Hamilton, ON, Canada; 5) Department of Human Genetics, Mount Sinai School of Medicine, New York, USA.

Thiamine responsive megaloblastic anemia (TRMA) is an autosomal recessive condition characterized by megaloblastic anemia, diabetes mellitus and sensorineural deafness caused by mutations in the thiamine transporter protein SLC19A2.

We describe a child of consanguineous first cousin East Indian parents who presented to us at 8 years of age with sensorineural deafness, insulin dependent diabetes mellitus, retinopathy and anemia since an acute febrile illness at age 3 years. Full mitochondrial work-up was normal. Hemoglobin(Hgb)was 41-100 g/L, with hypochromia (MCHC 310g/L), microcytosis, and dimorphic red cells. Hgb electrophoresis, retics, iron, B12 and folate levels were normal. Bone marrow showed sideroblastic anemia with macronormoblastic dyserythropoiesis.

Father had hypochromia, microcytosis and Hgb electrophoresis consistent with b-thalassemia trait; mother's was normal. Molecular analysis of the α -globin gene cluster revealed father is compound heterozygote for the rightward and leftward single α -globin gene deletions ($-\alpha^{3.7}/-\alpha^{4.2}$). The proband is heterozygous for the rightward single α -globin gene deletion ($-\alpha^{3.7}/aa$).

SLC19A2 mutation analysis identified a novel T439P (A1315C)substitution, homozygous in the proband and heterozygous in parents. Therapy with thiamine showed haemoglobin response from 87 to 115g/L in 3 weeks but no improvement in diabetes control over 2 years of therapy.

We report an unusual case of TRMA with microcytosis associated with α -thalassemia trait rather than macrocytic anemia highlighting the difficulties in diagnosis and illustrating that thiamine therapy may improve the anemia but not the diabetes in this rare condition.

Hermansky-Pudlak Syndrome Type-1: Screening Methods, Mutations, and Clinical Outcomes. *C.R. Hermos, M. Huizing, W.A. Gahl.* Heritable Disorders Branch, NICHD, NIH, Bethesda, Maryland.

Hermansky-Pudlak syndrome is an autosomal recessive disorder characterized by oculocutaneous albinism, a platelet storage pool deficiency and, in some patients, lysosomal accumulation of ceroid lipofuscin. HPS is associated with defects in the biosynthesis and/or processing of melanosomes, platelet dense bodies, and lysosomes. Four human genes (HPS1, ADTB3A, HPS3, HPS4) are associated with 4 subtypes of HPS.

We studied the molecular and clinical aspects of the HPS-1 subtype, caused by mutations in the HPS1 gene. A 16-bp duplication in exon 15 causes HPS-1 in 450 patients in northwest Puerto Rico; 13 other HPS1 mutations have been reported in non-Puerto Rican patients. We screened 26 HPS patients for HPS1 defects using northern blotting, SSCP, restriction enzyme analysis and direct sequencing. Six different HPS1 mutations were identified in 6 of the 26 patients. Four new mutations were discovered, including the first HPS1 missense mutation. New mutations include 624delG in exon 6 and 922T>C in exon 8 which appear to preserve RNA translation and 561delC in exon 5 and [1581delA;1594C>A] in exon 14 which result in no RNA by northern blot. The 6 newly diagnosed HPS-1 patients bring to 13 the total number of non-Puerto Rican individuals with HPS-1. One of 6 adult patients developed pulmonary fibrosis, and 2 patients ages 16 and 17 have granulomatous colitis. These complications are also common among Puerto Rican HPS-1 patients but have not arisen in HPS-2 and HPS-3 patients.

We conclude that the diagnosis of HPS-1, available only on molecular grounds, has important prognostic implications. In addition, the diagnosis may soon influence treatment decisions, since a clinical trial has recently shown that the antifibrotic agent, pirfenidone, slows the decline in pulmonary function associated with HPS1 disease. The screening methods employed in this study should help achieve the accurate molecular diagnosis of HPS-1.

Molecular, biochemical and clinical aspects of Smith-Lemli-Opitz syndrome in Cuban patients. *M.J.M.*

Nowaczyk^{1,2,3}, D. Martin Garcia⁴, A. Aquino⁴, M. Rodriguez⁴, B. Eng³, D. McCoughey³, J.S. Waye^{1,2}. 1) Dept Pathology & Molecular Medicine, McMaster Univ, Hamilton, ON, Canada; 2) Dept Pediatrics, McMaster Univ, Hamilton, ON, Canada; 3) Hamilton Regional Laboratory Medicine Program, Hamilton, ON, Canada; 4) Center of Medical Genetics, Sancti Spiritus, Cuba.

Smith-Lemli-Opitz syndrome (SLOS) is an autosomal recessive MCA-MR disorder caused by mutations in the 7-dehydrocholesterol reductase (DHCR7) gene. The diagnosis is based on the findings of elevated plasma 7-dehydrocholesterol (7DHC) levels. To date, more than eighty DHCR7 mutations have been reported in SLOS patients.

Cuba is the largest of the Caribbean islands, having a population in excess of eleven million. The Cuban population is predominantly African in origin, with 11% Cuban-African, 37% European Caucasian, and 51% of mixed European Caucasian and African ancestry. The European Caucasians are almost entirely of Spanish origin. Herein we report the molecular, biochemical and clinical aspects of eight SLOS patients from Cuba. These patients are at the mild end of the clinical spectrum. The Kelly-Hennekam severity scores were <20 for six patients, and 21 and 28 for the remaining two patients. The clinical diagnosis was confirmed by the demonstration of elevated plasma 7DHC levels. Nucleotide sequence analysis showed that one patient was homozygous for the T93M missense mutation, and the remaining patients were compound heterozygotes for T93M and other SLOS alleles (IVS8-1G>C, D234Y, V281M, F302L). Therefore, the T93M mutation is a common SLOS allele in the Cuban population.

The T93M mutation confers a relatively mild phenotype with paucity of physical findings associated with moderate to severe developmental and behavioral problems. This mutation was reported previously in a large proportion of Italian patients, raising the possibility that T93M may be a "Mediterranean mutation". Consistent with this view, the T93M mutation in our Cuban, Italian, and Greek SLOS patients is associated with the same haplotype.

Identification of twelve new arylsulfatase A gene mutations in metachromatic leukodystrophy (MLD) patients.

J.S. Waye^{1,2}, *B. Eng*², *L.M. Nakamura*¹, *N. Schokman*¹, *N. O'Reilly*¹, *M.J.M. Nowaczyk*^{1,2,3}. 1) Dept Pathology & Molecular Medicine, McMaster Univ, Hamilton, ON, Canada; 2) Hamilton Regional Laboratory Medicine Program, Hamilton, ON, Canada; 3) Dept Pediatrics, McMaster Univ, Hamilton, ON, Canada.

Metachromatic leukodystrophy (MLD, MIM 250100) is an autosomal recessive, metabolic disease caused by deficiency of arylsulfatase A activity. The estimated gene frequency is approximately 0.5%, corresponding to an incidence of 1 in 40,000 births. ARSA deficiency causes intralysosomal accumulation of cerebroside sulfate in the white matter of the central nervous system and in the peripheral nerves, leading to progressive demyelination and a variety of neurological symptoms. Clinically the disease is heterogeneous and different forms are classified according to the age of onset (infantile, juvenile, adult).

Surveys of MLD patients have identified more than eighty different *ARSA* gene mutations, with two mutations (IVS2+1G>A and P426L) accounting for up to 50% of the mutant alleles in some populations. The remaining MLD mutations are extremely rare or private.

We have investigated more than fifty MLD patients using multiplex ARMS assays to detect the pseudodeficiency (PD) allele and several common MLD mutations (IVS2+1G>A, I179S, P426L). This was followed by comprehensive nucleotide sequencing of the *ARSA* gene to detect rare mutations, and Southern hybridization to detect large deletions. Here we report the identification of eleven new microlesions in the *ARSA* gene: seven missense mutations (P155L, L181Q, C300Y, Y306H, G325S, E329K, Y429S), three frameshift mutations (g.203-204delTG, g.750-756delCCGCCGG, g.2590-2591insCCCC), and one splice donor site mutation (IVS5+1G>A). We also identified a 14.8 kb deletion that removes the entire *ARSA* gene. Molecular characterization of the deletion endpoints is consistent with homologous recombination between Alu repeat elements that flank the *ARSA* gene. Comprehensive mutation detection has facilitated carrier detection and prenatal diagnosis for several at-risk MLD families.

Characterization of Four Novel b-Galactosidase Gene Mutations and A Polymorphism in Taiwanese Patients with GM1-Gangliosidosis. *J.Y. Wu^{1,2}, C.F. Yang³, F.J. Tsai^{1,4}*. 1) Dept Medical Research, China Medical Col Hosp, Taichung, Taiwan; 2) National Genotyping Center at Academia Sinica, Taipei, Taiwan; 3) IBMS, ACademia Sinica, Taipei, Taiwan; 4) Dept Pediatrics, China Medical Col Hosp, Taichung, Taiwan.

GM1-gangliosidosis is an autosomal recessive lysosomal storage disease caused by a deficiency of acid beta-galactosidase (GLB1; EC3.2.1.23). Molecular analysis of the GLB1 gene has performed in two Taiwanese patients. The first patient (Patient 1) is a case of typical infantile, severe form, and the other one (Patient 2) had more severe presentations and a specific finding of cardiac involvement. Four novel mutations (H102D, A301V, G494V, c.945-7del) and one polymorphism (G23S) were identified. Patient 1 has found to have two missense mutations, H102D and A301V, and a G23S polymorphism. Patient 2 was presented with the G494V and c.945-7del mutations. Transient overexpression in COS-1 cells of cDNA encoding G494V, c.945-947del, A301V, H102D, G23S mutant b-galactosidases produced products with activities of 0, 0, 0, 12, 97.7 % compared with the cDNA clone for wild-type b-galactosidase. The mutations identified in patient 2 with cardiomyopathy are localized in the GLB1 gene region common to both the lysosomal b-galactosidase and b-galactosidase-like protein (also known as elastin binding protein, EBP), and may affect both molecules to present this specific clinical manifestations.

Association of Neurological Disability and X-Inactivation in Fibroblasts of Females Heterozygous for X-linked Adrenoleukodystrophy. *S.A. Fatemi, P.A. Watkins, A.B. Moser, L.M. Poetscher, N. Beauchamp, G.V. Raymond, H.W. Moser, S. Naidu.* Kennedy Krieger Institute, Baltimore, MD.

Objective: The degree of neurological involvement has been investigated extensively in affected males with X-linked adrenoleukodystrophy (X-ALD). However, there is limited data for heterozygote females. This study aimed to determine the range of neurological disability and its possible association with X-inactivation in fibroblasts of X-ALD heterozygotes. **Methods:** 76 X-ALD females between 8 and 76 years (median: 41.5, mean: 42.5 +/-15 years) were included in the study. The Kurtzke Expanded Disability Status Scale (EDSS) was used to rate the neurological impairment (range, 0:no abnormalities - 10:death). Brain MR Imaging (MRI) was performed in all subjects. In a subgroup of 40 patients indirect immunofluorescence analysis of cultured skin fibroblasts was performed. An antibody raised against the C-terminal 18 amino acids of the human peroxisomal ALD protein (ALDP) revealed a punctate, peroxisomal immunostaining pattern and average percentages of immunopositive and immunonegative cells were determined. **Results:** Nine patients were completely asymptomatic, while 67 demonstrated neurological abnormalities (Mean EDSS: 2.5, max. 8). A mixed population of normal and abnormal fibroblasts was demonstrated with a mean of 43 +/-17 % normal ALDP positive cells. Prominent bilateral cerebral white matter abnormalities were observed in the MRIs of two girls (13 & 14 years old) and of a 42 year old woman. These patients had absent or severely reduced ALDP expression (0, 1 and 7% immunopos. cells in the 14, 13 and 43 year old, respectively) suggesting skewed X inactivation. Patients age ($p=0.007$) and average percentage of immunoneg. cells ($p=0.05$) explained 35% of the variability of the EDSS using multiple regression analysis in patients without MRI abnormalities. **Conclusion:** MRI changes similar to cerebral childhood X-ALD in males were detected in heterozygote females who showed either absence or very low ALDP expression in fibroblasts. Furthermore, advanced age and reduced ALDP expression in fibroblasts were associated with a higher degree of neurological disability in X-ALD heterozygotes.

Mutations in exon 1 of *MLYCD* reveal a critical role for protein targeting and post-translational modification.

*P.J. Wightman*¹, *N. McGill*¹, *R. Santer*², *A. Ribes*³, *D.R. Thorburn*⁴, *D.R. FitzPatrick*¹. 1) MRC Human Genetics Unit, Western General Hosp, Edinburgh, Scotland; 2) Department of Paediatrics, University of Kiel, Germany; 3) Institut de Bioquímica Clínica, Corporacio Sanitaria, Spain; 4) The Murdoch institute, Royal Children's Hospital, Melbourne, Australia.

Malonyl-CoA decarboxylase (*MLYCD*) deficiency (OMIM 248360) is an autosomal recessive disorder characterised by malonic aciduria, developmental delay, seizure disorder, hypoglycemia, and cardiomyopathy. *MLYCD* genomic sequencing in six unrelated patients revealed three non-conservative missense mutations, two small frame-shifting deletions and two single base insertions that together accounted for 11/12 pathogenic alleles. Fibroblast cell lines were available from 5 of these patients and two previously reported patients with homozygous *MLYCD* mutations. Antisera raised to a C-terminal peptide detected a previously unrecognised 66 kDa *MLYCD* isoform in control fibroblasts. This band was undetectable in 3/7 patients cell extracts. In 3/7 patients the was substantially reduced in intensity including one with a 25-base deletion that changes the ORF between two possible initiating AUG codons (M1 & M40) thus ablating the mitochondrial signal peptide of *MLYCD* ensuring only the peroxisomal form of the protein is translated. One cell-line show an overall increase in protein levels with the 66 kDa band and a prominent smeary band of 68-83 kDa. This mutation (p.M40T) ablates the second AUG and thus only allows translation of the intramitochondrial form of *MLYCD*. Immunocytochemical analysis confirmed the predicted intracellular mislocalisation and demonstrated a third category of mislocalisation due to a mutation (p.G3D). Taken together these data suggest that both peroxisomal and mitochondrial localisation of *MLYCD* are critical for its normal function and that a novel targeting signal may reside in a 4 amino acid conserved N-terminal motif.

Nitrous oxide and 5,10-methylenetetrahydrofolate reductase deficiency. *R.R. Selzer¹, D.S. Rosenblatt², R. Laxova³, K. Hogan¹.* 1) Department of Anesthesiology, University of Wisconsin, Madison, WI; 2) Department of Human Genetics, McGill University, Montreal; 3) Department of Medical Genetics, University of Wisconsin, Madison, WI.

Nitrous oxide irreversibly oxidizes the cobalt atom of vitamin B12, inhibiting activity of the cobalamin-dependent enzyme methionine synthase. Methionine synthase converts 5-methyltetrahydrofolate and homocysteine to tetrahydrofolate and methionine, the principal substrate for methylation in many biochemical reactions including assembly of the myelin sheath, neurotransmitter substitutions, and DNA synthesis in rapidly proliferating tissues. We report the neurologic deterioration and death of a child anesthetized twice with nitrous oxide before the diagnosis of 5,10-methylenetetrahydrofolate reductase (MTHFR) deficiency was established. MTHFR catalyzes the synthesis of 5-methyltetrahydrofolate. Sequence analysis of MTHFR RNA transcripts and genomic DNA from the patient and family members, together with direct assays of fibroblast MTHFR activity, reveal that the enzyme deficiency was caused by a novel MTHFR mutation (1755G→A, which changes a conserved methionine to an isoleucine), co-inherited with two common MTHFR polymorphisms (677C→T, 1298A→C) each independently associated with depressed enzyme function. We propose that an acquired lesion of methionine synthase superimposed on an inherited lesion in folate metabolism caused the patient's death, with the observed neuropathologic and biochemical changes closely tied to those predicted by impairment of folate and methionine pathways, including demyelination, neuronal atrophy, and depressed levels of CSF biogenic amines. Because two of the three contributing variants are homozygous in over 10% of the population, routine use of nitrous oxide merits closer scrutiny. Whether children with these and related common polymorphisms in MTR, MTRR and CBS are predisposed to subtle but significant decrements in neurological performance following nitrous exposure in childhood remains an unanswered question.

Genetic Variation in a Gene Critical for Glutathione Synthesis. *M.L. Freeman¹, A.S. Willis², S.R. Summar³, S.M. Williams⁴, E. Dawson⁵, F. Barr⁶, M.L. Summar³.* 1) Radiation Oncology, Vanderbilt University Medical Center, Nashville, TN; 2) Molecular Physiology and Biophysics, Vanderbilt University Medical Center, Nashville, TN; 3) Pediatrics/Genetics, Vanderbilt University Medical Center, Nashville, TN; 4) Meharry Medical College, Nashville, TN; 5) BioVentures, Inc., Murfreesboro, TN; 6) Pediatric Cardiology, Vanderbilt University Medical Center, Nashville, TN.

Glutamate cysteine ligase (GCL), also known as g-glutamylcysteine synthetase, is heterodimeric enzyme that synthesizes the first step in the *de novo* synthesis of glutathione. Glutathione plays a role in a number of cellular processes, including the scavenging of free radicals to neutralize oxidative stress. The pathophysiology of several diseases, including neurodegenerative disease and progression of HIV infection, is thought to involve glutathione and oxidative stress. Polymorphisms in GCL have the potential to affect glutathione synthesis and, therefore, diseases in which glutathione may be important. We undertook the systematic screening for polymorphisms through single strand conformation polymorphism analysis of the exons and intronic flanking sequences of GCLC, the gene that encodes the catalytic subunit of GCL. We identified 11 polymorphisms in GCLC - 1 previously reported triplet repeat in the 5' UTR, 1 synonymous, 1 nonsynonymous, 2 insertion polymorphisms in the 3' UTR, and 6 intronic polymorphisms. We also determined allele frequencies for each polymorphism in group of 163 individuals that fits the demographics of the middle Tennessee area. Five polymorphisms have alleles with frequencies less than 5%; the others had alleles with a frequencies of 9% or greater. The nonsynonymous polymorphism C1384T is one of the rare polymorphisms and has been found only in individuals of African descent. These polymorphisms may provide a tool for association studies of diseases in which glutathione may be important.

X-linked adrenoleukodystrophy: clinical and biochemical findings in Brazilian patients. *R. Giugliani^{1, 3}, M. Wajner¹, A. Barschak¹, C. Cecchin¹, D. Zandon¹, G. Ferreira¹, G. Maegawa¹, L. Jardim^{1, 2}, L. Goulart¹, L. Sirtori¹, M. Chiochetta¹, M. Deon¹, C. Vargas^{1, 4}.* 1) Medical Genetics Unit, Hosp de Clinicas, Porto Alegre, RS, Brazil; 2) Department of Internal Medicine, UFRGS, Porto Alegre, Brazil; 3) Department of Genetics, UFRGS, Porto Alegre, Brazil; 4) Department of Clinical Analysis, UFRGS, Porto Alegre, Brazil.

Adrenoleukodystrophy (X-ALD) is an X-linked recessively inherited peroxisomal disorder, phenotypically heterogenous, characterized by progressive white-matter demyelination of the central nervous system and adrenocortical insufficiency. We investigated 32 male X-ALD patients varying in age from 7 to 39, diagnosed from 304 suspected patients referred for investigation. Plasma levels of very long chain fatty acids (VLCFA) were measured at our laboratory using gas chromatography (GC). Twenty five cases of childhood X-ALD and seven cases of adrenomyeloneuropathy (AMN) were diagnosed. Leukodystrophy, paraparesis and learning difficulty were the most frequent symptoms, appearing in 25, 13 and 12 of the patients, respectively. Physician awareness of X-ALD seems inadequate to judge by age at diagnosis and lengthy interval between the start of symptoms and diagnosis. This is the first published series of Brazilian patients with X-ALD. We determined signs and symptoms relevant for diagnosis, as early identification seems important for treatment outcome. In addition, diagnosis identifies carriers, who could benefit from genetic counselling and prenatal diagnosis.

Genotyping Errors and Variance Components Linkage Analysis on the X chromosome. *T.A. Daigneault.*
Biostatistics, University of Michigan, Ann Arbor, MI.

Identifying genotyping errors is crucial when considering large genotype data sets, since undetected genotype errors can greatly reduce evidence for linkage. The problem is especially important because the shift to single-nucleotide polymorphisms (SNPs) will lead to a greater proportion of hard to detect genotyping errors that do not produce Mendelian inconsistencies. To date, most authors have focused on the detection and treatment of genotyping errors for autosomal data. Here, we extend these methods to X chromosome analysis and evaluate their utility in variance components linkage analysis of X linked traits. We simulated 20 markers for both a 1-cM SNP map (2 equi-frequent alleles/marker) and a 5-cM microsatellite map (4 equi-frequent alleles/marker) in various nuclear family configurations with between 2 and 5 siblings, with and without parental information. In each pedigree, we changed the genotype of one individual per family. We checked for genotyping errors by finding Mendelian inconsistencies, and conducting a sensitivity analysis of the likelihood. As expected, checking for Mendelian inconsistencies alone leaves many errors undetected. For example, only 0-9% of SNP genotyping errors and 5-35% of microsatellite genotyping errors resulted in Mendelian inconsistencies for families with 3 siblings and no parents. For both maps, the overall detection rate exceeded 70% in families with 4 or more same sex siblings when maternal genotypes were not available. Paternal genotypes made little difference, but having the mother genotyped was as efficient as having both parents genotyped (97-98% errors detected for all size families). The overall detection rate was higher for the X chromosome than for the autosome. For example, in the X chromosome SNP map 48% of the errors were detected for only 2 genotyped female siblings, but only 17% of the errors were detected in the autosome map. In families with 3 siblings, having one genotype error per family can lead to a 30% loss of the LOD score in variance components analysis. In these simulations, our error checking strategy recovered 80% of the lost LOD score. Our results and software will be helpful for investigators interested in the mapping of X-linked traits.

Experimental spinal cord injury temporal profiling identifies cell cycle genes associated with neuronal damage: possible SNP candidates. *S. Di Giovanni*^{1,2}, *S. Knoblach*², *A.I. Faden*², *E.P. Hoffman*¹. 1) Children's National Medical Center, Washington DC; 2) Dep. of Neuroscience, Georgetown U, Washington DC.

Spinal cord injury is a major cause of disability, its clinical manifestation is highly variable depending upon the intensity and the site of the trauma, but variability seems to be present also between different individuals who sustained a similar level of injury. Much of the functional deficit results from delayed cellular consequences of injury repair mechanisms, and these are mediated by a large set of genes, strongly temporally regulated, mainly involved in neuronal fate or survival. To define the temporal series of gene expression changes following spinal cord injury and to identify possible SNP candidates, we employed spinal cord injury experimental model for an expression profiling study. Rats were subjected to a controlled impact injury at T8-T9 by weight drop and were sacrificed at four time points (30 min, 4h, 24h and 7 days), with 4 to 6 individual rat spinal cords expression profiled at each time point (total 84 profiles) using the U34A,B,C Affymetrix genechip containing about 27000 probe sets, including ESTs. Genes showing 40% or more present calls in 26 profiles by Affymetrix analyses were retained for further analysis, and p values (>0.05) and fold changes (2 fold threshold) correlated, with temporal and functional clustering. Specific RNAs were verified by QMF-RT-PCR using infrared primers, protein level quantified by western blot and localized by ICC. We found induction of DNA damage-inducible genes and genes favoring cell cycle progression at 4 and 24 hours after injury. Temporal profiling also allowed us to look for new candidate genes by nucleating ESTs that were temporally significantly co-regulated with genes with known function. Changes in mRNA expression were associated with changes in respective proteins as shown by western blots and ICC. Cell cycle and DNA damage related proteins were frequently localized in neurons showing signs of DNA damage and apoptotic features and are therefore likely to be important in modulating delayed cellular damage following spinal cord trauma. These genes may also represent good candidates for SNPs discovery in humans.

C-Reactive Protein is linked to regions on chromosome 10 and 5 in families with myocardial infarction. *U. Broeckel¹, C. Hengstenberg², K. Maresso¹, B. Mayer², S. Holmer², J. Erdmann², G. Schmitz³, L.J. Martin⁴, A.G. Comuzzie⁴, H.J. Jacob¹, H. Schunkert².* 1) Human and Molecular Genetics Center, Medical College of Wisconsin, Milwaukee, WI; 2) Clinic of Internal Medicine 2, Universitaet Regensburg, Germany; 3) Department of Clinical Chemistry, University of Regensburg, Germany; 4) Department of Genetics. Southwest Foundation of Biomedical Research. San Antonio, TX.

C-reactive protein (CRP) is a highly sensitive acute-phase marker of inflammation. Several studies have shown that CRP is strongly correlated with long term prognosis in patients with coronary heart disease (CHD) as well as healthy individuals, independent of traditional cardiovascular risk factors. While environmental components as well as drugs have been shown to influence CRP levels, recent reports have demonstrated a significant genetic component. In order to identify chromosomal regions linked to CRP, we performed a total genome scan in 513 families (1,406 individuals) ascertained for myocardial infarction.

A variance component approach was used to estimate heritability and to test for linkage with CRP. Initial analyses screened for general covariates including age, gender, body mass index (BMI), and LDL. Diabetes, CHD, systolic and diastolic blood pressure, cigarette smoking, and various medications as qualitative phenotypes. Heritability of CRP in a reduced model of just age and gender was 36%. In a model also incorporating diabetes, smoking and BMI, heritability was estimated at 31%. Qualitative covariates controlling for the effects of lipid-lowering drugs and aspirin treatment did not remain as significant covariates. In subsequent multipoint linkage analysis we identified two loci for CRP. A maximum LOD score of 3.02 was found at 141 cM on Chromosome 10 in addition to a loci at 151 cM on Chromosome 5 with a LOD of 2.23. These loci do not overlap with previously identified susceptibility loci for MI in this population.

In conclusion, this study represents the first total genome scan for CRP, demonstrating a significant genetic component, and identifying two distinct loci linked to CRP serum levels.

Genome-wide association study to identify genes related to myocardial infarction. *K. Ozaki¹, Y. Ohnishi¹, A. Iida¹, R. Yamada¹, T. Tsunoda¹, A. Sekine¹, H. Sato², H. Sato², M. Hori², Y. Nakamura^{1, 3}, T. Tanaka¹.* 1) SNP Research Center, The Institute of Physical and Chemical Research (RIKEN), Tokyo, Japan; 2) Department of Internal Medicine and Therapeutics, Osaka University Graduate School of Medicine, Osaka, Japan; 3) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, University of Tokyo, Tokyo, Japan.

To clarify genetic backgrounds in the pathogenesis of acute myocardial infarction (MI), we have launched a genome-wide association study in a Japanese population using 100,000 cSNPs. As a first step, we are now genotyping 94 MI patients and 658 general population by high-throughput multiplex PCR-Invader assay method. We temporarily chose p value of 0.01 to be threshold to select SNPs for further verification by expanding sample size. At present, we have screened 24,757 SNPs and 98% of them did not meet this threshold. When the rest of the SNP loci were re-examined with additional 1,000 MI patients and 1,000 general population, almost all of them did not show statistically significant association. However, one SNP locus showed a tight association, with a c^2 value of 21.6 ($p=0.0000033$) and odds ratio of 1.78 (95% confidence interval 1.39-2.27). We are now making a dense SNP map of this locus for linkage disequilibrium mapping, followed by functional analyses of gene products.

Examination of Candidate Chromosomal Regions for Type 2 Diabetes (T2DM) Reveals Evidence for a New Susceptibility Locus and Potential Epistatic Effects. *M.G. Pezzolesi¹, M. Nam¹, T. Nagase¹, T. Klupa¹, J.S. Dunn¹, S.S. Rich², J.H. Warram¹, A.S. Krolewski¹.* 1) Dept Genetics & Epidemiology, Joslin Diabetes Ctr, Boston, MA; 2) Wake Forest University School of Medicine, Winston-Salem, NC.

The search for major genes affecting the development of T2DM has been plagued by inconsistent linkage results. In a panel of 43 large Caucasian pedigrees in which diabetes segregates consistent with an autosomal dominant pattern, we genotyped markers in eight chromosomal regions previously reported as supporting linkage with T2DM. Previously, we have reported significant evidence of linkage on chromosome 20q (maximum LOD score, MLS=3.85) in this same panel. In the present analysis, candidate regions on 2q, 3q, 5q, 9q, and 10q yielded little evidence for linkage, regions on 1q (MLS=1.01) and 2p (MLS=0.67) gave only suggestive evidence of linkage, while a region on 8p (MLS=3.10) gave significant evidence of linkage. After increasing marker density on 8p, the MLS increased to 3.95 and the location shifted to a more telomeric position. In addition, conditional analyses were performed for each region and with our chromosome 20q data. The MLS for 1q and 20q significantly increased when conditioned on 2p (to 2.12 and 3.89, respectively) while the MLS at 8p decreased (from 3.95 to 1.75). When conditioned on 2p, the MLS for 9q increased to 1.15 (from 0.13), and the MLS for 9q increased to 0.52 (from 0.13) when conditioned on 20q. There did not appear to be an effect of conditioning on support for linkage to chromosome 8p.

In conclusion, while we were able to replicate suggestive linkage in our pedigrees on chromosomes 1q and 2p, we did not find evidence of linkage where previously reported on 2q, 3q, 5q, 9q, and 10q. However, our data did provide strong evidence to support a new susceptibility locus on chromosome 8p that appeared independent of other susceptibility loci in effect. Lastly, our conditional analysis supports evidence for two potential epistatic effects: interactions between 2p and (1q and 9q) and between 20q and (9q and 2p).

Otosclerosis and *COL1A1*. *W. Chen*¹, *M.J. McKenna*², *G. Van Camp*³, *R.J.H. Smith*¹. 1) Molecular Otolaryngology Research Laboratories, University of Iowa, Iowa City, IA, USA; 2) Department of Otolaryngology, Harvard Medical School, Boston, Massachusetts, USA; 3) Department of Medical Genetics, University of Antwerp, Antwerp, Belgium.

Statement of Purpose. Otosclerosis, a type of conductive deafness caused by abnormal bone homeostasis of the otic capsule, represents a frequent cause of hearing impairment among white adults. Although no causative genes have been cloned, a candidate gene genetic association study between otosclerosis and three collagen genes linked to mild forms of osteogenesis imperfecta (*COL1A1*, *COL1A2* and *COL2A1*) found a statistically significant association between otosclerosis and *COL1A1* (McKenna et al. 1998). We hypothesized that if this association is robust, it could be confirmed by single nucleotide polymorphism (SNP) genotyping. **Methods Used.** Proband from 130 families segregating otosclerosis were genotyped for six SNPs tightly linked to *COL1A1*. Data were compared to SNP genotypes of 174 controls. **Summary of Results.** One of the SNPs we genotyped is within a distinct cis element that regulates basal expression of *COL1A1* in osteoblasts. The SNP results from the deletion of one of eight consecutive thymidines. The genotypes of the 130 persons with otosclerosis were (TT, 52%; CT, 42%; CC, 6%); the genotypes of the controls were (TT, 73%; CT, 24%; CC, 3%). These differences are significant at the $p < 0.0006$ level (chi-square and exact test). **Conclusion.** This association suggests a common molecular basis of inheritance between some cases of otosclerosis and osteogenesis imperfecta. It also suggests that perturbations in the basal expression of *COL1A1* may be etiologically related to otosclerosis. Further investigation of this gene will be required to clarify its role in the pathogenesis of this disease. (Supported in part by NIH grant R01DC05218 to GVC and RJHS.).

A Refined Interval for the Autosomal Recessive Nonsyndromic Deafness Locus DFNB6. *C.A. Hodgkinson^{1,3}, S. Bohlega², S.N. Abu-Amero¹, M. Kambouris¹, E. Cupler², B.F. Meyer¹, V.A. Bharucha^{1,3}.* 1) Department of Genetics, KFSH&RC, Riyadh, Saudi Arabia; 2) Department of Neurosciences, KFSH&RC, Riyadh, Saudi Arabia; 3) Prince Salman Centre for Disability Research, Riyadh, Saudi Arabia.

Autosomal recessive nonsyndromic hearing loss has been linked to more than thirty different loci. The DFNB6 locus was previously identified in a single family and localized on chromosome 3p to a 14- to 20-cM interval bounded by the distal marker D3S1619 and the proximal marker D3S1766. We have identified a family exhibiting both autosomal recessive nonsyndromic deafness and autosomal recessive paraplegia. The paraplegic trait links to chromosome 13q14, but the deafness was excluded from this locus. In the course of performing a whole genome scan to localize the paraplegia locus we have been able to map the deafness to a 3Mb region on chromosome 3 that is completely contained within the interval previously described for DFNB6. It is therefore likely that DFNB6 and the gene at our locus are allelic. A recombination event in an affected individual localizes the underlying gene to a region bounded by D3S1298 and D3S3522. Additional mapping is currently being performed to further narrow the interval using microsatellite markers and Single Nucleotide Polymorphisms (SNPs). Also candidate genes for DFNB6 located within the interval are being interrogated by Mutation Detection Enhancement (MDE) Heteroduplex analyses and sequencing in an attempt to identify the causative gene.

Simultaneous phenotypic and genotypic dissection of neurodegeneration: Findings from the Kuopio Brain Bank.

*E.H. Corder*¹, *M. Pirskanen*², *M. Hiltunen*², *S. Helisalmi*², *A. Mannermaa*², *A. Koivisti*³, *H. Soininen*³, *M. Lehtovirta*³, *P. Hartikainen*³, *K. Ropponen*⁴, *R. Pirinen*⁴, *J. Bhm*⁴, *I. Alafuzoff*^{4,5}. 1) Demographic Studies, Duke Univ, Durham, NC; 2) Department of Clinical Genetics, Kuopio University Hospital; 3) Department of Neurology, Kuopio University Hospital; 4) Department of Pathology, Kuopio University Hospital; 5) Departments of Neuroscience and Neurology, Kuopio University.

Detailed clinical, autopsy and genetic information was investigated for the 850 subjects accessioned by the Kuopio Brain Bank. A pattern recognition approach called grade-of-membership analysis or GoM allowed identification of latent groups from numerous input variables. In this instance, six model-based groups were identified. They were defined by frequencies for the input variables and labeled as follows: 'No brain pathology' (I), 'Early death' (II), 'Cerebral infarcts' (III), 'Atherosclerosis & entorhinal AD' (IV), 'Limbic AD' (V), and 'Isocortical AD (VI)'. The order was established by increasing age at death. The labels summarize the pathologic findings. Importantly, genotypic frequencies for apolipoprotein E (APOE), alpha-2-macroglobulin (A2M) and interleukin-1-alpha (IL-1a) differed for the pathologic groups. The expected APOE associations were found: the frequency of e4/- and e4/4 increased with AD stage (e4+: 0% (IV), 51% (V), 73% (VI)) and was elevated for early death often due to MI or pulmonary embolism (46% (II)) and CNS infarct (44% (III)); e2/3 was protective. The highest A2M GG frequencies were found for limbic and isocortical AD (23%). Limbic AD was associated with AG or GG + APOE e34. IL-1a TT was associated with atherosclerosis not AD (21% (IV), 14% (V), 2% (VI)). These findings demonstrate that GoM may be a useful tool to relate sets of genotypes to multiple pathologic processes.

Empirical evaluation of pedigree stratification confirms parametric linkage to systemic lupus erythematosus (SLE) at 11q14 in African-American pedigrees with hemolytic anemia. *J.R. Kilpatrick¹, J.A. Jelly¹, J.B. Harley^{1,2,3}.*
1) Arthritis & Immunology Department, Oklahoma Medical Research Fnd, Oklahoma City, OK; 2) Department of Medicine, University of Oklahoma, Oklahoma City, OK; 3) US Department of Veterans Affairs Medical Center, Oklahoma City, OK.

The parametric LOD score method testing specific models of inheritance provides evidence of linkage at 11q14 with SLE in African-American pedigrees stratified by the presence of hemolytic anemia in at least one SLE affected family member (LOD = 4.5). In this strategy, 16 pedigrees were selected with hemolytic anemia from 56 African-American pedigrees multiplex for SLE. Six models of inheritance were tested and the highest LOD score recorded. The LOD score obtained should be interpreted allowing for multiple testing across the models considered and the 308 microsatellite markers in the genome scan. We, therefore, simulated the assignment of genotypes to the founders, the meiosis on and inheritance of chromosomal segments in pedigrees, and the six screening models applied in 10,000 replicates of the 16 pedigrees. This produced a normal distribution at every locus. The observed data from the original genome scan was most significant at the locus allegedly linked with $p = 1.06e-07$, closely corresponding to the original LOD score obtained. The only other locus showing a possible confirmatory effect was found at 5p15 with $p = 0.008$ where LOD=2.1 was previously found. A new effect was also found at 11p11 with $p = 0.0004$, which is more significant than the LOD=1.8 found in the same location in the original genome scan. These results show for this example that testing multiple models of inheritance in parametric linkage analysis does not significantly inflate the likelihood of false positive linkage.

Linkage analysis of minor histocompatibility genes causing graft-versus-host disease (GVHD) following allogeneic bone marrow transplantation. *J. Ohashi*¹, *E. Maruya*², *K. Tokunaga*¹, *H. Saji*². 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 2) HLA Laboratory, NPO, Kyoto, Japan.

Acute graft-versus-host disease (GVHD) is a major cause of morbidity and mortality after bone marrow transplantation. Incompatibility of the major histocompatibility antigen (HLA) is a primary cause of GVHD. However, even if bone marrow donor and recipient have identical HLA, GVHD still occurs 10-35%, indicating that genes outside of the HLA region, generally called immuno-dominant minor histocompatibility antigens (mHas), may be responsible for the development of acute GVHD. In order to detect mHas or GVHD loci, Lunetta and Rogus [(1998) *Genet Epidemiol* 15:595-607] have recently proposed a linkage analysis for transplant sib pairs in which GVHD has developed in the recipient (GVHD+). In this study we developed a new linkage approach where sib pairs in which GVHD has not developed in the recipient (GVHD-) are used as well as GVHD+ pairs. This new approach is regarded as a combination of linkage analyses for affected sib pairs and for discordant (affected/unaffected) sib pairs. Thus, four parameters are maximized here to obtain the maximum likelihood. In order to test a null hypothesis (no linkage) against an alternative hypothesis (linkage), a likelihood ratio statistic is calculated, and a computer simulation is performed for the calculation of P-value. A computer simulation showed that the use of GVHD- pairs possibly increases a statistical power of linkage analysis. We also performed a linkage analysis for our reported data of several candidate variants of mHas [Maruya et al. (1998) *Blood* 92:2169-2176]. Our results suggested that a linkage analysis is powerful for detecting a GVHD gene even in a candidate gene approach.

Evidence that Smith-McCort dysplasia and Dyggve-Melchior-Clausen dysplasia are allelic disorders that result from mutations in a gene on the long arm of chromosome 18. *N. Ehtesham¹, R.M. Cantor^{2,3}, L.M. King¹, K. Reinker⁵, B.R. Powell⁶, A. Shanske⁷, S. Unger⁸, D.L. Rimion^{1,2,3,4}, D.H. Cohn^{1,2,4}.* 1) Medical Genetics, Cedars-Sinai Research Institute, Los Angeles, CA; 2) Depts of Human Genetics; 3) Medicine and; 4) Pediatrics, UCLA Sch. of Medicine, Los Angeles, CA; 5) Univ. of Texas Health Sciences Center, San Antonio, TX; 6) Children's Hospital Central California, Madera, CA; 7) Children's Hospital at Montefiore, Albert Einstein College of Medicine, Bronx, NY; 8) Div. of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, Canada.

Smith-McCort dysplasia (SMC) is a rare autosomal recessive osteochondrodysplasia characterized by short limbs and a short-trunk with a barrel-shaped chest. The radiographic phenotype includes platyspondyly, generalized abnormalities of the epiphyses and metaphyses, and a distinctive lacey appearance of the iliac crest. Electron microscopy of chondrocytes demonstrates dilated cisternae of rough endoplasmic reticulum containing granular material. Radiographic and histological features of SMC are identical to Dyggve-Melchior-Clausen syndrome (DMC), a related autosomal recessive osteochondrodysplasia. However, patients with DMC also exhibit mental retardation. We performed a genome-wide scan in a consanguineous SMC family from Guam and found evidence for linkage to a region on chromosome 18q. Analysis of a second smaller SMC family was also consistent with linkage to this region, producing a maximum combined 2-point LOD score of 3.04 at a recombination fraction of zero for the marker at locus D18S450. A 10.7 cM region containing the disease gene was defined by recombination events in the larger family. Furthermore all affected children in that family were homozygous for a subset of marker loci within this region, defining a 1.5 cM interval likely to contain the defective gene. Analysis of three small, unrelated families with DMC provided evidence of linkage to the same region, consistent with the long-standing hypothesis that the two disorders are allelic. Thus the eventual identification of the disease gene is expected to define a new gene important for both skeletal development and brain function.

Genome Scan for QTLs Underlying Bone Size Variation at Ten Refined Skeletal Sites: Genetic Heterogeneity and the Value of the Subdivision of Traits. *Q.Y. Huang, F.H. Xu, H. Shen, H.Y. Deng, T. Conway, Y.J. Liu, Y.Z. Liu, J.L. Li, K.M. Davis, R.R. Recker, H.W. Deng.* Biomed Sci/Osteoporosis Res Ctr, Creighton Univ, Omaha, NE.

Bone size is an important determinant of osteoporotic fractures. To identify QTLs underlying variation in bone size, we conducted a whole-genome linkage scan in 53 pedigrees ascertained through a proband having BMD Z-scores < -1.28 at the hip or spine. Three hundred eighty microsatellite markers with an average spacing of 8.6 cM were genotyped. Lumbar 1 area, lumbar 2 area, lumbar 3 area, lumbar 4 area at the spine, femoral neck area, trochanter area, intertrochanter area at the hip, ultradistal radius area, mid-distal area and one-third distal area at the wrist, were measured by dual energy X-ray absorptiometry (DXA), and adjusted for age, height, weight, and sex. Two-point and multi-point linkage analyses were performed for each skeletal bone size, their composite measures and principal components using variance-components method implemented in the SOLAR package. Three chromosomal regions were identified with significant evidence of linkage (LOD>3.3) to bone size in at least one skeletal site: 1q22 and 10q21, for one-third distal area; 11p15, for lumbar 3 area; and fifteen with suggestive evidence (LOD>1.9), 2p25 and 1p13-21, for lumbar 1 area; 4q22-23, for lumbar 2 area; 7p21, for lumbar 3 area; 20p13, for lumbar 4 area; 2p24 and 7p14-15, for femoral neck area; 5p15 for trochanter area; 14p11 and 19p11-13, for intertrochanter area; 17q23, 2q37 and 9q21, for ultradistal radius area; 11q13-14, 14p11, 18q21, and 20q11-13, for one-third distal area. Our results indicated that the low power of QTLs mapping for principal components and composite measurements may result from genetic heterogeneity of complex traits. Results point to the value of the subdivision of traits to improve the power for detecting linkage.

Autosomal dominant familial calcium pyrophosphate dihydrate deposition disease (CPPDD) is caused by mutation in the transmembrane protein ANKH. *C.J. Williams¹, Y. Zhang², A. Timms², G. Bonavita¹, F. Caeiro³, J. Broxholme², R. Marchegiani³, A. Reginato⁴, R.G.G. Russell⁵, B.P. Wordsworth², A.J. Carr⁶, M.A. Brown^{2,5,6}.* 1) Dept Medicine/Rheumatology, Thomas Jefferson Univ, Philadelphia, PA; 2) Wellcome Trust Centre for Human Genetics, Oxford, U.K; 3) Hospital Privado, Cordoba, Argentina; 4) Division of Rheumatology, University of Medicine and Dentistry of New Jersey, Camden, NJ; 5) Oxford University Institute of Musculoskeletal Research, Oxford, U.K; 6) Nuffield Department of Orthopaedic Surgery, Nuffield Orthopaedic Centre, Oxford, U.K.

Familial autosomal dominant calcium pyrophosphate dihydrate (CPPD) chondrocalcinosis has previously been mapped to chromosome 5p15 in British, French and Argentinian pedigrees (CCAL2 - OMIM 118600). The ANKH gene which encodes a putative inorganic pyrophosphate transport transmembrane protein is encoded in this region. We sequenced all 12 exons and their exon-intron boundaries and 500bp of the promoter region in an Argentinian pedigree with autosomal dominant CPPD chondrocalcinosis. In all, 6 SNPs were identified and 2 insertions in the promoter region. One variant, a C to T transition at 14bp from the start codon, segregated with the disease in the family. Linkage of the mutation in the family was demonstrated with a LOD score of 9.6. This sequence change is predicted to cause a proline to leucine substitution at amino acid position 5. We did not observe this variant in 50 Northern Italian, 52 South American Hispanic, or 100 healthy British Caucasian controls, nor in 100 non-familial British Caucasians with CPPD chondrocalcinosis. Structural prediction programs were used to investigate the ANKH protein. Whilst these confirmed that the ANKH protein is almost certainly a transmembrane protein, the number of predicted transmembrane domains varied between 7 and 12, and agreement between programs as to the predicted orientation and structure was not high. We predict that as loss of function mutations of ANKH cause excess calcium hydroxyapatite deposition, the mutation that we have identified causes gain of ANKH function, raised extracellular inorganic pyrophosphate levels, and hence CPPD chondrocalcinosis.

Confirmation of the mapping of an Intracranial Aneurysm Predisposition Locus to Chr 7. *L.A. Cannon-Albright¹, J. Farnham¹, N.J. Camp¹, S. Neuhausen¹, G. Wood¹, G. O'Neil¹, H. Buswell², J. Tsuruda², D. Parker², J. MacDonald³.*
1) Medical Informatics, University of Utah School of Medicine, Salt Lake City, UT; 2) Radiology, University of Utah School of Medicine, Salt Lake City, UT; 3) Neurosurgery, University of Utah School of Medicine, Salt Lake City, UT.

Onda et al (2001) recently reported a significant linkage to chromosomal region 7q11 in a genomic search using 85 Japanese nuclear families with at least 2 affected sibs (104 sib pairs). In an attempt to replicate this finding, we performed linkage analysis in 12 extended high-risk IA pedigrees from Utah, comprising 44 IA cases. These pedigrees were ascertained from both a Utah genealogy resource linked to Utah death certificates (representing clusters of 2 or more individuals with a cause of death of aneurysm) or were self-ascertained in response to notices of the research study. All first-degree relatives of IA cases were screened with high-resolution MRA to detect aneurysms. Previously diagnosed IAs were confirmed by review of medical records and images. We genotyped 3 markers in the region of the maximum LOD reported by Onda et al (2001), covering a range of approximately 2cM. We performed two-point and multipoint parametric linkage analysis, employing general dominant and recessive models (moderate penetrance and very low sporadic rate). We used 2 diagnostic schemes (confirmed cases only, and all cases--which included 12 IA cases reported by family members, but not yet confirmed). Analyses utilizing the recessive model and including all cases yielded significant confirmation (two-point LOD = 2.18, theta = 0.0, p = 0.002 (D7S2518); multi-point LOD = 1.91, near D7S2518, p = 0.003. Our study is the first to confirm the linkage of the 7p11 locus in IA. This chromosome 7 region contains the elastin gene (ELN). Onda et al (2001) also reported a strong association with IA and a haplotype between the intron-20/intron-23 polymorphism of ELN (p=3.8 X 10⁻⁶). Analysis of additional markers and additional pedigrees, as well as association studies of SNPs in ELN will clarify whether ELN is the IA predisposition gene localized.

Candidate region on chromosome 20 for very-late onset Alzheimer Disease. *K.A.B. Goddard¹, J.M. Olson¹, H. Payami², M. van der Voet³, H. Kuivaniemi³, G. Tromp³.* 1) Epid/Biostat, MetroHlth Med Ctr, Case Western Reserve Univ, Cleveland, OH; 2) Neurology, Oregon Health Sciences Univ, Portland, OR; 3) Ctr Mol Med & Genetics, Wayne State Univ, Detroit, MI.

Recently, we reported a novel candidate region on chromosome 20 using a covariate-based affected sib-pair (ASP) linkage method to analyze 272 ASPs recruited as part of the NIMH Alzheimer Disease (AD) Genetics Initiative (Olson et al., *Am J Hum Genet*, 2002). ASPs linked to this region appear to be those with the oldest current age and, to a lesser extent, those with ApoE2 alleles. The 15 cM candidate region between D20S186 and D20S200 contains one particularly interesting candidate gene, cystatin C (CST3), which is located 1 cM from D20S200. CST3 is associated with late-onset AD, and co-deposits with amyloid- β in the brains of AD patients. We initiated a case-control study to further evaluate this candidate region. The cases include 49 NIMH ASPs (89 subjects) in the top 15% for mean current age, who are most likely linked to the candidate region. The controls are 129 healthy subjects recruited as part of a longitudinal study at OHSU, who have undergone extensive neuropsychological testing, and who met strict criteria for lack of dementia at study entry. The groups have comparable ages of 82-105 yrs for the cases (mean of 92 yrs), and 86-103 yrs for the controls (mean of 91 yrs). We examined microsatellite markers in the region and a CST3 haplotype of three SNPs in complete disequilibrium, including one that encodes an Ala/Thr polymorphism, for evidence of association with AD. The strongest evidence of association was found with D20S200 (c2 test; $p < 0.0001$). In addition, we constructed haplotypes for the 49 NIMH ASPs and their unaffected siblings, and identified a group of related haplotypes that are shared identical-by-descent (IBD) by ASPs in 61% of the families. Thus, we have identified a genetically homogeneous subset of very-late onset AD ASPs that share a group of related haplotypes IBD on chromosome 20, providing strong evidence of a susceptibility locus in this region. We continue to genotype additional markers to narrow the candidate region, and to further evaluate CST3 as a candidate locus.

Clinical and genetic studies in hereditary spastic paraplegia with thin corpus callosum. *C. Casali¹, E.M. Valente², E. Bertini³, G. Montagna³, C. Criscuolo⁴, G. De Michele⁴, M. Damiano¹, A. Pierallini⁶, F. Brancati², V. Sarano⁴, A. Rossi⁵, A. Tessa³, F. Cricchi¹, M. Muglia⁷, M. Carella⁸, G.A. Amabile¹, G. Nappi⁹, A. Filla⁴, B. Dallapiccola², F.M. Santorelli^{1,3}.* 1) Dept. Neurology, ORL & Rehab, La Sapienza Univ, Rome, Italy; 2) CSS-Mendel Institute, Rome; 3) Molecular Medicine and Department of Neurosciences, IRCCS-Bambino Ges, Rome; 4) Department of Neurological Sciences, Federico II University, Naples; 5) Institute of Neurological Sciences, University of Siena; 6) Department of Neurological Sciences, La Sapienza University, Rome; 7) Institute of Experimental Medicine and Biotechnology, CNR, Mangone (CS); 8) Telethon Institute of Genetics and Medicine (TIGEM), Naples; 9) Molecular Neurobiology, IRCCS-C. Mondino, Pavia.

Hereditary spastic paraplegias (HSP) are a group of neurodegenerative disorders characterized by progressive and prominent spasticity of the lower limbs. Autosomal dominant, autosomal recessive, and X-linked forms have been described. A complicated form of recessive HSP with thin corpus callosum (TCC) was first described in Japan, and most Japanese families studied showed linkage to chromosome 15q13-15. A recessive HSP locus (SPG11) has been mapped to chromosome 15q13-15 in Italian and North American families with and without TCC; it overlaps with the region identified in the Japanese families. We investigated 18 affected and 30 healthy individuals from 12 unrelated Italian families with recessive HSP-TCC. Clinical, neurophysiological, and neuroradiological studies were undertaken. Linkage to 15q13-15 could neither be confirmed nor excluded with certainty in six families. Five families showed evidence for linkage, identifying a 19.9 cM region between markers D15S1007 and D15S978 encompassing the SPG11 interval. In one family, linkage could be firmly excluded, confirming genetic heterogeneity. Our findings suggest that HSP-TCC is more frequent in Italy than was previously believed. The phenotype consists of pyramidal tract involvement confined to lower limbs with subsequent diffusion to upper limbs, and progressive cognitive impairment. While a major locus for HSP-TCC exists on chromosome 15q13-15, there is evidence for at least one other locus.

Refinement of PARK7 critical region on chromosome 1p36. *V. Bonifati^{1,2}, O. Schaap¹, J.M van Baren¹, J. van Dongen¹, P. Rizzu¹, C.M van Duijn³, G. Meco², B.A. Oostra¹, P. Heutink¹.* 1) Clinical Genetics, Erasmus University, Rotterdam, The Netherlands; 2) Department of Neurological Sciences, La Sapienza University, Rome, Italy; 3) Department of Epidemiology and Biostatistics, Erasmus University, Rotterdam, The Netherlands.

Three loci (PARK2, PARK6, and PARK7) have been identified for autosomal recessive, early-onset parkinsonism (AREP). We mapped the PARK7 locus in a large Dutch consanguineous family and confirmed these findings in an Italian consanguineous family. Initial haplotype analyses delineated in both these PARK7-linked families a critical region of about 16 cM flanked by marker D1S243 (telomeric) and D1S244 (centromeric). In the current physical maps of the human genome the PARK7 region spans about nine megabases, including many gaps between different contigs. The order of the contigs is still provisional and the internal assembly for some contigs has low reliability. The PARK7 region was saturated by typing all microsatellite markers available. For some contigs we also genotyped SNPs present in the public and Celera databases. Moreover, we performed extensive recombination analyses using new, polymorphic short tandem repeats that we identified by scanning the genomic sequence using software developed in our bioinformatic core. We identified several non-consanguineous families consistent with linkage to the PARK7 region, however, due to the small family size and locus heterogeneity in AREP, we consider these additional families as possibly linked to PARK7 locus. Therefore, in the fine-mapping phase we only used the two PARK7-definitely linked families. A single-contig-based work strategy has allowed us to reduce the critical region to 5.5 megabases flanked by markers Rep26 and Rep33X, excluding a large number of candidate genes. The refined PARK7 minimal critical region contains around 90 genes and EST clusters, including many predicted or confirmed genes coding for proteins of unknown function. This work has considerably reduced the PARK7 critical region. Cloning the defective gene at the PARK7 locus will allow to evaluate its frequency of involvement in AREP, and to accurately define the associated phenotype.

Microsatellite marker-based genome-wide association studies for Parkinson's disease by using the pooled DNA method. *Y. Momose^{1, 2}, M. Murata², G. Tamiya³, T. Ikuta³, A. Oka³, K. Okamoto³, K. Kobayashi¹, M. Tachikawa¹, Y. Yoshikawa³, M. Yamamoto⁴, N. Hattori⁵, Y. Mizuno⁵, I. Kanazawa⁶, H. Inoko³, T. Toda¹.* 1) Div Functional Genomics, Dept Post-Genomics and Diseases, Osaka Univ Grad Sch Med, Osaka, Japan; 2) Dept Neurology, Grad Sch Med, Univ Tokyo, Tokyo, Japan; 3) Dept Molecular Life Science II, Sch Med, Tokai Univ, Kanagawa, Japan; 4) Dept Neurology, Kanagawa Pref Central Hosp, Kagawa, Japan; 5) Dept Neurology, Sch Med, Juntendo Univ, Tokyo, Japan; 6) National Inst Neuroscience, NCNP, Tokyo, Japan.

Parkinson's disease (PD) is a complex disorder, with multiple genetic and environmental factors influencing disease risk. Although several causal genes for Mendelian-inherited PD have recently been identified, certain genetic factors associated with pathogenesis of idiopathic PD have not yet been clarified. To identify susceptibility genes for PD, we started microsatellite marker-based genome-wide association studies by using the pooled DNA method. For initial screening, we made a pooled DNA each from 124 patients with PD and 124 normal controls and started association studies with 30,000 polymorphic microsatellite markers that are arranged at intervals of approximately 100kb. We analyzed PCR products with the GeneScan™ software and compared the pattern of PCR products of pooled DNAs from patients with PD and controls by the software PickPeak exploited by Ishibashi et al. We have finished to check approximately 1600 markers and found some significant associations on chromosome 1 where other studies showed a linkage. Genes in linkage disequilibrium with these markers may be associated with pathogenesis of PD. We will continue the genome-wide association studies to find the susceptibility genes for PD.

Autosomal recessive cerebellar agenesis maps to chromosome 22q11 in an Israeli Arab family. *L. Levin, N. Magal, L. Basel-Vanagaite, G. Halpern, M. Shohat.* Dept Medical Genetics, Rabin Medical Ctr, Petah Tikva, Israel.

Cerebellar agenesis, the absence of or only partial development of the cerebellum, can occur alone or as part of several syndromes including Joubert syndrome, which has been mapped in some families to 9q34.3, Lissencephaly (7q22), Meckel Syndrome (17q22-23), Rutledge Lethal Multiple Congenital Anomaly (11q12-q13), Hydroletharus Syndrome (11q23-q25), Spastic Ataxia, Charlevoix-Saguenay Type (13q12), Isolated Non-Ketotic Hyperglycinemia Type 1 (9p22), and Acrocallosal Syndrome (13p13.3-p11.2). These are all autosomal recessive disorders, with symptomatology similar to that of non-syndromic cerebellar agenesis. The symptoms and signs common to all include hypotonia, ataxia, nystagmus and developmental retardation.

We have recently seen a consanguineous family where the parents are first cousins and have six children. Three are normal, and three, all girls, have cerebellar agenesis with a typical clinical picture with no specific additional findings. We performed a linkage study in order to map the disease-causing gene in our family. We excluded linkage to each of the genes for the above-mentioned syndromes associated with cerebellar agenesis. We then performed a whole genome screening, which revealed linkage to D22S315 (chromosome 22q11) (max $Z = 2.7$, $q = 0.01$). The size of the original candidate locus was approximately 22Mb. We then carried out further linkage studies using polymorphic markers, and were able to reduce the size of the locus to approximately 5Mb. Mapping the gene in this family will provide a tool for prenatal diagnosis and will enable us to identify carriers within the small village where the family lives and where there are several other similarly consanguineous families. The discovery of the gene will further enhance our understanding of brain development.

Linkage analysis in an Italian family with autosomal recessive Hereditary Spastic Paraplegia. A. Magariello¹, A.L. Gabriele¹, R. Mazzei¹, F.L. Conforti¹, A. Patitucci¹, T. Sprovieri¹, L. Mangone², L. Morgante³, A. Epifanio³, P. La Spina³, M. Muglia¹. 1) Institutes of Neurological Sciences, National Research Council, Mangone, CS, Italy; 2) Institute of Neurology, School of Medicine, Catanzaro, Italy; 3) Neurology Clinic, University of Messina, Messina, Italy.

Hereditary spastic paraplegia (HSP) is a heterogeneous group of disorders of the motor system, characterized clinically by slowly progressive lower extremity spasticity and weakness, in which dominant, recessive and X-linked forms have been described. While autosomal dominant HSP has been extensively studied, autosomal recessive HSP is less well known and it is considered a rare form. Until now, five families (four Tunisian and one Algerian) with recessive HSP linked to chromosome 8p11-8q13 have been published. The HSP locus was mapped in a region of 32.2 cM flanked by the markers PLAT and D8S279. In the current study, we report a small Italian (AR)HSP family linked to chromosome 8. Using additional markers located between PLAT and D8S279, we were able to refine the HSP region. Negative lod scores were obtained in the two-point linkage analysis by using STR markers on chromosome 15 and 16, whereas positive lod scores were obtained for D8S509, D8S1828, D8S285, D8S1102, D8S1723, D8S260, D8S1840 and D8S279 with a maximum lod score of 1.46 at D8S260 marker. The two affected siblings were homozygous for the markers D8S1102, D8S1723 and D8S260. According to the Genethon map, haplotype reconstruction revealed that the patients shared a common 8.2 cM region of homozygosity encompassing the D8S1102, D8S1723 and D8S260 markers. Based on recombination events in our Italian family, we could map the (AR)HSP gene between D8S285 and D8S1840, thus refining the HSP region by approximately 20 cM, from 32.2 to 12cM.

Program Nr: 1535 from 2002 ASHG Annual Meeting

Genome-wide scan in 115 Attention Deficit Hyperactivity Disorder (ADHD) Affected Sibling Pair families. *M.N. Ogdie¹, I.L. Macphie², S.E. Fisher², C. Franks², S. Minassian¹, J.J. McCracken⁴, J.T. McGough³, A.P. Monaco², S.F. Nelson¹, S. Smalley³.* 1) Human Genetics, UCLA, Los Angeles, CA; 2) Wellcome Trust Centre for Human Genetics, Oxford University, Oxford, UK; 3) Dept. of Psychiatry, UCLA, Los Angeles, CA; 4) UCLA Neuropsychiatric Institute, Los Angeles, CA.

Attention Deficit Hyperactivity Disorder (ADHD) is a common, highly heritable neurobehavioral disorder with childhood-onset characterized by hyperactivity, impulsivity, and inattention. As part of an ongoing study into the genetic etiology of ADHD, we performed a genome scan in 115 nuclear families comprised of 479 individuals and 166 Affected Sibling Pairs (ASPs). This cohort constitutes a replication set for which the previous results have been reported (S.E. Fisher et al., 2002). Individuals were genotyped with a set of polymorphic microsatellite markers that define a ~10cM map across the entire genome. The current linkage analysis attempts to replicate the initial evidence for linkage, including multipoint LOD scores exceeding 1.5 for regions on 5p12, 10q26, 12q23 and 16p13, as well as identify additional candidate regions. We are conducting multipoint nonparametric analyses in MERLIN v 1.0.

Confirmation and refinement of the SPG5A locus for pure autosomal recessive hereditary spastic paraplegia. S.

Jeffery¹, P. Wilkinson^{1,2}, T.T. Warner², A.H. Crosby¹. 1) Dept Medical Genetics, St George's Medical Sch, London, England; 2) Department of Clinical Neurosciences, Royal Free and University College Medical School, London, UK.

The term hereditary spastic paraparesis (HSP) is used to describe a group of clinically and genetically heterogeneous neurodegenerative disorders in which the predominant feature is progressive spasticity of the lower limbs. The phenotype is generally categorised as 'pure' when symptoms and signs are confined to those of a spastic paraparesis, or 'complicated' if there are additional neurological or other clinical features. The SPG5A locus, a 32cM region spanning the centromeric area of chromosome 8, was the first pure autosomal recessive form of HSP in which linkage was established using a small group of Tunisian families. Since then there have been no further reports of conclusive linkage to this locus. We have identified a large consanguineous English family with a similar pure HSP phenotype. Homozygosity mapping using microsatellite markers from chromosome 8 confirmed linkage to the SPG5A locus with a maximum multi-point LOD score of 4.84 between markers D8S1833 and D8S285. This has established that this form of HSP is not confined to the Tunisian population and points towards a possible common phenotype for SPG5A linked HSP. Loss of homozygosity occurred at markers D8S1051 and D8S1807 defining these as the flanking markers and refining the SPG5A locus to a 23cM region on the long arm of chromosome 8. Direct sequencing of the putative LOC157677 gene in affected individuals, whose predicted protein product is an AAA protein with a high degree of homology to the proteasome 26S subunit, has excluded this as a candidate gene from a causative role in the pathogenesis of this disease.

Association between SNPs at the PARK3 locus and Onset Age of Parkinson Disease. *S. Karamohamed, A. Herbert, A.L. DeStefano, C.M. Shoemaker, J.B. Wilk, K.M. Sullivan, G. Xu, J.S. Fink, R.H. Myers and GenePD study.* Neurology, Boston Univ Sch Medicine, Boston, MA.

Parkinsons disease (PD) is a common neurodegenerative disorder characterized by pathological degeneration of the substantia nigra, loss of dopamineergic neurons, and a symptom triad of rigidity, resting tremor and bradykinesia. Although evidence for potential susceptibility loci for PD on several chromosomes has been obtained by genome-wide scans no gene contributing to idiopathic PD has been mapped. In this study, a region on chromosome 2p14-p12 showing linkage to age at onset of PD, which harbors several candidate genes, was fine mapped using microsatellite and single nucleotide polymorphisms (SNPs) that were available from the NCBI database. MALDI TOF mass spectroscopy was used to evaluate SNPs either within or very near candidate genes spanning about 2 Mb. A total of 867 patients with PD, including more than 250 PD affected sibling pairs, and 249 controls were examined in this study. Association between SNPs and onset age of PD was assessed using regression analysis. Several SNPs close to potential candidate genes produced statistically significant association, including one (G/T, $P=0.006$) associated with about 8 years difference in age-onset. In addition, another SNP (G/A, $P=0.04$) located approximately 110 kb downstream of the region was associated with an approximately 7 years difference in age-onset between PD patients who do and do not possess the rare allele. This region is being further evaluated using additional SNPs in order to fine map the area.

Hereditary sensory neuropathy with cough and gastroesophageal reflux linked to chromosome 3. *C. Kok¹, M.L. Kennerson^{1,2}, P.J. Spring³, A.J. Ing⁴, J.D. Pollard³, G.A. Nicholson^{1,2}.* 1) Neurobiology, ANZAC Research Institute, Sydney, NSW, Australia; 2) Molecular Medicine Laboratory, Concord Hospital, Concord, NSW, Australia; 3) Institute of Clinical Neurosciences, Royal Prince Alfred Hospital & University of Sydney, NSW, Australia; 4) Department of Respiratory Medicine, Concord Hospital, NSW, Australia.

Hereditary sensory neuropathy type 1 is a group of dominantly inherited degenerative disorders of the peripheral nerves. A new form of HSN 1, HSN with gastroesophageal reflux (GOR) and cough has only recently been recognised by Pollard and colleagues. Initial clinical and linkage studies excluding known hereditary neuropathy and GOR loci have been described by Spring et al and Nicholson et al (in press, *Muscle and Nerve*, Abstracts of Xth Congress on Neuromuscular Diseases). The onset of the cough is between the second and the fourth decades with repeated throat clearing, often induced by lying flat. Later patients can suffer from paroxysms of cough, which occurs spontaneously, after eating, or after inhalation of strong odours and/or perfumes. 24 Hour oesophageal pH monitoring, shows that the cough is temporally related to acid reflux in the distal and proximal oesophagus. Sensory loss, mainly affecting the feet and legs, occurs later. Neurophysiological studies show an axonal neuropathy. To map the chromosomal location of the gene mutation causing the disorder, 26 members of a large family were recruited including 4 affected females and 4 affected males. A genome wide screen using 383 microsatellite markers at 10 cM intervals was undertaken. Two point linkage analysis has shown the most likely location for the gene causing HSN with cough and GOR lies on chromosome 3 ($Z_{max}= 4.17$ at $\theta=0.0$). Further studies are continuing to refine the genetic interval and to carry out positional cloning and candidate gene screening.

A GABRA6 Coding Variant is associated with the NEO-PI Domain Neuroticism, a Risk Factor for Depression.
S.M. Villafuerte¹, S. Sen², R.M. Nesse^{3,4}, J. Hopcian⁷, L. Gleiberman⁵, A.B. Weder⁵, M. Burmeister^{1,2,3,6}. 1) Mental Health Research Inst, University of Michigan, Ann Arbor, MI; 2) Neuroscience Program, University of Michigan, Ann Arbor, MI; 3) Department of Psychiatry, University of Michigan, Ann Arbor, MI; 4) Department of Psychology and Institute for Social Research, University of Michigan, Ann Arbor, MI; 5) Department of Internal Medicine, University of Michigan, Ann Arbor, MI; 6) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 7) Kalamazoo College, Kalamazoo MI.

Psychiatric disorders are considered to be influenced by multiple genes and the environment. An increased interest has arisen in the study of personality traits as risk factors that are correlated with depression and/or severity of depression. The strong genetic basis of such traits increases the power to detect genes that confer vulnerability to depression. As has been proposed, high scorers of Neuroticism, measured by the NEO Personality Inventory (NEO-PI), have shown a significant and consistent association with depression. The Gamma-aminobutyric acid (GABA) system has been extensively studied in psychiatric disorders such as alcoholism, anxiety and most recently in unipolar depression where cortical GABA levels are reduced. Furthermore, evidence for linkage to bipolar disorder has been reported by several independent studies to chromosome 5q. These lines of evidence prompted us to investigate a coding SNP, Pro385Ser, located in the second intracellular domain of the GABA A6 receptor (GABRA6) subunit adjacent to a putative phosphorylation site, in 391 subjects of a large community sample (Tecumseh sample) who completed the NEO-PI questionnaire. The more common, Pro-Pro genotype was associated with significantly higher mean Neuroticism scores ($p = 0.007$). Within the Neuroticism domain, the facets Anxiety, Depression, Hostility, and Vulnerability were associated with GABRA6 Pro-Pro genotype ($p = 0.026$, $p = 0.014$, $p = 0.011$ and $p = 0.013$ respectively). Our results suggest that GABRA6 should be investigated as a candidate gene for depression and bipolar disorder.

A strong association of the *XmnI* promoter polymorphism of the gamma globin gene (HBG2) to Alzheimers Disease in the NIMH sibling dataset. Perry, R.T., Hill, W.D., Wiener, H., Harrell, L., Gearhart, D.A., Kutlar, F., Kutlar, A., Blacker D., Tanzi R.E., McInnis M.G., Bassett S.S., Go, R.C.P. R.T. Perry¹, W.D. Hill^{2,3}, H. Wiener¹, L. Harrell¹, D.A. Gearhart^{2,3}, F. Kutlar², A. Kutlar², D. Blacker⁴, R.E. Tanzi⁴, M.G. McInnis⁵, S.S. Bassett⁵, R.C.P. Go¹.
1) Univ. Alabama-Birmingham, Birmingham, AL; 2) Medical College of Georgia, Augusta, GA; 3) VAMC, Augusta, GA; 4) Massachusetts General Hospital, Boston, MA; 5) Johns Hopkins Univ., Baltimore, MD.

Proteins that interact with b-amyloid peptides (Ab) may mediate Ab toxicity or deposition and thus contribute to the pathogenesis of Alzheimer's disease (AD). While using a phage display of a human brain cDNA library to identify proteins that interact with Ab, the gamma (G)-globin subunit of fetal hemoglobin (Hb F) was identified and shown to bind to Ab, an interaction later confirmed by surface plasmon resonance. Later, we determined Ab 1-42 permissively binds to the oxidized metHb forms of both adult and Hb F but not to the normal reduced forms, and that adult metHb binds with significantly higher affinity than the fetal form. Free Hb, released from damaged RBCs, is normally oxidized in the plasma to metHb. We hypothesize that this metHb can interact with free plasma Ab and release the heme group. Free heme readily enters endothelial cells and is a potent source of reactive oxygen species that can cause damage to the cells - similar to AD vascularpathology. We used family-based association testing to look at the *XmnI* polymorphism (C®T) at bp -158 in the promoter region of the G-globin gene (HBG2) in the NIMH sibling dataset (n=481 familes). In the presence of various stressors this *XmnI* SNP causes an increase in Hb F expression in adults. We found a significant protective association of this SNP to AD in families with at least two affected and one unaffected siblings (p=0.005), with an age of onset > 50 years (p=0.010) and > 70 years (p=0.013), and families not homozygous for the APOE4 allele (p=0.015). Hb F may be less toxic than adult Hb in its interaction with Ab and a higher level of G-globin expression may be relatively protective when there is a high level of vascular Ab.

Linkage mapping of a novel susceptibility locus for moyamoya disease to chromosome 8q22. *K. Sakurai¹, J. Nakayama¹, H. Ikeda², T. Yoshimoto², K. Ikezaki³, M. Fukut³, T. Arinami¹.* 1) Medical Genetics, Basic Medical Sciences, Tsukuba, Ibaraki, Japan; 2) Department of Neurosurgery, Tohoku University Graduate School of Medicine, Sendai, Iwate, Japan; 3) Department of Neurosurgery, Tohoku University Graduate School of Medicine, Kyushu University, Fukuoka, Fukuoka, Japan.

Moyamoya disease (MIM 252350) is characterized by stenosis or occlusion of the terminal portions of the bilateral internal carotid arteries and by abnormal vascular networks at the base of the brain. There is a high incidence of moyamoya disease in Asia, especially in Japan. Although most of the cases appear to be sporadic, within 10% occur as familial cases. Multifactorial inheritance is estimated with lambda s greater than 40. Thus the genetic factor for moyamoya disease has been expected and there have been several linkage studies of families with moyamoya disease, and indicated that susceptibility loci for the disease are located on chromosomes 3p, 6q, and 17q. We searched for loci linked to the disease by a genome-wide screening on 12 nuclear families with moyamoya disease-affected sib-pairs (46 members, 12 sib-pairs, 2 families lacking a paternal sample), using 428 microsatellite markers. We used the nonparametric linkage (NPL) score (Zall) and MLS for multipoint analysis and Zlr and nonparametric LOD statistics for single point analysis. Transmission disequilibrium test (TDT) was done with the SIB-PAIR program. We found significant evidence for linkage to 8q22 [maximum LOD score (MLS) of 3.6] and suggestive evidence for linkage to 12p13 (MLS = 2.3). The present study provides a novel locus for moyamoya diseases.

Catatonic schizophrenia: confirmation of linkage to chromosome 15 and further evidence for genetic

heterogeneity. A. Reis^{1,2}, F. Ruschendorf^{2,3}, D. Seelow^{2,4}, A.B. Ekici^{1,2}, G. Stober⁵. 1) Inst. of Human Genetics, University of Erlangen-Nuremberg, 91054 Erlangen, Germany; 2) Gene Mapping Center, Max-Delbruck-Center, Berlin; 3) Inst. of Medical Biometry, Informatics and Epidemiology, University of Bonn; 4) Fachbereich Biologie, Chemie, Pharmazie, Free University Berlin; 5) Dept. of Psychiatry and Psychotherapy, University of Wurzburg.

We earlier reported on significant evidence for linkage on chromosome 15q15 in periodic catatonia, a sub-phenotype of the schizophrenic psychoses. The disorder is characterized by qualitative hyperkinetic and akinetic psychomotor disturbances through acute psychotic episodes, and debilitating symptoms in the long term with psychomotor weakness, grimacing facial movements, and apathy. Here, we confirm mapping of a major gene locus on chromosome 15q15 in a second genome scan in a new set of four multiplex families. Non-parametric multipoint linkage analyses identified a broad region with a maximum peak of $Z_{all} = 3.91$ ($p = 0.0063$) and $Z_{lr} = 3.04$ at D15S1234 ($p = 0.0013$), satisfying conventional criteria for confirmed linkage. Parametric affected-only analyses gave maximum HLOD score of 1.65 (D15S1234) with an estimated 47% of families linked. Analysis of individual families showed that one large family showed linkage while two other could be clearly excluded, confirming genetic heterogeneity. No other locus reached suggestive levels of significance. Haplotype analysis on chromosome 15 in this and previously linked families placed the susceptibility region to a 11 cM interval between marker D15S1042 and D15S659. Periodic catatonia is the first sub-phenotype of the schizophrenic psychoses with confirmed linkage despite existence of considerable genetic heterogeneity.

Family-based and case-control studies identify BDNF as a risk locus for bipolar disorder. *P. Sklar^{1,2}, J. Smoller¹, M. Freedman¹, M. Daly², A. Tahl², MG. McInnis³, P. Bennett⁴, Y-M. Lim⁵, G. Kirov⁶, I. Jones⁴, M. Owen⁶, J. Rosenbaum¹, G. Sachs¹, N. Craddock⁴, JR. DePaulo³, ES. Lander².* 1) Psychiatry, Harvard Medical School, Boston, MA; 2) Whitehead Institute Genome Center, Cambridge, MA; 3) Johns Hopkins University, Baltimore, MD; 4) University of Birmingham, Birmingham, UK; 5) Columbia University, NY, NY; 6) University of Wales, Cardiff, UK.

Previous data has identified an allele of the gene BDNF as a risk factor for bipolar disorder in a sample of 136 proband-parent trios. Excess transmission of Val66Met SNP located in the proBDNF protein was detected (T/U, 53/34, $p=0.042$). We now report replication samples that provide independent confirmation of the association between this SNP and bipolar disorder. The first replication sample consisted of 197 parent-proband trios (NIMH samples). Genotyping of Val66Met reveals replication of the original association between Val66 and bipolar disorder with a T/U ratio of 75/56, $p=0.048$. Genotyping in an additional 145 parent-proband trios from the UK demonstrated a trend in the same direction (T/U=38/32, $p=0.17$). In a case-control study of 122 bipolar patients and 122 controls the Val allele was more frequent as expected (Val allele=81.4% cases, 77.9% controls). A genomic control analysis of 37 randomly distributed, unlinked markers revealed no systematic stratification between the cases and the controls. A pooled P value of 0.022 for the family-based and case-control replication samples was obtained by calculating the expected mean and variance of the number of risk alleles found in cases given the number of samples analysed. Under a multiplicative model, the transmission ratio and the odds ratio are estimators of the genotypic relative risk. A pooled value was obtained for all samples of 1.33. In summary, we present data from 600 bipolar probands indicating that the Val66 allele is a risk allele for bipolar disorder. These data are supported by haplotype analyses identifying an undertransmitted haplotype uniquely marked by the rare Met66 allele in all patient samples studied that may be protective for bipolar disorder.

A fifth locus implicated in Autosomal Dominant Hypercholesterolemia. *D. Allard*¹, *M. Abifadel*^{1,2}, *JP. Rabès*^{1,3}, *L. Villéger*¹, *M. Varret*¹, *A. Derré*¹, *C. Junien*^{1,3}, *C. Boileau*^{1,3}. 1) INSERM UR383, Necker-Enfants Malades Hospital, Paris, France; 2) Saint-Joseph University, Beirut, Lebanon; 3) Ambroise Paré Hospital, Paris, France.

Autosomal Dominant Hypercholesterolemia (ADH) is one of the most common hereditary diseases characterized by a selective increase of LDL particles, giving rise to premature mortality from cardiovascular complications. Most of the cases of ADH are caused by mutations in the Low Density Lipoprotein Receptor gene (LDLR) or in the gene encoding its ligand: apolipoprotein B (APOB). On going work in our laboratory has shown that mutations in at least two other genes (HCHOLA3 and HCHOLA4) also account for ADH. By linkage analysis, we excluded the involvement of the APOB and LDLR genes in a new large French pedigree (HC92). HC92 comprises three generations. Among the 35 family members who gave informed consent and were investigated, 15 are affected. We tested 8 markers for the HCHOLA3 region and 3 markers for the HCHOLA4 region. No common haplotype segregation with the disease was found in these two genomic regions. We concluded that linkage was excluded between the disease and both these loci. Consequently, we hypothesize that the ADH phenotype of this pedigree could be due to another new locus. In conclusion, our results show that the ADH phenotype is far more heterogeneous than previously assumed and that mutations in 5 genes are involved.

A Promoter Polymorphism of 5-Lipoxygenase is Associated with Carotid Atherosclerosis in the Human

Population. *H. Allayee*¹, *J.H. Dwyer*², *J. Fan*², *K.M. Dwyer*², *R.A. Mar*¹, *A.J. Lusis*³, *M. Mehrabian*³. 1) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA 90095; 2) Department of Preventive Medicine, USC Keck School of Medicine, Los Angeles, CA 90033; 3) Department of Medicine, David Geffen School of Medicine at UCLA, Los Angeles, CA 90095.

Coronary artery disease (CAD) is the most common cause of death in Western societies and develops as a result of the complex interaction between genetic and environmental factors. Using a knockout mouse model, we previously demonstrated that 5-lipoxygenase (5-LO) confers dramatic resistance to atherosclerotic lesion formation and decreases fasting plasma insulin, even in the presence of highly elevated cholesterol levels. To test whether 5-LO is associated with atherosclerosis and insulin levels in the human population, we genotyped a promoter polymorphism, consisting of a variable number of tandem Sp1/Egr-1 binding sites, in 460 individuals phenotyped for carotid intima-media thickness (IMT). The results demonstrate that individuals who are homozygous for the deletion alleles of the polymorphism have significantly higher IMT ($.740 \pm .122\text{mm}$ vs. $.650 \pm .093\text{mm}$; $P < .0003$) than those individuals with genotypes of either wildtype or addition alleles. These results remained statistically significant ($P < .04$) even after adjustment for multiple risk factors, including age, lipid levels, blood pressure, and medication. Furthermore, the same individuals with deletion alleles also exhibited significantly higher ($P < .0008$) fasting plasma insulin levels. These findings are consistent with those observed in the mouse and demonstrate that genetic variation in the 5-LO gene is associated with surrogate markers of CAD in humans as well. Importantly, the effect on IMT is only partially mediated by conventional biologic risk factors, which suggests that 5-LO is a strong risk factor for atherosclerosis. Additional studies with other mouse models and human populations will be required to replicate these findings and may help to determine the functional basis for this association.

Discovery of genetic markers for myocardial infarction risk. *B. Jordan¹, K.L. Lunetta¹, M.A. Varlaro¹, L. Yan², P.A. Jordan¹, F. Kelley¹, F. Lysholm², R. Sanders², J. Dunker², S. Toth², K.G. Ardlie¹.* 1) Genomics Collaborative, Inc., Cambridge, MA; 2) Pyrosequencing, Inc., Westborough, MA.

Establishing a genetic risk profile for myocardial infarction (MI) could be a valuable tool in prescribing preventative treatment tailored to individual patients. Many genes in different pathways are likely to contribute to risk for this complex trait. We chose to investigate genes in the renin-angiotensin-aldosterone system (RAAS) because they play a key role in regulating blood pressure, which in turn affects cardiovascular disease risk. The RAAS pathway has also been implicated in heart failure, MI, and ventricular remodeling after MI. Previous studies of the association between RAAS gene polymorphisms and MI risk have had mixed results, and have typically been assessed on small sample populations, so further study with a larger sample size is warranted. We investigated 12 single nucleotide polymorphisms (SNPs) in three RAAS genes based on initial findings from an unpublished Eureka Medical study: angiotensinogen (AGT), angiotensin converting enzyme (ACE), and angiotensin II receptor type 1 (AGTR1) in a large sample of US and Polish Caucasians. We genotyped 693 non-diabetic patients who had suffered an MI (370 of which also have hypertension), 396 patients with type 2 diabetes and an MI, 658 patients with hypertension but no MI, and 659 healthy controls. We tested individual SNPs and haplotypes across each gene for association with MI risk and other outcomes. No single SNP was significantly associated with MI risk after correction for multiple tests, although two AGTR1 SNPs were significant predictors of MI among hypertensives at the nominal .05 level. In addition, haplotypes for all three genes showed suggestive evidence for association with MI risk among hypertensives.

A high-throughput SNP typing system for genome-wide association studies in patients with myocardial infarction. *Y. Ohnishi, T. Tanaka, K. Ozaki, A. Sekine, Y. Nakamura.* SNP Research Ctr, RIKEN, Tokyo, Japan.

SNPs are useful markers for identifying genes responsible for and/or associated with common diseases and for directing personalized medical care. Furthermore, because they are so frequent in the genome and can be genotyped quite easily, SNPs can serve as markers for a whole genome association study. However, one of the most difficult issues to be solved for the whole-genome association study using SNPs is reduction of the amount of genomic DNA for genotyping. The presently-available technologies require too large quantity of genomic DNA to be practical. To overcome this problem, we combined the Invader assay with multiplex PCR performed in the presence of Taq polymerase antibody as well as a novel 384-well card system that reduced a reaction volume. We amplified 96 genomic DNA fragments simultaneously in a single tube, and analyzed each SNP by the Invader assay. Since we used 10-20 nanogram of genomic DNA as a template for multiplex PCR, the amount needed to assay one SNP was only 0.1-0.2 nanogram. Our results strongly indicate the feasibility of undertaking genome-wide association studies using blood samples of only 5-10 milliliter. Using these technologies, which allow us to perform as many as 450,000 typings in one day, we had already screened 60,000 SNPs at present. As a result, we had identified some loci where significant association ($p < 10E-4$) was observed. We made a dense SNP map in those loci, and then myocardial infarction related genes were identified. Now we perform the functional analysis about these genes.

Linkage analysis between DNA markers on human chromosome 13q and factor VII levels in families of patients undergoing coronary arteriography. *S.H. Jee^{1,3}, J.E. Lee², Y. Jang³, T.H. Beaty⁴*. 1) Graduate School of Health Sci., Yonsei University, Seoul, Seoul, South Korea; 2) DNA Link, Inc, Seoul, Korea; 3) Cardiovascular Genome Center, Seoul, Korea; 4) Johns Hopkins University, MD, USA.

An elevated plasma level of factor VII is a risk factor for coronary artery disease. However, in general, the genetic studies of factor VII have identified alleles associated with low levels and not high levels of factor VII activity, and R353Q on 13q34 is a good example. The aim of this study was to determine whether 13q region contains specific loci that affect elevated plasma factor VII activity or not. Maximum likelihood methods were used to fit several genetic and non-genetic models of inheritance to these data to determine whether an unobserved Mendelian major gene could explain the familial distribution of factor VII in 661 family members of 112 probands who underwent elective coronary arteriography. DNA polymorphisms, R353Q, were determined. A genomic scan to detect loci related to factor VII was conducted in 29 extended pedigree (126 individuals). We selected 6 polymorphic microsatellite markers (D13S1265, D13S1315, D13S261, D13S285, D13S1295, and D13S293) on chromosome 13q. Factor VII activities were adjusted for age, gender, body mass index, smoking, alcohol consumption, menopause status, and triglycerides prior to this segregation analysis. Adjusted factor VII activities showed strong familial aggregation with an estimated parent-offspring correlation of 0.34, sibling correlation of 0.36 and a smaller spouse correlation of 0.16. Mendelian single-locus models with either two or three underlying genotypic distributions of factor VII activities were best supported by these data. In linkage analysis, a putative major gene with a codominant allele for elevated factor VII activity gave evidence against linkage (LOD score of 4.19 at D13S285 with a recombination fraction from 0.001). The segregation analysis showed that factor VII was under strong genetic influence, following the Mendelian model. However, factor VII showed no linkage to the 13q region, indicating the major gene effect influence in factor VII was not explained by these loci.

Exclusion of chromosome 2 and 14 coronary artery disease loci in an American Caucasian population. *G. Shen*^{1, 2, 3}, *S. Rao*^{1, 2, 3}, *R. Cannata*^{1, 2, 3}, *E. Zirzow*^{1, 2, 3}, *A. Bakos*^{1, 2, 3}, *E. Topol*^{1, 2, 3}, *Q. Wang*^{1, 2, 3}. 1) Department of Cardiovascular Medicine; 2) Department of Molecular Cardiology; 3) Center for Molecular Genetics; Cleveland Clinic Foundation, Cleveland, OH 44195, USA.

Coronary Artery Disease (CAD) and Myocardial Infarction (MI) are the leading cause of mortality and morbidity in the developed countries. In the United States, 12.6 million people are affected with CAD, 7.5 million people develop MI, and over half a million people die from CAD each year. CAD is believed to be caused by interactions between genetic and environmental factors. Two genome-wide scans, one in the Finnish population and the other in the German population, have produced evidence for linkage of CAD to D2S129 on chromosome 2q21.1-q22 and D14S1426 on 14q, but the responsible genes remain to be cloned. To evaluate these findings, we studied an American Caucasian population (GeneQuest) consisting of 2030 individuals from 428 families with premature CAD (atherosclerotic CAD occurring to males of < 45 years of age and females of < 50 years of age). The average family size was 4.7 members, and relevant clinical, physiological and biochemical data were obtained. The GeneQuest population contained 1303 sibling pairs. We genotyped markers D2S129 and D14S1426 in our GeneQuest population with an ABI 3100 Genetic Analyzer. The genotyping data was analyzed using Haseman-Elston regression. No significant evidence was observed for linkages of the GeneQuest population to chromosome 2q21.1-q22 and 14q CAD loci. A P-value of 0.411 was obtained for marker D2S129 and a P-value of 0.589 was found for marker D14S1426. These results suggest that the susceptible gene(s) in the GeneQuest population may be different from that in the Finnish and German populations.

A whole genome linkage approach identifies a novel ApoA1 mutation causing five percent of familial hypoalphalipoproteinemia in the Dutch population. *M. Samuels¹, G.K. Hovingh², J.A. Kuivenhoven², M.-P Dube¹, H. Verschoof¹, Y.P. Goldberg^{1,3}, J.J.P. Kastelein², M.R. Hayden^{1,3}, A. Brownlie¹.* 1) Xenon Genetics, Inc., Burnaby, BC, Canada; 2) Academic Medical Ctr, Univ of Amsterdam, Amsterdam, Netherlands; 3) Dept of Medical Genetics, Univ of British Columbia, Vancouver, BC, Canada.

The regulation of HDL-cholesterol in humans is of great therapeutic interest, given that HDL-C has been shown to correlate with risk for coronary artery disease (CAD). We have taken a family-based linkage approach to identify genes controlling HDL-C levels. As part of an effort to identify novel genes, we conducted a genome scan of approximately 800 genetic markers on non-ABCA1 families of Dutch origin. We used linkage and haplotype analysis to identify regions of the genome that co-segregated with disease. In one Dutch family, a multipoint LOD score of 3.8 was observed on chromosome 11. Subsequent haplotype analysis confirmed perfect segregation of a 13cM interval, spanning the ApoA1 gene, in this family. Sequencing the ApoA1 coding region in genomic DNA from affected individuals revealed a novel point mutation resulting in the amino acid substitution L178P. The mutation segregated on the affected haplotype, consistent with the low HDL-C phenotype in the family, and was not observed in 374 control chromosomes. Among 94 additional Dutch individuals with low HDL-C, 5 more carriers were identified (5.3%). These individuals occurred in extended pedigrees in which the variant also cosegregated with the phenotype. In all, a total of 33 mutation carriers were identified, providing an unprecedented study group for analysis of biochemical phenotypes and CAD risk. The L178P variant was shown to be significantly associated with low HDL-C, based on comparison of the 33 mutation carriers to 48 related non-carrier controls ($p < 0.0001$). In those carriers over the age of 20, a significant effect of the mutation on CAD was noted, as 9/30 carriers were affected with CAD as compared to 2/83 related non-carrier controls ($p = 0.00048$). These results demonstrate the ongoing value of linkage approaches to complex disease.

Association of the PIA polymorphism with platelet activation following coronary stent implantation. *C. Stranieri¹, E. Trabetti¹, D.J. Angiolillo², A. Fernandez-Ortiz², E. Bernardo², C.F. Barrera², M. Viveros², M. Sabate², C. Macaya², P.F. Pignatti¹.* 1) Sect Biol & Genetics, Mother-Child, Biol & Genetics, Verona, Italy; 2) Cardiovascular Institute-San Carlos University Hospital, Madrid, Spain.

The PIA polymorphism (Leu33Pro) of the GPIIIa gene has been suggested to play an important role in coronary thrombosis. In vitro studies have shown differences in platelet sensitivity towards antiplatelet drugs related to this polymorphism, suggesting a pharmacogenetic role. The aim of the study was to assess the influence of PIA polymorphism on platelet activation following a loading dose of clopidogrel in pts undergoing coronary stent implantation (CSI). Platelet activation was assessed as GPIIb/IIIa (anti-Fibrinogen-FITC) expression in platelets stimulated with 2M ADP using whole blood flow cytometry at baseline, 10 min, 4h, and 24h, following CSI. Genotype distribution in 32 pts was: 26 pts (81%) homozygous PIA1/PIA1 and 6 (19%) heterozygous PIA1/PIA2. A similar distribution was observed in 42 healthy control volunteers: 32% PIA1/PIA2. GPIIb/IIIa activation (expressed as percentage of positive platelets) was higher in PIA1/PIA2 pts at all time points ($p=0.03$). Clopidogrel reduced platelet activation following the fourth hour after CSI in PIA1/PIA1 pts up to 36,25% more than PIA1/PIA2 pts ($p=0.04$). No differences in fibrinogen level, platelet count, risk factors, and clinical status were observed between groups. Conclusion: The PIA polymorphism of the GPIIIa gene seems to be associated with different patterns of platelet activation in pts with coronary disease. In particular, PIA1/PIA2 pts undergoing CSI may have a greater GPIIb/IIIa activation and a lower response to clopidogrel than PIA1/PIA1 pts. If these preliminary data will be confirmed in a larger sample, different antithrombotic treatments could be suggested after genotyping for the PIA polymorphism.

Association & linkage study of ADHD using a polygenic model. *L. Park*¹, *K. Nummy*², *C. Huang-Pollock*³, *M. Rappley*⁴, *J. Nigg*³, *K. Friderici*². 1) Genetics Program; 2) Microbiol. & Mol. Gen; 3) Dept. of Psychology; 4) Peds/Hum. Dev.; Michigan State University, East Lansing, MI.

Attention-deficit hyperactivity disorder (ADHD) is a heritable disorder characterized by inappropriate inattention, hyperactivity and impulsiveness in children that is now known to persist into adulthood in a substantial percentage of cases. A polygenic model probably best explains the inheritance of ADHD, and there has been excitement in the field about reported positive effects for single candidate genes. Yet few replicated studies associate ADHD with specific genes, especially in adults. Because patients respond positively to psychostimulant medications, variants of genes involved in dopamine and serotonin function have been most often investigated as risk alleles for ADHD. We typed 5 genes in both adult ADHD (14 control, 31 affected) and childhood ADHD (33 control, 42 affected). Diagnostic criteria for ADHD were directly evaluated using standardized rating scales to assess DSM-IV criteria, severity, onset, duration, and impairment. Previously reported polymorphisms were analyzed for the dopamine transporter, dopamine D4 receptor, serotonin transporter, and 5-hydroxytryptamine receptor. In addition we examined the α -2A-adrenergic receptor (ADRA2A) as a candidate. For ADRA2A, 7 SNPs in the regulatory region of the gene were identified and the 3 which were present in the population at an allele frequency of >10% were analyzed for linkage. None of the five genes had highly significant association or linkage with ADHD using TDT and case-control methodologies. However, one of the SNPs in the promoter region of ADRA2A locus showed association with ADHD in the adult sample. These data support other results in suggesting that when ADHD is carefully assessed using DSM-IV criteria, individual catecholaminergic genes likely to be contributing to ADHD symptoms may be expected to contribute only a small component to the overall constellation of symptoms that comprise this phenotype. Large sample sizes, definition of behavioral and cognitive subtypes, and use of cognitive and physiological endophenotypes are recommended to evaluate genetic contributions to ADHD.

Apparent uniparental disomy in a familial case of autism spectrum disorder. *A.L. Haefele¹, D.A. Figlewicz¹, C.J. Stodgell²*. 1) Neurology, University of Rochester, Rochester, NY; 2) OB/GYN, University of Rochester, Rochester, NY.

Autism spectrum disorders (ASDs) are known to have a strong genetic etiology. Recent genome-wide scans have suggested that one, if not more of these responsible genes reside on chromosome 7q. This suggestion has been supported by candidate gene studies that have associated genes found on Chr. 7q (e.g., WNT2, RELN, and FOX2P) with autism and language disorders. This study screened 60 pedigrees with at least one person having an ASD for sharing of alleles on 9 genetic markers and the gene RELN. These markers were spaced, on average, every 10 cM starting at the centromere, and included regions close to those where significant LOD scores were found in other studies. At this point there is no evidence for significant linkage at these markers. However, based on the genotypes of the markers examined, there appears to be a uniparental disomy in one of the pedigrees. In the pedigree, the proband shares the same genotype with the mother starting at marker d7s1843 and continuing to marker d7s1826 where her sister, who has a language delay, appears to have only one of her father's alleles. These data suggest that one of the genes important to the ASD phenotype may be located close to d7s1826 and d7s1826. Supported by NICHD PO125466, a Collaborative Program of Excellence in Autism.).

Vervet monkey (*Chlorocebus aethiops*) as primate model for the genetic study of complex traits - reconstruction of a complete pedigree structure of a captive vervet colony. R.A. Ophoff^{1, 2}, Y. Wang¹, M. Tampilic¹, J. Bailey³, M. Jorgensen³, L. Fairbanks³, N.B. Freimer^{1, 2, 3}. 1) UCLA Center for Neurobehavioral Genetics, Dept of Psychiatry, UCLA, Los Angeles, CA; 2) Dept of Human Genetics, UCLA, Los Angeles, CA; 3) Neuropsychiatric Institute, UCLA, Los Angeles, CA.

The vervet monkey, also known as the African Green monkey, is widely used in biomedical research. A captive population at the UCLA-VA Vervet Research Colony (VRC) contains over six hundred normally reared animals in an extended six-generation pedigree founded by a limited number of captured animals from St. Kitts (West Indies) between 1975 and 1987. Phenotypes relevant to a number of different psychiatric and medical disorders have been assessed in all colony members, using consistent and reliable protocols. Preliminary heritability analyses have found significant genetic contributions to these traits. Our goal is to develop genetic resources that will allow this colony to be used to identify susceptibility loci for a number of complex (behavioral) traits.

As a first step in our efforts we developed a panel of informative microsatellite markers to be used for paternity testing and extension of the pedigree of the VRC. We tested 86 human highly-polymorphic fluorescently-labeled microsatellite markers that were used successfully for previous human mapping projects. Applying a standard PCR protocol (with low stringency conditions), about 60% of the markers amplified successfully and 34 of these markers revealed 2 alleles in eight random vervet subjects from the colony. From these amplicons we selected the 16 most informative markers that amplified well with scoreable and reproducible alleles. Genotyping of all available subjects from the colony (n=624) revealed an average of 4.8 alleles per marker. Statistical analysis is underway to verify and complete the pedigree structure of the colony. Once the pedigree structure of the vervet colony is confirmed we will generate a vervet genetic map.

Program Nr: 1555 from 2002 ASHG Annual Meeting

Genetic study of inherited Human Disease using a new mutant mouse, Sims (Sexual Immaturity, Megaencephaly, and Seizure): phenotype and chromosome mapping for positional cloning. *b. oh¹, s. koo², s. jin¹, d. park¹, k. lee², s. jung², k. kimm¹*. 1) Genome Research Institute, National Institute of Health, Seoul, Korea; 2) Division of Genetic Disease, National Institute of Health, Seoul, Korea.

Among the experimental animals, mouse has been highlighted as an excellent model system because mouse, one of the smallest mammals, is similar in development, genetics, and physiology to human. In addition the genetic and developmental information in mouse have been accumulated to make the study easier and faster than any other mammals. Sims, a new mutant mouse has a mild tremor and seizure and are sterile in either sex. The uterus in the affected female and seminal vesicle in the affected male are smaller than their normal litters and there is no detectable testosterone in the serum of the affected male. In addition the brain of the mutant is 30% heavier than that of littermate at their 3 month-old, probably because it continuously grows even after the puberty in the mutant mouse. Intraspecies cross to CAST/Ei was carried out and the 37 affected mice was analyzed for the linkage and the gene was mapped on chromosome 18, 20 cM from the centromere. To identify the gene, the fine genetic map and physical map of sims has been performed to obtain the 0.5Mb contig of the region, and the candidate genes located in the region have been identified.

Genetic Origins in a South American Clefting Population. *A.R. Vieira¹, J.C. Karras², I.M. Orioli³, E.E. Castilla⁴, J.C. Murray¹.* 1) Dept Pediatrics, Univ Iowa, Iowa City, IA; 2) College of Dentistry, Univ Iowa, Iowa City, IA; 3) Dept Genetics, UFRJ, Rio de Janeiro, Brazil; 4) Dept Genetics, Fiocruz, Rio de Janeiro, Brazil/CONICET, Buenos Aires, Argentina.

It has been proposed that susceptibility to clefting in South America is related to Amerindian ancestry where clefting has a higher frequency than the other admixed populations (Caucasian and African) that make up the diverse racial mix of current South Americans. To clarify the genetic origins in and establish a method for genetic mapping a South American population affected with clefting had mitochondrial DNA variation and Y chromosome markers studied. 217 subjects and matched controls were selected through Latin-American Collaborative Study of Congenital Malformations (ECLAMC). The case group showed a higher frequency of Native American haplogroups and a lower frequency of African haplogroups ($p < 0.00001$). Also, the case group showed a much higher frequency of the specific native American haplogroup D than the control group ($p < 0.00001$). For the Y chromosome markers, the case group showed a lower frequency of the African-specific marker YAP ($p = 0.002$) and a higher frequency of the Native American-specific marker DYS199 ($p < 0.00001$). Even though there are differences found in the frequencies of the markers studied, the contribution of each founder population is similar for both groups. Results suggest a strong Native American maternal contribution and a strong Caucasian (Spanish and Portuguese) paternal contribution to the population studied. The implications of this finding include the possibility of using admixture mapping approaches to this population.

The gene for Juvenile Hyaline Fibromatosis maps to chromosome 4q21. *S. Hanks*¹, *M. Dunstan*², *M.D. Teare*³, *A. Futreal*⁴, *F.M. Pope*⁵, *N. Rahman*¹. 1) Section of Cancer Genetics, Institute of Cancer Research, Sutton, Surrey, UK; 2) Dept of Psychological Medicine, University Hospital of Wales College of Medicine, Cardiff, UK; 3) Mathematical Modelling and Genetic Epidemiology Group, University of Sheffield, Sheffield, UK; 4) Cancer Genome Project, The Wellcome Trust Sanger Institute, Hinxton, Cambs, UK; 5) Connective Tissue Matrix Genetics Group, Division of Life Sciences, Kings College London, UK.

Juvenile Hyaline Fibromatosis (JHF) (MIM 228600) is an autosomal recessive condition that typically presents in the first few years of life with nodular skin lesions, on the scalp, face and hands. The distribution and burden of lesions tends to increase throughout childhood, often necessitating recurrent excision. Gum hypertrophy typically develops and may also require excision. Progressive flexion contractures of joints increasingly limit movement and may result in individuals becoming wheel-chair bound in early adulthood. Diagnosis is confirmed by skin histology which typically shows an abundance of a homogenous, amorphous hyaline material. We performed a genome-wide linkage search in two families with JHF from the same region of Gujerat and identified a region of homozygosity on chromosome 4q21. Dense microsatellite analyses within this interval in five JHF families from diverse origins demonstrate that all are compatible with linkage to chromosome 4q21 generating a multipoint LOD score of 5.5. Meiotic recombinants place the gene for juvenile hyaline fibromatosis within a 7cM interval bounded by D4S2393 and D4S395. The minimal interval contains 19 known genes and 47 predicted genes. Of the known genes, a number are potentially of interest as candidates, including Bone morphogenetic protein 3 (*BMP3*), Fibroblast growth factor 5 (*FGF5*) and the homolog of mouse BMP-2 inducible kinase (*BIKE*).

Program Nr: 1558 from 2002 ASHG Annual Meeting

An SNP study of candidate genes in Cleft Lip and Palate. *R. Ingersoll¹, S. Hiebler¹, M. Campbell¹, J. Barton¹, F.W. Schuler¹, L. Kasch¹, I. McIntosh¹, T. Beaty², A.F. Scott¹.* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine; 2) Department of Epidemiology, Bloomberg School of Public Health, Johns Hopkins University.

We are investigating the genetics of non-syndromic cleft lip and palate by identifying single nucleotide polymorphisms (SNPs) in candidate genes identified by linkage analysis, animal models or presumed function. SNPs are identified in coding region, 3' UTR and promoter sequences by PCR amplification and direct sequencing of DNAs from unrelated parents of 15 probands. We are taking advantage of the increasingly complete human genome sequence and NCBI resources such as OMIM, LocusLink and Map Viewer to identify genes and genomic sequence. Sequences are aligned manually and visually inspected for differences. As of June 2002, PCR primers have been designed for 564 amplicons from 48 genes. Fifteen genes have been completely sequenced (156 amplicons) and 189 amplicons from an additional 16 genes have been studied from other genes. A total of 375 SNPs have been identified of which 86 (23%) occur in exons and 41 (48% of cSNPs; 11% of total SNPs) of which result in amino acid changes (nsSNPs). Allele frequencies will be determined for each SNP in a collection of trios obtained through a proband with a non-syndromic oral cleft (cleft lip with or without cleft palate and cleft palate only). Previous studies of these case-parent trios have shown evidence of linkage in the presence of disequilibrium for several candidate genes, in particular MSX1 and TGFB3. Both of these genes have been screened and a number of novel SNPs were identified. To date, 150 SNP assays have been developed for the Illumina bead-array platform and 253 CLP samples genotyped.

Identification of Type 1 Diabetes linked genes on chromosome 21. *R. Bergholdt, J. Nerup, F. Pociot.* Steno Diabetes Center, Gentofte, Denmark.

Background and Aim: In a recent genome wide linkage analysis for Type 1 Diabetes Mellitus (T1DM)-susceptibility loci in 408 Scandinavian multiplex families, a newly identified locus on the distal part of chromosome 21, especially revealing linkage to T1DM in the Danish population with a maximum LOD score of 2.33 ($P=0.009$), was identified. The linked region on chromosome 21 comprises 20 Mb, which in this region equals approximately 35 cM. The aim of the study was to characterize and fine-map a genetic region on chromosome 21 showing linkage to T1DM.

Material and methods: DNA from 155 Danish T1DM sib-pair families were used, all probands with age at onset below 30 years. 20 microsatellite markers were chosen, covering the 35 cM region on chromosome 21. The 155 sib-pair families were typed for all 20 markers. Collection and allele-calling of data were done using the software programs GeneScan, GenoTyper and GeneMapper, followed by multipoint LOD score analysis of all the markers using GeneHunter. Genotyping of SNPs were performed by RFLP-PCR or MS-PCR.

Results: Multipoint LOD score analysis of 20 new microsatellite markers and the 7 chromosome 21 markers used in the scandinavian genome-scan, in a Danish collection of 155 sib-pair families, revealed two separate loci, showing linkage to T1DM. For locus 1, covering 4 cM, a peak LOD score of 3.19 ($P=0.0005$) was obtained, whereas locus 2, covering approximately 3 cM, had a peak LOD score of 2.83 ($P=0.0018$). The regions below the peaks are analyzed for candidate genes. 4 known SNPs in coding regions of the CBR1 gene and 1 SNP in the CBR3 gene, have been typed, none revealing T1DM association. Furthermore the two most common mutations in the AIRE gene, coding for APECED (autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy), has been examined in 100 diabetic patients, no mutations were identified.

Conclusion: Fine-mapping of a T1DM linked region on chromosome 21 has narrowed the linked region into two separately linked regions with peak LOD scores of 3.19 and 2.83, respectively. This suggests that one or several T1DM linked genes exist in the region.

GENETIC HETEROGENEITY IN AUTOSOMAL DOMINANT ALPORTS SYNDROME (ADAS). *F. Boaretto¹, S. Savoldi³, D. Santon¹, S. Crovella^{1,2}, M. Martone³, M. Artero³, M. Pennesi², G. Panzetta³, A. Amoroso^{1,2}.* 1) Medical Genetics, University of Trieste, Trieste, TS, Italy; 2) IRCCS Burlo Garofolo, Trieste, TS, Italy; 3) Nephrology and Dialysis Service, Cattinara Hospital, Trieste, TS, Italy.

Alports Syndrome (AS) is a genetically heterogenous glomerulonephritis (GN) with X-linked (for mutations of the COL4A5 and/or COL4A6 genes), autosomal recessive (for alterations of the COL4A3 and/or COL4A4 genes), and autosomal dominant (AD) forms. ADAS is due to mutations in the COL4A3 and/or COL4A4 genes or, when associated with a platelet defect (Fechtner's Syndrome), to mutations in the MYH9 gene. We studied a 3 generation family affected by GN with microhematuria, dominant transmission, and unfavorable prognosis (2 members in ESRD), in which AS presented also in the pediatric age range. Renal biopsy, performed in 2 patients, showed normal glomerular cellularity without sclerosis in LM; Ig and C3 deposits were absent in IF. EM, performed only in the proband, demonstrated alterations of the GBM consistent with AS. Neurosensory deafness was absent in all subjects examined; ophthalmologic studies in 5 affected members revealed modest lenticular opacities in a single pediatric patient. Macrothrombocytopenia, lipid abnormalities and hypertension, which have been previously described in ADAS, were absent in the present study. We analysed 11 members (9 affected and 2 unaffected) after informed consent. In order to exclude the known loci, we used published markers D1S498, D1S305 (locus ADAS with hypertension), D2S396, D2S159, D2S2345, D2S126, D2S277 (COL4A4\4A3), D2S283, D2S426, D2S272 (MYH9). The two-point linkage analyses were performed with the computer program MLINK from the LINKAGE Package (Ver. 5.2), assuming a penetrance of 0.95, AD transmission, no recombination sex difference and gene frequency of 1/10.000. We obtained negative LOD scores with values <-2 for about all markers analysed, at recombination fraction $\theta=0$. These results further confirmed the genetic and clinical heterogeneity of ADAS and suggested that other GBM components may be involved in the pathology, codified by as yet unidentified genes, which a genome-wide study, currently in progress, may localize.

Further evidence for linkage of specific language impairment to 13q21 from an American sample. *C.W. Bartlett¹, J.F. Flax¹, M.W. Logue³, V.J. Vieland³, P. Tallal¹, L.M. Brzustowicz^{2,4}*. 1) Center for Molecular and Behavioral Neuroscience, Rutgers University, Newark, NJ; 2) Department of Psychiatry, University of Medicine and Dentistry New Jersey, New Jersey Medical School, Newark; 3) Department of Biostatistics, Division of Statistical Genetics, College of Public Health and Department of Psychiatry, College of Medicine, University of Iowa, Iowa City; 4) Department of Genetics, Rutgers University, Piscataway, NJ.

Specific language impairment (SLI) is characterized as a failure to develop language normally, in absence of explanatory factors such as low intelligence, inadequate educational opportunity, hearing impairments or neurological difficulties. Previously, we demonstrated linkage of SLI to 13q21 in five Canadian families of Celtic ancestry with a HLOD of 3.92 under a recessive mode of inheritance with a reading impairment phenotype (Bartlett et al 2002, AJHG). In attempt to replicate these results in a different sample, we have genotyped a dense linkage map of the 13q21 region with a set of 22 American nuclear and extended families (N = 279) ascertained for at least two affected pedigree members. The maximum two-point HLOD score was > 1.5 using the same phenotype and genetic parameters that gave the strongest evidence for linkage in the Canadian dataset. Using both samples, HLOD for multipoint linkage was 4.92. To further characterize the strength of evidence in the region, we used the posterior probability of linkage to combine the datasets. The PPL is specifically designed to accumulate linkage evidence across datasets in a statistically rigorous way. Based on the original set of families, the PPL was 53% at D13S1317; after updating with our current data the PPL at this marker is 93% (preliminary calculation). These data indicate that the 13q21 locus segregates not only in Canadian families of Celtic ancestry, but also in American families ascertained for SLI. These results increase the possibility that the 13q21 autism locus found in American families, is the same demonstrated in our SLI sample.

Evidence of Linkage and Association between the Lipoprotein Lipase Gene (LPL) and Insulin Resistance in Hispanic Hypertension Families. *X. Guo¹, L.J. Raffel¹, M.O. Goodarzi^{1,2}, K.D. Taylor¹, A.H. Xiang³, M. Quinones², C. Samayoa¹, W.A. Hsueh², T.A. Buchanan³, J.I. Rotter¹.* 1) Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) UCLA School of Medicine, Los Angeles, CA; 3) USC Keck School of Medicine, Los Angeles, CA.

We have previously shown that blood pressure (BP) and insulin resistance (IR) cosegregate in Hispanic families and that there most likely are gene(s) contributing to both BP and IR. Previous studies have shown evidence of linkage and/or association of the HindIII polymorphism in the LPL gene with IR, as well as IR-associated hypertension, dyslipidemia, and atherosclerosis. However, in most cases insulin sensitivity was assessed by indirect methods. To further examine the role of the LPL gene in IR, we genotyped 390 members of 77 Hispanic families for six SNPs in the 3' region of LPL (7315, 8292, 8393, 8852, 9040, 9712). Families were ascertained via a hypertensive proband and insulin resistance was directly assessed via hyperinsulinemic euglycemic glucose clamps in the adult offspring. Multipoint linkage analyses were performed using SIBPAL2. Association between the six SNPs, LPL haplotypes and IR-related traits were evaluated using the QTDT program. Significant linkage was found with IR as measured by clamp glucose infusion rate (GINF, $p=0.0042$). Applying the population stratification model for haplotype association analysis in QTDT, the combined SNP haplotype 'CAGGCA' was found to be associated with higher GINF (less IR) ($p=0.023$). In further examination of association with each SNP individually, we found that SNP 9712 contributes the most to the association ($p=0.01$); allele 2 (presence of adenine) is associated with less IR than allele 1 (presence of guanine). These results support a direct role for the LPL gene in determining insulin resistance, confirming our previous observation of linkage in Mexican American coronary artery disease families. Variation in the 3' end of the LPL gene is most likely involved in determining IR. In addition, we have identified a specific haplotype that is associated with increased insulin sensitivity in this hypertensive Hispanic population.

Refinement of the critical region for Nance-Horan Syndrome to 1.3Megabases on chromosome X. *K.P. Flowers¹, J.E. Craig^{2,3}, D.A. Mackey^{1,2,4}, J.M. Stankovich¹, J.D McKay¹, M.M. Sale^{1,5}.* 1) Menzies Ctr Pop Health Res, Univ Tasmania, Hobart, Australia; 2) Centre for Eye Research, University of Melbourne, Royal Victorian Eye and Ear Hospital, Melbourne, Australia; 3) Dept Ophthalmology, Flinders Medical Centre, Adelaide, Australia; 4) Dept Ophthalmology, Royal Children's Hospital, Melbourne, Australia; 5) Dept Internal Medicine, Wake Forest University School of Medicine, Winston-Salem, USA.

Nance-Horan Syndrome is an X-linked disorder characterised in hemizygous males by bilateral congenital cataract and dental anomalies including screw-driver blade shaped incisors and supernumerary teeth. Female carriers may be affected with mild Y-sutural cataracts, with little or no loss of vision, with or without characteristic dental anomalies. The disorder has previously been linked to a 3.5cM region (5.8Mb) on Xp22.3-p22.1. A large pedigree with Nance-Horan Syndrome was ascertained through the Royal Childrens Hospital, Melbourne, Australia. Linkage analysis was performed at seven markers across a 10cM region using MLINK. The maximum two-point LOD score was 2.2 which is considered significant on the X chromosome. X-linked GENEHUNTER PLUS was used for multipoint and haplotype analysis. A putative shared haplotype was observed between distantly related branches of the family at the two adjacent markers that gave the highest two-point LOD scores. Four novel microsatellite markers, located by searching the draft genome sequence for dinucleotide repeats 15 units or greater in length, were typed to confirm this shared haplotype. The maximum LOD score obtained using all eleven markers was 2.8. Recombinations were observed in two individuals which refine the critical region to a 1.3Mb region on Xp22.3. This is a significant reduction from the previous region and will assist with gene identification for this disorder.

Genome-wide linkage analysis of body mass index across 28 years of the Framingham Heart Study. LD. Atwood¹, N. Heard-Costa¹, LA. Cupples², CE. Jaquish³, PWF. Wilson⁴, RB. D'Agostine⁵. 1) Neurology, Boston Univ Sch Medicine, Boston, MA; 2) Biostatistics, Boston Univ Sch Public Health, Boston, MA; 3) National Heart, Lung, Blood Institute, Bethesda, MD; 4) Medicine, Boston Univ Sch Medicine, Boston, MA; 5) Mathematics, Boston Univ, Boston, MA.

We performed genome-wide linkage analysis of six separate measurements of body mass index (BMI) taken over a span of 28 years from 1971 to 1998 in the Framingham Heart Study. Variance components linkage analysis was performed on 330 families using 401 polymorphic markers. The number of individuals with data at each exam ranged from 1930 in 1971 to 1401 in 1998. Sex, age, and age² were included as covariates in the model.

There was substantial evidence for linkage on chromosome 6 between 139cM and 166cM in the area of *D6S1009*, *GATA184A08*, *D6S2436* and *D6S305*. The six measurements had maximum lodscores of 4.64, 2.29, 2.41, 1.40, 0.99, and 3.08 at 144.4cM, 139.6cM, 141.2cM, 142.8cM, 166.0cM, and 166.0cM, respectively on chromosome 6. There was also evidence for linkage of multiple measures on chromosome 11 between 115cM and 131cM in the area of *D11S1998*, *D11S4464* and *D11S912*. The six measures had maximum lodscores of 0.61, 3.27, 1.30, 0.68, 1.30, and 2.29 at 129.4cM, 119.0cM, 115.0cM, 131.0cM, 115.0cM, and 117.0cM, respectively, on chromosome 11. Both of these regions have been reported in previous studies. Chromosome 8 is the only other chromosome in which at least two datasets had a lodscore greater than 2.0 in the same region. The region containing *D8S1106*, *D8S1145*, and *D8S136* had lodscores of 0.80, 2.78 and 2.29, and 1.01 at 26.0cM, 30.4cM, 30.4cM, and 41.2cM for datasets 1-4. The maximum at 30.4cM is within 10cM of the lipoprotein lipase gene (LPL), which has been linked or associated with BMI or other obesity traits in previous studies.

Evidence in the same regions from multiple measurements indicates that linkage studies of BMI are robust with respect to measurement error. It is unclear if variation in lodscores in these regions is due to age effects, varying sample size, or other confounding factors.

Identification of susceptibility genes in human systemic lupus erythematosus (SLE): Evidence of linkage disequilibrium on chromosome 20. *P.M. Gaffney¹, R.R. Graham¹, W.A. Ortmann¹, P.S. Ramos¹, S.A. Selby¹, P.R. Rodine¹, K.B. Shark¹, K.L. Moser¹, C.D. Langefeld², S.S. Rich², T.W. Behrens¹.* 1) Department of Medicine, University of Minnesota, Minneapolis, MN; 2) Department of Public Health Sciences, Wake Forest University School of Medicine, Winston-Salem, NC.

SLE is a chronic autoimmune disease characterized by the loss of immunologic tolerance to self-antigens. The clinical manifestation of SLE results from complex interactions between environmental factors, hormonal factors and susceptibility alleles on multiple genes. Our group originally reported linkage at 20p12-13 and 20q11-13 in a collection of 105 sib-pair families with SLE. We now report the results of fine mapping these loci in our family collection of 231 sib pair and 185 trio families. Sixty-four microsatellite markers were genotyped in the regions of 20p12-13 and 20q11-13. The average inter-marker distance was less than 500 kb across both linkage intervals. Genotype data was analyzed using MERLIN, a software package that performs rapid multipoint linkage analysis using sparse inheritance trees and automatically removes unlikely genotypes that can potentially reduce evidence for linkage. The maximal LOD score in the 20p12-13 interval was at marker D20S894 (LOD=2.13, $p=0.0009$). This marker is located approximately 820 kb telomeric from the previously reported best marker in the interval (D20S186, LOD=1.77). The maximal LOD score in the 20q11-13 interval was at marker D20S880 (LOD=1.35, $p=0.006$) approximately 205 kb centromeric to our previously reported best marker (D20S119, LOD=1.64). To investigate evidence for linkage disequilibrium (LD) we used the Pedigree disequilibrium test (PDT). Evidence for LD was found for marker D20S604 (allele 6, $p=0.016$; allele 7, $p=0.034$) within the 20p12-13 linkage interval and markers D20S836 (allele 7, $p=0.018$) and D20S176 (allele 7, $p=0.021$; allele 8, $p=0.002$) within the 20q11-13 linkage interval. Future work will focus on genotyping additional microsatellite and single nucleotide polymorphism markers in the sequence flanking markers D20S604, D20S836, and D20S176. Haplotype based approaches will then be used to better define the regions of LD prior to gene identification.

Genome scan for glaucoma loci in a Costa Rican POAG family. *G. Chavarria Soley*¹, *L. Villalobos*², *C.Y. Mardin*³, *J. Azofeifa*¹, *A. Reis*⁴, *K. Michels-Rautenstrauss*⁴, *B. Rautenstrauss*⁴. 1) INISA, University of Costa Rica, San Jose, Costa Rica; 2) Private Practice, San Jose, Costa Rica; 3) Dep. of Ophthalmology, FAU, Erlangen, Germany; 4) Institute of Human Genetics, FAU, Erlangen, Germany.

Adult onset primary open angle glaucoma (POAG) is one of the major causes of blindness in the world. The disease results in optic nerve damage and a visual field loss, often accompanied by elevated intraocular pressure. Currently 7 loci (GLC1A-GLC1E) and two genes (MYOC, OPTN) are known to be involved in glaucoma. We studied 26 members, 7 patients, from a Costa Rican family with autosomal dominant inheritance of the POAG. After exclusion of MYOC mutations we performed a genome scan with microsatellite markers (mostly Weber panel) with the purpose of identifying the genomic location of candidate gene(s) responsible in the development of glaucoma in this family. The initially calculated two-point lod scores were followed by parametric and non-parametric multipoint linkage analysis. Chromosomes 8 and 9 presented the highest, suggestive two-point lod scores with a value of 2.00 for markers D8S549 and D8S560 and 1.8 for marker D9S1826 (=0 for the three lod scores). For the parametric multipoint linkage analysis location scores higher than 1.50 were found for chromosomes 2, 6, and 8 with values of 1.60, 1.75, and 2.00, respectively. For the non-parametric multipoint analysis the highest scores for the NPL_all statistic are in chromosomes 6, 8 and 12 with values of 1.90, 1.94, and 1.82 respectively. From the known loci only GLC1B (chr. 2) maps to these regions. Mutations in OPTN (chr. 10) are probably excluded, hence this family is promising for the identification of a novel glaucoma candidate gene.

HTR1D and OPRD1 SNPs exhibit significant association to anorexia nervosa. *A.W. Bergen^{1,5}, M.B.M. van den Bree^{1,6}, M. Yeager^{1,5}, J.K. Ganjei¹, R. Welch^{1,5}, K. Haque^{1,5}, S. Bacanu², D.E. Grice³, W.H. Berrettini^{3,4}, C. Bulik⁴, K. Klump⁴, M. Fichter⁴, K. Halmi⁴, A. Kaplan⁴, M. Strober⁴, J. Treasure⁴, B. Woodside⁴, W.H. Kaye^{2,4}.* 1) Biognosis U.S., Inc. (Dissolved); 2) University of Pittsburgh, Pittsburgh, PA; 3) University of Pennsylvania, Philadelphia, PA; 4) The Price Foundation Collaborative Group (www.anbn.org); 5) Core Genotyping Facility, NCI, NIH; 6) University of Wales, Cardiff, UK.

The Price Foundation Collaborative Group (www.anbn.org) has collected a sample of 196 families with two or more relative pairs affected with DSM-IV Anorexia Nervosa (AN) (Kaye et al., *Biol Psych* 2000;47(9):794-803). The family sample has been genotyped with a whole genome linkage panel of microsatellite markers (Weber). The genes for the serotonin 1D receptor (HTR1D) and the opioid delta receptor (OPRD1) are found on chr1p36.3-34.3, a region of the genome observed to be linked to anorexia nervosa (AN) in a linkage analysis of DSM-IV AN diagnosis (Grice et al., *Am J Hum Genet* 2002;70(3):787-792). The entire HTR1D locus and a portion of the OPRD1 locus were evaluated for sequence variation by resequencing. Nine SNPs (four HTR1D SNPs and five OPRD1 SNPs) were chosen for genotype assay development and genotyping was performed on 191 unrelated individuals fulfilling DSM-IV criteria for AN, 442 relatives of AN probands and 98 psychiatrically screened controls. Linkage analysis of these nine SNPs with 33 chr1 microsatellite markers in 37 families with ARPs concordantly affected with restricting AN substantially increased evidence for linkage of this region from an NPL score of 3.45 to 3.91. Statistically significant genotypic, allelic and haplotypic association to AN in the case:control design was observed at both candidate genes with effect sizes for individual SNPs of 2.63 (95%CI=1.21-5.75) for HTR1D and 1.61 (95%CI=1.11-2.44) for OPRD1. In parents and probands only, three SNPs at HTR1D with found to be exhibit significant transmission disequilibrium ($p < 0.05$). The combined statistical genetic evidence suggests that HTR1D and OPRD1 may be involved in the etiology of AN. This abstract does not represent the opinion of the NIH, DHHS, or the Federal Government.

Linkage Analysis in 5 Large Colombian Families with Autosomal Dominant Congenital Cataract. *T. Arguello*¹, *M.L. Tamayo*^{1,2}, *J.C. Prieto*¹. 1) Instituto de Genetica Humana, Universidad Javeriana, Bogota, Colombia; 2) Fundacion Oftalmologica Colombiana, Bogota, Colombia.

Congenital cataract is a clinically and genetically highly heterogeneous eye disorder, with and autosomal dominant (ADCC) inheritance being most common. The genetics of this condition are complex with more than 18 loci for ADCC identified to date. We have investigated a large Colombian population of 5 informative ADCC families. Each family span 4 generations and consisted of more than 20 family members. In all the pedigrees the morphology of the cataract varied in density and severity being the most common the zonular pulverulent, nuclear and posterior polar phenotype. Genotyping and two point linkage analysis were perform to asses linkage to four genes responsible for ADCC localized in chromosomes 1, 2, 21 and 22. The specific regions were mapped using 8 highly polymorphic microsatellites markers (D1S514, D1S2669, D1S2721, D2S117, CRYGPCR1, D21S1446, D22S1028 and D22S315). We have demonstrated linkage to chromosome 1q close to the gene that encodes connexin 50 in one family with positive Lod scores for markers D1S514 ($Z_{max}=2.74$, $max=0.0$) and D1S2669 ($Z_{max}=3.38$, $max=0.0$). Three point analysis gave a maximum Lod score of 18.17 ($max=0.01$) between these two markers. In addition, we have excluded linkage to the other regions with markers D2S117 ($Z_{max}=-2.36$, $max=0.01$) CRYGPCR1 ($Z_{max}=-10.2$, $max=0.01$) D21s1446 ($Z_{max}=-4.04$, $max=0.01$) and D22S315 ($Z_{max}=-3.32$, $max=0.01$). The cataract showed a wide intrafamilial variation, although the majority of affected individuals had pulverulent and polar posterior cataract. In the remaining families we have excluded linkage of the phenotype to these genetic markers with negative Lod scores for all of them. In conclusion, our results indicate that there is a considerable genetic heterogeneity; therefore, to elucidate the mechanism underlying the presence of the ADC, further linkage studies using closed linked polymorphic markers are first necessary to identify if the phenotype of the ADCC in these Colombian families is due to the known cataract loci described in the worldwide population, or if it correspond to a new genetic form.

Genome scan of familial abdominal aortic aneurysms: a candidate region. *S.G. Buxbaum¹, H. Shibamura², J.M. Olson¹, G. Tromp², H. Kuivaniemi^{1,3}.* 1) Dept Epidemiology/Biostat, Case Western Reserve Univ, Cleveland, OH; 2) Center for Molecular Medicine and Genetics, Wayne State University School of Medicine, Detroit, Michigan; 3) Department of Surgery, Wayne State University School of Medicine, Detroit, Michigan.

Familial aggregation of abdominal aortic aneurysms (AAAs) has been demonstrated. First degree relatives of AAA patients have been shown to have increased risk of AAA with up to 18% of brothers and 5% of sisters having AAA. Population-based ultrasonography screening studies have also emphasized family history as an important risk factor for AAA. Formal segregation studies have demonstrated that AAAs are likely to have a genetic etiology with an autosomal inheritance pattern.

We used a total of 96 families with at least two living members diagnosed with AAA for a two-phase two-stage genome scan. DNA was isolated from blood samples from affected relative pairs (ARPs) and their unaffected relatives, if available. In the Stage I of Phase I we carried out a whole genome scan on 65 affected relative pairs (ARPs). In this scan, five chromosomal regions exceeded our exploratory threshold lod score of 0.8. One region had a lod score of 4.4 with covariate analysis and was selected for further study. In Stage II of Phase I we used additional markers in the region with the highest LOD score and genotyped an additional 121 ARPs at these markers. This gave a total of 186 ARPs (183 full sib pairs and 3 half sib pairs) in the 96 families. In our sample 71% of the ARPs were brother-brother pairs. In a multipoint linkage analysis including the number of affected first degree relatives of the proband as a covariate we found a LOD score of 1.9 using the LODPAL program in S.A.G.E.

Cosegregation of glaucoma with locus GLC1B (2q12-q13) in a Peruvian family with heterogeneous onset and a recombination within the critical region. *R. Fujita*¹, *M.L. Guevara-Fujita*¹, *R. Perez-Grossman*², *J. Richards*³. 1) Instituto de Genetica y Biologia Molecular, Universidad de San Martin de Porres, Alameda del Corregidor Cdra. 15, La Molina, Lima, Peru. rfujita@amauta.rcp.net.pe; 2) Instituto de Cataratas y Glaucoma, Lima, Peru; 3) W.K. Kellogg Eye Center, U. of Michigan, Ann Arbor, MI, USA.

Glaucoma is a group of ophthalmic disorders having degeneration of the optical nerve as common symptom, with high ocular pressure as a frequent clinical sign. Genetics of glaucoma has developed dramatically and several genes have been localized in different chromosomes as a previous step to reveal its etiology. We have screened 9 Peruvian families with markers of three different glaucoma locations in chromosomes 1 (1q24.3-q25.2), 2 (2qcen-q13) and 3 (3q21-q24). A family with 7 patients and 5 normal individuals, had dominant glaucoma cosegregating with markers from 2cen-q13, location of the glaucoma region (locus) GLC1B. This is the second study reporting association to markers associated to GLC1B. We have also seen that there is onset heterogeneity since there are adult and juvenile onset as reported originally before for other GLC1B families, with ocular pressures between 22 and 30 mm Hg. In our case, patients of the same generation had similar either adult or juvenile onset. One normal person elder than his affected brothers has a recombinant chromosome within the critical region: he shares markers cosegregating with glaucoma within the terminal side of the critical region whereas he does not share associated markers within the proximal side. We especulate that his normal status refines the location of GLC1B from 2qcen-q13 to 2qcen-q12. Acknowledgement: We thank the patients and their relatives by its participation. This work was supported by Universidad de San Martin de Porres Funds.

A QTL Influencing Triglyceride Levels Resides on Chromosome 13: The HERITAGE Family Study. *M.F. Feitosa¹, I.B. Borecki¹, T. Rankinen², J.P. Després³, A.S. Leon⁴, J.S. Skinner⁵, J.H. Wilmore⁶, M.A. Province¹, C. Bouchard², D.C. Rao¹.* 1) Div Biostatistics, Washington Univ, MO; 2) Pennington Biomedical Research Center, Louisiana Univ, LA; 3) Physical Activity Sciences Lab, Laval Univ, Canada; 4) Sch Kinesiology & Leisure Studies, Univ Minnesota, MN; 5) Dep Kinesiology, Indiana Univ, IN; 6) Dep Health & Kinesiology, Texas A & M Univ, TX.

Dyslipidemias are major etiologic contributors to atherosclerosis and coronary heart disease and targets for intervention. It is well known that lipids and lipoproteins are heritable and efforts to identify relevant quantitative-trait loci (QTL) are underway. Lipid profiles were assessed both at baseline and after 20 weeks of endurance-exercise training in 99 White and 101 Black families. Phenotypes were adjusted for age, sex, BMI, use of cardioprotective agents, hormonal intake and smoking; responses to training were further adjusted for baseline levels. A genomewide linkage scan involving 509 markers was conducted using a multipoint variance-components approach, separately by race and using race-specific marker allele frequencies. There was strong evidence for linkage on chromosome 13q12-14 with HDL triglycerides (TG) at baseline in White families, with the maximum multipoint lod score (LOD) of 3.9 ($p=0.00001$) at marker D13S1493. Suggestive linkage was also observed in the same region, at marker D13S219, with LOD of 2.2 ($p=0.00077$) for training response LDL-TG. Other suggestive linkages ($2.0 \leq \text{LOD} \leq 2.9$) were detected in White families on chromosomes 1q41-42 with LDL, 2p22-25 with LDL and 2p32 with TC/HDL, 5q22 with TC/HDL, 7p21 with LDL-APOB and LDL, 8q24 with LDL and LDL-APOB, 10-p14 with LDL-TG, 12q21-24 with HDL and HDL-TG, 14q31 with LDL-TG and TC, 15q26.2 with TC/HDL, 19p13 with LDL-TG, all phenotypes at baseline; and only 12q21-24 with HDL and HDL₂ in responses to training. In Black families, suggestive linkages were found on chromosomes 1q41-42 with TC and LDL-APOB at baseline, and 12q14 with TC/HDL in response to training. In summary, we have strong evidence for a QTL on 13q12-14 influencing triglycerides levels, both at baseline and in response to training.

Mapping a Gene for Dupuytren Contracture in Two Swedish Families. *F.Z. Hu^{1,2}, A. Nyström³, A. Ahmed¹, R. Dopico¹, I. Mossberg⁴, M. Palmquist⁵, J. Gladitz¹, M. Rayner⁶, J.C. Post¹, R.A. Preston¹, G.D. Ehrlich^{1,2}.* 1) Center for Genomic Sciences, Allegheny Singer Research Inst, Pittsburgh, PA; 2) Department of Human Genetics MCP Hahnemann School of Medicine, Pittsburgh, PA; 3) Departments of Plastic Surgery and Orthopedics, University of Nebraska School of Medicine, Omaha NB; 4) Department of Plastic Surgery, University of Umea, Umea Sweden; 5) University of Linkoping School of Medicine, Linkoping, Sweden; 6) Department of Otolaryngology University of Minnesota, School of Medicine, Minneapolis MN.

Dupuytren contracture (DC) (OMIM 126900) is widely regarded as the most common inherited connective tissue disease of mankind. It is characterized biochemically by increased levels of collagen III deposition and increased levels of hydroxylation and glycosylation of the collagen cross links. These phenomena are characteristic of granulomatous disease and scarification. Together with the fact that DC is more highly penetrant among persons with chronic hand trauma suggests that the DC phenotype results from a defect in the wound repair mechanism. DC is most frequently observed among the xanthocroi peoples of Northern Europe where its most common manifestations are thickening of the palmer fascia and contracture of the fingers. We have ascertained two large Swedish families in which Dupuytren contracture is inherited in an autosomal dominant manner with high penetrance by the sixth decade of life. In the current study blood was collected from all affected and informative unaffected family members for the performance of familial linkage analyses. Using a highly multiplex genotyping approach a genome-wide scan was performed at a resolution of 8 cM for all autosomes using the ABI PRISM linkage mapping set 2. Linkage was established to a 30 cm region of chromosome 16. Fine structure mapping of this region produced a maximal multipoint LOD score of 4.49 at marker D16S3068. We have identified a common allele at this marker for all affected persons in both families which is suggestive of a common founder.

Combined genome scan results for 266 pedigrees multiplex for systemic lupus erythematosus (SLE): significant evidence of genetic linkage at 1q22-23 and 11p13. *J.A. Kelly¹, J. Reid¹, J. Kilpatrick¹, B. Harris¹, C.K. Berry-Brattan¹, S. Frank¹, D. Hutchings¹, C. Cooney¹, S. Johnson¹, D. Bacino¹, K. Rossacci¹, T. Aberle¹, B. Namjou¹, S.K. Nath¹, G.R. Bruner¹, R.H. Scofield^{1,2,3}, J.A. James^{1,2,3}, J.B. Harley^{1,2,3}.* 1) Dept. Arthritis/Immunology, OMRF, OKC, OK; 2) Dept. of Medicine, University of Oklahoma Health Sciences Center, OKC, OK; 3) US Dept. of Veterans Affairs Medical Center, OKC, OK.

Systemic lupus erythematosus (SLE) is a complex genetic autoimmune disorder. We have previously reported results from an initial sample of 94 pedigrees with significant linkages at 1q22-23 and 1q41 identified in the 31 African-American pedigrees using model-based parametric methods. Using non-parametric methods and an additional 32 pedigrees, significant linkage was later reported at 4p16-15 in 77 European-American pedigrees. Here, we report results within the initial 126 pedigrees using model-based parametric methods and the results from an independent sample of 140 multiplex SLE pedigrees used to confirm previous findings as well as establish linkages in the combined 266 pedigrees. The first 126 pedigrees are linked at 1q22-23 (FcγRIIA, LOD=4.4), with eight regions demonstrating suggestive linkage (LOD³1.9) on chromosomes 1q, 3p, 7p, 11p, 11q, 12p, 12q and 13q. The additional 140 multiplex SLE pedigrees confirmed linkage to FcγRIIA (LOD=1.3), identified significant linkage at 11p13 (D11S1392, LOD=3.4) and four additional regions containing suggestive genetic linkages (1p, 3p, 7p and 14q). When the 266 pedigrees were combined, significant linkage was again identified at 1q22-23 (FcγRIIA, MLOD=3.9) and 11p13 (D11S1392, MLOD=3.8). Furthermore, a confirmatory effect at D16S3253, which, according to the UCSC December 2001 freeze, is < 1 cM telomeric to a significant linkage identified in Minnesota, was also observed (LOD=1.2), independently supporting linkage to this region. These data, together with other reported results, provide further evidence and independent confirmation of susceptibility genes for SLE residing at 1q22-23 and 11p13.

Linkage Analysis between Apo AI-CIII-AIV Cluster and Plasma Lipid Levels in Cardiovascular Disease Family.

Y.S. Jang^{1,2,4}, *E.K. Im*^{1,4}, *J.H. Kwon*^{1,2}, *E.Y. Cho*^{1,2,4}, *S.J. Bae*¹, *S.H. Jee*³, *H.Y. Park*^{1,2}. 1) Dept Cardiology, Yonsei Cardiovascular Research, Seoul, South Korea; 2) Brain korea 21 project for medical sciences, yonsei university; 3) Department of epidemiology and disease control; 4) cardiovascular genome center, Yonsei university medical center.

Background Cardiovascular disease (CVD) is a complex disorder, which the genetic contributions have significant roles with environmental factors. In the many studies, increased plasma lipid levels except HDL-cholesterol were directly correlated with cardiovascular risk. The aim of this study was to determine whether Apo AI-CIII-AIV gene cluster region (chromosome 11q23) contains specific loci that affect plasma lipid concentration or not. **Methods and Results** The 701 individuals from 93 CVD families were recruited. We collected genealogical informations for all participants and measured plasma lipid levels. Segregation analysis showed that the LDL-cholesterol follows the codominant Mendelian model with 61.2% of the variation and the equal transmission model. For HDL-cholesterol, the segregation analysis showed a dominant Mendelian model accounted for 51.8% of the variation. For linkage analysis, we selected 30 families (305 individuals) those have a relatively large number of subjects and multi-generation comparatively. In the analysis for the HDL-cholesterol, none of genetic markers at Apo AI-CIII-AIV gene cluster showed LOD score as evidence of linkage. In the analysis for the LDL-cholesterol, the highest LOD score was found at D11S912 of 130.9 cM (LOD score =1.18, p=0.099). To confirm the linkage between a putative gene that affects LDL-cholesterol level and D11S912, we reanalyzed the linkage with 21 families that favored a codominant Mendelian model, but there was no significant difference in LOD score. **Conclusion** The segregation analysis showed both LDL-cholesterol and HDL-cholesterol are under the genetic influences, following the Mendelian model. However, HDL-cholesterol showed no linkage to the Apo AI-CIII-AIV gene cluster, indicating the major gene effect influence in HDL-cholesterol is not explained by these loci. For LDL-cholesterol, we found the tentative linked loci at 11q23.

Is autosomal dominant nonsyndromic deafness in a Brazilian pedigree linked to DFNA7/DFNM1? *K. Lezirovitz, M.C.C. Braga, P.A. Otto, R.C. Mingroni-Netto.* Centro de Estudos do Genoma Humano, Dept Biol, Inst de Biociencias, Univ de Sao Paulo, Sao Paulo, Brazil.

Autosomal dominant inheritance accounts for 10% to 20% of hereditary nonsyndromic deafness. To date 34 nuclear *loci* associated with autosomal dominant nonsyndromic deafness have been described and among these 17 have been identified. We ascertained a large Brazilian family with 16 cases of autosomal dominant nonsyndromic sensorineural deafness. The majority of affected individuals have postlingual progressive hearing loss, initially affecting only high frequencies. The penetrance rate of the defect in this family was estimated to be 96% among individuals aged 35 years or more. Linkage analyses were performed in 24 individuals in four generations: seven of them had normal hearing, 16 were affected, and the affection status of one of them was unknown. The 35delG connexin 26 mutation and the A1555G mitochondrial mutation, two important causes of hereditary nonsyndromic deafness, were excluded. Linkage to DFNA2, DFNA10 and DFNA18, three *loci* involved in autosomal dominant nonsyndromic deafness, was also excluded. However, suggestive two-point lod scores were obtained within a region spanning ~20cM at 1q21-q24, which contains the DFNA7 *locus* as well as DFNM1, a modifier *locus* of DFNB26. The highest two-point lod score, 2.09 for $Q=0.07$, was obtained with marker D1S416. A 40 year-old individual who inherited the putative risk haplotype presents a slight hearing deficit (20dB) in all frequencies. If this individual is considered affected, the maximum lod score rises to 2.69 for this marker. However, a lod score of 5.76 would be expected in case of complete linkage. Nonpenetrant individuals and possible cases due to phenocopies could be influencing the results, but the possibility remains that more than one *locus* is involved in the manifestation of deafness in this pedigree.

Dark Dentate Disease (DDD - A Novel Dominantly-Inherited Spinocerebellar Ataxia Phenotype. *M.A. KNIGHT^{1, 2}, E. STOREY^{3, 4}, J. DIXON⁴, H. RUNDLE⁴, P.Q. THOMAS^{1, 2}, R.J.M. GARDNER^{1, 3}, S.M. FORREST^{2, 5}.* 1) MURDOCH CHILDRENS RESEARCH INSTITUTE, ROYAL CHILDRENS HOSPITAL, MELBOURNE, VIC; 2) DEPARTMENT OF PAEDIATRICS, UNIVERSITY OF MELBOURNE, MELBOURNE, VIC; 3) GENETIC HEALTH SERVICES VICTORIA, MELBOURNE, VIC; 4) THE DEPARTMENT OF NEUROSCIENCES, MONASH UNIVERSITY, ALFRED HOSPITAL CAMPUS, MELBOURNE, VIC; 5) THE AUSTRALIAN GENOME RESEARCH FACILITY, WEHI, PARKVILLE, VIC.

SCAs 1, 2, 3, 6 or 7 account for a minority of Australian pedigrees with dominant spinocerebellar ataxia (SCA). This prompted a search for SCA pedigrees with novel phenotypes, resulting in this description of DDD. We have studied a large Anglo-Celtic kindred with thirteen affected members. A notable observation has been the calcification of the dentate nucleus, palatal tremor and dysphonia in family members. The age of onset ranged from 19-64 years. Pedigree information does not permit a firm conclusion as to whether or not anticipation exists. Gene testing excluded the known SCA loci for SCAs 1, 2, 3, 6, 7 and 8, and molecular linkage analysis excluded SCAs 4, 5, 6, and SCAs10-17. Thus we hypothesised that this might represent a new SCA clinical phenotype necessitating the performance of a full genome scan. Simulation analysis of the pedigree indicated a maximum LOD score of 6.9 with the power to exclude at an average of 10.6-cM either side of any marker. Upon analysis of the genome-wide scan we found linkage to chromosome 11, very close to the existing locus for SCA5. While DDD maps to the same broad region of chromosome 11 as SCA5, it is phenotypically quite distinct from that disorder, in which dentate calcification, palatal tremor and dysphonia have not been seen in the two pedigrees reported to date. This suggests that we may have a novel phenotypic variant of SCA5 or a new locus that maps in the vicinity of SCA5 on chromosome 11. Subsequent fine mapping in this area has revealed that linkage to the SCA5 locus cannot be excluded, and further collaborative work to define the marker order in this region is in progress. Candidate genes identified using bioinformatics are currently being screened to identify the disease-causing mutation.

Identification of loci involved in familial idiopathic scoliosis. *C.M. Justice*¹, *N.H. Miller*², *B. Marosy*², *J. Zhang*³, *A.F. Wilson*⁴. 1) Genometrics Section, NHGRI/NIH, Baltimore, MD; 2) Department of Orthopaedic Surgery, Johns Hopkins University, Baltimore, MD; 3) Department of Genetics, Johns Hopkins School of Medicine, Baltimore, MD; 4) CIDR, Johns Hopkins University, Baltimore, MD.

Idiopathic scoliosis (IS) is a structural lateral curvature of the spine present in the late juvenile or adolescent period in otherwise normal individuals. It affects 2-3% of the pediatric population, and 0.2-0.5% of the population require active treatment. Idiopathic scoliosis is believed to be a complex genetic disorder in which expression of the disease state may depend on several genetic and possibly environmental factors. Previous studies have suggested autosomal dominant, X-linked and multifactorial modes of inheritance. In this study, 204 families with at least two individuals with a lateral curvature greater than or equal to 10 degrees were ascertained and clinically characterized. Phenotypes include degree of lateral curvature, curve type, age of onset and sex. A genome-wide screen for 1198 individuals was performed at the Center for Inherited Disease Research, using a modified Weber marker set consisting of 391 short tandem repeat markers. In order to reduce heterogeneity and maximize the possibility of identifying potential loci for the disease trait, scoliosis was analyzed both as a quantitative trait and as a qualitative trait, in which the curvature determining the threshold for affectation status was set at values of 10, 20, 30, 40 and 50 degrees. The families were also stratified on the ratio of the likelihood of each family given an X-linked model relative to that of an autosomal model. Model independent sib-pair linkage analysis was performed on these various subsets. Candidate regions were identified on chromosomes 1, 6, 8, 9 and 16.

A novel susceptibility gene for systemic lupus erythematosus (SLE), SLER1, maps to chromosome 5p15.3 in multiplex SLE families overlapped with rheumatoid arthritis. *S.K. Nath, B. Namjou, J. Kilpatrick, J.A. Kelly, J.A. James, J.B. Harley.* Arthritis & Immunology, Oklahoma Medical Res Fndn, Oklahoma City, OK.

Systemic lupus erythematosus (SLE) is a chronic, complex and genetically heterogeneous human autoimmune disease. For disorders with a poorly known biochemical basis, like SLE, identification of the genes is a prerequisite or key to their understanding its biological basis. Despite considerable effort to identify susceptibility loci for SLE, no specific genes have yet been localized by human SLE genome scan approach. SLE is often associated with other autoimmune diseases such as rheumatoid arthritis (RA), which may indicate a common genetic predisposition for both of these disease manifestations. We identified 36 families multiplex for both SLE and RA: 19 African-American (AA), 14 European-American (EA) and 3 others from our ongoing SLE genetics project. Genome-wide linkage analyses were conducted using 330 microsatellite markers separately for each ethnic group. Based on the initial genome scan, a significant evidence of linkage (LOD=5.3) was identified at chromosomal location 5p13.3 for EA families and a suggestive evidence (LOD=2.45) of linkage was identified at chromosomal location 4q for AA. Conversely, on chromosome 5 the maximum lod score for AA was .77, and on chromosome 4 the maximum for EA was .20. Then 6 additional markers were genotyped on 5p15.3 for further narrow the linkage interval. The maximum parametric and non-parametric LOD scores were 6.9 and 6.2, respectively. The P-values associated with these lod scores were 1.7×10^{-8} and 2.6×10^{-7} , respectively. The linked region spans about 16 cM. To our knowledge this is the most significant evidence of linkage for SLE to date. These results suggest that grouping families based on their clinical features and racial origin not only isolates genetically homogeneous families but also increases power to detect linkage for complex diseases like SLE.

Autosomal Dominant Stargardt Macular Dystrophy: Clinical Features and Linkage Analysis in A Large Greek Family.

G. Karan¹, K. Fan¹, G. Kitsos², Z. Yang¹, E. Economou-Petersen³, M. Grigoriadou⁴, K. Psilas², M.B. Petersen⁴, D.J. Zack⁵, K. Zhang¹. 1) Moran Eye Center and Program in Human Molecular Biology & Genetics, University of Utah, Salt Lake City, UT; 2) Department of Ophthalmology, University of Ioannina, Ioannina, Greece; 3) Drakopoulion Blood Bank Center, Athens, Greece; 4) Department of Genetics, Institute of Child Health, Athens, Greece; 5) Wilmer Eye Institute, Johns Hopkins University.

Purpose: Stargardt macular dystrophy (STGD) is the most common hereditary macular dystrophy and is characterized by decreased central vision, macular atrophy and flecks. In most instances STGD is inherited as an autosomal recessive or simplex trait. A recessive locus was assigned to chromosome 1p (STGD1). Loci for autosomal dominant Stargardt-like macular dystrophy have been mapped to chromosomes 6q (STGD3) and 4p (STGD4). We describe our effort to characterize clinical phenotype and map the disease gene in a large Greek family. **Methods:** Clinical examinations were performed. Genomic DNA was obtained from the blood of 29 members and genotyped using STR markers. Linkage analysis was performed using the LINKAGE 5.1. **Results:** We describe a large five-generation pedigree with dominant Stargardt-like macular dystrophy from Epirus, Greece. The family is consisted of 234 individuals with 24 affected members. Clinical examination revealed visual acuity ranging from 20/25 to 20/200 with age at onset between 7 and 18 years. Fundoscopic examination showed loss of foveal reflex, "beaten bronze" appearance of the foveal region, and flecks of varying degrees. The disease was symmetric in the two eyes and progressive with age. Linkage analysis with STR markers excluded linkage to known STGD loci, and a genome wide search is in progress. **Conclusions:** We have identified a family with Stargardt-like macular dystrophy likely representing a new disease locus. Identification of another causative gene for STGD will aid in our understanding of the pathogenesis of this disease, and allow the development of therapeutic agents.

Linkage analysis of primary microcephaly in Indian families. A. Kumar¹, S. Blanton², M. Markandaya¹, S.C. Girimaji³. 1) MRDG, Indian Institute of Science, Bangalore, India; 2) Department of Pediatrics, University of Virginia Health Science Center, Charlottesville, USA; 3) Department of Psychiatry, NIMHANS, Bangalore, India.

Microcephaly (small head) is a condition in which the head circumference of an affected individual is greater than 3 SD below the mean for age and craniosynostosis is not present. Microcephaly occurs due to a variety of reasons such as intrauterine infections, drugs taken during pregnancy, prenatal radiation exposure, maternal phenylketonuria and birth asphyxia, which are the rare causes of microcephaly. The majority of microcephaly cases arise as the result of a variety of genetic mechanisms including cytogenetic abnormalities, single-gene disorders and syndromes of as-yet-undetermined etiology. Primary microcephaly (MCPH, MIM 251200) appears to be a distinct subtype. It is defined by the absence of associated malformations and of secondary or environmental causes. It is inherited as an autosomal recessive trait. Mental retardation in primary microcephaly ranges from mild to severe, but other neurological deficits are absent. Primary microcephaly shows genetic heterogeneity with five known loci: MCPH1 on chromosome 8p22-pter, MCPH2 on chromosome 19q13.1, MCPH3 on chromosome 9q34, MCPH4 on chromosome 15q and MCPH5 on chromosome 1q31. We have ascertained nine families with primary microcephaly from India. On examination, the head circumferences of the affected individuals were found to be greater than 5-7 SD below the population age-related mean. All the affected individuals had mild to severe mental retardation and none were able to read and write, but could speak at least a few words and had basic self-care skills. To establish linkage of these nine Indian families to known MCPH loci, microsatellite markers were selected from the candidate regions of each of the five known MCPH loci and used to genotype the families. The results showed that 3/9 families were linked to the known MCPH5 locus on chromosome 1q31 with a combined lod score of 5.3864. The work is in progress to establish linkage of other six families using a genome-wide linkage screen (Supported by SDTC grant PC11014).

Genetic analysis of spirometric measurements. *A. Malhotra¹, R.E Kanner², M.F. Leppert¹, S.J. Hasstedt¹.* 1) Department of Human Genetics, University of Utah, Salt Lake City, UT; 2) Pulmonary Division, University of Utah, Salt Lake City, UT.

Lung function defects such as chronic obstructive pulmonary disease (COPD) are a common and increasing cause of death worldwide. Although environmental factors such as cigarette smoking are associated with COPD, only 10-20% of heavy cigarette smokers develop this disease. Therefore, genetic factors may play a role in the etiology of COPD. In addition, familial clustering and heritability estimation studies of traits related to lung function suggest the role of genes.

FEV₁ (Forced Expiratory Volume in 1 second) and FVC (Forced Vital Capacity) were measured on 264 members of 26 Utah pedigrees. These volume measurements are reduced in lung function defects and serve as criteria in the diagnosis of certain lung function abnormalities. In addition, a reduced FEV₁/FVC ratio is observed in individuals suffering from airways obstructions. Genetic analysis of these phenotypes will provide further insight into the role of genetic factors in the development of lung disease.

A segregation analysis of the FEV₁/FVC ratio has led to the inference of a major locus underlying the inheritance of this phenotype. Assuming the inferred dominant and recessive models, two-point and multipoint linkage analyses were performed using GENEHUNTER. Two-point lod scores of >2 (highest lod score = 2.70) were observed on chromosome 5q. A multipoint lod score of >3 was obtained in this region providing evidence for linkage. This region will be fine mapped to further localize the gene. No model could be inferred for the traits FEV₁ and FVC. Nonparametric linkage analyses were performed on FEV₁, FVC, and the ratio FEV₁/FVC. Two-point lod scores of >1.5 were obtained in several regions suggesting the presence of genetic heterogeneity. Multipoint linkage analyses are currently being performed for all three phenotypes.

Search for linkage disequilibrium with febrile seizures in the *FEB4* region on chromosome 5. J. Nakayama^{1, 2}, N. Yamamoto¹, K. Hamano³, N. Iwasaki², A. Matsui², T. Arinami¹. 1) Department of Medical Genetics, Institute of Basic Medical Sciences, University of Tsukuba, Ibaraki, Japan; 2) Department of Pediatrics, Institute of Clinical Medicine, University of Tsukuba, Ibaraki, Japan; 3) Department of Pediatrics, Kitaibaraki Municipal General Hospital, Ibaraki, Japan.

Febrile seizures (FS) are the most common form of childhood seizures, and they occur in about 7% of Japanese children. Three putative FS loci, *FEB1* (chromosome 8q13-q21), *FEB2* (chromosome 19p), and *FEB3* (chromosome 2q23-q24) linked to some large Caucasian families have been mapped. Furthermore, we have previously reported significant evidence for linkage of febrile seizures to chromosome 5q14-q15 (*FEB4*) in Japanese families (Hum Mol Genet 2000;9:87-91). Significant linkage disequilibrium between FS and the marker D5S652 was observed. To identify responsible mutation(s) for FS, we screened three genes, the proprotein convertase subtilisin/kexin type 1 gene (*PCSK1*), the calpastatin gene (*CAST*), and the type 1 tumor necrosis factor receptor shedding aminopeptidase regulator gene (*ARTS-1*), which have been mapped within 500kb from this marker. The entire coding region of these genes was screened by single-strand conformation polymorphism (SSCP) or denaturant high-performance liquid chromatograms (DHPLC) analysis in 48 unrelated Japanese patients with FS. A total of 61 polymorphisms/variants were identified. We genotyped these polymorphisms by PCR-RFLP and direct sequencing methods in 48 FS families (n=192) and performed the transmission disequilibrium test. The IVS21-65A allele of *CAST* and the -103T allele of *PCSK1* were more frequently transmitted to FS patients (p=0.0095 and p=0.032, respectively). We also identified 21 polymorphisms/variants within 5kb from D5S652. We examined 4 polymorphisms of these polymorphisms by TDT and significant linkage disequilibria between these polymorphisms and FS were observed. Our data indicate that there is a gene responsible for FS between *PCSK1* and *CAST*, probably near D5S652, although no known gene has been mapped around D5S652.

Refinement of the candidate region for spinocerebellar ataxia type 4 (SCA4) in a large German kindred. *Y. Hellenbroich, C. Zuehlke, H. Pawlack, E. Schwinger.* Institute of Human Genetics, University of Luebeck, Luebeck, Germany.

Spinocerebellar ataxia type 4 (SCA4) is an autosomal dominant disorder mapped to chromosome 16q22.1 in a large Utah kindred. The clinical phenotype is characterized by cerebellar ataxia with sensory neuropathy. In addition, a pure cerebellar ataxia in six Japanese families is also linked to the same candidate region suggesting to be an allelic disorder with different clinical features. Here, we present a five-generation family from northern Germany with clinical findings similar to the SCA4-family from Utah linked to the same locus. A maximum lod score of 5.21 ($q=0.00$) was achieved with marker D16S496 in a genomewide linkage scan with a panel of 402 markers. Haplotype analyses further refined the gene locus in a 3.69-cM interval between D16S3019 and D16S512. Furthermore, we investigated the interrupted CAG sequence of the HRIHFB2206 gene coding for the largest polyglutamine tract of all known genes in the candidate region and could exclude a repeat expansion at this locus. Nevertheless, the anticipation of disease onset and severity in this family points to a repeat expansion as the underlying mutation for SCA4.

A genome-wide scan identifies a major susceptibility locus for leprosy susceptibility in Vietnamese families. *M.T. Mira*¹, *A. Alcaïs*², *N.V. Thuc*⁴, *N.T. Huong*⁴, *V.H. Thai*⁴, *M. Girard*¹, *A. Verner*³, *M.C. Phuong*⁴, *T.J. Hudson*³, *L. Abel*², *E. Schurr*¹. 1) McGill Centre for the Study of Host Resistance, McGill University, Montreal, Canada; 2) INSERM U 436, Paris, France; 3) Montreal Genome Center, Montreal, Canada; 4) Dermatology Hospital, Ho Chi Minh City, Vietnam.

Leprosy, an infectious disease caused by *Mycobacterium leprae*, presents itself in different clinical manifestations, ranging from single lesion paucibacillary to multiple lesion multibacillary forms. To identify genomic regions linked with susceptibility to leprosy, we performed a genome-wide scan in leprosy families from South Vietnam containing both paucibacillary and multibacillary cases. A total of 87 multiplex nuclear families (433 individuals) were genotyped for 395 highly informative microsatellite markers spanning the entire human genome and interspersed by 10 cM on average. Non-parametric linkage analysis initially pointed to 11 genomic regions distributed along 9 chromosomes showing suggestive evidence for linkage with either leprosy per se or leprosy type (lod score > 1.5). The addition of a large number of new microsatellite markers brought the information content along all the 11 regions to 95% on average. Analysis of the high density maps revealed strong evidence for linkage between one chromosomal region and leprosy "per se" (lod score of 4.21; $P = 0.000005$). Furthermore, association between leprosy and microsatellite markers underlying the peak lod score was detected in a family-based study using an independent sample of 208 simplex Vietnamese families ($P = 0.00006$). Finally, chromosomal region 6p21, overlapping the HLA complex, presented a lod score of 2.85 ($P = 0.00016$) when tested for leprosy "per se", and 2.64 ($P = 0.0002$) when tested for leprosy type. The remaining 9 regions submitted to fine mapping failed to show significant evidence for linkage with the tested phenotypes (lod scores < 1.5). These results strongly suggest the existence of at least one major locus for the control of susceptibility to leprosy "per se". They are also in accordance with the generally accepted idea for a role of the HLA region in controlling disease susceptibility and clinical form of leprosy.

Confirmation of linkage and refinement of a new gene locus for Nephronophthisis type 4 and Senior-Loken syndrome on chromosome 1p36.3. *E. Otto¹, J. Hoefele¹, R. Ruf¹, A.M. Mueller¹, K.L. Hiller¹, M.T.F. Wolf¹, M.J. Schuermann¹, A. Becker¹, H.C. Hennies², P. Nuernberg², F. Hildebrandt¹.* 1) Department of Pediatrics, University of Michigan, Ann Arbor, MI; 2) Mikrosatellitenzentrum, MDC, Berlin, Germany.

Nephronophthisis (NPH), the primary genetic cause for chronic renal failure in children, is an autosomal recessive cystic kidney disease. The association of NPH with retinitis pigmentosa is known as Senior-Loken syndrome (SLS). Three gene loci (NPHP1, 2, and 3) have been mapped for NPH, while only the gene (NPHP1) for NPH1 has been identified. Some SLS patients also show linkage to the NPHP1 and NPHP3 loci. By total genome search for linkage we recently identified a new gene locus (NPHP4) for NPH type 4 and SLS in 6 NPH multiplex families and in one large SLS kindred (*Am J Hum Genet* 70:1240, 2002).

Following exclusion of mutations in the NPHP1 gene and of linkage to NPHP2 and NPHP3, we here performed haplotype analysis at the NPHP4 locus in 38 additional multiplex families with NPH (24 families) and with SLS (14 families). Haplotypes demonstrated compatibility with linkage to NPHP4 in 14 out of 24 NPH families (58%) and in 9 out of 14 SLS families (64%).

Furthermore, newly generated polymorphic markers were typed on key recombinants from F30, narrowing the disease locus to 1.2 Mb in size.

We conclude that linkage to a fourth locus (NPHP4) for NPH and SLS was confirmed, and that there is evidence for at least one additional locus for NPH and SLS. Mutational analysis of candidate genes is now performed to identify the gene responsible for NPH type 4 and Senior Loken Syndrome.

A novel locus for non-syndromic autosomal dominant hearing loss mapped to chromosome 16p13.3. *X.C. Li¹, S.A. Kim¹, H.M. Saal², R.A. Friedman¹*. 1) Dept Cell & Molecular Biol, House Ear Inst, Los Angeles, CA; 2) Human Genetics Division, Children's Hospital Medical Center, University of Cincinnati College of Medicine, Cincinnati, OH.

Hearing loss is the most common sensory defect in humans. A genetic linkage study was conducted on a large multigenerational US family with nonsyndromic autosomal dominant progressive hearing loss. The age of onset of the hearing impairment in this family varies from the first decade to the early twenties. Most affected individuals have demonstrated bilateral severe-to-profound sensorineural hearing loss, mainly in the middle and high frequencies. The deafness gene segregating in this family is mapped to a 10 cM interval near the telomere region on chromosome 16p13.3. A maximum lod score of 4.07 was obtained with marker D16S3401 at $q = 0$. Several good candidate genes have been identified in this interval, such as a voltage-dependent calcium channel gene *CACNA1H*, a chloride channel gene *CLCN7* and two claudin genes.

Evidence suggesting BRD2 is the EJM1 locus for Juvenile Myoclonic Epilepsy. *D.K. Pal¹, O. Evgrafov³, M. Durner², C. Gilliam³, D.A. Greenberg².* 1) Psychiatry, Columbia University, New York, NY; 2) Stat Genet Divn, Biostatistics Dept, Columbia University, New York, NY; 3) Genome Center, Columbia University, New York, NY.

Several reports have demonstrated linkage of juvenile myoclonic epilepsy to the HLA region of chromosome 6. Our group found significant association to alleles at the DQB1 and BRD2 loci (1). The objectives of the present study were to define the region more precisely using densely spaced SNP markers and to identify possible causative mutations. **METHODS:** 20 JME probands, taken from families with positive lod scores (lod >0.1) at the 6p locus, and 46 unlinked JME probands, were typed for 11 SNPs between HLA-DP and HLA-DQ. Haplotype frequencies were compared in a case-control design. Additionally, all exons and splice sites in the region were tested for mutations in four linked families. **RESULTS:** One consistent haplotype was identified in positive lod score families, which was significantly more frequent than in comparison chromosomes (Odds ratio: 5.8, 95% CI:1.7-19.4, p=0.001). This haplotype extended to the boundary of the BRD2 gene and contained the associated CA repeat allele. There was no significant evidence of linkage disequilibrium beyond the gene boundaries. Sequencing of 20 probands from families with positive lod scores revealed 3 missense mutations, 1 small deletion and 1 DNA alteration which could potentially affect splicing. These variants, and 2 other missense mutations described in the literature, were not consistently associated with JME. **CONCLUSION:** Other reports of loci in common disease also have failed to find consistent mutations in exons of associated loci. While we cannot yet exclude the rest of the DQ-DP HLA region, the presence of a SNP haplotype, plus our evidence of association with an allele of a microsatellite marker only in linked families, continues to suggest that BRD2 is EJM1. 1. Greenberg DA, Durner M, Keddache M, et al. Reproducibility and complications in gene searches: linkage on chromosome 6, heterogeneity, association, and maternal inheritance in JME. *Am J Hum Genet.* 2000 Feb;66(2):508-16. Supported by grants: NS31775, NS27941 and MH48858.

Fine mapping of a schizophrenia susceptibility locus on 13q32 in a Canadian Sample. *D.M. Waterworth¹, E.W.C. Chow², A.S. Bassett², L.M. Brzustowicz^{1,3}*. 1) Dept Genetics, Rutgers Univ, Piscataway, NJ; 2) Department of Psychiatry, University of Toronto, and Schizophrenia Research Program, Queen Street Division, Centre for Addiction and Mental Health, Toronto, Ontario; 3) Department of Psychiatry, UMDNJ, New Jersey Medical School, Newark.

Schizophrenia is a complex and variable disorder that is characterized by cognitive, social and affective impairment, and by the presence of psychotic symptoms. In our previously reported genome scan of 22 Canadian families (n=297), an HLOD of 3.81 at D13S793 on 13q32-33 was found, replicating previous findings at D13S174 (around 9cM proximal to D13S793) by Blouin et al in multiplex pedigrees of mostly European descent (NPL 4.18; p= 0.00002). Bipolar disorder has also been linked to this region in a number of studies. Since our last report, a number of additional subjects with DSM-III-R diagnoses and two additional families have augmented the size and power of the collection (n=350), though a small number of subjects currently have a provisional diagnosis. A multipoint using the same markers as previously reported generated an HLOD of 2.52 at D13S793 in this extended data set. A dense map (average 0.8 cM spacing) of microsatellite markers was constructed around D13S793 on 13q32 in order to refine the position of this putative locus. Eighteen additional microsatellite markers were typed over a 16cM (»13Mb) region, ranging from D13S1300 to D13S274. Parametric linkage analysis was performed using LINKAGE for four models, dominant or recessive for each of a narrow or broad diagnostic classification, as before. The maximum 2-point LOD score was obtained for D13S154 (HLOD 2.7) with the broad dominant model. One large family generates a LOD score of 2.3 alone, and restricts the linked interval to between D13S71 and D13S786. Although the addition of new markers and subjects has led to reduction in the LOD score at this locus, the families that appear linked are consistent in terms of location and model. The close proximity between our linkage peak and that of the bipolar groups suggests that the two disorders may indeed share a common susceptibility locus on 13q32.

Canine model of idiopathic epilepsy. *M.C. Roberts¹, E.E. Patterson², P.J. Armstrong², J.R. Mickelson¹*. 1) Veterinary PathoBiology, Univ Minnesota, St Paul, MN; 2) Small Animal Clinical Sciences, Univ Minnesota, St Paul, MN.

Mutations in a number of genes for primary idiopathic epilepsy (IE) have recently been defined in humans, however there are many more forms of IE for which the mode of inheritance is complex and the genetic basis has not been identified. The domestic dog has a high occurrence of IE, with up to 3% of purebred dogs being affected. Because of a strong founder effect, purebred lines of dogs can be very useful for dissecting the genetic basis of the more complex human conditions. The Vizsla is a breed in which we have identified lines of dogs that produce pups with IE. Around three years of age the affected dogs suffer from partial seizures, partial onset seizures with secondary generalization, and/or primary generalized seizures with a median frequency of nine a year. DNA and phenotypes have been collected from 159 dogs that can be assembled into one large pedigree or nine smaller pedigrees that span three generations. Segregation analysis suggests an autosomal recessive mode of inheritance, but a polygenic model with a gene of major effect cannot be ruled out. A full genome scan has been initiated on these dogs, utilizing 295 polymorphic canine microsatellite markers with an average spacing of 11 cM. There are seven gaps greater than 20 cM and two of the smaller chromosomes have only one informative marker. Parametric and nonparametric linkage analysis has identified nine possible regions of interest. Follow-up marker analysis will be done on these regions and other areas where the markers are not highly informative in the pedigrees. Identification of genes for epilepsy in this and other breeds of dog will be very useful for comparative genetic studies of human epilepsy.

Linkage analysis of quantitative traits related to Syndrome X and stature on Kosrae, Federated States of Micronesia. *D. Shmulewitz¹, S.C. Heath², Z. Han¹, L. Petukhova¹, S.A. Auerbach³, M.L. Blundell¹, S. Boger¹, S. Oplanich¹, S. Signorini¹, P.C. Verlander¹, J.D. Winick¹, M. Yifrach¹, J. Ott¹, J.L. Breslow¹, M. Stoffel¹, J.M. Friedman¹.* 1) Starr Center for Human Genetics, The Rockefeller University, New York, NY; 2) Centre National de Genotypage, Evry, France; 3) Health Resources and Services Admin., Dept. of Health and Human Services, New York, NY.

Syndrome X, a term used for the observed clustering of metabolic disorders, includes obesity, type II diabetes, hypertension, and dyslipidemia/heart disease. These disorders have been shown to have underlying complex genetic inheritance. We performed a complete genome scan for height and 14 quantitative traits related to these disorders in the population on the Pacific island of Kosrae, which has a high prevalence of the Syndrome X disorders. The present study included 1709 individuals from Kosrae who are part of one large pedigree. These have been genotyped for 360 microsatellite markers (10.2 cM autosomal map) using the ABI 3700 capillary electrophoresis methods at the Genotyping Core Facility at Rockefeller University. Linkage analysis was carried out with the reversible jump Markov chain Monte Carlo method Loki, which can carry out segregation and linkage analysis on quantitative traits in large pedigrees with multipoint analysis and covariate corrections (Heath, 1997). This resulted in the identification of quantitative trait loci for body mass index (chromosome 18), serum leptin levels (5), hip circumference (10), weight (18), fasting blood sugar (1), systolic blood pressure (20), arterial blood pressure (9), apolipoprotein B (2), total cholesterol (12, 19), and height (1, 5, 10, 15, 19). These are promising regions that merit further study, to try to identify the causal genes for these traits and their effect on disease pathogenesis. Heath, S. (1997). Markov chain Monte Carlo segregation and linkage analysis for oligogenic models. *Am.J. Human Genet.* 61: 748-60.

Genome wide screen of a panel of multigenerational families in Adams Oliver Syndrome. *A. Skoura¹, S. Sifakis¹, F. Goodman², R. Winter², A. Lin³, D. Basel¹, P. Beighton⁴, M.W. Kilpatrick¹, P. Tsipouras¹.* 1) Pediatrics, UConn Health Center, Farmington, CT; 2) Molecular Medicine, ICH, London; 3) Dept of Newborn Med, Childrens Hosp, Boston MA; 4) Human Genetics, UCT, Cape Town.

The Adams Oliver syndrome is a heterogeneous disorder characterized by aplasia cutis congenita of the scalp, truncation defects of the distal limbs and a myriad of associated clinical presentations which include cardiac anomalies, cutis marmorata, renal anomalies, polymicrogyria and a variety of other neurological manifestations. The observed phenotypic variability in this disorder complicates the clinical diagnosis and the identification of a causative gene would be of great diagnostic benefit. In addition, the identification of the genetic basis of this phenotype has the potential to further our understanding of the intricate developmental pathways that direct the embryonic ectoderm. To this end, we have undertaken a genome wide scan using a human marker screening set, which comprises 378 autonomic primer pairs that cover the entire genome at an average spacing of 9cM. The initial phase of the screening was limited to the single multigenerational family available to us at the time, which comprised 14 individuals, 6 of which were phase known meioses. Two-point lod scores were calculated using Mlink and considered significant if greater than 2. Using this criterion, several loci were found to be significant, generating 2-point lod scores of 2.24 (D2S1790, 2p11.2), 2.17 (D13S1807, 13q14) and 2.21 (D15S1507, 15q22). Additional markers were then used to further delineate these regions and the next phase of the project was initiated. This second phase included expanding the cohort to include 4 additional families, bringing the total number of individuals investigated to 48. The total number of affected persons now amounts to 23, of which 15 are phase known meioses. This expanded panel of five families is currently being analysed in an attempt to identify the locus responsible for this disorder. In addition, we will utilize this data to investigate the possibility of genetic heterogeneity, as has been observed for several other skeletal dysplasias.

A validated set of SNPs for linkage mapping studies. *M.D. Rhodes¹, D. Dailey¹, P. Dong¹, D.A. Gilbert¹, C. Scafe¹, Y. Wang¹, M. Laig-Webster¹, X. Su¹, R. Koehler¹, H. Avi-Itzhak¹, J. Ziegler¹, L. Wogan¹, E. Spier¹, F. de la Vega¹, E. Reied², J. Brooking³, F. Dudbridge³, A.M. Dearlove³, M.R. Yuille³.* 1) Genomic Assays Business, Applied Biosystems, Foster City, CA; 2) Department of Medical Genetics, University of Cambridge, Cambridge CB2 2XY UK; 3) MRC geneservice (UK HGMP RC), Babraham, Cambridge CB2 4AT UK.

We will present data on a validated set of SNPs selected to be used for human linkage mapping experiments. These SNPs were selected by the SNP consortium (<http://snp.cshl.org>) as a subset of all the SNPs analyzed. The SNPs were chosen based their positions and informativeness based on initial population frequency .In collaboration with the SNP consortium Applied Biosystems and Celera Genomics then undertook further validation studies.

The first step of this process was to design 5 nuclease assays using Taqman probes for all 2000 identified assays . Population frequencies for these assays were assessed in three different populations, African-American, Asian and Caucasian. The markers were also typed against several multi-generational CEPH families to ensure mendelian inheritance and generate genetic distances.

Data will be presented on the distribution of the SNPs across the genome, in genetic and physical distances, comparisons with existing Microsatellite mapping sets will be shown. Practical use of the SNP set will be presented based on a retrospective study of hereditary spastic paraplegia . . The practical and analytical Implications of shifting from microsatellites to SNPs will be discussed.

Contribution of genetic variants at CARD15 and the chromosome 5q31 locus to Crohn's disease. *C.G. Mathew¹, M. Mirza¹, S. Fisher¹, K. King¹, J. Hampe², J. Sanderson³, A. Forbes⁴, J. Mansfield⁵, A. Cuthbert¹, S. Schreiber², C.M. Lewis¹.* 1) Div Med & Molec Genetics, GKT Sch Medicine, King's Coll London, Guy's Hospital, London, UK; 2) Dept General Internal Medicine, Christian-Albrechts-University, Kiel, Germany; 3) Dept Medicine, GKT Sch Medicine, King's Coll London, St Thomas' Hospital, London, UK; 4) St Mark's Hospital, Harrow, Middlesex, UK; 5) Dept Gastroenterol Hepatol, Univ Newcastle, Royal Victoria Infirmary, Newcastle,.

Inflammatory bowel disease (IBD) is a complex disorder with 2 phenotypic classes, Crohn's disease (CD) and ulcerative colitis (UC). Rioux et al (Nat Genet 29:223-8) recently reported the association of a common haplotype in the cytokine gene cluster on chromosome 5q31 with CD. We have tested this locus for association with disease in a large cohort of European families and patients with IBD. A single nucleotide polymorphism representative of this haplotype (SNP IGR2063b) was genotyped in families containing a total of 511 CD and 320 UC offspring, and tested for association by transmission disequilibrium. Excess transmission of the G allele of C2063G was observed in CD ($p=0.011$), but not in UC. The SNP was then genotyped in 414 unrelated British cases of CD, 387 cases of UC and 362 controls. The G allele frequency was 50.2% in CD, 40.1% in UC and 42.4% in controls, thus confirming significant association with CD ($p=0.0024$). The combined effect of the 5q31 and CARD15 loci was investigated in 558 unrelated CD patients who had been genotyped for the C2063G SNP and for the 3 disease susceptibility SNPs in CARD15. The frequency of SNP 2063G in CD patients with CARD15 genotypes of $-/-$, $-/+$ and $+/+$ was 45.0%, 54.4% and 56.6% respectively. Logistic regression was used to estimate risks conferred by the 5q31 and CARD15 loci. The risks for the 2063CG and GG genotypes in the absence of CARD15 mutations were 1.23 and 1.52 respectively. The highest risk for CD was 32.68 for the genotype CARD15 $+/+$, 5q31 2063GG. The combined population attributable risk for these 2 loci was 62%. Our data therefore provide support for the existence of a CD susceptibility gene of moderate effect on chromosome 5q31.

An Insertion/Deletion Polymorphism in the Human Immunoglobulin V_H Region Identified by Analyzing Single Spermatozoa with 32 Markers. *S. Pramanik, H. Li.* Department of Molecular Genetics, Microbiology and Immunology/The Cancer Institute of New Jersey, UMDNJ-Robert Wood Johnson Medical School, 195 Little Albany Street, New Brunswick, NJ 08903, USA.

The presence of relatively large insertion/deletion polymorphisms in the human immunoglobulin V_H region is implicated by many studies. However, the extent, location and impact of these polymorphisms remain unclear because these polymorphisms are mostly present in heterozygous state, human somatic cells are diploid and it is difficult to determine the physical structure of a region on single chromosomes. The present study was designed, for the first time, to identify insertion/deletion polymorphisms by analyzing a large panel of selected marker sequences in single sperm. Thirty-two markers were selected as unique sequences spaced by ~5 kb that were located near the 3' end of the V_H region. A two-round multiplex PCR protocol was used to amplify these marker sequences from single sperm samples prepared from nine unrelated healthy sperm donors. The parental haplotypes with respect to these markers in the sperm donors were determined by examining the presence or absence of these markers. Results indicate that seven clustered markers in six of the 18 haplotypes were missing and likely represented an insertion/deletion polymorphism with a size of ~35 kb. The ratio for the sperm donors homozygous for the insertion haplotype, the heterozygous haplotype and the homozygous for the deletion haplotype was 4:4:1 which perfectly matched the expectation from Hardy-Weinberg Equilibrium. Three V_H gene segments (2-10P, 3-9 and 1-8), of which two are functional are affected by this insertion/deletion polymorphism. Our results indicate that >10% individuals in the human population may not have these gene segments in their genome and ~ 44% may not have these gene segments in one of their two haplotypes. The biological impact of this polymorphism would be very interesting to study. The approach used in this study could be applied to understand the physical structure and diversity in many chromosomal regions.

Mutation screening of the Split Hand Foot Malformation (SHFM3) by Positional Transcript Analysis. *D. Basel*¹, *T. Homfrey*², *M.W. Kilpatrick*¹, *P. Tsipouras*¹. 1) Pediatrics, Univ Connecticut Hlth Ctr, Farmington, CT; 2) St. Georges Hospital Medical School, London, UK.

Split Hand-Foot Malformation (SHFM) is a non-syndromic disorder, characterized by variable defects of the hands and feet. It is known to occur in a sporadic or familial fashion and has an incidence of 1:18,000 livebirths. SHFM3 was localized to 10q24 in 1996 and it was anticipated that the human homologue of the mouse gene for *Dactylaplasia*, a murine mutant closely resembling the SHFM3 phenotype, would harbor a causative mutation. The absence of a mutation, either in this gene, or in several candidate genes, including FGF8, neuralized, beta-transducin, CHUK, WNT8b and SFRP5, selected for their potential role in the embryonic development of the apical ectodermal ridge, led us to develop a new approach that we term Positional Transcript Analysis (PTA). We first defined a narrow critical region, spanning 4 Megabases, by genotyping several large families and comparing this data to previously reported information. *In silico* analysis of the region identified 65 transcripts comprising both known genes and putative coding sequences. The transcripts were subdivided into three categories; 26 known genes, 13 putative genes and 26 putative transcripts comprising segments of uncharacterized open reading frame. Fragments encompassing these 65 transcripts are being generated by RT-PCR of cDNA derived from whole blood and screened by two methodologies; conformation sensitive gel electrophoresis and chemical cleavage of mismatched base pairs. The observation that several genes involved in the signaling pathways between the apical ectodermal ridge and the posterior mesenchyme of the developing limb bud are clustered within this critical region is compelling evidence that the mutation responsible for SHFM3 involves this signaling cascade. The identification of further candidates by Positional Transcript Analysis allows more directed mutational screening by sequencing. To date several polymorphisms have been identified and it is our expectation that this approach may be helpful in identifying the causative mutation in SHFM3.

Localization of the Gene for a Novel Autosomal Recessive Neuromuscular Disease Featuring Tremulous and Myoclonic Dystonia with MRI White Matter Alterations. *M. Kambouris^{1, 2}, S.A. Bohlega¹, D. Trabzuni¹, P. Carroll¹, B.F. Meyer¹.* 1) King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia; 2) Yale University School of Medicine, New Haven CT, USA.

A novel autosomal recessive neuromuscular disorder characterized by tremor of juvenile onset, dystonia, myoclonus, spasticity, preserved cognitive cerebellar and peripheral nervous system functions with diffuse white matter alterations in brain MRI is segregating in two consanguineous sibships, parts of one extended family. Central conduction times for visual, motor and sensory systems are all prolonged. Lysosomal, peroxisomal, mitochondrial and other metabolic abnormalities were excluded. Homozygosity mapping localized the offending gene to Hsa 17p33 with LOD=3.89 at Q=0. The expected homozygous genotype in all affected individuals was for markers D17S1298 and D17S1537. Additional mapping is currently performed for narrowing of the linkage interval with microsatellite markers and Single Nucleotide Polymorphisms (SNPs). The linkage interval boundaries at present (9.5 million bp at the physical map, contig #NT_010692.7) are defined by the presence of heterozygosity for an informative distal SNP in affected individuals within the MYO1C gene (an excluded positional candidate) and genetic recombination for the proximal marker D17S974. Positional candidate genes screened for pathogenic sequence alterations include i) GABA (A) receptor-associated protein that clusters Gamma-aminobutyric acid (A) neurotransmitter receptors (ligand-gated chloride channels that facilitate inhibitory neurotransmission) by mediating interaction with the cytoskeleton. ii) Synaptobrevin 2 (VAMP2) vesicle associate membrane protein 2 (part of a protein complex involved in the docking and/or fusion of synaptic vesicles with the presynaptic membrane. iii) CHRN (Cholinergic receptor, nicotinic, binds acetylcholine and opens an ion-conducting channel across the plasma membrane) both E and B1 subunits. Mutation screening is by Mutation Detection Enhancement (MDE) Heteroduplex analyses and sequencing. The unique phenotype and localization to 17p33 are consistent with the identification of a novel neuromuscular disorder.

ARH and HCHOLA3: Two different genes at 1p both implicated in familial hypercholesterolemia. *M. Varret¹, M. Abifadel^{1,2}, L. Villegier¹, A. Robin¹, D. Allard¹, M. Devillers¹, JP. Rabes^{1,3}, C. Junien^{1,3}, C. Boileau^{1,3}.* 1) INSERM U383, Hosp Necker-Enfants Malades, Paris, France; 2) University Saint-Joseph, Beirut, Lebanon; 3) Hosp Ambroise Pare, Paris, France.

Familial hypercholesterolemia (FH), one of the frequent monogenic disease is of autosomal dominant transmission in the vast majority of cases and mainly caused by mutations in the low density lipoprotein receptor gene (LDLR) or in the gene encoding its ligand: apolipoprotein B. However we have shown that more than 30% of autosomal dominant hypercholesterolemia (ADH) cases are not associated with mutations in either these two loci. We reported one large French autosomal dominant pedigree (HC2) in which we excluded linkage to the LDLR and APOB genes and mapped a new locus called HCHOLA3 (previously FH3). The HCHOLA3 gene is now located in a 1.6cM interval between D1S211 and D1S2130 at 1p34. Recently, Garcia et al. described autosomal recessive hypercholesterolemic families with mutations in a new gene localized on chromosome 1: the ARH gene that encodes an adaptor protein probably interacting with the LDL receptor. ARH is located at 1p35 between markers D1S2885 and D1S1152. However, its precise localization is not known because the regional contig is incomplete. The genetic proximity of the ARH gene to the FH3 locus intrigued us. Thus we investigated a possible identity of these two genes by linkage analysis, and systematic sequencing of the ARH gene in affected subjects of the HC2 family. We genotyped 9 microsatellite markers in the region between FH3 and ARH and found no common haplotype segregating with ADH in the HC2 family. No mutation was detected by Southern blot analysis and by sequencing the ARH cDNA of affected subjects in HC2 family. Furthermore, we identified the P202S polymorphism. Although Garcia identified a missense mutation (P202H) at the same codon in one of ARH families, the P202S variation did not segregate with the trait in HC2 and was also found in normolipidemic subjects with a frequency of 0.55 among 100 subjects tested. In conclusion, our results show that despite the fact that ARH and FH3 are in neighbouring genetic regions, they are two different genes implicated in FH.

Genome screen of Alzheimer's disease in a recent genetically isolated population. *C.M. Van Duijn, K. Sleegers, P. Heutink, G. Roks, J. van Swieten, P. Snijders, L. Sandkuijl, B.A. Oostra.* Epidemiology & Biostatistics and Clinical Genetics, Erasmus MC, Rotterdam, Netherlands.

Genetically isolated populations may yield opportunities to identify genes involved in complex genetic disorders such as Alzheimer's disease (AD). Although there is ongoing debate on the use of genetically isolated populations such as the Finnish, recently isolated populations have shown large extents of linkage disequilibrium between markers. To localise new susceptibility genes for AD in a recent genetically isolated population in the Netherlands. The study population comprised a genetically isolated Dutch village of 20.000 inhabitants. The population was founded 300 years ago by 150 subjects and is characterized by rapid growth and minimal immigration. We ascertained 150 AD patients, of whom at least 79% were related within 14 generations. For the genome scan, 44 cases with probable AD (mean age 71.6) were selected who were related to each other within 8 generations. A full genome screen was performed using 420 markers at a marker spacing of 10 cM. The data were analysed using a modification of the method of Terwilliger taking into account patient relationships. Further, we used homozygosity mapping in clusters with (multiple) loops in the pedigree. Preliminary analysis of the genome scan shows positive findings at two markers flanking APOE. In total 16 regions were found with similar p-values or lower. Using a cut off p-value of 0.05, positive hits were also found for chromosomes 3, 4, 6, 7, 10, 11, 12, 14 and 18. At present we are fine typing the identified areas to minimize the regions further. Our preliminary analyses suggest that recent genetically isolated populations are a useful tool for identifying regions of interest that might include new susceptibility genes for AD.

A Targeted Linkage Scan for Nonsyndromic Cleft Lip and Palate. *R.E. Schultz¹, M.E. Cooper², E.K. O'Brien¹, K.A. Graf¹, M.L. Marazita², J.C. Murray¹.* 1) Dept Pediatrics, U of Iowa; 2) School Dental Med, U of Pittsburgh.

Cleft lip and palate (CL/P) is a complex multifactorial disorder present in 1/1000 live births. About 70% of cases are nonsyndromic (NS), with no other associated abnormalities. Fifteen loci were examined for linkage to NS CL/P. Loci were chosen based on previous suggestive findings and include 1p36, 2p13, 4p16, 4q31, 6p23, and 14q24. Polymorphic markers in these regions were genotyped on 36 Filipino families comprising 344 individuals with 126 affecteds. Parametric linkage analysis was performed by FASTLINK, and nonparametric analysis was done by SIMIBD 1.21. FBAT 1.2 carried out the TDT analysis. Five markers yielded suggestive results on the 36 families: the MSX1-CA repeat on 4p16, the microsatellite repeat markers GATA8A05 on 4q31 and D6S1029 on 6p23, and SNPs within the TGFA (2p13) and RFC1 (21q22) genes. MSX1-CA gave a maximum LOD of 1.20, a SIMIBD p-value of 0.2, and a TDT multiallele p-value of 0.76. D6S1029 had a maximum LOD of 0.31, a SIMIBD p-value of 0.06, and a TDT multiallele p-value of 0.76. GATA8A05 had a maximum LOD of 1.12, a SIMIBD p value of 0.244, and a TDT multiallele p value of 0.22. When divided into CL and CLP families, the LOD for GATA8A05 in the CLP group increased to 2.05. RFC1 yielded no positive LOD scores for the 36 families, but had a SIMIBD p-value of 0.088. A TGFA SNP had a maximum LOD of 0.44 but more noteworthy was the SIMIBD p-value of 0.01. The parametric LOD scores for MSX1-CA and GATA8A05, and the SIMIBD p-values for D6S1029, and RFC1 are suggestive while the SIMIBD p-value of 0.01 for TGFA is significant. Genotyping is underway on more markers in these regions and on an additional 70 families with 149 affecteds for validation of these results. Since the *Msx1* mouse knockout has cleft palate and MSX1 mutations have been found in rare cases of syndromic CL/P, this locus is plausible for linkage. Previous studies have also found evidence of linkage of NS CL/P to 4q31 and 6p23, and there are several candidate genes in these regions, including AP2 on 6p23 and FGF2, MADH1, and BMPR1B on 4q31. TGFA has long been considered a candidate gene for NS CL/P. This research was supported by NIH grant DE-08559.

Isolation of novel microsatellite markers on chromosome 6p12-q12 region after *in silico* search of human genome sequence databases. J.-I. Kim¹, H. Rhee¹, Y.-M. Lee², J.A. Park², J.-S. Lee^{1,2}. 1) Brain Korea 21 Project, Yonsei University College of Medicine, Seoul, Korea; 2) Department of Clinical Genetics, Yonsei University College of Medicine, Seoul, Korea.

Microsatellite markers are still useful tools in genome analysis including DNA diagnosis. In addition, it may also provide more valuable information than SNP markers for some genes. In the present study, we have tried to develop new microsatellite markers within chromosome 6p12-q12 region using human genome sequence databases. Human genome sequence databases at UCSC and NCBI were used for *in silico* search of candidate regions of microsatellite markers. Computer program eTRF(Exact Tandem Repeats Finder) was developed to investigate the chromosomal region of 20Mb. After *in silico* search, 61 regions were identified as possible microsatellite markers that contain (CA) or (TG) repeats more than 20 times. Twenty-one among 61 regions which were found to be unique in human genome were selected for experimental validation. PCR primers were designed from flanking sequences of each region and heterozygosity were obtained with 50 individuals among Korean population. All of 21 regions revealed containing microsatellite markers. Heterozygosities were between 0.4 - 0.9 and the maximum difference among the alleles were 12bp on average in Korean population. Many disease genes are mapped to chromosome 6p12-q12 such as congenital nystagmus 2, cone-rod dystrophy 7, Leber congenital amaurosis and dilated cardiomyopathy. Our results would be useful resources to facilitate the identification of these disease genes.

Program Nr: 1601 from 2002 ASHG Annual Meeting

A system approach to high throughput microsatellite analysis. *A. Wheaton, L. Joe, S. Bay, B. Johnson, J. Briggs, C. Brown, O. Ostadan, T. Hatch, Y. Lou.* Applied Biosystems, Foster City, CA.

The completion of the human genome project has introduced a new paradigm in human disease research. With an increasing emphasis on complex diseases, investigators need cost effective, precise tools to rapidly scan the genome for variations. Researchers using traditional methods for high throughput microsatellite analysis face multiple obstacles, such as assay design, sample loading and detection, and data interpretation. Applied Biosystems has taken a system-wide approach to remove these barriers by: developing a pre-configured assay (the ABI PRISM® Linkage Mapping Set v2.5); and introducing a production level capillary electrophoresis instrument, along with highly automated analysis software. The Applied Biosystems 3730 DNA Analyzer, a 48 capillary system, offers the ideal platform for high throughput microsatellite analysis. With the capacity for 48 runs per day, the 3730, in concert with 5-dye chemistry, can generate over 46,000 genotypes per day. The system is completed with GeneMapper™ version 3.0, a fully integrated analysis solution that simplifies the allele calling process. We describe the benefits of this system for high throughput automated microsatellite analysis.

Mapping of a gene for juvenile nephronophthisis to chromosome 1p36. *S. Saunier¹, G. Mollet¹, R. Salomon¹, O. Gribouval¹, F. Silbermann¹, C. Antignac^{1,2}*. 1) Inserm U423, Necker Hospital, Paris, France; 2) Department of Genetics, Paris 5 University, Necker Hospital, Paris, France.

Nephronophthisis (NPH) is an autosomal recessive kidney disorder representing the most frequent inherited cause of chronic renal failure in children. Modifications of the tubules with widening of the basement membrane, interstitial fibrosis and later on, cysts at the cortico-medullar junction are the prominent histological features of the disease. Three loci have been identified, one on chromosome 2q13 (*NPHP1*) for the more common juvenile form, and 2 on chromosomes 9q22 (*NPHP2*) and 3q21 (*NPHP1*) for the infantile and adolescent forms respectively. *NPHP1* encodes a protein (nephrocystin) that contains an SH3 domain and which is implicated in cell-cell and cell-matrix interaction processes through interaction with intracytoplasmic proteins. Since genetic heterogeneity has been shown in juvenile NPH, we undertook a genome-wide linkage analysis in 8 families that were excluded from the 3 known NPH loci and identified a new disease locus, *NPHP4*, on chromosome 1p36. A total of 395 markers were analyzed. We found no evidence of linkage to the 2q13 locus neither to the 3q21 and 9q22 locus previously reported, while two adjacent markers *DIS214* and *DIS2667* on chromosome 1p36 demonstrated segregation with the disease haplotype. The evidence of linkage was highly significant with a maximum two-point lod score for *DIS214* (lod score: 5.3, $q = 0.05$). Haplotype analysis identified a gene interval of 8.7-cM. These results confirm the recent data by Schuermann et al. (*Am J Hum Genet*, 2002, 70:1240-47). Mutational analysis of candidate genes in this region is currently performed in order to identify a new causative gene for NPH. Interestingly, in one of the family linked to this new locus, the 3 affected children present with NPH and Cogan syndrome, a rare neurological disorder, characterized by oculo-motor apraxia and vermis hypoplasia, suggesting a pleiotropic effect of this gene as it has been shown for *NPHP1*. Of note, 4 families were not linked to this locus indicating further genetic heterogeneity.

Program Nr: 1603 from 2002 ASHG Annual Meeting

Three model SNP genotyping assays for human disease: venous thrombosis, breast cancer, and familial Mediterranean fever. *M.D. Dobbs, R.M. Oda, Z. Jiang, S.K. Boyer.* Biological Systems Organization, Beckman Coulter, Inc., Fullerton, CA.

Single nucleotide polymorphisms (SNPs) are the subject of many novel technology development activities because of their high genome density. The ideal SNP genotyping assay will be very accurate, inexpensive, easy to perform, and capable of high throughput. Single-base primer extension utilizes the inherent accuracy of DNA polymerase to determine the presence or absence of specific nucleotides at SNP sites. Single-base extension can also be utilized on several different hardware platforms, and has the advantage of being easily multiplexed. The CEQ™ DNA Size Standard 80 and CEQ™ SNP-Primer Extension Kit were developed for Beckman Coulter's CEQ™ 8000 Genetic Analysis System to provide CEQ users an accurate, inexpensive, simple, and robust solution for multiplex SNP scoring and validation based on single-base extension technology. We present three model multiplex SNP assays for important human diseases: Venous Thrombosis (coagulation factor V gene), Breast Cancer (*brca-1* and *brca-2* genes), and Familial Mediterranean Fever (*MEFV* gene). The assays demonstrate high accuracy and improved throughput through automation and compare favorably with other techniques. The SNP protocols on the CEQ are model methods that can be applied to any other set of SNP polymorphisms.

Implementation of High Throughput SNP genotyping. *J.M. Moore¹, B. Blumenstiel¹, M. DeFelice¹, J. Roy¹, H. Nguyen¹, N. Hattangadi¹, A. Lochner¹, M.J. Daly¹, D. Altshuler^{1,2}, S.B. Gabriel¹.* 1) Center for Genome Research, Whitehead Institute, Cambridge, MA; 2) Departments of Genetics and Medicine, Harvard Medical School; Department of Molecular Biology, Massachusetts General Hospital, Boston, MA.

Our goal is to implement a high quality, scaleable SNP genotyping pipeline. We present data on three aspects of MassArray (Sequenom) platform. First, we have carried out production level genotyping. As part of the TSC Allele Frequency program we scaled SNP genotyping over eight-fold during 2001, averaging 720,000 genotypes per month (80% assay pass rate) over the last six months. Over 15,000 SNPs from the public map were genotyped in multiple population samples. We find an error rate of <0.4% based on reproducibility in duplicate genotypes and inheritance inconsistencies in families. Overall 83% of assays attempted passed all quality checks and were successfully genotyped.

Second, to assess pooled genotyping as a method to rapidly validate candidate SNPs, we implemented a process for genotyping on pooled DNA samples. We have rapidly screened over 10,000 SNPs with this approach across three populations and have directly compared allele frequency estimates from DNA pools to actual frequencies determined from individual genotypes for over 1,000 assays. We find the standard deviation of discrepancy between the measures is 0.05.

Third, we carried out a comparison of the MassArray platform to two additional platforms, Invader (Third Wave) and Taqman (Applied Biosystems). Using a common set of 192 SNPs, we attempted to design assays and genotype a single set of 96 DNA samples. Of assays successfully designed, Sequenom offered the highest rate of assay conversion (86%), with the others producing similarly robust assay design of 75% and 80% by Invader and Taqman, respectively. Error rates were acceptably low in all three methods (<0.5%). In conclusion, we have successfully implemented individual and quantitative genotyping on MassArray and find that this platform, as well as the others evaluated offer robust assay design and accurate genotyping.

Program Nr: 1605 from 2002 ASHG Annual Meeting

Evaluation of new microsatellite analysis software on the MegaBACE platform using multiple populations and marker panels. *E. Shipstone, J. Ellerbrock, D. Meyers, A. Merla, M. Reagin, P. Herzer.* Genomics Applications, Amersham Biosciences, Piscataway, NJ.

A new microsatellite analysis software package, Genetic Profiler v2.0 was evaluated using multiple populations and marker panels. Samples from Amish, Ashkenazi and Mormon populations were used to test the analysis capabilities of the software. Custom marker panels were designed using the software's marker panel editor feature. Markers from various regions of chromosomes 10, 14 and 15 were used to evaluate the capability of the software to identify and characterize di-, tri- and tetranucleotide repeats. Genetic fingerprinting, fragment analysis and expression analysis by peak area calculation were performed. Genetic Profiler v2.0 represents an improvement for analyzing microsatellite data on the MegaBACE platform.

Discovery of single nucleotide polymorphisms in eleven genes involved in muscle function: efficiency of a systematic sequencing approach compared to bioinformatic extraction with five SNP databases. *J.M. Devaney, B.T. Harmon, E.P. Hoffman.* Research Center for Genetic Medicine, Childrens National Medical Center, Washington, DC.

Moving on from the completion of the human genome sequence, studies on DNA variation between individuals will contribute further to the understanding of human genetics. For example, single nucleotide polymorphisms (SNPs) can significantly contribute to the characterization of the genes predisposing an individual to muscle hypertrophy. We report a SNP survey of coding and non-coding regions of eleven genes involved in muscle function, by two successive methods. First, we used high-throughput sequencing of 96 ethnically diverse (36 Caucasian samples, 29 African-American samples, 26 Hispanic samples, and 5 Asian samples) samples to examine around 2.4 million bps. Following sequencing, we examined the traces using a combination of PhredPhrap and PolyPhred software packages that enable rapid analysis for sequence variation amongst the 96 samples. Using this method we discovered 23 SNPs (4 non-synonymous). Second, we compared our newly discovered SNPs to the list of SNPs found for the same eleven genes in five available SNP databases: Celera SNP database, jSNP, dbSNP, HGVbase, and HGMD. Interestingly, we discovered eleven SNPs (three non-synonymous) in the cardiac ankyrin repeat protein gene and none of the SNPs discovered are present in the SNP databases. Therefore, identification of variation in genes should involve high-throughput sequence analysis combined with database searching.

Fine-mapping the bipolar affective disorder locus on chromosome 18q22: A report from the half-way point. *Y-S. Chen¹, N. Akula¹, T. Schulze¹, J.R. DePaulo², N. Cox¹, J. Badner¹, K. Hennessy¹, T. Nguyen¹, F.J. McMahon¹.* 1) University of Chicago, Chicago, IL (USA); 2) Johns Hopkins University, Baltimore, MD (USA).

Several studies have detected evidence of genetic linkage between bipolar affective disorder and chromosome 18q22. Linkage analysis of our clinically-selected subset of families also supports linkage in this region and defines a 5 MB interval containing 10 consecutive microsatellite markers with lodscores >3 . Sequencing in this region is still in progress, encompassing a 60-BAC contig with 3 gaps, 5 known, and up to 25 predicted genes. In order to determine the genetic variation that accounts for the linkage evidence in this region, we are performing systematic linkage disequilibrium mapping with SNPs at 25 kb density. All SNPs are genotyped in 100 cases and 100 ethnically-matched (CEPH) controls by single-base extension methods. We have now completed genotyping and association analysis on 86 SNPs at a median intermarker distance of 58 kb. Linkage disequilibrium analysis between adjacent markers reveals D' values greater than 0.3 across 53% of the region. The majority of SNPs show no evidence of association. Three widely-spaced SNPs show evidence of association at the $p < 0.05$ level. One SNP shows evidence of association at the $p < 0.01$ level, and all of the linkage evidence in this sample is contained in those 17 families segregating the associated allele. Five nearby SNPs spanning a 10 kb interval also show evidence of association at the $p < 0.05$ level, but none of these SNPs partitions the linkage evidence or increases the evidence of association in haplotype-based analysis. These findings do not convincingly account for the linkage evidence on 18q22, but may warrant replication testing in other samples.

Pharmacogenetic analysis in a Gleevec™/Glivec® study of patients with CML identifies an association between fluid retention and a polymorphism in IL1B. *R. Malinowski¹, R. Capdeville², I. Gathmann², S. Kudaravalli¹, M.H. Polymeropoulos¹, M.A. Dressman¹ and IRIS (International Randomized IFN vs STI571) Study Group.* 1) Pharmacogenetics, Novartis Pharmaceuticals Corporation, Gaithersburg, MD; 2) Novartis Pharma AG, Basel, Switzerland.

Gleevec™/Glivec® (imatinib, STI571), an inhibitor of the *bcr-abl* tyrosine kinase, has been shown to be highly effective in the treatment of chronic myelogenous leukemia (CML). Fluid retention was a frequent adverse event involving Gleevec™, occurring in 47-56% of patients in three Phase III clinical trials. Fluid retention described here generally consists of periorbital and facial edema in the skin and subcutaneous region. Pharmacogenetic analysis was completed on a subset of 109 patients from a Phase III study of Gleevec™ versus Interferon- α combined with cytarabine in patients with newly diagnosed previously untreated Philadelphia chromosome positive chronic myelogenous leukemia in chronic phase. We examined 70 SNPs from 26 genes to identify surrogate markers for fluid retention. An association was discovered between the -511 polymorphism in the interleukin-1 beta gene (IL1B) and the adverse event of fluid retention in female patients treated with Gleevec™ ($P = 0.004$). Female patients with the CC genotype for the -511 IL1B polymorphism are 13.0 times more likely to experience fluid retention than those with a non-CC genotype (95%CI 2.07-81.48). The IL1B SNP, representing a C>T transition, is found 511 base pairs upstream from the transcription start site of the IL1B gene. This polymorphism is reportedly in linkage disequilibrium with the -31 polymorphism that functionally relates to a decreased level of expression of the IL1B gene. The association of the autosomal -511 IL1B polymorphism with edema in females is surprising but may be related to the increased incidence of edema observed in women compared to men treated with Gleevec™.

Genetic variants associated with increased susceptibility for Down syndrome-associated Atrioventricular Septal

Defects. *K.F. Kerstann¹, S.B. Freeman¹, E. Feingold², L.J. Bean¹, M. Meltzer³, A. Heffner³, G. Capone^{3,4}, S.L.*

Sherman¹. 1) Dept. of Human Genetics, Emory University School of Medicine, Atlanta, GA; 2) Dept. of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 3) Div. of Neurology and Developmental Medicine, Kennedy Krieger Institute, Baltimore, MD; 4) Dept. of Pediatrics Johns Hopkins Medical Institutions, Baltimore, MD.

Atrioventricular septal defects (AVSD) occur in about 20% of live births with Down syndrome (DS), while in only 3-4/10,000 live births with euploid chromosome complements. This increased risk among individuals with DS must be associated with increased dosage of chromosome 21 specific genes. However, the observation that only 20%, not 100%, of DS individuals have AVSD suggests that genetic variation and/or environmental factors influence the susceptibility of this birth defect. The increased dosage of a gene(s) on chromosome 21 may lead to altered regulation or function of the chromosome 21 specific gene(s) and/or may cause downstream effects on other non-chromosome 21 genes. The overall goal of this project is to identify genes and environmental factors that lead to the susceptibility of AVSD among individuals with DS. We have begun by testing the hypothesis that genes on chromosome 21 play a role in heart development and that when in triplicate, specific allelic forms lead to susceptibility for AVSD. We have focused on 21q22.2-22.3, between markers D21S55 and COL6A2, a proposed critical region for congenital heart defects (CHD) and specifically on genes within this region found to be expressed in fetal heart. Of particular interest is SH3BGR, a gene within the critical region and shown to be expressed during heart development. The genetic variation within SH3BGR is primarily contained within a set of 20 SNPs that fall into 5 previously reported haplotype blocks. This variation is being compared between 54 individuals with DS and complete AVSD(cases) and 92 individuals with DS and no CHD(controls). Newly developed statistical methods for comparison of trisomic genotypes, incorporating a TDT approach will be used to assess differences among cases and controls.

The polymorphisms in the eosinophil cationic protein gene and its influence on the serum ECP level. E.

Noguchi^{1,2}, *A. Iwama*³, *J. Nakayama*^{1,2}, *K. Ichikawa*², *M. Shibasaki*², *T. Arinami*¹. 1) Department of Medical Genetics, University of Tsukuba, Tsukuba, Ibaraki, Japan; 2) Department of Pediatrics, University of Tsukuba, Tsukuba, Ibaraki, Japan; 3) Department of Immunology, University of Tsukuba, Tsukuba, Ibaraki, Japan.

Asthma is characterized by reversible airway obstruction and airway inflammation. Serum levels of eosinophil cationic protein (ECP) might reflect eosinophilic airway inflammation and asthma activity. However, the serum ECP levels are not elevated in some asthmatic patients, even when they are symptomatic. In this study, we screened for polymorphisms in ECP and analyzed the associations of these polymorphisms with asthma and serum ECP levels in 137 Japanese families identified through asthmatic children. We identified three polymorphisms (-393C/T, -38C/A and 124Arg/Thr) in human ECP. We did not find associations between these polymorphisms and asthma by transmission disequilibrium test. However, we found that serum ECP levels in subjects with the -393T allele were significantly lower than those in subjects with the -393C allele. A reporter construct with the -393T allele showed significantly lower promoter activity than one with the -393C allele. These data indicate the -393T allele has low transcriptional activity compared with that of the -393C allele and that measurement of ECP levels for the assessment of asthma activity may be improved when done in combination with genotyping of the -393C/T polymorphism.

Haplotype-based association of DRD2 gene to alcoholism with antisocial personality disorder. *K. Xu, J. Tabuman, C.H.D. Bau, M. Virkkunen, M. Linnoila, E. Ferro, W. Astor, D. Goldman.* Lab Neurogenetics, NIAAA/NIH, Rockville, MD.

Because of the role of the D2 receptor in reinforcement, the DRD2 gene has been extensively studied in addictive behaviors, but with conflicting results. One critical problem has been a focus on a limited number [or even one, usually the Taq1A locus] of nonfunctional markers at the gene. To better understand the relationship of DRD2 variants and addictions, we have genotyped [using 5 nuclease assays] DRD2 using a panel of ten loci, including the functional loci Ser311Cys and -141delC, and this panel spans the 80 kb of chromosome 11q23 that contains the entire DRD2 gene region, including a 50 kb intron separating the non-coding first exon from the remainder of the exons. We have completed haplotype-based analyses using four loci including the two functional loci plus Taq1A [10 kb downstream] and Taq1B [located in IVS 1]. Linkage was performed in a Finnish population composed of 63 alcohol dependence (AD) with antisocial personality disorder (ASPD) and 141 unaffected individuals. Frequency of the Taq1B A allele was higher in individuals with AD plus ASPD than in the unaffected group (Chi-square = 7.314, 2 df p = 0.026, for genotype ; Chi-square = 5.298, 1 df p = 0.021 for allele frequency). There was no association of any of the other three SNPs with AD plus ASPD. The overall 11 haplotypes comparison between AD plus ASPD and control group was significant different. (Chi-square = 23.47 10 df p = 0.009). Moreover, the haplotype CACG was more abundant in AD with ASPD group (0.188) than in the unaffected group (0.067) (Chi-square = 7.689 1df p = 0.006). Taken together, we conclude that the DRD2 gene may be a susceptibility gene for AD with ASPD in a Finnish population, warranting efforts to close in on the locus that may be influencing vulnerability through altered DRD2 function.

Analyses on the association of Fcγ receptor family and *TNFR2 (TNFRSF1B)* polymorphisms with susceptibility to rheumatoid arthritis in Japanese. C. Kyogoku¹, N. Tsuchiya¹, K. Matsuta², T. Shibue¹, K. Tokunaga¹. 1) Dept of Human Genetics, The University of Tokyo, Tokyo, Japan; 2) Matsuta Clinic, Tokyo, Japan.

We recently reported a new polymorphism of *FcγRIIB* gene (*FCGR2B*), which alters Ile at position 232 to Thr (*I232T*) within the transmembrane domain, and its association with SLE in Japanese. Functional importance of *FcγRIIB*, as well as other *FcγRs*, in RA has previously been shown; therefore, we examined whether *FCGR* polymorphisms were associated with susceptibility to RA in Japanese. *TNFR2* is another candidate gene located on one of the chromosomal regions implicated from genome-wide linkage studies, and recent studies demonstrated that *TNFR2-196R/R* genotype was significantly increased in familial RA in Caucasians. Our previous study showed a tendency of increase of *196R/R* genotype in Japanese sporadic RA ($P=0.10$). Therefore, we genotyped additional patients and controls to further test the association of *196R/R* in Japanese.

Genotyping of *FCGR2B-I232T*, *FCGR2A-H131R*, *FCGR3A-F176V*, *FCGR3B-NA1/2* and *TNFR2-M196R* polymorphisms were performed in 382 Japanese patients and 303 healthy individuals for *FCGRs*, and in 588 patients and 308 controls for *TNFR2*.

Significant difference in the distribution of genotype, allele carrier and allele frequencies was not observed between RA and controls in *FCGR* genes. However, when the subjects were stratified according to the carriage of *HLA-DRB1* shared epitope (SE), significant increase of *FCGR3A-176F/F* genotype was observed in SE positive RA (55.9%) compared with SE positive controls (41.5%) ($P=0.009$).

As for *TNFR2*, a tendency of increase of *196R/R* genotype in RA (2.9%) compared with controls (1.0%) was observed ($P=0.07$). However, estimation of genotype relative risk, which adjusts control data for Hardy-Weinberg equilibrium, indicated significant association of *196R/R* genotype with RA ($c^2=6.2$, $P=0.01$, OR:2.3).

These results indicated that *FCGR3A-176F/F* genotype confers risk for RA through genetic interaction with *HLA-DRB1* SE, and *TNFR2-196R/R* genotype may be a weak, but true, risk factor in the sporadic RA, in Japanese.

Examination of Candidate Genes on Chromosome 7 in Autism. *H.B. Hutcheson¹, L.M. Olson¹, Y. Bradford¹, S.E. Folstein², S.L. Santangelo³, J.S. Sutcliffe¹, J.L. Haines¹.* 1) Dept. Molecular Physiology and Biophysics, Program Human Genetics, Vanderbilt University Medical Center, Nashville, TN; 2) Dept. of Psychiatry, New England Medical Center/Tufts University School of Medicine, Boston, MA; 3) Psychiatric & Neurodevelopmental Genetics Unit, Massachusetts General Hospital, Boston, MA.

We previously reported a method for examining haplotype data in the CLSA chromosome 7-linked families to narrow the most likely chromosome 7 autism candidate region (*AUTS1*) to a 3 cM interval located between D7S496-D7S2418. In this study, we chose to examine 4 candidate genes (*NRCAM*, *LRRN3*, *KIAA0716*, *LAMB1*) based on their proximity to the microsatellite marker corresponding to the highest LOD score in this subset of thirty families (D7S1817), their expression patterns, and their biological relevance to autism. We analyzed 36 intronic and exonic single nucleotide polymorphisms (SNPs) and one microsatellite marker spaced at ~10kb intervals within and around these 4 candidate genes. This was done to provide as complete coverage as possible since linkage disequilibrium (LD) can vary dramatically across even very short distances within a gene. Association analysis included both single locus (PDT) and multilocus (TRANSMIT) approaches. We also examined the extent of LD within these genes and across this region. As expected, we observed blocks of significant LD within each of these genes but did not observe significant LD across genes since these genes span a distance of 3.5Mb. None of the polymorphisms in *NRCAM*, *LRRN3*, or *KIAA0716* singly or in combination gave *P* values <0.05 suggesting that none of these genes is associated with autism susceptibility in this subset of chromosome 7-linked families. However, analysis of *LAMB1*, which encodes a protein that has an integral role in embryonic axonal guidance, revealed suggestive evidence for allelic association, including one individual SNP (*P*= 0.02) and three separate two-SNP haplotypes across the gene's transcriptional unit (0.007, 0.012, and 0.012). Currently, we are screening the 34 exons of *LAMB1* for susceptibility variants in autistic individuals.

An autoimmune diabetes locus (*Idd21*) on mouse chromosome 18. *R.J. Hall¹, J.E. Hollis-Moffat¹, M.E. Merriman¹, R.J. Bridges¹, R.A. Green¹, G. Williams¹, D. Baker², T.R. Merriman¹.* 1) Biochemistry Department, University of Otago, Dunedin, New Zealand; 2) Department of Neuroinflammation, Institute of Neurology, University College London, London, UK.

Autoimmune diabetes occurs spontaneously in the non-obese diabetic (NOD) mouse and is used to model human type 1 diabetes (T1D). The condition is precipitated by the action of multiple insulin-dependent diabetes (*Idd*) genes which cause a loss of immune self tolerance and subsequent destruction of insulin-secreting pancreatic b-islet cells in the NOD mouse. Genes of the major histocompatibility complex (MHC) are the major genetic determinant of disease with at least twenty other non-MHC loci contributing to a lesser extent. A meta-analysis of genome-wide linkage scans suggests the presence of an autoimmune disease locus on distal mouse chromosome 18 - this region is orthologous to human chromosome 18q12-q21 (which contains the T1D locus *IDDM6*) and rat distal chromosome 18 (which contains the T1D locus *Iddm3*). In this study we present evidence for linkage of mouse chromosome 18 to diabetes in a (ABH x NOD)F1 x NOD backcross. A consomic strain of NOD with chromosome 18 derived from the diabetes resistant strain ABH was generated (NOD.ABH-Chr18). These mice show a delayed onset and an overall reduced frequency of diabetes when compared to the parental NOD mice ($P < 0.0001$). However, no difference in the amount of inflammation within the endocrine pancreas was observed at 8 - 9 weeks of age. Our data confirms the presence of a diabetes susceptibility locus on mouse chromosome 18, which we have named *Idd21*.

Investigation of Human Chromosome 3q for a Major Susceptibility Gene for Diabetic Nephropathy using Linkage Disequilibrium Mapping. *D.P.K. Ng, J.J. Rogus, A. Antonellis, L.H. Canani, Y. Makita, D. Moczulski, M. Nam, W.H. Walker, A. Smiles, J.H. Warram, A.S. Krolewski.* Section on Genetics and Epidemiology, Joslin Diabetes Center, Boston, MA.

Strong evidence from linkage studies supports the presence of a major susceptibility gene for diabetic nephropathy (DN) on human chromosome 3q. Recently, we undertook a systematic search of a 1.2 Mb chromosomal region which contains a number of positional candidate genes for DN. These include genes for angiotensin II type 1 receptor (*AGTR1*), carboxypeptidase A3 (*CPA3*) and carboxypeptidase B1 (*CPB1*). Based on our physical map (also supported by Human Genome Project and Celera Genomics draft assemblies), these genes are encompassed within a ~750 kb region. To scrutinize this promising region, 48 single nucleotide polymorphisms, 4 insertion/deletions and 5 microsatellites were developed. Allele frequencies were compared between 94 type 1 diabetic patients with advanced DN (Cases) and 94 patients who have remained normoalbuminuric despite >15 years of diabetes (Controls). Distortion in allele distribution was observed for six markers (markers 34, 35, 37, 38, 41, 54) ($P < 0.05$). The region was next partitioned into haplotype blocks (Daly et al. 2001) as defined by the occurrence of historical recombinations. Adapting the algorithm of Hudson and Kaplan (1985), 20 blocks were defined in this region. Frequencies of common (i.e. >5%) haplotype tags (Johnson et al. 2001) in each block were compared and significance was assessed empirically. Subsequent 2-marker haplotype analyses revealed that the '2-1' haplotype formed from markers 37 and 38 (both in *CPB1* locus but residing in separate haplotype blocks), was more prevalent among Cases (41%) than Controls (25%) (nominal significance after adjustment for multiple comparisons). Our ongoing work involves confirming positive markers using larger Case-Control studies and TDT analyses. Strategies are currently being developed to test 'super-haplotypes' derived from combinations of individual block haplotypes. This approach allows for the possibility that the DN susceptibility allele(s) may be associated with only a subset of common haplotypes within a given block.

Genetic Linkage of Francois-Neetens fleck (mouchetée) Corneal Dystrophy to Chromosome 2q35. X. Jiao¹, F.L. Munier², D.F. Schorderet², B.I. Rubin¹, J. Smith¹, J.F. Hejtmancik¹. 1) National Eye Inst, NIH, Bethesda, MD; 2) Oculgenetic Unit, Jules Gonin Eye Hospital and Division of Medical Genetics, Lausanne, Switzerland.

Francois-Neetens fleck (mouchetée) corneal dystrophy is an autosomal dominant corneal dystrophy characterized by scattered small clear flecks occurring at all levels of the corneal stroma. The number of flecks usually varies from tens to hundreds, but can be rare and the flecks can even occur unilaterally. Clinically, although CFD may occasionally cause mild photophobia, patients are typically asymptomatic and have normal vision, the disease most often being found on routine examination. We report linkage of the CFD locus to D2S2289 ($Z_{\max} = 5.92$, $q = 0$), D2S325 ($Z_{\max} = 4.67$, $q = 0$), D2S317 ($Z_{\max} = 3.68$, $q = 0$), D2S143 ($Z_{\max} = 4.37$, $q = .03$), and D2S2382 ($Z_{\max} = 4.71$, $q = 0$) on chromosome 2q35. Multipoint analysis confirmed linkage to the region between D2S117 and D2S396 with a maximum multipoint lod score of 6.38 located at D2S157. Candidate genes in this region are currently being screened for mutations.

Transmission/disequilibrium tests of microsatellite polymorphic markers nearby skeletal muscle ion channel genes in Thai families with thyrotoxic periodic paralysis. *W. Jongjaroenprasert¹, A. Al-chalabi¹, S. Nakasatian³, B. Ongphiphadthanakul⁴, R. Rajatanavin⁴, T. Himathongkum³, R.G. Dluhy², R.H. Brown¹.* 1) Cecil B Day Laboratory for Neuromuscular Research, Massachusetts General Hospital East, Charlestown, MA02129, USA; 2) Division of Endocrinology and Hypertension, Brigham and Women's Hospital, Boston, USA; 3) Theptarin Hospital, Bangkok, Thailand; 4) Endocrine Unit, Ramathibodi Hospital, Mahidol University, Thailand.

Thyrotoxic periodic paralysis (TPP) is characterized by periodic episodes of hypokalemia and weakness in thyrotoxic patients. It has been predominantly described in male Oriental population. Clinical features are similar to familial hypokalemic periodic paralysis (FPP). Defects in genes encoding three types of skeletal muscle ion channels have been implicated in FPP. We have therefore performed a family-based study to test the hypothesis that alleles defined by microsatellite polymorphic markers within 1cM of these three ion channel genes are over-represented in TPP which would potentially implicate the associated ion channels in the pathogenesis of TPP. Genotyping of Microsatellite markers within 1 cM of the genes coding for ATP-sensitive potassium channel (KCNJ11), Kir-related peptide (ABCC9), voltage-gated potassium channel (KCNC4), Mink-related peptide 2 (KCNE3), alpha-1s subunit of the L-type voltage-dependent calcium channel (CACNA1S) and the alpha subunit of the voltage dependent, type IV, sodium channel (SCN4A) were obtained using an automated DNA sequencer (Licor) with and RFLP Scan software. The significance of association of specific alleles with the TPP trait was evaluated by TDT and sib-TDT. Pedigrees of 30 Thai TPP patients were studied. All patients were males with thyrotoxicosis secondary to Graves disease. High serum thyroid hormone and low potassium levels were confirmed during weakness. Genotypes were obtained on 133 individuals (30 cases and 103 family members). We did not detect evidence of association or over-representation of any of the above microsatellite polymorphic markers with the TPP trait in these 30 pedigrees. These data suggest that polymorphisms or variants within these six genes are not related to the pathogenesis of TPP.

An E23K SNP in the islet ATP-sensitive K⁺ channel gene (Kir6.2) contributes to the risk of type 2 diabetes in Caucasians. *L. Love-Gregory¹, J. Wasson¹, J. Lin², G. Skolnick¹, B. Suarez², M. Permutt¹.* 1) Div Metabolism, Washington Univ Sch of Medicine, St Louis, MO; 2) Psychiatry-Instruction & Research, Washington Univ Sch of Medicine, St. Louis, MO.

It is still unknown as to whether common or rare variants are the culprits in the development of type 2 diabetes (T2D) and if these susceptibility loci will have a single allele altering risk or if combinations of these variants will affect risk. One such common polymorphism occurs in Kir6.2 (KCNJ11 gene on 11p15.1), a subunit of the inwardly rectifying ATP sensitive K⁺ channel (involved in the regulation of insulin secretion in pancreatic b-cells). In Hani EH et.al., *Diabetologia* (1998), we reported an association between the Kir 6.2 E23K polymorphism (KK) genotype and T2D in a case-control meta-analysis. Recently, Schwanstecher C, et al., *Diabetes* (2002) demonstrated a dose-dependent reduction in ATP sensitivity of the Kir6.2 E23K variant. Hence, we decided to re-evaluate the common E23K polymorphism by genotyping an additional population (Ashkenazi Jewish-unpublished) and including the UKPDS data. Here we assessed the relative risk associated with the (K) allele and the homozygous E23K (KK) status.

The results of this analysis showed that the homozygous E23K (KK) genotype was more frequent in the T2Ds than the control group [0.18 (n=1153) vs 0.11 (n=1076), respectively, corrected p=1.0 x 10⁻⁴]. When the relative risks from the 6 studies were weighted by their sampling variance, meta analysis indicated that the K allele increases risk by an average of 13% (95% CI: 1.07 to 1.18) which translates into an average attributable relative risk of 11.4% for the populations in these studies. This suggests that if this sample population were monomorphic for the non-risk allele (E), the prevalence of T2D would be 11.4% lower in this group. The KK homozygote is at greatest risk (RR=1.28, 95% CI: 1.19 to 1.37). This confirms that the E23K (KK) genotype increases susceptibility to T2D and is comparable to the risk associated with PPARγ Pro12Ala (a variant that has consistently been shown to be associated with an increase in risk of T2D).

Association Studies of Apolipoprotein AV and Familial Combined Hyperlipidemia. *R.A. Mar¹, H. Allayee¹, G.M. Dallinga-Thie², R.M. Cantor¹, T.W.A. de Bruin³, A.J. Lusi¹.* 1) Dept. of Human Genetics, UCLA, Los Angeles, CA 90095; 2) Dept. of Medicine, University Hospital, Utrecht, The Netherlands; 3) Dept. of Internal Medicine, University of Maastricht, The Netherlands.

Familial combined hyperlipidemia (FCH) is a complex, heterogeneous disorder characterized by elevated levels of plasma cholesterol and/or triglycerides. Multiple studies have reported linkage to the apolipoprotein (APO) AI-CIII-AIV region on chromosome 11q. The minor alleles of three restriction site polymorphisms, XmnI and MspI located in APOAI and SstI in APOCIII, were previously shown to be more frequent in 18 Dutch FCH probands and hyperlipidemic relatives compared to normolipidemic controls. These alleles were also associated with elevated plasma cholesterol, triglycerides, apoB and apoCIII levels. APOAV, located 30kb downstream of APOAIV, has recently been shown to influence plasma triglycerides in mice and humans. To investigate the role of APOAV in FCH, a promoter and two intronic SNPs were genotyped in 80 Dutch FCH probands and 100 unrelated controls as well as in a US population of 400 combined hyperlipidemics and 230 normolipidemic controls. The minor alleles of the two intronic SNPs, but not the promoter polymorphism, were more frequent in the US combined hyperlipidemics compared to controls ($P < 0.025$ and 0.05). These SNPs were also associated with elevated plasma triglycerides in both combined hyperlipidemics and controls ($P < 0.005$ and 0.01). Although no significant difference in the frequency of the SNPs was observed between the Dutch probands and controls, the XmnI, MspI, and SstI genotypes were used to build haplotypes with the APOAV SNPs. Pairwise measure of linkage disequilibrium between the SstI polymorphism and each of the three SNPs in APOAV yielded $|D'|$ values of 1.00 for all three SNPs in the proband group, but only $|D'|$ values of 0.552, 0.554, and 0.417 in the spouses. The strong LD observed between polymorphisms in APOCIII and APOAV in FCH probands, but not the spouses, suggests that both genes play a causal role in FCH. Taken together, these data further indicate the complex genetic contribution of this gene cluster to FCH as well as lipid levels in the general population.

Program Nr: 1620 from 2002 ASHG Annual Meeting

Tests for Association for Quantitative and Censored Traits. *O. Mokliatchouk.* Mathematics & Computer Sci, Drexel Univ, Philadelphia, PA.

The intended use of the transmission/disequilibrium test was detecting linkage when population association exists with a particular marker. Recently it also has been used to test for association when linkage between a disease locus and a marker exists. The motivation for such test is the necessity to narrow large candidate regions identified by classical linkage analysis. The modification of the transmission/disequilibrium tests is necessary when the method is used for testing association in the case of data on families with more than one offspring. Such modifications are proposed for the cases of quantitative and censored traits. Results of simulations that explore the performance of the proposed tests are described. The procedures are illustrated through an analysis of data on APOE genotype, a mutation of alpha-2 macroglobulin gene (A2M) and Alzheimer's disease.

Identification and analysis of polymorphisms within STAT1: association with asthma and associated phenotypes.

A.K.S. Wysong¹, T.D. Howard¹, G.A. Hawkins¹, H. Jongepier², D.S. Postma², D.A. Meyers¹, E.R. Bleeker¹. 1) Center for Human Genomics, Wake Forest Univ Sch of Med, Winston-Salem, NC; 2) Dept of Pulm, Univ Hospital, Groningen, the Netherlands.

Asthma is a chronic inflammatory disorder of the bronchial airways characterized by allergic responses and bronchial hyperresponsiveness. Asthmatic inflammation has been shown to be both directed and propagated by the secretion of a series of specific cytokines. Because cytokine effects often depend on signal transducers and activators of transcription (STATs), STAT1 is a functional candidate gene for influencing inflammatory disease. In addition, STAT1 is located on chromosome 2q33, where evidence of linkage has been observed in genome screens for asthma and associated phenotypes. To evaluate its role in asthma and associated phenotypes, we have sequenced all 25 STAT1 exons in 96 individuals for SNP identification. We performed association studies with over 10 SNPs in Dutch, Caucasian, Hispanic, and African-American asthma populations. We observed significant associations ($p < 0.05$) of several polymorphisms throughout STAT1 with allergy and asthma related phenotypes (e.g., bronchial hyperresponsiveness, FEV1, and log IgE). These data suggest that variations within STAT1 may contribute to the pathophysiology of allergy or asthma.

Analysis of a dense SNP based map in a psoriatic cohort defines genetic variation at PSORS1, the major psoriasis susceptibility locus. *C.D. Veal¹, F. Capon^{1,2}, M.H. Allen³, E.K. Heath¹, J. Evans¹, A. Jones³, S. Patel¹, D. Burden⁴, D. Tillman⁴, J.N.W.N. Barker³, R.C. Trembath¹.* 1) Division of Medical Genetics, University of Leicester, Leicester, England; 2) Division of Human Genetics, "Tor Vergata" University of Rome, Italy; 3) St John's Institute of Dermatology, Kings College, London, England; 4) Department of Dermatology, Western Infirmary, Glasgow, Scotland.

Psoriasis is a common cutaneous disorder characterised by keratinocyte hyperproliferation, immune cell infiltration and angiogenesis. The major susceptibility locus (PSORS1), located within the MHC on 6p21.3, has been refined by linkage disequilibrium (LD) mapping to an approximate 200kb region including genes with reported association to psoriasis (HLA-C, HCR and CDSN). However, data interpretations have been compounded by a lack of detail for the background pattern of LD across the region. In order to identify single nucleotide polymorphisms (SNPs) of relevance to psoriatic disease chromosomes, and to further characterise the LD within this region, we sequenced 64kb in segments across this interval in 8 psoriatic individuals who were heterozygous for previously identified microsatellite high risk haplotypes. A cohort of UK caucasian affected offspring trios (n=171) were genotyped for SNPs displaying a frequency greater than 20% (n=59). Significant deviation ($p < 0.001$) from expected transmission of alleles was observed for SNPs across the entire region, however strongest association was seen for SNPs located 7kb centromeric of HLA-C ($p < 0.00000001$). Examination of haplotypes found these SNPs to be exclusive to over transmitted chromosomes, all other variants in the region were also present on under or neutrally transmitted chromosomes, including those within HCR and CDSN. These data demonstrate the power of SNP haplotype-based association analyses and provide high-resolution dissection of the genetic variation across the PSORS1 interval.

Comparative Genetic Study of Tuberculosis, Asthma and Inflammatory Bowel Disease Susceptibilities. A.H. Poon¹, A. Jiménez-Corona², M. Palacios-Martínez², J. Sifuentes-Osornio³, A. Ponce-de-León³, M. Bobadilla³, M. Kato³, C. Laprise⁶, A. Bitton⁷, P.M. Small⁴, M.L. García García², T. Hudson⁵, E. Schurr¹. 1) Centre for the Study of Host Resistance, McGill University, Quebec, Canada; 2) Instituto Nacional de Salud Pública, Cuernavaca, Mexico; 3) Instituto Nacional de Ciencias Médicas y de Nutrición Salvador Zubirán, Mexico City, Mexico; 4) Medicine, Stanford University, CA, USA; 5) Montreal Genome Centre, Quebec, Canada; 6) Complexe Hospitalier de la Sagamie and University of Quebec at Chicoutimi, Quebec, Canada; 7) Division of Gastroenterology, McGill University Health Centre, Quebec, Canada.

Tuberculosis (TB), caused by *Mycobacterium tuberculosis*, is the leading cause of death due to a single pathogen. It has been suggested that genetic polymorphisms predisposing to TB are protective for atopy/asthma or inflammatory bowel disease (IBD). We analysed candidate TB susceptibility loci for their association with TB in a Mexican population and tested for inverse genetic associations with asthma and IBD in two large Canadian family panels of both diseases.

The TB case-control study included 643 subjects, the asthma study recruited 182 nuclear families and the IBD study recruited 104 families. We genotyped three *NRAMP1* polymorphisms (c.274C>T, D543N, 1799+del14)(acc.# L32185), the *TNFA*-308A>G polymorphism (acc.# X02910) and two *VDR* polymorphisms (g.12022A>G, g.46160A>G)(acc.# AC004466) by TaqMan assays. Results were analyzed by the chi square test, the combined transmission disequilibrium test (TDT)/sib TDT and the family-based association test (FBAT) program according to study design.

For TB, we observed associations for genotype *VDR*g.46160G/G (p=0.027), allele *VDR*g.12022A (p=0.015) and allele *TNFA*-308A (p=0.047). For asthma, allele *VDR*g.46160A was associated with its subphenotypes (0.072 < p < 0.125). For IBD, allele *TNFA*-308G was associated with disease susceptibility (p=0.036).

Our results provide experimental evidence of the hypothesis that genetic variants predisposing to TB are protective for atopy or IBD and vice versa.

Association of variation between *GABRB3* exon 3 and 155CA-2 with Autistic Disorder. *L.A. Weiss*¹, *D. Gonen*², *S.J. Kim*², *Z. Yang*², *N.J. Cox*¹, *E.H. Cook*². 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Psychiatry, University of Chicago, Chicago, IL.

Autistic Disorder (AD) has been shown to be in linkage disequilibrium with *GABRB3* 155CA-2, a dinucleotide marker in intron 3 of *GABRB3*, in two samples (nominal $p \leq 0.001$ in each) but not several other samples (Buxbaum, et al. *Mol Psychiatry* 2002; 7: 311-6; Cook, et al. *Am J Hum Genet* 1998; 62: 1077-83.). Sequence in this intron was independently obtained and several SNPs 3' of *GABRB3* 155CA-2 did not show significant LD (nominal $p > 0.01$) with AD in this sample (Kim, et al. *Am J Hum Genet* 2000; 67 (suppl.): 1773.). The laboratory obtained sequence that filled in the previous ~ 10 kb gap between *GABRB3* exon 3 and *GABRB3* 155CA-2. Direct sequencing of PCR products was performed to screen for variation in 10 AD probands selected for having at least one copy of the overtransmitted *GABRB3* 155CA-2 103 allele. Fifteen SNPs and 4 length variants were discovered by this method. Of the fifteen SNPs and two simple insertion/deletion polymorphisms, only eight unique patterns were observed, and the rest of the variants were in perfect LD with one of these eight markers. Four of these SNPs (representing four of the eight unique patterns) were genotyped by SBE-FP in 92 AD trios, and the two simple length variants were genotyped by amplification with fluorescently labeled primers and capillary electrophoresis. Two variants, which are in perfect LD in this sample, were associated with AD as determined by the Transmission/Disequilibrium Test (local SNP ID: GABRB3-SNP09 and D15S1539 nominal $p=0.0082$). Haplotype TDT analysis of adjacent markers showed p -values for markers GABRB3-SNP09 and GABRB3-SNP11 of 0.001 and for markers GABRB3-SNP05 and D15S1540 of 0.012.

Linkage and segregation analysis of phenotypic subtypes of dyslexia. *N. Chapman*¹, *R. Igo*², *J. Thompson*³, *W. Raskind*¹, *V. Berninger*³, *E. Wijsman*^{1,2}. 1) Dept of Medicine; 2) Dept of Biostatistics; 3) Dept of Educational Psychology, Univ. Washington, Seattle WA.

Reading disability (RD), or dyslexia, has a genetic basis. We are studying quantitative phenotypic components of RD in families ascertained through a proband with RD. Analysis of phenotypic subtypes, along with adjustment for covariates, may have increased power to detect linkage, over the use of qualitative phenotypes. Also, use of the Bayesian Monte Carlo Markov chain methods increases the efficiency of data use. These methods allow multilocus trait models, in the presence of very large numbers of markers in joint linkage and segregation analysis. Pseudoword reading efficiency (PR) and Word-ID (WID) are of particular interest, because of previous reports of evidence of linkage of analogous measures to several genomic regions.

We carried out Bayesian segregation analysis, and Bayesian joint linkage and segregation analysis, for PR and WID. We analyzed chromosomes(ch) 6, 15, and 18, all of which have been reported as showing evidence for linkage to similar RD-related phenotypes. For PR adjusted for age, sex and verbal IQ, the posterior mean number of quantitative trait loci (QTLs) was ~4.1, of which ~1.7 of the QTLs contribute at least 5% to the total variance. When PR is also adjusted for the effects of Word Attack (WA), the number of QTLs contributing to PR drops by ~1. The posterior mean number of QTLs for WID is ~3.6. Linkage analysis of these two measures, using all markers per ch from a 10 cM scan, provided evidence against linkage of PR to ch 6 and 15, and against linkage for WID to ch 6 and 18, with intensity ratios (IR) - posterior to prior rates of accepted models with particular QTL map positions - below 1. For PR, an IR of ~2.7 was found for ch 18 at 70 cM, and for WID an IR of ~3.7 was found for ch 15 at ~50 cM. These results provide weak evidence in support of RD loci on ch 15 and 18, but no evidence of RD loci on ch 6. Additional analyses, using covariates and/or joint analysis of multiple chromosomes will be needed to fully evaluate evidence for linkage of these phenotypes.

Localisation and fine mapping of a recombination hotspot on chromosome 19. *J. Jones*¹, *A. Cox*², *A.G. Wilson*¹. 1) Division of Genomic Medicine, University of Sheffield, Sheffield, South Yorkshire, UK; 2) Institute of Cancer Studies, University of Sheffield, Sheffield, South Yorkshire, UK.

The rate of recombination across the human genome, calculated by comparisons between genetic and physical map distances, has been shown to be highly variable. Recent reports indicate the presence of recombination hotspots, where the rate of recombination is significantly higher than that seen in other chromosomal regions. One indication of the presence of such a hotspot is the consequent breakdown of linkage disequilibrium in the region.

Recent analysis of chromosome 19p13 revealed patterns of linkage disequilibrium indicative of the presence of a recombination hotspot in a 1Mb region, defined by markers D19S406 and D19S427 (McCarthy et al, 2001). Further data shows a disease-locus defining recombination event within this region (Faivre et al, 2002).

Recombination analysis of 19p13 was performed by genotyping both DNA from families and single sperm. Familial analysis is dependent on the availability of samples from both parents and at least 2 children. It is also dependent on the parents being heterozygous for the markers tested in order for inherited haplotypes to be determined. Single sperm typing is a powerful tool that eliminates the need for the collection of extensive family samples, although heterozygosity at the marker of interest is still essential.

Initial genotyping data of 14 informative families has identified 2 recombinations in 28 meioses. This is double the expected recombination rate for a region of this size. Further analysis of 100 families is currently underway in order to increase the power of the study and prove the presence of a hotspot by identification of an elevated recombination rate. The refinement of the region of recombination, including the use of SNP mapping, will also be described.

A fourth locus of postaxial polydactyly type A/B on chromosome 7p11.2-q32. *R.J.H Galjaard¹, A.P. Smits², J.H.A.M. Tuerlings², A. Bais¹, A. Bertoli¹, G. Breedveld¹, E. de Graaff¹, B.A. Oostra¹, P. Heutink¹.* 1) Clinical Genetics, Erasmus Medical Center, Rotterdam, Netherlands; 2) Human Genetics, University Hospital Nijmegen, Netherlands.

Postaxial polydactyly (PAP) is the occurrence of one or more extra ulnar or fibular digits or parts of it. In PAP-A the extra digit is fully developed and articulates with the fifth or an additional metacarpal/metatarsal, while it is rudimentary in PAP-B. Isolated PAP usually segregates as an autosomal dominant trait, with variable expression. Three loci are known for PAP in humans. PAP-A1 (including PAP-A/B in one patient) on 7p13 caused by mutations in the *GLI3* gene. PAPA2 on 13q21-q32 in a Turkish kindred with PAP-A only, and a third one (PAP3) in a Chinese family with PAP-A/B on 19p13.1-13.2. We identified a fourth locus in a large Dutch six generation family with 31 individuals including 11 affecteds. Their phenotype varied from either PAP-A, or PAP-B to PAP-A /B with or without partial cutaneous syndactyly. We performed a whole genome search. Linkage was found between PAP and markers of chromosome 7. The highest LOD score was obtained at marker D7S1799 ($Z_{max}=3.18; \theta=0cM$). The phenotype was mapped between markers D7S820 and GATA63F08 of chromosome 7p11.2-q32. To our knowledge we are the first to present and discuss the genotype of a patient with PAP-B of both hands only without showing PAP-A.

Program Nr: 1628 from 2002 ASHG Annual Meeting

Exclusion of 113 Kb of IDDM-8 interval by linkage disequilibrium analysis. *A. Davoodi-Semiromi, J-D. Shi, D. Hopkins, C-Y. Wang, J-X. She.* Department of Pathology, Immunology and Laboratory Medicine, Center for Mammalian Genetics and Diabetes Center of Excellence, College of Medicine, University of Florida, Gainesville, FL 32610, USA.

We previously analyzed 15 markers on chromosome 6q and a strong evidence of association was obtained at D6S446 using affected-sib-pair analyses in 104 Caucasian families. In this study, we attempted to narrow the interval to a small region suitable for positional cloning using new microsatellite markers and single nucleotide polymorphisms (SNPs) in 668 families with type 1 diabetes (T1D). Four new markers including two microsatellite markers and two SNPs in the IDDM 8 interval were identified. We found a significant association with one of the microsatellite marker designated D6S2724 in Caucasian populations including Americans, French and Italians. We did not, however, find a significant association when British, Mexican-American, Korean and Chinese populations were screened. The overall result for the entire data sets was very significant ($P \leq 0.00006$). We ruled out the PDCD2 gene as a candidate gene for T1D since we did not find any association when two SNPs within this gene were typed against a large number of diabetic families. In this study we excluded BAC 191N21 (113 Kb) within the IDDM-8 interval for further investigation since we were unable to find a putative transcript for the IDDM-8 gene.

Haplotype and linkage disequilibrium architecture for human cancer-associated genes. *P.E. Bonnen¹, P. Wang¹, M. Kimmel², R. Chakraborty³, D.L. Nelson¹.* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Department of Statistics, Rice University, Houston, TX, 77030; 3) Center for Genome Information, Department of Environmental Health, University of Cincinnati, Cincinnati, OH, 45267.

To facilitate association-based linkage studies we have studied the linkage disequilibrium (LD) and haplotype architecture around five genes of interest for cancer risk: ATM, BRCA1, BRCA2, RAD51, and TP53. Single nucleotide polymorphisms (SNPs) were identified and used to construct haplotypes that span 93-200 kb per locus with an average SNP density of 12 kb. These markers were genotyped in four ethnically defined populations that contained 48 each of African Americans, Asian Americans, Hispanic Americans, and European Americans. Haplotypes were inferred using an expectation maximization (EM) algorithm and the data were analyzed using D, R², Fishers exact, and the four gamete test for recombination. LD levels varied widely between loci from continuously high LD across 200 kb to a virtual absence of LD across a similar length of genome. LD structure also varied at each gene and between populations studied. This variation indicates that the success of linkage-based studies will require a precise description of LD at each locus and in each population to be studied. One striking consistency between genes was that at each locus a modest number of haplotypes present in each population accounted for a high fraction of the total number of chromosomes. We conclude that each locus has its own genomic profile with regard to LD and despite this there is the wide spread trend of relatively low haplotype diversity. As a result, a low marker density should be adequate to identify haplotypes that represent the common variation at a locus thereby decreasing costs and increasing efficacy of association studies.

SNPing OF LOR GENE IN PSORIASIS PATIENTS. *E. Giardina*¹, *F. Capon*¹, *A. Tacconelli*¹, *S. Chimenti*², *G. Zambruno*³, *G. Novelli*¹. 1) Dept Biopathology, Tor Vergata Univ, Rome, Italy; 2) Department of Dermatology, Tor Vergata Univ, Rome, Italy; 3) Molecular and Cellular Biology Unit, IDI IRCCS, Rome, Italy.

Psoriasis (OMIM 177900) is a chronic, hyper-proliferative skin disorder affecting approximately 2% of Caucasians. The disease is inherited as a complex trait and genome-wide scans have allowed to map at least 7 susceptibility loci (PSORS 1-7). We assigned the PSORS4 locus to chromosome 1q21 and have recently refined the susceptibility interval to a 100 kb segment containing the LOR gene. LOR encodes loricrin, a major keratinocyte structural protein, which is under-expressed in psoriatic lesions. We report here the genetic analysis of LOR as a PSORS4 positional candidate. We have re-sequenced the gene in 8 Italian patients carrying disease associated alleles at two PSORS4 microsatellite loci. This analysis identified 1 SNP in the promoter region, a non-conservative substitution and a 6bp in-frame duplication in exon 2. Typing of 90 trios demonstrated that all three variants are common in the Italian population, the frequency of minor alleles being > 0.25. An assessment of Hardy-Weinberg equilibrium (HWE) among patients' chromosomes identified a significant heterozygous excess ($p = 1.8 \times 10^{-4}$) for the exon 2 SNP. The analysis of 40 unrelated healthy controls confirmed that this SNP is in equilibrium among unaffected, indicating that the deviation from HWE observed in patients is likely to be disease-related. Work funded by the Italian Ministry of Health.

A comparative study on the block structure of linkage disequilibrium in the Japanese and Korean populations. *T. Akesaka*¹, *K. Song*², *J. Ohashi*¹, *S.G. Lee*², *K. Tokunaga*¹. 1) Department of Human Genetics, University of Tokyo, Tokyo, Japan; 2) Department of Biochemistry, University of Ulsan College of Medicine, Seoul, Korea.

The extent of linkage disequilibrium (LD) in human genome provides the important information for the identification of variations which predispose to human diseases. However, the strength of LD may differ among human populations as well as chromosomal regions. We investigated LDs and haplotypes defined by SNPs in chromosome 1p36.2 region in the Japanese and Korean populations. Forty SNPs in 300 kb region encompassing from the tumor necrosis factor receptor 2 (TNFR2: TNFRSF1B) gene to the procollagen-lysine, 2-oxoglutarate 5-dioxygenase (PLOD) gene were examined by means of fluorescence correlation spectroscopy combined with the PCR-sequence specific primer method (PCR-SSP-FCS) in 200 healthy Japanese and by direct sequencing in 96 healthy Koreans. Analysis of LDs between two SNP pairs demonstrated clear contrasts in LD strength among different regions. Interestingly enough, a long range block with strong LDs of approximately 80kb including three genes was found in both Japanese and Koreans. And three common haplotypes composed of more than 20 SNPs were observed from the block in both populations. However, in the regions around TNFR2 and CD30 (TNFRSF8) genes, significant LD was observed only within the genes. LD strength and haplotype frequencies were similar between Japanese and Koreans, probably because of strong genetic affinities between the two populations.

Estimation of haplotype frequencies and diplotype configuration for each subject using pooled DNA data. *T. Ito*^{1,2}, *S. Chiku*³, *E. Inoue*^{1,4}, *M. Tomita*¹, *N. Kamatani*^{5,6}. 1) Gene Discovery Team, Japan Biological Information Research Center, Tokyo, Japan; 2) Mitsubishi Research Institute, Inc., Tokyo, Japan; 3) Fuji Research Institute Corporation, Tokyo, Japan; 4) NEC Corporation, Tokyo, Japan; 5) Division of Statistical Genetics, Institute of Rheumatology, Tokyo Women's Medical University, Tokyo, Japan; 6) Institute of Rheumatology, Tokyo Women's Medical University, Tokyo, Japan.

Haplotype inference is important for many genetic approaches including the process of assigning a phenotype to a genetic region. Usually the frequencies of haplotypes as well as diplotype configuration of each subject are estimated from a set of genotypes of the subjects in a population. We have developed an algorithm to infer haplotype frequencies from pooled DNA data. The input data are the genotypes in pooled DNA samples each of which contains the quantitative genotype data from 1-10 subjects. The algorithm infers by the maximum likelihood method both frequencies of the haplotypes in the population as well as sets of diplotype configurations in the pooled samples by expectation-maximization (EM) algorithm. The algorithm was implemented in the computer program "ldpooled". Using this program, the published genotype data for SAA gene as well as smootheline gene were analyzed. Our study has shown that the haplotype frequencies in a population can be inferred although with some limitations from the pooled DNA data by the maximum likelihood method. Our present method may be useful when the genotyping is performed on pooled DNA.

SNP analysis and linkage disequilibrium map of the human chromosome 22 using Arrayed Primer EXTension (APEX) technology. *E. Lohmussaar*^{1,2}, *J. Zernant*², *R. Mägi*³, *T. Puurand*², *N. Tõnisson*², *I. Valvas*², *G. Slavin*², *A. Kurg*¹, *M. Remm*^{1,3}, *A. Metspalu*^{1,2}. 1) IMCB University of Tartu/Estonian Biocentre; 2) Asper Ltd. Tartu, Estonia; 3) Biodata Ltd. Tartu, Estonia.

One of the goals of the human genome project is to further understand the genetic basis of human variation. DNA sequence variants across the genome are responsible for a variety of phenotypes such as disease risk or variable drug response. The whole-genome linkage disequilibrium mapping and haplogroup description are the prerequisites for genome wide association studies. Using the completed sequence of human chromosome 22 and the extensive set of genetic variants across 22q, we have performed genotyping of Estonian and German samples and CEPH families with 1279 SNP markers (at a median spacing of 35 kb). An array with 5200 oligonucleotides was designed to genotype each SNP twice from both DNA strands simultaneously using APEX technology. Allele frequencies, Hardy-Weinberg equilibrium data and heterozygosities were calculated for each genotyped marker. We have characterized the patterns of linkage disequilibrium and calculated D for the whole 33Mb of chromosome 22q. Our results show several areas of the chromosome with very high level of LD, notably at positions 11-16 Mb and 21-27 Mb of the reference sequence. We also estimated the average extent of useful LD ($D > 0.5$) and similar results were obtained in analysis of separate populations of unrelated individuals. It appears that the major problem was the low minor allele frequency (less than 10%), which means that the quality of SNPs in current public databases is an important issue and will need additional testing in order to find out useful SNPs in regarding to genotyping technology. Construction of LD maps across the human genome and identifying haplotypes in individual genomic regions will facilitate the identification and characterization of genetic variants responsible for common complex diseases.

Linkage disequilibrium at the dopamine transporter locus (*SLC6A3*). A.M. Kang^{1,2}, A.J. Pakstis², K.K. Kidd². 1) Dept Linguistics, Brain & Language Track; 2) Dept Genetics, Yale U, New Haven, CT.

The dopamine transporter (DAT; locus *SLC6A3*) is implicated in disorders like Parkinson's Disease, substance abuse problems, attention-deficit hyperactivity disorder (ADHD), and bipolar disorder. Most early studies used a case-control association design with a single 3'-UTR VNTR, which likely was not testing the entire locus because of its ~50-kb length. Elucidating the linkage disequilibrium (LD) pattern at this telomeric locus is important to determine the appropriate number and spacing of polymorphisms needed for haplotype association studies.

We report allele frequencies in 38 worldwide populations for seven single nucleotide polymorphisms (SNPs) and two variable number tandem repeats (VNTRs) spanning the entire ~50 kb locus. Preliminary LD analyses including only the five most heterozygous SNPs on 35 populations demonstrate consistently low overall disequilibrium across all geographic regions, as measured by r^2 ; this pattern differs from that observed at *DRD2* and *PAH* from similar studies in our lab. F_{ST} calculations for the SNPs show a particularly high value of .37 for an intron 9 SNP, compared to a reference distribution obtained in our lab from 94 biallelic sites (mean = .14, s.d. = .07), possibly suggesting some selective pressure at or around this site.

Pairwise LD across smaller segments was quite variable among, and even within, geographic regions. A 15-kb segment spanning the 5' third of the locus (promoter to intron 4) showed little disequilibrium in populations from Africa, SW Asia, Europe, and much of east Asia. Even three of the four North American populations had little LD. A 20-kb segment from intron 4 to intron 9, representing the middle third of the locus, showed no LD in any European or east Asian population but high levels in some African and SW Asian populations. The 3' end (~16 kb) spanning intron 9 to the 3'-UTR showed high LD in many SW Asian and European populations but not in other geographic regions. These results suggest ~16-kb spacing of SNPs may not be sufficiently dense coverage at this locus. [Supported in part by NIH grants GM57672 and MH62495].

Analysis of a strong candidate gene for late onset Alzheimer's disease within the 1-lod interval on chromosome

10. *P. Nowotny¹, A. Myers¹, A. Mander³, H. Marshall¹, P. Holmans³, R. Crook⁴, S. Smemo¹, M. Dunston⁵, M. Hamshere⁵, M. O'Donovan⁵, L. Jones⁵, J. Williams⁵, M.J. Owen⁵, J. Hardy⁴, A. Goate^{1,2}.* 1) Dept Psychiatry, Washington Univ Sch Medicine, St Louis, MO; 2) Department of Genetics, Washington University School of Medicine, St. Louis, MO, United States; 3) MRC Biostatistics Unit, Cambridge, United Kingdom; 4) Department of Neuroscience, Mayo Clinic Jacksonville, FL, United States; 5) Department of Psychological Medicine, Cardiff, United Kingdom.

We performed a two-stage genome screen to search for novel risk factors for late onset Alzheimer's disease (AD). In the first stage, 16 regions gave a multipoint lod score greater than 1. In the second stage we followed up in these regions with more samples and markers. The strongest evidence for linkage in the second stage was on chromosome 10, where we obtained a peak multipoint LOD score (MLS) of 3.9. Urokinase-plasminogen activator (PLAU), a gene putatively involved in the degradation of β -amyloid, the toxic fragment of APP, maps within our linkage peak on chromosome 10. We have analyzed 12 polymorphisms within this gene, including three coding variants. None of the coding variants were significantly associated with risk for LOAD in the case-control series we examined. We also found no significant frequency differences in seven additional non-coding SNPs. The most common haplotype formed from three non-coding polymorphisms (2 intronic and one synonymous change) spanning exons 8 and 9 of PLAU has a lower risk for LOAD than other haplotypes. The haplotype does not appear to account for our linkage results on chromosome 10. There are two possible explanations for these results: that there is variation elsewhere in the PLAU gene or in a neighboring gene in linkage disequilibrium with the SNPs genotyped in this study that influences risk for AD or alternatively this result could represent type I error. We are currently genotyping additional SNPs in a 50kb region flanking the PLAU gene to evaluate these alternatives.

APOE promoter region is associated with age at onset of Amyotrophic Lateral Sclerosis. *Y-J. Li¹, M.A. Pericak-Vance¹, J.L. Haines⁴, N. Siddique², D. McKenna-Yasek³, E.R. Martin¹, W-Y. Hung², P. Sapp³, C.I. Allen¹, W. Chen², B. Hosler³, A.M. Saunders¹, L. Dellefave², R.H. Brown Jr.³, T. Siddique².* 1) Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Dep't Neurology, Northwestern Univ Med School, Chicago IL; 3) Day Neuromuscular Lab, Mass Gen Hosp, Boston, MA; 4) Program in Human Genetics, Vanderbilt Univ, Nashville, TN.

Amyotrophic lateral sclerosis (ALS) is a progressive neurologic disorder with midlife onset and a rapid downward course of paralysis ending in death. Several studies have investigated the relationship between APOE and ALS but generally small datasets were used and the conclusions were inconsistent. We investigated APOE and its promoter region in 461 families with at least 1 case of ALS. We genotyped 5 SNPs in addition to the APOE functional polymorphism. The designation of each SNP is based on its distance in basepairs from the beginning of exon1. SNP-491AT, SNP-427CT, and SNP-219GT are located in the APOE promoter region, SNP+113CG in intron1, and SNP+5361CT in APOE 3' region. The PDT and TRANSMIT (TRM) programs were used to test markers for linkage and association with ALS. By using the full dataset (461 families), no markers demonstrated significant association to ALS. We also examined a possible role of APOE on age at onset (AAO) by stratifying based on the AAO of affecteds. The AAO in our ALS dataset ranged from 15 to 81 years old. For the PDT and TRM tests we found that SNP-219GT ($p=0.04$, 0.03 , respectively) and SNP+5361CT ($p=0.01$, 0.04 , respectively) showed significant association to ALS in the families with $AAO \geq 50$ (165 families). To further test this age related hypothesis, we treated AAO as a quantitative trait and performed association analysis in the full dataset. The TDTQ5 method implemented in QTDT program was employed. SNP-219GT and SNP+113CG showed evidence of association to AAO (both $p=0.03$), as did the APOE functional polymorphism ($p=0.002$, with the APOE2 allele protecting against earlier onset). Our findings suggest that APOE may express its strongest effect on the risk of ALS through AAO rather than on the risk alone.

A complete ascertainment haplotyping in a SNP-intensive gene: Clear population-specific haplotypes in the Cardiac Ankyrin Repeat Protein (CARP) gene. *B.T. Harmon, J.M. Devaney, E.P. Hoffman.* Research Center for Genetic Medicine, 111 Michigan Ave., NW Washington, DC 20010.

The response to exercise varies widely between individuals and is considerably influenced by genetic variables. We have a SNP association study underway where 1,400 young adults are exercised to quantitate 4 phenotypes (entry strength, entry muscle size by MRI, percentage change in strength after 12 wks supervised resistance exercise, percentage change in size) (Factors Affecting Muscle Size and Strength; FAMuSS). In parallel, high throughput and highly sensitive SNP screening is being pursued, with genotyping of ethnically diverse individuals to determine SNPs predisposing to muscle size and strength. One gene strongly implicated in the response of muscle and heart to exercise is the cardiac ankyrin repeat protein (CARP) gene. The CARP gene was screened for SNPs in DNA from 96 individuals representing a variety of different ethnic backgrounds. SNPs were detected by direct sequencing of coding sequences, exon/intron boundaries, and the 5 and 3 UTRs using ABI 3100 automated sequencers. We identified 10 novel SNPs and 1 deletion in the CARP gene, none of which were identified by existing SNP resource databases. We used Clark's haplotype subtraction algorithm to resolve the SNPs into haplotypes, many of which were population-specific. Of the 10 SNPs found, 3 changed an amino acid, and 4 were found to be private SNPs that were present in only a single individual of the 96 studied. This analysis shows that a gene that is highly responsive to the physiological variable of exercise is a hot spot for SNPs.

Association of angiotensin converting enzyme (ACE) gene with hypertension and ACE level in Nigerians. Y.

Jiang¹, X. Zhu¹, N. Bouzekri², R. Ward³, A. Adeyemo³, A. Luke¹, R.S. Cooper¹. 1) Preventive Med & Epidemiology, Loyola Univ Chicago Med Ctr, Maywood, IL; 2) Medicine, University of Ibadan, Ibadan, Nigeria; 3) Department of Biological Anthropology, University of Oxford, Oxford.

Angiotensin converting enzyme (ACE) gene has been reported to be associated with cardiovascular disease (CVD). Hypertension is an important risk factor in CVD. To identify the susceptibility SNPs of the ACE gene, 829 Nigerians from 207 families were genotyped at 32 single nucleotide polymorphisms (SNPs) within the ACE gene. 300 unrelated individuals are included in the first haplotype inference using PHASE. The SNPs were then grouped into 6 blocks such that pairwise linkage disequilibrium were strong ($D' \geq 0.8$) within each block. Association of hypertension and ACE level with ACE haplotypes were tested within each block using TRANSMIT. We identified two haplotypes in two blocks that were associated with hypertension. TCCA (ace1 ace2 ace3 ace4_2400) (freq=4.6%) global p=0.0071; ADGAAGG (newace6_8578 aceI_D_1448_14488_14521 ace8_14521_15214)(freq=28.4%) global p=0.0933. This haplotype (ADGAAGG) is also significantly associated with systolic blood pressure (p=0.0017) using regression model under dominant mode of inheritance after adjusting sex and age. Significant association of ACE haplotypes with ACE level were identified in two blocks. CCCT (29%) (ace1 ace2 ace3 ace4_2400) global p=0.0021; ATTCCA (6.9%), ACTCCG (42.7%), and ACTTCG (26.1%) (_15444_19942_20058_20120_20326_20397) with global p=0.0032. Our results suggest possible relationship of these haplotypes (blocks) with hypertension.

The efficacy of using haplotypes to assay common variation in genes. *M. Loomer^{1,2}, S.B. Gabriel^{1,2}, J. Platko^{1,2}, C. O'Donnell^{2,3}, M.J. Daly¹, E.S. Lander^{1,2,4}, J.N. Hirschhorn^{1,2,5,6}.* 1) Center for Genome Research, Whitehead Institute, Cambridge, MA; 2) Cardiogenomics PGA, NHLBI; 3) NHLBI Framingham Heart Study, Framingham, MA; 4) Biology, MIT, Cambridge, MA; 5) Genetics, Harvard Med. School, Boston, MA; 6) Genetics and Endocrinology, Children's Hospital, Boston, MA.

Surveys of random genomic regions have shown that the genome contains large "blocks" of linkage disequilibrium; these blocks contain a few common haplotypes that are highly correlated with publicly available common SNPs in the block (Gabriel et al., Science 2002). We surveyed haplotype patterns in genes and tested whether common haplotypes in genes are correlated not only with publicly available SNPs but also with common SNPs discovered by directed resequencing.

For analysis, we chose 33 genes, all candidates for regulating cardiovascular traits. Using TSC and BAC overlap SNPs, we defined blocks. We identified additional SNPs within these blocks by resequencing exons and nearby introns in a multiethnic panel of 40 individuals. Within the blocks, we defined a "framework" of common haplotypes in a sample of 92 Caucasian individuals from 12 multigenerational pedigrees (96 independent chromosomes). We also analyzed the relationship between block boundaries and gene landmarks.

To date, we have genotyped enough common SNPs to analyze 22 of the 33 genes, covering 1.1 Mb of genomic DNA. We successfully genotyped 353 SNPs in these genes, of which 274 were polymorphic and 243 had minor allele frequencies >5%. Haplotype blocks defined by these SNPs averaged between 20 and 25 kb in length (covering 814 kb), and there were generally 3-6 common haplotypes per block, consistent with earlier results from random genomic regions. 27 SNPs identified by resequencing had minor allele frequencies >5% and resided within the haplotype blocks defined by our framework. Of these 27 SNPs, only 5 defined new haplotypes that were not already present within the framework. We conclude that common haplotypes within blocks of linkage disequilibrium are likely to capture most of the common variation within their span.

A NEW CROHN'S DISEASE PREDISPOSING *CARD15* HAPLOTYPE IN ASHKENAZI JEWS. *K. Sugimura*^{1,2}, *K.D. Taylor*¹, *Y-C. Lin*¹, *T. Hang*¹, *D. Wang*¹, *Y-M. Tang*¹, *N. Fischel-Ghodsian*¹, *S.R. Targan*², *J.I. Rotter*¹, *H. Yang*¹. 1) Medical Genetics; 2) IBD Center Res. Lab.; Cedars-Sinai Medical Center, Los Angeles, CA.

Aim: Crohn's disease (CD) is an inflammatory bowel disease (IBD) that occurs with a 2-3 fold higher frequency in Jews. *CARD15* was identified to be the IBD1 gene that is located on chr.16q12 and showed significant linkage to CD by multiple groups. Three *CARD15* coding variants (R675W, G881R, and 980fs) are associated with CD individually. Since more than 70% of CD patients do not have any of these major *CARD15* disease-predisposing mutations (DPMs), the aim of this study was to determine if additional DPMs exist at the IBD1 locus in the high-risk Jewish group.

Methods: Six microsatellite markers spanning IBD1 (34cM) were genotyped in 28 Jewish CD families and two-point linkage analysis using SIBPAL from SAGE was performed. SNPs in *CARD15* (R675W, G881R, 980fs; plus a *CARD15* background marker S241P and a new SNP as described below) were genotyped in the families and in a Jewish case control panel (114 CD, 80 controls) using TaqMan MGB. **Results:** Significant linkage of IBD1 to CD in Jews remained after excluding the 3 major *CARD15* DPMs (mean allele sharing, MAS, 0.47 to 0.70 with a peak at D16S403, $p = 0.0008$). These data suggested the existence of additional predisposing genes at the IBD1 locus or additional *CARD15* DPM(s) in Jews. Furthermore, in the Jewish case-control sample, the S241P background haplotype without any of the three known DPMs was significantly associated with CD (OR=3.13, $p=0.0023$). This suggested the existence of unrecognized DPMs on a S241P haplotype in Jews. Sequencing of *CARD15* translated regions from Jewish patients with ($n=7$) and without ($n=5$) the S241P haplotype identified one new variant (IVS8+158, JW1). The S241P-JW1 combination defined a more specific haplotype associated with an even further increased risk for CD in Jews (OR=5.75 $p=0.0005$) than that provided by S241P alone. **Conclusion:** These results suggest that, in Ashkenazi Jews, other predisposing genes in the IBD1 locus or other DPMs on the *CARD15* S241P-JW1 haplotype may lead to CD in this high risk group.

Program Nr: 1641 from 2002 ASHG Annual Meeting

Linkage disequilibrium mapping using genotype data from unrelated individuals. *T. Wang*¹, *H. Jacob*². 1) Division of Biostatistics; 2) Human and Molecular Genetic Center, Medical College of Wisconsin, Milwaukee, WI.

Linkage disequilibrium (LD) approach has been successfully used for fine mapping of disease genes. Reconstruction of haplotypes are essential in most of current LD studies. We develop a multipoint LD method to estimate joint genotypic frequencies of a QTL and multiple markers using observed phenotypic trait values and marker genotypes directly. A summarized statistic is proposed as an overall association measure between the QTL and markers. Detection of the QTL position can then be performed based on this association pattern. A permutation procedure is also implemented for testing of the association.

Sample size estimates for candidate gene case-control studies in pharmacogenetics. *L.J. Sheffield.* Genetic Health Services Victoria, Murdoch Childrens Research Institute, University of Melbourne, Melbourne, Victoria, Australia.

Mapping studies using linkage disequilibrium methods frequently use the TDT or case-control design. The case-control design is statistically more powerful but may be prone to bias due to population sub-stratification. It is not always possible to genotype parents in pharmacogenetic studies and so case-control designs are often used. Population sub-stratification can be controlled for by matching controls with cases for variables like ethnic group. This presentation presents details of sample size estimates for case-control studies of candidate genes for disease or drug effect (pharmacogenetics). There are some newly described methods for sample size calculation for case-control studies when whole genome wide linkage disequilibrium studies are planned. It has been suggested that these studies require 100,000-500,000 polymorphisms. At present very few such studies are performed because of the cost of typing so many markers. Most studies being performed today are either of candidate genes or candidate gene regions of a particular chromosome. As such they do not require the stringent Bonferroni correction that whole genome scans do. I suggest a correction for 50 independent tests for candidate gene studies. I present sample size estimates for candidate gene case-control studies for the first time with different marker frequencies. It should be noted that until recently the only method available for estimating such sample sizes was the classical statistical approach which does not assume any genetic model. A comparison is made with this approach which both over estimates and underestimates the sample size for the dominant model which it is closest in concept to the genetic methods. For example for an odds ratio of 3 (Type I error of .001, power of 80%) the classical method suggests 148 cases and controls need studying whilst the genetic methods estimate 132 of each for the dominant model and 219 for the additive model. As the known genotypic relative risk (for each genotype) may be able to be estimated from previous work the genetic methods should be used.

Genome-wide distribution of linkage disequilibrium in the Samoan population. *H.-J. Tsai*¹, *G. Sun*², *D. Smelser*², *D.E. Weeks*^{1, 4}, *S. McGarvey*³, *R. Deka*². 1) Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Environmental Health, University of Cincinnati, Cincinnati, OH; 3) International Health Institute, Brown University, Providence, RI; 4) Biostatistics, University of Pittsburgh, Pittsburgh, PA.

Recently, whole genome scanning for susceptibility loci based on linkage disequilibrium (LD) has been proposed as a powerful strategy for mapping common complex diseases, especially in isolated populations. In this study, we have recruited 176 families from US territory of American Samoa, and 96 unrelated controls from American Samoa and the independent country of Samoa. We have examined the distribution of LD in the family, control and combined data separately by using 382 autosomal microsatellite markers across the whole genome. We have tested the relationship between adjusted multiallelic disequilibrium and recombination by fitting a regression model. We have obtained a slope of -0.022 (SE = 0.006, P = 0.00052) for family data, and a slope of -0.022 (SE = 0.004, P < 0.00001) for combined data. Based on our results, LD decays steadily as recombination between autosomal markers increases in the Samoan population. These results imply that it may be feasible to do genome-wide LD mapping in the Samoans. Supported by NIH grants AG09375, HL52611, DK55406, and DK59642.

Program Nr: 1644 from 2002 ASHG Annual Meeting

Detecting Linkage Disequilibrium between Genes. *B.A. Salisbury, J.C. Stephens, A. Windemuth, J.A. Schneider, R.S. Judson.* Genaissance Pharmaceuticals, New Haven, CT.

Techniques for detecting and measuring Linkage Disequilibrium (LD) between complex loci such as genes are in their infancy. We have explored several new approaches empirically using data acquired by sequencing functional regions of genes. A special emphasis was placed on contrasting SNP-based and haplotype-based (whole-gene) LD tests. We considered the effects of sample size, population structure, and physical distance on test power and LD strength. All factors we examined were important. Of the dozens of genes we looked at, most were drawn from Chromosome 19, including an apolipoprotein gene region with remarkably variable patterns of LD. We sampled as deeply as several hundred unrelated individuals, who represented broad ethnic diversity.

Molecular Screen of Retinoid-Related Orphan Receptor Gamma as a Positional Candidate Gene for Type 2 Diabetes. *H. Wang, WS. Chu, SC. Elbein.* Dept Endocrinology, Central Arkansas Veterans healthcare System and University of Arkansas for Medical Science, Little Rock, AR.

The retinoid-related orphan receptors ROR alpha, beta, and gamma constitute a subfamily of nuclear orphan receptors. ROR gamma (RORC) is induced during adipocyte differentiation and functions as an active transcription factor to induce the expression of PPAR gamma. Thus, RORC is a candidate gene for diabetes pathogenesis. Furthermore, RORC is located on chromosome 1q22, a region that has been linked to type 2 diabetes in Utah, French and English Caucasians, Pima Indians, and Old Order Amish. To test the hypothesis that mutations of RORC account for part of this linkage, we screened 11 exons of the RORC gene for variants, including 1-kb upstream, intronic regions flanking the exons, and the entire 3 untranslated region (UTR), spanning approximately 25 kb. We used SSCP analysis under 2 conditions with bi-directional fluorescent sequence confirmation to screen 32 subjects including 16 Utah Caucasian individuals from families showing linkage to chromosome 1 and 16 diabetic African American individuals. We detected 11 single nucleotide polymorphisms (SNPs), ranging from the promoter region to intron 10. Only 1 SNP was nonsynonymous, resulting in Ala to Gly at residue 464 (exon 10). All other SNPs were noncoding. One SNP (intron 3) was unique to Caucasians, and three SNPs (A464G, intron 2, intron 6) were specific to African American subjects. We initially typed 6 SNPs spanning the gene from the promoter to 3 UTR in 131 unrelated Utah Caucasian cases (61 members of familial T2DM kindreds) and 118 ethnically matched controls. Two SNPs (intron 8, A464G) were very rare or absent in Caucasians and not analyzed. Allele frequencies for the remaining 4 SNPs did not differ between cases and controls ($p > 0.2$). Three of the 4 SNPs were in strong linkage disequilibrium ($D > 0.85$), but the single SNP at the most 3 end of the gene showed no significant linkage disequilibrium with the more 5 SNPs. Although available data suggest that RORC cannot explain the linkage of T2DM in this region, additional typing is in progress, and work is also in progress to test for metabolic abnormalities.

The effect of LD structure on genotype-phenotype relationships at the *DBH* locus. C.P. Zabetian^{1,2}, S.G. Buxbaum³, R.C. Elston³, M.D. Kohnke⁴, G.M. Anderson⁵, J. Gelernter^{6,7}, J.F. Cubells^{6,7}. 1) Dept of Neurology, Univ of Washington, Seattle, WA; 2) Dept of Neurology, VAPSHCS, Seattle, WA; 3) Dept of Epidemiology and Biostat, Case Western Reserve Univ, Cleveland, OH; 4) Univ Hospital of Psychiatry and Psychotherapy, Tuebingen, Germany; 5) Child Study Ctr, Yale Univ, New Haven, CT; 6) Dept of Psychiatry, Yale Univ, New Haven, CT; 7) Dept of Psychiatry, VACHS, West Haven, CT.

Advances in technology, including the growing public database of some 2.7 million candidate single nucleotide polymorphisms (SNPs), promise to make genome-wide linkage disequilibrium (LD) mapping of loci influencing complex traits feasible in the near future. Recent studies have suggested that the extent of LD throughout the genome is extremely variable even at intragenic scales, and that the genome might be divided into discrete 10-100 kb "blocks" of LD. Whether such blocks of LD, defined statistically based on common SNPs, will be useful for detecting associations with genes underlying complex traits is presently unknown, and few studies have examined the effect of LD on the association of specific markers to traits using real data. The *DBH* gene, which encodes dopamine beta-hydroxylase (DBH) and is the major quantitative trait locus for plasma DBH activity, is well suited as a simple model to address this question. We recently demonstrated that a single putative functional SNP (-1021C®T) in the *DBH* promoter accounted for 35-52% of the total variation in plasma activity levels in 3 distinct populations. Here, we present evidence that in general, LD extended over short distances at the *DBH* locus. The extent of LD between -1021C®T and 11 surrounding biallelic markers strongly influenced the strength of association of each marker to plasma DBH activity. This relationship was better captured by measures of LD that are relatively dependent on allele frequencies, such as d^2 . The most distant markers in the 5' upstream region and 3' half of the gene were not significantly associated with DBH activity. These findings provide further evidence that a thorough understanding of LD structure will be necessary prior to designing genome-wide LD mapping studies.

Linkage disequilibrium in the *NIDDM1* and *CYP19* regions of chromosomes 2 and 15. *J.K. Wittke, I. Yoshiuchi, H. Mashima, C. Roe, N.J. Cox.* Dept. of Human Genetics, The University of Chicago, Chicago, IL.

Previous studies mapped susceptibility loci for type 2 diabetes (T2D) to the *NIDDM1* region of chromosome 2 (Hanis et al, Nat Genet 1996; Horikawa et al, Nat Genet 2001) and the *CYP19* region of chromosome 15 (Cox et al, Nat Genet 1999) using data from a genome screen on Mexican Americans (MA) from Starr County, TX. Linkage disequilibrium (LD) among SNPs typed for the follow-up studies conducted in these regions reveal differences in the extent of LD. We used all SNPs with a minor allele frequency >0.1 (59 on chromosome 2 and 47 on chromosome 15), and calculated D' for SNP pairs using haplotype frequencies estimated with an EM algorithm. The same subjects (108 MA patients with T2D and a random sample of 112 MA, all unrelated) were typed for both the chromosome 2 and the chromosome 15 SNPs. In the random sample, the proportion of marker pairs on chromosome 15 with $D'>0.9$ was significantly greater than on chromosome 2 to a distance of 55kb (where 4% of pairs have $D'>0.9$ on chromosome 2). The proportion of marker pairs with $D'>0.33$ was significantly greater for chromosome 15 than for chromosome 2 to a distance of 120 kb. We also found more haplotype diversity across the *NIDDM1* region than across the *CYP19* region, and both regions show more haplotype diversity than was reported for markers across the 5q region in a different population (Daly et al, Nat Genet 2001). Finally, although overall patterns of LD were similar in the patient and random samples for both the chromosome 2 and chromosome 15 markers, a higher proportion of marker pairs showed extensive LD in the patient sample in the *NIDDM1* region than in the random sample. These differences in LD are apparent only for markers less than 20 kb apart and are largely attributable to higher LD among SNPs in the *CAPN10* gene in the patient sample relative to the random sample. The differences in LD between the *NIDDM1* and *CYP19* regions suggests that it will be more difficult to detect association of genetic variation with disease in the *NIDDM1* region than in the *CYP19* region, because LD extends over a shorter distance. Lesser LD in the *NIDDM1* region will also lead to more tightly localized disease associations.

A Tobit Variance-Component Method for Analyzing Truncated Trait Data. *M.P. Epstein, X. Lin, M. Boehnke.*
Dept Biostatistics, Univ Michigan, Ann Arbor, MI.

Variance-component methods are flexible and powerful procedures for mapping genes that influence quantitative traits. However, variance-component methods make the critical assumption that the quantitative trait data within a family either follows, or can be transformed to follow, a multivariate normal distribution. Violation of the multivariate normality assumption can occur if trait data are truncated at some threshold value. Trait truncation can arise in a variety of ways, including assay detection limitation or confounding due to medication.

Valid inference of truncated data in linkage analysis requires the development of a modified variance-component method that directly models the truncation. We present such a method, which we call the tobit variance-component method. Using simulated data, we compare and contrast the characteristics of the traditional and tobit variance-component methods for linkage analysis of truncated trait data. Our results suggest that (1) analyses of truncated data using the traditional variance-component method leads to severe parameter underestimation and a modest increase in false positive linkage findings, while (2) analyses with the tobit variance-component method lead to unbiased parameter estimates and type I error for linkage tests that is slightly conservative.

As an example, we simulated latent trait data with overall genetic heritability of 0.75 for 400 sibtrios and truncated the lower 25% of the data. Analyzing the truncated data with the traditional method yielded empirical type I error rates of .0663 and .0183 for nominal $p=0.05$ and 0.01, respectively. Also, mean parameter estimates were only 55%-70% of the true simulating values. Analyzing the same data using the tobit method yielded empirical type I error rates of .0503 and .0094, respectively, and unbiased parameter estimates.

Genetic mapping of two loci for familial hypercholanemia in the Amish. V. Carlton¹, E. Puffenberger², A. Knisely³, B. Shneider⁴, D. Morton², G. Salen⁵, L. Bull¹. 1) University of California, San Francisco, CA; 2) Clinic for Special Children, Strasburg, PA; 3) King's College Hospital, London UK; 4) Mount Sinai School of Medicine, NY; 5) UMDNJ-New Jersey Medical School, East Orange, NJ.

Familial hypercholanemia (FHC) is a rare childhood disorder characterized by elevated serum concentrations of bile acids and nutritional malabsorption. To study the genetic basis of FHC, we performed a 5 cM whole genome screen on Amish patients. We initially used a conservative approach by considering affected only those 5 patients who met strict criteria (definite FHC); similarly, but less severely affected patients were classified as possible FHC. Genome screen data were analyzed using a linkage disequilibrium approach by searching for shared haplotypes in the definite FHC patients. Three of the 5 definite FHC patients were homozygous for a shared haplotype (a statistically significant finding). The region was genotyped in 9 additional possible FHC patients (4 from families included in the genome screen and 1 each from 5 additional families), 6 of whom were found to be homozygous for the haplotype identified in the genome screen. We infer the presence of an FHC locus in this region, which we term *fhc1*. A candidate gene in this region was sequenced and found to contain a putative mutation not seen on 190 Caucasian control chromosomes; this gene's product is associated with tight junctions. Several unaffected siblings of children with FHC are also homozygous for the disease-associated change. We infer that this mutation in the candidate gene for *fhc1* exhibits incomplete penetrance. Several Amish patients do not share the *fhc1* disease-associated haplotype. Further study of these patients identified a second shared haplotype elsewhere in the genome, pointing to a second FHC locus, *fhc2*. A disease associated haplotype in the *fhc2* region is shared homozygously by 3 affected siblings and one patient in another family. A candidate gene in this region was sequenced and found to contain a putative mutation not seen on 182 Caucasian control chromosomes. To our surprise, one Amish patient does not share the *fhc1* or *fhc2* disease associated haplotypes. We infer that a third FHC locus exists in the Amish.

ADHD: DRD4 Linkage analysis in extended pedigrees. *M. Arcos-Burgos¹, D. konecki¹, D.A. Pineda², F. Lopera², J.D. Palcio², K. Berg¹, X. Castellanos³, J. Bailey-Wilson¹, M. Muenke¹.* 1) NHGRI, NIH, Bethesda, MD; 2) University of Antioquia, Colombia; 3) NYU Child Study Center, NY.

Despite several linkage and linkage disequilibrium studies showing significant positive association/linkage, the co-segregation of DRD4 mutations with ADHD has not yet been found. Extended pedigrees can be a powerful and feasible method to determine co-segregation of polymorphisms with a trait. Here we are presenting a candidate gene approach for DRD4 by using 15 extended families coming from a genetic isolate, segregating ADHD. We genotype two intragenic DRD4 polymorphisms and 4 surrounding STR markers (D11S4177-D11S4046-D11S4146-D11S1323). Parametric and non-parametric linkage analyses assuming or not heterogeneity were performed. The two point results are reported in Table 1. A review of each family showed that 4 families presented results that are significantly suggestive of linkage. We had a very low value of informativeness to the DRD4 intragenic markers and therefore other markers will be necessary in screening the gene.

Marker	LOD_score	a HLOD	NPL_score	p-value
D11S4177	1.66	1.0, 1.67	1.44	0.08
D11S4046	1.25	1.0, 1.25	1.54	0.07
PromDRD4	-5.28	0.0, 0.0	-0.62	0.72
VNTR-DRD4	-1.36	0.2, 0.03	0.52	0.27
D11S4146	-3.25	0.3, 0.83	1.07	0.13
D11S1323	-3.40	0.3, 0.8	1.06	0.13

Mapping of a new autosomal dominant non-syndromic hearing loss (DFNA43) to chromosome 2q12. *E. Flex*^{1,2}, *M. Mangino*^{1,2}, *M. Mazzoli*³, *A. Martini*⁴, *A. Pizzuti*^{1,2}, *B. Dallapiccola*^{1,2}. 1) IRCCS S. Giovanni Rotondo CSS-Mendel Institute, Rome, Italy; 2) Department of Experimental Medicine and Pathology, University of Rome La Sapienza, Rome, Italy; 3) U.O.A. Otorinolaringoiatria Az. Ospedaliera di Padova Padova, Italy; 4) Department of Audiology, University of Ferrara, Ferrara, Italy.

Hearing impairment (HI) is the most frequent sensory defect characterised by a large genetic heterogeneity. Approximately 80% of genetic hearing losses are non-syndromic and 15-25% of them exhibit an autosomal dominant inheritance. We analysed an Italian three-generation family in which a non-syndromic hearing impairment is transmitted as an autosomal dominant trait. Onset of HI in all affected subjects occurred in the second decade of life with subsequent gradual progression from moderate to profound loss. HI was bilateral and symmetrical, involving all frequencies. After excluding known DFNA loci using markers, listed on the Hereditary Hearing Loss Homepage (URL: <http://dnalab-www.uia.ac.be/dnalab/hhh>), a genome wide scan was conducted with 358 highly informative microsatellite markers using the ABI PRISM Linkage Mapping Set (PE Applied Biosistem, USA). Significant linkage ($Z_{max}=4.21$; $q=0$) was obtained with markers of chromosome 2p12. This result was confirmed by multipoint analysis ($Z_{max}=4.51$), using the location score method. Haplotype analysis defined a 9.6 cM disease-gene interval, non overlapping with all loci identified on chromosome 2. Fine mapping and identification of candidate genes are in progress. Work supported by Italian Ministry of Health.

Genetic mapping of Cobalamin C deficiency: putative linkage to 1q. J.L. Atkinson^{1, 2}, A. Paterson^{1, 3}, D. Renaud⁴, J.T.R. Clarke^{5, 6}, B. Wilcken⁷, D. Bulman⁸, J.M. Rommens^{1, 2}. 1) Program in Genetics & Genomic Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Departments of Molecular & Medical Genetics, University of Toronto, Toronto, Ontario, Canada; 3) Public Health Sciences, University of Toronto, Toronto, Ontario, Canada; 4) Division of Child and Adolescent Neurology, Mayo Clinic, Rochester, MN; 5) Clinical & Metabolic Genetics, The Hospital for Sick Children, Toronto, Ontario, Canada; 6) Pediatrics, University of Toronto, Toronto, Ontario, Canada; 7) Biochemical Genetics Service, The Children's Hospital at Westmead, Sydney, Australia; 8) Ottawa Health Research Institute, Ottawa, Ontario, Canada.

Cobalamin C deficiency (*cblC*) is a rare autosomal recessive disorder (OMIM 277400) that usually presents in infancy with failure to thrive, developmental delay, hypotonia, and haematological abnormalities. It is the most common intracellular cobalamin processing disorder. Although vitamin therapies can be considered, diagnosis is difficult due to the diverse symptoms, and their varying degree of severity. DNA from ten families with *cblC* deficiency have been collected with 10 patients and a total of thirty-six individuals. Diagnosis was confirmed through complementation studies. Six affected individuals are offspring of consanguineous marriages predicting that gene mutations are homozygous-by-descent. A genome scan with markers positioned at 25 cM intervals was conducted, along with additional markers to achieve a 10 cM interval scan, for a total of 287 loci. Two-point linkage analyses were performed with each marker yielding positive lod scores for six loci at D1S2134, D1S1609, D2S441, D5S2488, D10S1423 and D16S2616. Five of these were eliminated upon examination of additional neighbouring markers, positioned within 1cM-5cM distances. D1S2134 gave a homogeneity lod score of 2.93 at $q = 0$. Exclusion of all alternate remaining genome regions with multi-point exclusion mapping and the refinement of the interval surrounding D1S2134 is continuing in order to focus our candidate gene analysis and positional cloning effort to identify the gene responsible for *cblC* deficiency.

Feasibility of complex pedigrees in an isolated population for QTL mapping of cholesterol levels. *M. Falchi¹, P. Forabosco¹, E. Petretto¹, A. Angius¹, C. Cappio Borlino², I. Persico¹, G.B. Maestrale¹, M. Fanciulli¹, D. Bebbere¹, D.A. Prodi¹, C. Fraumene¹, M.A. Palmas², P.M. Melis¹, M. Pirastu¹.* 1) Istituto di Genetica delle Popolazioni, CNR, Alghero, Sassari, Italy; 2) SharDNA, Cagliari, Italy.

A powerful approach to mapping complex-disease genes is to study isolated, founder population where genetic and environmental heterogeneity is reduced. Our study was performed on an isolated sub-population from Sardinia, consisting of a unique large, complex pedigree in 16 generations. This population may provide significant power to the identification of QTLs such as serum lipids levels. The study sample included 758 subjects, for whom serum total cholesterol (TC), LDL and HDL cholesterol levels were measured. All individuals were genotyped for a 5 cM microsatellite map (NHLBI Genotyping Service). Standard methods are computationally challenging in extremely large and complex pedigrees and do not account for genetic heterogeneity. We follow a multi-step approach based on increasing pedigree size and complexity, maximizing trait heritability among family members. In the first stage variance components linkage analysis was conducted using five large families (largest of 206 individuals) for a total of 261 phenotyped subjects. Heritabilities were 0.40 for TC, 0.37 for LDL and 0.41 for HDL, all resulting highly significant. The highest multipoint lodscore was found on chromosome 18 ($Z=2.07$) for LDL. The same region was also found to be involved in TC variability ($Z=1.84$). Other regions showing multipoint lodscores >1 were obtained on chromosomes 2, 4 and 18 for TC and LDL, and on chromosomes 1, 3 and 19 for HDL. Among the candidate loci associated with serum lipid levels, linkage evidence was maximized for a large family of 936 individuals on 19p13.2 for TC, near the LDLR locus ($Z=3.24$), thus suggesting a major role for this gene in our population. Our study shows that methods used to simplify the whole pedigree are extremely important. Indeed, even in such a homogeneous isolated population, genetic and environmental heterogeneity among subunits of the pedigree may play a significant role on the power of our studies.

Linkage to chromosome 14q in Alzheimer's Disease (AD) without psychotic symptoms. *D. Avramopoulos¹, M.D. Fallin², S.S. Bassett¹*. 1) Psychiatry, Johns Hopkins University, Baltimore, MD; 2) Epidemiology, Johns Hopkins University, Baltimore, MD.

The genome scans performed so far on Late Onset Alzheimer's Disease (LOAD) have not consistently produced positive findings at any chromosomal locus. The lack of such findings could be due to the genetic heterogeneity of LOAD. One way to reduce heterogeneity is to study additional phenotypic information and use them as covariates in the analysis. A number of new linkage methodologies are now attempting to make use of such covariates. One common finding in AD patients is the presence of psychotic symptomatology, namely hallucinations and delusions. The presence or absence of such symptoms might be related to the genetic background leading to disease and could therefore increase our chance to detect linkage for the disease if it is used as a covariate in the analysis. As part of the NIMH genetics initiative we have collected and performed a 9 cM genome scan on 457 LOAD pedigrees. For the subset of pedigrees collected by Johns Hopkins (n=148), we have information on the presence of such symptoms. We have used the computer program LODPAL, which allows the inclusion of covariates in the non-parametric linkage analysis, taking into account the presence of hallucinations. This analysis provided a strong linkage signal on chromosome 14q around the PS1 locus. The results suggest that the presence of hallucinations has a negative effect on linkage in the region, thus linkage is only present in the absence of hallucinations. SSCP screening of PS1 in 28 individuals linked to the region did not reveal any coding region mutations. Further studies are needed to exclude PS1 and identify the gene linked to LOAD without psychotic symptoms.

Ordered Subset Analysis in Primary Open-Angle Glaucoma (POAG): Evidence for Linkage to Chromosomes 14 and 15. *R.R. Allingham¹, J.L. Wiggs², E.R. Hauser¹, M.A. Hauser¹, F.L. Graham¹, K.R. LaRocque¹, B.W. Broomer¹, E.A. del Bono², J.R. Shi³, J.L. Haines³, M.A. Pericak-Vance¹.* 1) Duke University Medical Center, Durham, NC; 2) Massachusetts Eye and Ear Infirmary, Boston, MA; 3) Vanderbilt University Medical Center, Nashville, TN.

Ordered Subset Analysis (OSA) was used to reduce the impact of phenotypic heterogeneity underlying POAG (Hauser et al. 1998; Ghosh et al. 2000). OSA evaluates evidence for linkage in the presence of heterogeneity. We sought to identify homogeneous family subgroups on the basis of age of diagnosis (AOD). Mean and minimum AOD for the affecteds in a family were analyzed separately as covariates in the OSA analysis.

Eighty-six multiplex families with completed genotype and covariate information were included in this analysis. Multipoint lod scores were calculated using information from all available affected relative pairs via GENEHUNTER-PLUS software package incorporating Kong and Cox's model (Kruglyak et al. 1996; Kong et. al. 1997). These multipoint lod scores were used to calculate the OSA statistic. However, AOD covariate information did yield a significant increase in the LOD scores seen in chromosomes 14 and 15 with empirical p-values ≤ 0.05 . When this data set was analyzed using mean AOD, the peak OSA_LOD score for chromosome 14 was 3.68 (DLOD=1.90) at D14S72 (subset=fourteen families). Similarly, the peak for chromosome 15 was 3.19 (DLOD=1.78) at GABRB3 (subset=sixteen families). We had similar increases in the peak LOD score when we analyzed minimum AOD. There is significant overlap between the families linking to both chromosomes. We have identified homogeneous phenotypic subsets of families that contribute to linkage on both chromosomes 14 and 15. These data provide evidence that AOD is a useful stratification variable in identifying genes in POAG. Support: The Glaucoma Research Foundation, Barkhouser Glaucoma Research Fund, and NIH Grant EY 10886.

POSTERIOR POLAR CATARACT: CLINICAL SPECTRUM AND GENETIC ANALYSIS IN A LARGE FAMILY. *S. Finzi¹, Y.Y. Li¹, T.N. Mitchell¹, A. Farr¹, O. Sundin², I.H. Maumenee¹.* 1) Johns Hopkins Center for Hereditary Eye Disease; 2) Laboratory of Developmental Genetics, Johns Hopkins Medical Institutions, Baltimore, MD.

PURPOSE: Congenital cataracts affect about 6 patients per 10,000 births and frequently cause blindness in infants. Inherited cataracts account for up to half of all congenital cataracts. They are clinically and genetically heterogeneous. Loci for autosomal dominant posterior polar cataracts have been mapped to chromosomes 1p36, 16q22, 20p12-q12 and 11q22-q22.3. The purpose of this study is to present the clinical findings and the genetic analysis in a large family with autosomal dominant congenital posterior polar cataracts. **METHODS:** A four-generation American family with congenital posterior polar cataracts was identified. Forty-four members of the family were examined ophthalmologically and a total of 20 patients were diagnosed with congenital cataracts. Blood samples were collected with consent for genetic analysis of 28 patients of whom 15 were affected. After exclusion of known loci for posterior polar cataract, a genome-wide screen was conducted with a set of 170 markers spaced at 25-cM intervals. **RESULTS:** We mapped dominant congenital posterior polar cataract to chromosome 10q24. The maximal LOD score of 4.52 at recombination fraction $q = 0$ was obtained for marker D10S574. On haplotype analysis a 13cM interval between loci D10S1680 and D10S467 was identified, which included the PITX3 gene. On sequencing the coding region of PITX3, we found a 17 base pair duplication in exon 3. The mutation was co-inherited with the disease in all instances. The insertion resulted in a frameshift, altering 82 C-terminal amino acids. **CONCLUSION:** This study provides further evidence for genetic heterogeneity of autosomal dominant posterior polar cataract. Although Semina EV(1998) described the same genotype in one patient with anterior segment mesenchymal dysgenesis (ASMD) with cataracts, the common phenotype of this mutation is probably posterior polar cataract and a modifier gene could cause the anterior segment abnormalities in the previously described patient.

Evidence for interaction between CARD15 and the IBD4 locus (chr. 14) in Crohns disease families. *Y. Lin, K.D. Taylor, T. Hang, N. Fischel-Ghodsian, J.I. Rotter, H. Yang.* Medical Genetics, Birth Defects Ctr, Cedars-Sinai Medical Ctr, Los Angeles, CA, USA.

Background: Genome-wide searches for inflammatory bowel disease (IBD) susceptibility genes by multiple centers have identified putative Crohn's disease (CD) loci on chr. 6 (IBD3), 12 (IBD2), 14 (IBD4) and 16 (IBD1). CARD15 was recently identified to be the CD IBD1 gene. The aim of this study was to examine the potential interaction between CARD15 and other putative CD loci. **Methods:** 91 Caucasian CD multiplex sibpair families (sibship size 2: n=78, 3:12, 4:1) were genotyped for 3 CD associated CARD15 SNPs (R675W, G881R, and 980fs) and 18 microsatellite markers spanning the IBD2, IBD3 and IBD4 loci with a mean spacing of 7 cM. Two-point linkage analyses using SIBPAL in SAGE were performed in all families and by stratifying on CARD15 genotype. Families with at least one individual with a CARD15 mutation were CARD15+ (n=50; CARD15- n=41). Independent sample T-test was used to compare mean allele sharing (MAS) at each marker between groups. **Results:** In all CD families, borderline to significant linkage was observed across 8 markers at IBD2 (MAS=0.54-0.62, p=0.09-0.00002). Significant linkage was observed at IBD3 at D6S289 and D6S1060 (MAS=0.55, 0.56; p=0.03-0.04). MAS at IBD4 ranged 0.49-0.53 (p=0.08 at D14S261). For IBD3, CARD15- appeared to have a higher mean MAS (0.51-0.58) than CARD15+ families (0.48-0.55), although the differences were not statistically significant. Most interesting, for IBD4, the CARD15+ MAS (0.52-0.58) was consistently higher than CARD15- (0.44-0.52) at all 4 markers. In particular, MAS at D14S261 showed a significant difference between CARD15+ and CARD15- families (0.58 vs. 0.48, p=0.047) indicating a potential interaction between CARD15 and the IBD4 locus. **Conclusions:** There appears to be an interaction between CARD15 and the IBD4 locus (on chr. 14). CD families with a CARD15 mutation have a higher mean allele sharing for the IBD4 locus than those without. This study demonstrates that stratifying on CARD15 genotype may help to dissect the genetic factors predisposing to CD and thereby help identify other genes responsible for the disease.

An initial genome scan for type 1 Diabetic Nephropathy susceptibility loci in the Finnish population. *A.M. Osterholm¹, B. He¹, J. Pitkäniemi², I. Reynisdóttir³, T. Berg¹, J. Tuomilehto², K. Tryggvason¹.* 1) MBB, Matrix Biology, Karolinska Institute, Stockholm, Sweden; 2) The Finnish National Public Health Institute, Helsinki, Finland; 3) DeCODE Genetics, Reykjavik, Iceland.

Diabetic nephropathy (DN) is one of the severe complications affecting patients with type 1 and type 2 diabetes, and is the main cause of end stage renal disease in the Western world. DN is pathologically characterized by thickening of the glomerular basement membrane (GBM), which distorted the glomerular filtration barrier. Clinically, it is manifested by persistent proteinuria and progresses to impaired renal functions. However, the pathogenic mechanisms of DN are still unknown. Several epidemiological studies have provided evidence for genetic determinants of nephropathy. Loci linked to DN have been suggested on chromosomes 3, 7, 9 and 20, but no specific genes have been reported to be directly associated with DN. In the present study, our aim is to search for genes responsible for type 1 diabetic nephropathy using a genome-wide scan strategy. Sib pair families were collected from Finland. A dense marker map consisting of 900 markers with an average spacing of 4 cM was used. Discordant sib pairs (DSP), where siblings are concordant for type 1 diabetes, but discordant for nephropathy, were applied to map disease loci. In an initial genome wide scan, 868 markers, covering the 22 autosomal chromosomes plus the X chromosome, were successfully genotyped in 71 Finnish DSPs. Linkage analysis suggested four loci with a maximum lod score (MLS) above 1 on four chromosomes (3q, 4q, 16q and 22p). The highest observed MLS was 2.3 ($p=5.7 \times 10^{-4}$) on 4q. The locus on 3q (MLS 1.7) is a confirmation of a previous finding in an American Caucasian population. This locus has been investigated further in a separate study. Another two loci on 16q and 22q showed MLS of 1.44 and 1.45 respectively. Follow-up studies with additional markers as well as families will be carried out on chromosomes 4, 16 and 22. These three loci have not been reported previously and the suggested linkage will be investigated.

No evidence for a locus influencing Lp(a) levels on chromosome 1. *B.T. Heijmans¹, M. Beekman¹, N.G. Martin², J.B. Whitfield³, N.L. Pedersen⁴, U. DeFaire⁴, H. Snieder⁵, N. Lakenberg¹, P. de Knijff⁶, R.R. Frants⁶, G.J.B. van Ommen⁶, C. Kluit⁷, G.P. Vogler⁸, P.E. Slagboom¹, D.I. Boomsma⁹.* 1) Molecular Epidemiology, Leiden University Medical Centre, Leiden, The Netherlands; 2) Queensland Institute for Medical Research, Brisbane, Australia; 3) Clinical Biochemistry, Royal Prince Alfred Hospital, Sydney, Australia; 4) Medical Epidemiology, Karolinska Institute, Stockholm, Sweden; 5) Georgia Prevention Institute, Medical College of Georgia, Augusta, United States of America; 6) Human and Clinical Genetics, Leiden University Medical Center, Leiden, The Netherlands; 7) TNO Prevention and Health, Leiden, The Netherlands; 8) Biobehavioral Health, Center for Developmental and Health Genetics, Pennsylvania State University, PA, USA; 9) Biological Psychology, Free University of Amsterdam, Amsterdam, The Netherlands.

Plasma levels of lipoprotein(a) (Lp(a)) were long believed to be influenced by the LPA locus at chromosome 6q27 only. A recent report, however, suggested the presence of a second locus on chromosome 1 influencing Lp(a) (Broeckel et al. Nat Genet 2002;30:210). We performed a linkage study aimed at replication of this finding in 1445 twin pairs, of whom 483 were dizygotic and 962 monozygotic. As expected, we obtained highly significant evidence for linkage (LOD=9.8) with Lp(a) plasma levels at the LPA locus on chromosome 6. Next, we analysed chromosome 1 and a LOD score of 1.6 was obtained at 251 cM from pter. However, the two putative QTLs at chromosome 6 and 1 together explained 126% of the variation in Lp(a) levels (44% and 82% for chromosome 1 and 6, respectively), which likely resulted from an overestimation of effect sizes, a common phenomenon in genome-wide linkage analyses. We, therefore, modelled both putative QTLs simultaneously. When we analysed this two-locus model, the positive LOD score at chromosome 1 completely disappeared. Moreover, the chromosome 1 locus now explained none of the variation in Lp(a) plasma levels. Our data provide no evidence for an additional locus at chromosome 1 influencing Lp(a) plasma levels and we are thus unable to replicate the previously reported linkage result.

A second generation genome scan for rheumatoid arthritis. *J. Osorio y Fortea*¹, *C. Pierlot*¹, *E. Petit-Teixeira*¹, *S. Cailleau-Moindrau*¹, *C. Sardou*¹, *C. Stalens*¹, *P. Dieudé*¹, *G. Cornélis*^{1,2}. 1) GenHotel / Laboratoire de Recherche pour la Polyarthrite Rhumatoïde, 91057, Evry, Université Paris7 - université d'Evry, France; 2) Unité de Génétique Clinique, Hôpital Lariboisire, Assistance Publique Hôpitaux de Paris, Université d'Evry, France; 3) INSERM, Hôpital Kremlin Bicêtre 78-80 rue du Général Leclerc, 94276, Le Kremlin Bicêtre, France; 4) Laboratoire Statistique et Génome, Génopôle, tour Evry2 , 91000, Evry, France.

Background : Rheumatoid Arthritis (RA, OMIM number180300) is the most frequent autoimmune disorder (1% prevalence). Searching for susceptibility loci outside the HLA region, genome scans have been reported in French, Japanese, American and English RA families. The genetic information extracted was only partial, and the resolution was from 10 to 12 cM. As these scans used different genetic map, a meta-analysis is difficult. **Objective :** To refine our genome scan to a resolution below 4 cM, in order to extract all genetic information and facilitate future meta-analysis. **Methods :** 88 Caucasian Affected Sib Pair (ASP) families were genotyped with 1109 microsatellite markers (77% mean heterozygosity) defining the finest panel ever used in a genome scan for a human disease (3.5 cM). Fluorescent technology was used on ABI sequencer with GenScan and Genotyper softwares. Multipoint model free linkage analysis was performed using GeneHunterPlus program. **Results :** Preliminary analysis of the first 1000 markers showed linkage in the HLA region (lowest p-value = 0.0007) and suggested loci (p-value < 5%) different than those observed in our initial 12 cM scan. Altogether, 66 markers defining 12 non-overlapping loci were observed, resulting in 150 Mb of genome sequence, *i.e.* about 1500 potential candidate genes. **Conclusion :** We have refined our RA genome scan to a resolution below 4 cM, allowing us to extract all genetic information and facilitate future meta-analysis.

No linkage in the FSH-receptor region for age at natural menopause in Dutch sibpairs. *H.S. Kok^{1,2,4}, K.M van Asselt^{1,2,4}, L.A Sandkuijl³, P.H.M Peeters², Y.T van der Schouw², E.R te Velde⁴, D.E Grobbee², P.L Pearson¹.* 1) Department of Medical Genetics, University Medical Center, Utrecht, The Netherlands; 2) Julius Center for Health Sciences and Primary Care, University Medical Center Utrecht, Utrecht, The Netherlands; 3) Department of Medical Statistics, Leiden University Medical Center, Leiden, The Netherlands; 4) Department of Reproductive Medicine, University Medical Center Utrecht, Utrecht, The Netherlands.

Objectives: Age at natural menopause is a retrospective marker for timing of reproductive events such as onset of sub- and infertility. Natural age at menopause exhibits a 20-year spread in the population. Several studies have noted previously that environmental factors account for only a small part of the variation in age at menopause. Heritability estimates of 0.53 and 0.63 have been reported for age at menopause in twin studies and an estimate of 0.85 for sisters. Our aim is to locate regions in the genome that might contain genes contributing to the genetic variation in age at menopause by performing a whole genome scan. However, in women exhibiting premature ovarian failure (age at menopause before age 40), a study has previously reported association with the FSH-receptor. This could be a candidate gene for the normal variation in age at menopause. Preceding the genome scan, we performed a sibpair study with 5 markers in the FSH-receptor region. Materials and methods: Blood samples of pairs of menopausal sisters with ages at menopause in the extremes of the natural menopause age distribution (before 45 or after 55 years) were collected. Where possible, parents or additional siblings were included for phase-determination. DNA was isolated and information on factors that could influence age at menopause was collected from all siblings. The Haseman-Elston as well as a variance components model were applied to analyze the data. Results: The total number of included families is 124. We detected no linkage in the FSH-receptor region for age at menopause.

A genome scan for allergic asthma and related phenotypes in an Italian population sample. *G. Malerba¹, E. Trabetti¹, C. Patuzzo¹, C. Migliaccio¹, R. Galavotti¹, M.C. Lauciello¹, L. Xumerle¹, L. Pescollderungg², A.L. Boner¹, M. Lathrop³, P.F. Pignatti¹.* 1) Mother-Child & Biol, Genetics, Univ Verona, Verona, Italy; 2) Institute of Paediatrics, Hospital of Bolzano, Bolzano, Italy; 3) Centre National de Genotypage, Paris, France.

A genome scan with 394 microsatellite polymorphic markers has been performed on 123 Italian families (604 individuals genotyped) ascertained through an allergic asthmatic child. Four qualitative phenotypes related to allergy or asthma have been investigated: asthma, bronchial hyperresponsiveness to methacholine challenge (BHR), total serum elevated IgE and skin prick test positivity to common allergens (SPT). Statistical analysis was performed by non parametric linkage analysis implemented in the computer program Merlin. Markers on 7 sites of chromosomes 1, 4, 9, 11, 13 and 15 showed a suggestive linkage ($p < 0.01$) with at least one of the 4 phenotypes investigated: D1S213 with elevated IgE ($p = 0.0012$), D4S426 with asthma ($p = 0.003$), D9S286 with elevated IgE ($p = 0.0006$) and SPT ($p = 0.001$), D9S1690 with elevated IgE ($p = 0.004$), D11S4191 with BHR ($p = 0.008$), D13S156 with elevated IgE ($p = 0.0004$) and D15S127 with asthma ($p = 0.009$). These preliminary results will be further investigated looking for two loci interactions and performing transmission disequilibrium tests using markers used for this genome scan, and additional biallelic markers located in the linked regions.

Genetic linkage analysis of ADPKD1 and ADPKD2 in several Iranian families using highly polymorphic microsatellite markers. *A. Hajibeigi¹, R. Radpour¹, M.M. Haghghi¹, M. Ohadi¹, B. Broumand², A.R. Afzal³, H. Najmabadi¹.* 1) Genetic Research Center, U. of Social Welfare and Rehab, tehran, tehran, Iran; 2) Rasoul Akram U.Hospital. Medical Science of Iran university. Tehran. Iran; 3) Medical Genetics Unit, St George's Hospital Medical School, London, UK.

Autosomal dominant polycystic kidney disease (ADPKD) is one of the most common genetically heterogeneous disorders affecting human with the incidence of about 1:1000 in all population. Three loci have been identified causing disease. One located on the short arm of chromosome 16 (ADPKD1) accounts for about 85-90% of the PKD patients, and ADPKD2 gene on chromosome 4 that approximately accounts for 15% of the cases. ADPKD3 has been identified but with unknown genomic locus. In this study the linkage analysis was performed using KG8, 16AC2.5, SM7, D4S1534, D4S231 and D4S423 markers linked to both ADPKD1 and ADPKD2 in five affected Iranian families. In parallel to this study, the genomic DNA of 50 unrelated healthy individuals were used to determine frequency, heterozygosities and PIC for each marker. Our results showed the highest heterozygosities and PIC values for all markers and the most informative markers were KG8 and SM7 for PKD1 and D4S231 for PKD2. Our data indicate that three of the five families had linkage to PKD1 whereas one family was linked to PKD2 gene. The other one was uninformative due to the family structure.

Program Nr: 1664 from 2002 ASHG Annual Meeting

A high throughput and accurate method for SNP genotyping using Sequenom MassARRAY™ system. *K. McKernan, C. Fujii, J. Ziauddin, J. Malek, P. McEwan.* Agencourt Bioscience Corp., Boston, MA.

Mass spectrometry has proven to be a rapid, easily multiplexed, and highly accurate SNP genotyping technology. An obstacle of mass spectrometry-based technologies can be the expense of the required instrumentation. Agencourt Biosciences SeeSNP™ Genotyping method is a multi-stage process based on the Sequenom MassARRAY platform, which combines primer extension technology with MALDI-TOF mass spectrometry. By measuring the molecular weight of primer extension products using mass spectrometry, the MassARRAY system is capable of SNP genotyping with unprecedented levels of accuracy without the need for labeling or separation steps. The MassARRAY platform combined with Agencourts genomic expertise and fully-automated facility create a cost effective SNP genotyping service which provides the high quality, high throughput SNP analysis necessary for the completion of large scale pharmacogenomic studies.

SNP Analysis of Candidate Genes Associated with Type 2 Diabetes in Chinese Han Population. *H. Sun¹, J. Zhao², W. Du¹, H. Wang³, J. Zuo¹, B. Qiang⁴, Y. Shen⁴, Z. Yao⁴, W. Huang⁵, Z. Chen⁵, M. Xiong², F. Fang¹.* 1) Institute of Basic Medical Sciences, Chinese Academy of Medical Sciences & Peking Union Medical College, Beijing 100005, China; 2) Human Genetics Center, The University of Texas, Health Science Center, Houston TX 77225, USA; 3) Peking Union Medical College Hospital, Beijing 100730, China; 4) Chinese National Human Genome Center at Beijing, Beijing 100176, China; 5) Chinese National Human Genome Center at Shanghai, Shanghai 201203, China.

In order to clone the susceptibility genes of type 2 diabetes in Chinese Han population in the 1p36.33-36.23 region that localized by genome screening in our former research, we conducted case-control study by using the third generation of genetic marker, single nucleotide polymorphism (SNP). The results showed that 3 SNPs, resided in PRKCZ, UTS2 and SLC2A5 gene respectively, might be associated with the disease. There was statistical difference of their allele frequency between case and control groups, especially the SNP rs436045 in PRKCZ gene, which showed significant discrepancy and implied possible association with the disease. A set of SNPs located upstream and downstream from rs436045 in PRKCZ gene were selected to conduct case-control study and linkage disequilibrium (LD) analysis. The results suggested that 5 SNPs extending about 7kb were in the same haplotype block and there was significant discrepancy of their haplotype frequency between case and control groups. To search for the causal loci, we constructed 10 reporter plasmids containing different alleles of the 5 SNPs and transferred them to HepG2 cell. As a result, the reporter gene activity of different alleles of 2 SNPs, rs427811 and rs809912, were obviously different. We infer that these 2 SNPs might be susceptibility loci of the disease. They play a role in the pathogenesis of the type 2 diabetes by affecting the expression level of PRKCZ gene.

Chromosomal mapping of Essential Tremor. A. Shatunov¹, J. Jankovic², R. Elble³, N. Sambuughin⁴, Y. Zhang⁵, A. Dagvadorj¹, J. Ji⁵, H-S. Lee¹, M. Hallett¹, L.G. Goldfarb¹. 1) National Institute of Neurological Disorders and Stroke, Bethesda, MD; 2) Baylor College of Medicine, Houston, TX; 3) Southern Illinois University School of Medicine, Springfield, IL; 4) Barrow Neurological Institute, Phoenix, AZ; 5) BBI Biotech Research Laboratories, Gaithersburg, MD.

Hereditary essential tremor (ET) is the most prevalent movement disorder that occurs in about 1 of 200 to 300 people. ET is a heterogeneous entity expressed by phenotypically distinct types of disease: monosymptomatic postural or action tremor that increases during active movement and disappears at rest (T), and tremor combined with variably expressed focal dystonia (T-D). Both types are inherited with an autosomal dominant pattern. The T-type of ET was recently mapped to loci at 3q13 and 2p25, but analysis of other reported families did not support linkage to these locations. To further genetic characterization of ET we performed genome-wide scan in two large American families. Family A included 12 definitely affected individuals, most of them with the T-D phenotype. Seven patients in family B had T phenotype. Definite ET patients were considered as affected and all other family members were designated as unknown. GENEHUNTER and a newer MERLIN packages were used for multipoint calculations with both non-parametric (NPL) and parametric (LOD) statistics and exact compound P-values. Chromosome maps were adopted from the Marshfield web site with some corrections based on NCBI sequences in the candidate regions of the genome. Family A showed suggestive linkage at locus 6p22 (GENEHUNTER: NPL=2.70, p=0.003; LOD=1.78; MERLIN: NPL=2.89, p=0.002; LOD=1.21, p=0.009). The highest scores in family B were observed at two loci: 3p14 (GENEHUNTER: NPL=4.61, p=0.015; LOD=1.88; MERLIN: NPL=3.14, p<0.001; LOD=0.76, p=0.03) and 6p24 (GENEHUNTER: NPL=4.61, p=0.015; LOD=1.88; MERLIN: NPL=4.71, p<0.001; LOD=0.91, p=0.02). The distance between the markers showing maximal scores in families A and B within the 6p22-p24 locus is approximately 18.5 cM.

A genome-wide scan in type 2 diabetes mellitus provides independent replication of a susceptibility locus on 18p11 and suggests existence of novel loci on 2q12 and 19q13. C. Wijmenga¹, J.H. van Tilburg¹, L.A. Sandkuij^{1, 3}, E. Strengman¹, P.L. Pearson¹, T.W. van Haefen². 1) Dept Medical Genetics, Univ Medical Ctr, Utrecht, Netherlands; 2) Dept Internal Medicine, Univ Medical Ctr, Utrecht, Netherlands; 3) Departments of Medical Statistics, Leiden Univ Medical Ctr, Leiden, Netherlands.

It is well established that diabetes mellitus is a multifactorial disease, in which many genes interact not only with each other but also with environmental factors. Factors such as age, physical activity, diet, and obesity play a major role in the disease aetiology. We performed a genome-wide scan in Dutch Caucasian sibpairs with type 2 diabetes (T2D), with the aim of identifying susceptibility loci in the Dutch population. We found an interesting LOD on chromosome 18, in a region previously described by Parker et al. in a BMI-stratified subset of Finnish/Swedish patients. When we made a similar stratification our LOD increased from 0.7 to 2.3 between D18S471 and D18S843 in the 20% most obese pedigrees (DS-20%). This finding indicates that our data set consists of two subtypes, an obese pedigree group and a lean group. Analysis of the 80% lean pedigrees (DS-80%). revealed modest indications of linkage to regions on chromosomes regions 2q12 and 19q13 (multipoint LOD scores of 1.5 and 1.2, respectively). Although these loci do not reach suggestive LOD scores, they might indicate the existence of novel loci involved in T2D in the Dutch population. Our results for chromosome 18 clearly replicate the linkage to this region found in a Finnish/Swedish population and previously reported by Parker et al. Combined with our finding it indicates that a novel gene resides in the 18p11 region, which forms part of an, as yet unidentified, pathway involved in T2D and obesity.

Genome-wide scan in a subset of obese type 2 diabetes patients and subsequent QTL mapping for BMI suggests linkage to two distinct loci on chromosome 11. *J.H.O. van Tilburg¹, L.A. Sandkuijl^{1,3}, E. Strengman¹, P.L. Pearson¹, T.W. van Haeften², C. Wijmenga¹.* 1) Dept Medical Genetics, Univ Medical Center, Utrecht, the Netherlands; 2) Dept Internal Medicine, Univ Medical Center, Utrecht, the Netherlands; 3) Dept Medical Statistics, Leiden Univ Medical Center, Leiden, the Netherlands.

It is well established that type 2 diabetes mellitus (T2D) is a multifactorial disease, in which many genes interact not only with each other but also with environmental factors. Factors such as age, physical activity, diet, and obesity play a major role in the disease etiology. Like diabetes, obesity is also a complex trait that is determined by multiple genetic and environmental factors. In recent years, several single-gene defects responsible for obesity in rodents and, in rare cases, for human obesity have been identified. To further study diabetes and obesity, we undertook a genome-wide analysis for diabetes in the most 20% obese families from a Dutch Cohort of T2D patients and stratified the whole data set by BMI. We looked for susceptibility loci involved in diabetes and subsequently searched for quantitative trait loci (QTL) influencing obesity using variance components (VC) analysis. The most promising regions found so far in both the genome-wide scan and in the QTL mapping for BMI are on chromosome 11. A maximum LOD score of 1.7 was obtained between markers D11S2362 and ATA34E08 (region 11p15-13) in the genome-wide scan and a VC LOD score of 2.4 was obtained between markers D11S940 and D11S2000 (region 11q22) in the QTL mapping. Although the loci are 100 cM apart, both are interesting. It was shown by Hani et al. that the region 11p15-13 harbors the SUR1 gene, which is a key component in glucose-stimulated insulin secretion and also showed that a certain variant of SUR1 is associated with morbid obesity and T2D. On region 11q22 linkage was reported with BMI and T2D in Pima Indians. We therefore conclude that the two loci on chromosome 11 are involved in both obesity and T2D; further research is necessary in this region to elucidate the implications of the loci.

Linkage of Autistic Disorder to chromosome 15q11-q13 using phenotypic subtypes. *Y. Shao¹, M.L. Cuccaro¹, E.R. Hauser¹, K.L. Raiford¹, C.M. Wolpert¹, S.L. Donnelly¹, L.A. Elston¹, S.A. Ravan², R.K. Abramson², H.H. Wright², G.R. DeLong¹, J.R. Gilbert¹, M.A. Pericak-Vance¹.* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC 27710; 2) W.S. Hall Psychiatric Institute, University of South Carolina, Columbia, SC 29202.

Autistic disorder (AutD) is a complex genetic disease. It is postulated that several genes contribute to the underlying genetic risk of developing AutD. However, both etiologic and genetic heterogeneity confound the discovery of these AutD susceptibility genes. The chromosome 15q11-q13 has been identified as a candidate region based on both the frequent occurrence of chromosomal abnormalities and suggestive linkage and association findings. Ordered subsets analysis (OSA) is a novel method to identify a homogeneous subset of families that contribute to linkage in a chromosomal location. Thus OSA can be potentially used to help fine map and localize the susceptibility gene in a chromosomal area. A component representing insistence on sameness (IS), derived from a principle component analysis using data of 221 AutD patients from the repetitive behaviors/stereotyped patterns domain in the ADI-R, was used as a covariate in OSA analysis. Families sharing severe degree of IS (~25% of the 81 total AutD multiplex families) increased the linkage evidence on 15q11-q13 at the GABRB3 locus from LOD score 1.45 to 4.71. These results support previous reports implicating the involvement of g-Aminobutyric Acid Receptor Subunit genes in AutD and further show that the homogeneous subtype in AutD increases the power to map disease susceptibility genes in complex traits.

The Third Genetic Locus (GLC3C) for Primary Congenital Glaucoma (PCG) Maps to Chromosome 14q24.3. *M. Sarfarazi, I. Stoilov.* Molecular Ophthalmic Genetics Laboratory, Surgical Research Center, University of Connecticut Health Center, Farmington, CT.

A five-generation consanguineous family segregating for Primary Congenital Glaucoma (PCG) in an autosomal-recessive manner was ascertained and samples were obtained from 13 available individuals. Family members were genotyped with a group of polymorphic DNA markers flanking the two previously published PCG loci of *GLC3A/CYP1B1* on 2p21 and *GLC3B* on 1p36. Critical recombination events indicated that this PCG family is not linked to either of these two loci. In order to identify the chromosomal location for this family, we next initiated a genome-wide scan. Automated fluorescent genotyping was performed with the CHLC/Weber human screening set (Version 9; Research Genetics). Genotyping of 235 polymorphic markers identified only one (D14S53) that showed reduction in homozygosity in all PCG affected individuals as compared to the unaffected members. Saturation mapping and haplotype analysis with 6 additional markers (D14S61, D14S42, D14S983, D14S1020, D14S74 and D14S1000) revealed that all affected individuals share a region of homozygosity that is defined by markers D14S42, D14S983, D14S1020 and D14S74. Statistical evidence for linkage evaluation was carried out with MLINK subcomponent of the LINKAGE package (FASTLINK version). The highest two-point LOD score of 2.44 was obtained with a CA-repeat marker (ERR2b) that is located at the 3-prime end of Estrogen-Related Receptor Beta (*ESRRB*) gene. Four-point linkage analysis between PCG and DNA markers of ERR2b, ERR2a (a CA-repeat marker at the 5-prime end of *ESRRB* gene) and D14S74 produced a maximum LOD score of 3.09. Therefore, our data suggests that the third PCG locus (GLC3C) is located on chromosome 14q24.3, within a region of approximately 2.9 cM that is flanked by D14S61 and D14S1000. The physical distance between these two markers is estimated to be around 6 Megabases. There are more than 20 known genes within the newly identified GLC3C interval including, Neurexin-3 (*NRXN3*) and *ESRRB*. Mutation screening of these two candidate genes is currently in progress. Supported by a NIH grant (EY-11095) to MS.

The Power of Genome-Wide Haplotype Analyses for Complex Traits. *B.K. Rana*¹, *S.B. Gabriel*², *S.F. Schaffer*², *M.J. Daly*², *D. Altshuler*^{2,3}, *N.J. Schork*¹. 1) Polymorphism Research Laboratory, Dept of Psychaitry, Univ California, San Diego, La Jolla, CA; 2) Whitehead MIT Center for Genome Research, Cambridge, MA; 3) Departments of Genetics and Medicine, Harvard Medical School; Department of Molecular Biology and Diabetes Unit, Massachusetts General Hospital, Boston, MA.

The haplotype map effort aims to facilitate the discovery of disease-predisposing genes via association mapping. Association mapping, however, is complicated by a number of factors, not the least of which is the fact that, in the absence of a prior knowledge about the location of a disease gene, one may have to test literally tens of thousands of possible genomic sites for association with the disease. Multiple testing of this sort can potentially lead to many false positive results. Although the haplotype map project will yield information that will allow us to eliminate such redundant tests, the power of this approach has not been adequately addressed. Here we use the analytic strategy recently outlined by Schork (*American Journal of Human Genetics* (2002) 70:1480-1489) and the haplotype block data recently described by Gabriel et al. (*Science* (2002) May 23) to assess the power of genome-wide association studies that make use of haplotype information. Our results describe the likely performance of and thus requirements for the discovery of disease genes by haplotype mapping approaches.

Linkage analysis of 3 candidate gene polymorphisms with bone density in a sample of Italian families. A.

Sangalli¹, G. Malerba¹, V. Braga², E. Petrelli¹, L. Xumerle¹, S. Adami², M. Mottes¹. 1) Sect Biol & Genetics, Mother & Child, Biol & Gen, Verona, Italy; 2) Dept of Rheumatology, Valeggio S/M, University of Verona, Italy.

Osteoporosis is one of the major and growing health care problems around the world largely related to the general aging of developed countries populations. Several studies have reported that 60-80% of the variance in bone phenotype measurement is genetically determined. Several case-control studies in candidate genes reported association of vitamin D receptor (VDR), collagen 1 alpha1 (COL1A1) and estrogen receptor (ER) gene polymorphisms with bone phenotype. A sample of 119 Italian families (563 individuals genotyped) ascertained through an osteoporotic individual has been genotyped for the ER-PvuII, VDR-FokI, and COL1A1-Sp1 polymorphisms. A variance component linkage analysis has been performed for bone density z-score values of femoral neck, spine, and total hip. The preliminary results indicate that none of the polymorphisms investigated is significantly linked to bone density levels of the 3 sites studied: COL1A1-SpI: $p=0.07$, $p=0.08$, $p=0.5$ at spine, femoral neck and total hip, respectively; VDR-FokI: $p=0.5$, $p=0.4$, $p=0.4$ at spine, femoral neck and total hip, respectively; ER-PvuII: $p=0.3$, $p=0.14$, $p=0.07$ at spine, femoral neck and total hip, respectively. Additional genetic markers in the genes, a transmission disequilibrium test for quantitative traits and a more sophisticated analysis taking into account possible covariates could help in dissecting the association of the genes with bone phenotypes in this sample of Italian families.

A Genome Scan For Lupus-Related Autoimmunity Genes. *P.S. Ramos*¹, *J.A. Kelly*², *C.M. Meyer*¹, *A.N. Leiran*¹, *W.A. Ortmann*¹, *J.B. Harley*^{2,3,4}, *K.L. Moser*¹. 1) Department of Medicine, Division of Rheumatic and Autoimmune Diseases, University of Minnesota, Minneapolis, MN; 2) Arthritis and Immunology Program, Oklahoma Medical Research Foundation, Oklahoma City, OK; 3) Department of Medicine, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 4) US Department of Veterans Affairs Medical Center, Oklahoma City, OK.

The possibility that different autoimmune phenotypes may share underlying genetic components has been suggested by several studies. Pedigrees containing systemic lupus erythematosus (SLE) probands are known to have an increased incidence of other autoimmune diseases (~13%), as well as autoimmune serologic abnormalities relative to normal controls. The goal of this study was to identify loci that predispose to humoral autoimmunity in human SLE. Based on the presence of specific autoantibodies commonly associated with SLE, we have defined a novel phenotype for lupus-related autoimmunity (LRA). From our collection of 229 pedigrees multiplex for SLE, we reclassified 1668 total subjects (525 SLE affecteds) for the LRA phenotype and genotyped 279 markers. A total of 850 individuals were reclassified as having the LRA phenotype. We used the revised Haseman-Elston algorithm (SIBPAL) to identify regions of increased allele sharing within these pedigrees. In the European-American families the strongest evidence for linkage was found at 7p15 (D7S1808, $p=0.0005$), 7q21 (D7S2204, $p=0.0005$) and 15q25 (D15S211, $p=0.0016$). The strongest evidence for linkage in the African-American pedigrees was found at 12q24 (D12S2070, $p=0.0006$). Linkage to 7p15 ($p=0.002$), 12q24 ($p=0.008$) and 15q25 ($p=0.0048$) was also observed when all the pedigrees were analyzed together. Comparison of our data to previously reported results indicates some overlap with linkages previously identified in SLE (7q21), rheumatoid arthritis (7p15) and inflammatory bowel disease (12q24), while the effect at 15q25 appears to be novel. These results provide evidence of the presence and locations of genes that are involved in the susceptibility to development of an intermediate autoimmune phenotype and are likely to help further unravel the complexity of SLE as well as other autoimmune diseases.

A genome-wide scan for age-related maculopathy shows evidence of linkage on chromosome 12. *J.H. Schick¹, S.K. Iyengar¹, K. Reading¹, R. Liptak¹, C. Millard¹, K. Lee², S. Tomany², R. Klein², R.C. Elston¹, B.E. Klein².* 1) Epidemiology & Biostatistics, Case Western Reserve Univ, Cleveland, Ohio; 2) Department of Ophthalmology and Visual Sciences, University of Wisconsin Medical School, Madison, Wisconsin.

Age-related maculopathy (ARM), a multifactorial disorder characterized by loss of peripheral central vision, is a leading cause of blindness in the elderly. The importance of genetics in its etiology has been demonstrated by family and twin studies. We conducted the first stage of a genome-wide linkage scan in a selected sample by genotyping 353 autosomal markers in 325 participants comprising 257 sib pairs in the Beaver Dam Linkage Studies of Age-Related Ocular Disorders, including six markers from two candidate gene regions identified on chromosome 1, plus 23 second stage fine mapping markers on chromosome 12. Multipoint linkage analysis was performed using SIBPAL (S.A.G.E. 4.1) to identify regions linked to this degenerative disease. We took as the dependent variable a modified Wisconsin severity scale which is dependent on the size, type, and area of retinal drusen, pigmentary abnormalities, geographic atrophy and exudative macular degeneration. We adjusted this quantitative trait for age and age² prior to conducting the linkage analysis. There was empirical evidence of linkage on chromosome 12: at D12S1300 ($p = 0.0304$), D12S309 ($p = 0.0500$), D12S1671 ($p = 0.0241$), D12S346 ($p = 0.0034$), D12S1588 ($p = 0.0154$), D12S727 ($p = 0.0241$), PAH ($p = 0.0177$), D12S360 ($p = 0.0180$) and D12S338 ($p = 0.0351$). In addition, seven markers located on three other chromosomes were found to be significant for linkage with ARM at a level of $p = 0.05$: chromosome 3 at D3S1259 ($p = 0.0455$), D3S1744 ($p = 0.0209$), and D3S1763 ($p = 0.0004$); chromosome 5 at D5S2500 ($p = 0.0261$); chromosome; and chromosome 16 at D16S769 ($p = 0.0045$), D16S539 ($p = 0.0160$) and D16S621 ($p = 0.0208$). Second stage fine mapping is also being conducted in regions of chromosomes 3, 5 and 16 that demonstrate possible evidence of linkage. This study is supported in part by U.S.P.H.S. research grants GM28356 and EY10605, resource grant RR03655 and training grant HL07567.

Characterization of Asthma, Atopy and Associated Phenotypes in Multiplex Asthma Families. *M.C. Speer¹, P.J. Helms², W. Anderson³, K. Barnes², A. Berg², S. Brewster³, K. Carlsen², J. Gerritsen², C. Haynes¹, W. Lenney², P. Manasco³, A. Roses³, M. Pericak-Vance¹, M. Silverman², P. Sly², J. Sundry², J. Tsanakas², J. Vance¹, M. Hauser¹, M. Whyte².* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Genetics of Asthma International Network; 3) Glaxo-Smith-Kline, Research Triangle Park, NC, and Greenford, UK.

Asthma is a common, complex disorder with genetic and environmental components. We have established an international network of 11 sites, each collecting 100 nuclear families with at least two siblings (age 7-35) with a physician diagnosis of asthma (PDA). We have begun to characterize the genetic contributions to asthma first via genomic screening. In all subjects (including parents) the following measurements were performed: respiratory questionnaire including detailed family history and environmental risk factor assessment; bronchial reactivity (PC20-methacholine); reversibility of airway obstruction; skin-prick tests and serum total IgE. Genomic screening of 365 families of Caucasian descent was performed with 389 markers, an approximate 7 cM genomic screen. Eight phenotypes were considered including PDA, atopic asthma, atopy-broad (at least one SPT ³ 3 or IgE > 100 IU), atopy-conservative (at least one SPT ³ 3), strict asthma (2 of 3 symptoms + BHR), BHR (bronchial hyperresponsiveness), log IgE, and slope of the methacholine dose-response curve. We identified 11 regions of interest in which at least one phenotype generated a lod score ³ 2.0. The most interesting regions include those spanned by D8S1136-D8S1132 (max lod of 2.5 with positive results for 5 phenotypes), 21pter-21qter (max lod score of 2.5 with positive results for 3 phenotypes), and D15S816-D15S87 (max lod score 2.2 with positive lod scores for 3 phenotypes). The highest lod score of 2.8 was obtained for IgE, spanned by D10S1221-D10S1432. The GAIN sample represents the largest series of asthma families investigated via genomic screening to date. The enhanced power associated with the increased sample size has led to the identification of several genomic regions that may be associated with asthma and/or asthma-related phenotypes.

A Genome-Wide Scan for Human Essential Hypertension Susceptibility Genes. *L.R. Griffiths¹, M.P. Johnson¹, R.A. Lea¹, S. Rutherford^{1,2}, R.P. Curtain¹, S. Hooker¹, C. Hutchins¹, D.R. Nyholt^{1,3}, M. Galley⁴, P. Kelly⁴, P. Reed⁴ and Genomics Research Centre, School of Health Science, Griffith University, Southport, Australia.* 1) Genomics Research Centre, School of Health Science, Griffith University, Southport, Australia; 2) Department of Pathology, University of Virginia Health System, Charlottesville, Virginia (present affiliation); 3) Genetic Epidemiology Laboratory, Queensland Institute of Medical Research, Royal Brisbane Hospital, Herston, Brisbane, Australia (present affiliation); 4) Gemini Genomics Pty Ltd.

Although essential hypertension is a major contributor towards human cardiovascular morbidity and mortality within Western populations, its aetiology has still not been clearly defined. It is clear that hypertension is a complex multifactorial trait involving both environmental and genetic components. In addition, hypertension tends to cluster with a number of related conditions including insulin resistance, obesity, dyslipidemia and diabetes, a disorder collectively termed metabolic syndrome or syndrome X. This report presents findings of a hypertension genome wide linkage scan in a Caucasian affected sib-pair cohort totalling 177 sib-pair comparisons. Single marker data using a two locus disease model provided significant evidence for linkage to a region on chromosome 20q (LOD 3.98, $P = 0.00002$) and evidence suggesting linkage to two other genomic regions (LOD 2.61, $P = 0.0005$ and LOD 3.22 $P = 0.0001$). Interestingly, a previous study has reported the same 20q locus (D20S107) in an independent obesity genome scan and in addition this region has also been implicated in diabetes. It is possible that this chromosome 20q region may harbour a major susceptibility gene that plays a role in the development of the complex phenotype associated with Syndrome X.

Linkage analysis and candidate gene investigation in osteoarthritis. *T. Forster, K. Chapman, L. Marcelline, J. Loughlin.* University of Oxford, Institute of Musculoskeletal Sciences, UK.

Knowledge about the pathways and mechanisms involved in the initiation and progression of osteoarthritis (OA) is sparse. By identifying genes conferring susceptibility to OA further insights in to this complex disease will be gained.

A previous genome-wide linkage scan of 481 families, each having at least one affected sibling pair, by our group identified five chromosomal regions that are likely to contain susceptibility genes, on chromosomes 2, 4, 6, 11 and 16.

To date finer linkage mapping, using polymorphic microsatellite markers at an average density of one marker every 3.3 cM in a total of 571 families, has allowed the regions on these chromosomes to be narrowed. Finer mapping of chromosome 16 has confirmed the existence of two separate susceptibility loci on this chromosome with maximum multipoint LOD scores (MLS) of 1.7 and 1.9. The first locus, which directly overlaps with a locus identified in a large Icelandic pedigree with primary, early onset hip OA, appears to be largely accounted for by affected female sibling pairs with hip OA. The second locus is more pronounced in affected female sibling pairs with hip or knee OA. A conditioning analysis indicates that these two chromosome 16 loci are interacting, suggesting that susceptibility resides in shared biological pathways.

Two loci have also been identified on chromosome 4. The first at 4q12-24 is accounted for by affected female sibling pairs. The second locus, identified in the total knee replacement strata, is located at 4q25-q35. This locus shows overlap with OA loci identified independently by two other groups. Both loci show a maximal MLS of 1.6.

Concurrently, single nucleotide polymorphisms (SNPs) in candidate genes within these regions have been identified and are being genotyped in cohorts of cases and controls. Genes targeted are those involved in the development, synthesis and maintenance of tissues within the joint and includes those encoding for the interleukin-4 receptor and xylosyltransferase I.

Genetic associations with cardiovascular risk and their dependence on sex. *J.A. Ellis, S.B. Harrap.* Physiology, University of Melbourne, Melbourne, Victoria, Australia.

Consideration of genotype-by-environment interactions in variance component based linkage analyses of quantitative traits is a well-established methodology. Although the idea has received relatively little attention, the interaction of genotypes with male and female *physiological* environments (genotype-by-sex) may be potentially important¹. This is especially true for diseases that display sex differences such as cardiovascular disease and also for genes relevant to sex determination. We have performed association analyses of several sex steroid related genes, including the genes encoding 5 α -reductase (*SRD5A1* and *SRD5A2*) and the estrogen receptors (*ERa* and *ERb*) with common risk factors for cardiovascular disease. Single nucleotide polymorphisms were genotyped in healthy Caucasian men (n = 386) and women (n = 332) from the general population of the Victorian Family Heart Study². Using ANOVA with adjustments for age and BMI, associations were sought with systolic blood pressure (SBP), diastolic blood pressure (DBP) and plasma fibrinogen in all subjects with adjustments for sex, and in males and females separately. No associations were demonstrable in the combined analyses. However, several associations were noted in males or females alone. The involvement of these genes in cardiovascular risk is currently being further tested using transmission disequilibrium tests and sib-pair linkage analyses. However, the results raise the possibility that mathematical adjustment for sex might be inappropriate if phenotypic effects of genotype are predicated on the sexual phenotype. Failure to consider genotype dependence on sex in genetic analyses of cardiovascular risk and other sex-relevant conditions may obscure contributing loci.

Joint-analysis of two genome-wide scans conducted in Finnish study samples in schizophrenia and bipolar disorder. *J. Ekholm^{1,3}, M. Kestilä¹, J. Ekelund¹, T. Kieseppä², T. Paunio¹, P. Haimi¹, T. Varilo¹, M. Perola^{1,3}, T. Partonen², J. Lönngqvist², L. Peltonen^{1,3}.* 1) Department of Molecular Medicine; National Public Health Institute, Helsinki, Finland; 2) Mental Health and Alcohol Research; National Public Health Institute, Helsinki, Finland; 3) Department of Human Genetics; University of California Los Angeles, Los Angeles, USA.

We have carried out joint linkage analysis in families ascertained for schizophrenia or bipolar disorder by combing the raw genotype data from two genome-wide scans. Our aim was to localize potential loci, predisposing to a broader psychotic phenotype and playing a role in both diseases. Two diagnostic categories were assigned prior to the statistical analysis of the combined data set; 1) families diagnosed with psychotic disorder (psy) and 2) families diagnosed with affective disorder (aff). The total study sample of 2579 and 2198 subjects respectively from 313 families were screened with 339 markers spanning the genome. Twenty-seven loci exceeded a two point $Z_{max} > 1.0$, four of them exceeding a Z_{max} of 2.0 on chromosomes 1q32 ($Z_{max} = 2.48$: aff), 4q32 ($Z_{max} = 2.62$: aff), 5q11 ($Z_{max} = 2.56$: psy) and Xq25 ($Z_{max} = 2.45$: psy). The sample ascertained for bipolar disease was significantly smaller (331 subjects, 40 families), however, all four loci except for 5q11 represented linkage peaks also in the genome scan for bipolar disease. We propose that these chromosomal regions represent putative candidate loci for psychosis generally, and that pooled data analyses of study samples ascertained for traditional psychiatric traits should be pursued for different trait components to characterize the molecular background of these complex disease entities.

Linkage and association analysis of candidate genes for diabetic nephropathy. *K. Gogolin Ewens¹, R.A.V. George¹, L.K. Southworth¹, F.N. Ziyadeh², R.S. Spielman¹.* 1) Dept of Genetics, Univ of Pennsylvania School of Medicine, Philadelphia, PA; 2) Renal-Electrolyte and Hypertension Division and Penn Center for Molecular Studies of Kidney Diseases, Dept of Medicine, Univ of Pennsylvania School of Medicine, Philadelphia, PA.

Familial clustering of diabetic nephropathy (DN) suggests the existence of susceptibility genes that contribute to this disorder. In order to identify these genes, we have analyzed 72 candidate genes for linkage and association with DN. Families were ascertained through a proband with diabetes and end-stage renal disease (ESRD). DN in diabetic sibs of the proband was defined by an elevated albumin/creatinine ratio (ACR>300 mg/mg) in two of three urine samples collected six weeks apart. Diabetic sibs were considered unaffected for DN if they had normoalbuminuria (ACR<30 mg/mg), had duration of diabetes >15 years, and were not taking any ACE (angiotensin converting enzyme) inhibitor or AGTR1 (angiotensin receptor 1) blocker medications. Microsatellite markers within 50 kb of each candidate gene and/or SNPs in the gene were genotyped in 60 parent-child trios and 18 multiplex families. Nominally significant TDT results were obtained at nine genes, including two reported previously by others: AGTR1 and ACE. In the AGTR1 region, Moczulski et al. (*Diabetes*,47:1164,1998) found evidence for linkage (but not association) with DN using two polymorphic markers, ACTA and D3S1308 (15 kb and 600 kb 3' from AGTR1, respectively). We found an elevated TDT at both markers (D3S1308 allele 7: 37 (65%) of 57 transmissions, $c^2=5.1$; ACTA allele 6: 15 (71%) of 21 transmissions, $c^2=3.9$). These results support a role for the AGTR1 gene region in DN. An association between the D allele of the insertion/deletion polymorphism in ACE and DN has been reported in some studies but not others. In our study, we found evidence for elevated transmission of the D allele to DN offspring (31 (67%) of 46 transmissions; $c^2=5.6$). Nominally significant results were also found with markers in or near AGER, AQP1, COL1A1, HSGP2, PRKCB, TIMP3 and TGFBR3. However, in view of the small sample size in this study, these results must be considered preliminary.

Haplotype association analysis of bone mineral density and chromosome 1p36 candidate genes. *M. Devoto*^{1,2}, *H. Li*¹, *H. Rodriguez*³, *M. Koch*³, *H.S. Tenenhouse*⁴, *A. Tenenhouse*⁵, *L.D. Spotila*³. 1) Dept. of Research, Nemours Children's Clinic, Wilmington, DE; 2) Dip. di Oncologia, Biologia, e Genetica, Universita' di Genova, Italy; 3) Dept. of Bioscience and Biotechnology, Drexel University, Philadelphia, PA; 4) Dept. of Pediatrics and Human Genetics, McGill University, Montreal, Canada; 5) Metabolic Bone Centre, Montreal General Hospital, Montreal, Canada.

Osteoporosis is a common complex trait, characterized by reduced skeletal strength and increased susceptibility to fracture. Low bone mineral density (BMD) is the most important risk factor for osteoporosis, and several studies have confirmed the importance of genetic factors in determining variability of BMD. We have identified a candidate region for BMD in a sample of 42 families of individuals with low BMD. Our maximum multipoint lod-score by variance component linkage analysis was 3.53 for linkage of femoral neck BMD to a QTL located near marker D1S214 on 1p36. The empirical p-value by simulation analysis was equal to 0.0001. Two candidate genes located within the chromosomal interval 1p36.2-1p36.3, TNFRSF1B and PLOD, have been scanned for single nucleotide polymorphisms (SNPs) within their coding and promoter regions. These two genes are separated by about 200 kb. We detected four SNPs within TNFRSF1B and six SNPs within PLOD that were present with a frequency of greater than 5% in a sample of 104 North American individuals of European descent. Significant linkage disequilibrium among these SNPs was observed over a large interval within both genes. Haplotypes were reconstructed by means of a Bayesian algorithm implemented in the program Haplotyper, and haplotype association to BMD was investigated by linear regression analysis. TNFRSF1B haplotypes showed a statistically significant association with femoral neck BMD ($p=0.01$), whereas PLOD haplotypes demonstrated a statistically significant association with spinal BMD ($p=0.04$). These findings are consistent with a role of chromosome 1p36.1-p36.2 in BMD variability, and support the hypothesis that variations in these or in other nearby genes are important in conferring susceptibility to osteoporosis.

Linkage disequilibrium analysis in a susceptibility region for Bipolar Affective Disorder on 8q24. *S. Cichon¹, J. Schumacher², R. Kaneva², A. Van Den Bogaert¹, T.G. Schulze³, D.J. Müller⁴, M. Gross⁵, H. Fangerau⁵, T. Becker⁶, C. Richter², S. Ohlraun⁷, M. Rietschel⁷, P. Propping², M.M. Nöthen¹.* 1) Dept Medical Genetics, Univ Antwerp, Wilrijk, Belgium; 2) Inst Human Genetics, Univ Bonn, Bonn, Germany; 3) Dept Psychiatry, Univ Chicago, Chicago; 4) Mental State Hospital Bonn, Bonn; 5) Dept Psychiatry, Univ Bonn, Bonn; 6) Inst Medical Biometry, Informatics, Epidemiology (IMBIE), Univ Bonn, Bonn; 7) Central Inst Mental Health, Mannheim, Germany.

A genome wide screen for linkage to bipolar affective disorder (BPAD) has suggested a new susceptibility locus on 8q24 (Cichon et al., 2001). Marker D8S514 gave a two-point LOD score of 3.62 and a GENEHUNTER-NPL score of 3.56 ($p=0.00029$). The positive linkage region is large and extends over 30 cM. In an attempt to narrow down the linked region, we have performed linkage disequilibrium (LD) analysis in a sample of 119 parent-offspring trios with BPAD using the Transmission Disequilibrium Test (TDT). Part of the triads (53) were extracted from the genome screen families, the other 66 triads were independent. In a first step, eight microsatellite markers were tested for LD that are located in the highest linked region (about 5 Mb). Individual markers and two-marker haplotypes were tested for LD. TDT analysis revealed two regions of interest: One is characterized by preferential transmission of two particular two-marker haplotypes (markers A-C, $p=0.008$; markers B-C, $p=0.035$). A second region is located more centromeric. A particular allele of maker D ($p=0.01$) and the two-marker haplotype D-E ($p=0.001$) were preferentially transmitted. To follow up this finding, we have isolated new polymorphic STR markers in the region which are currently being analyzed by TDT.

Case selection strategies for association studies in linkage candidate regions. *T.E. Fingerlin, M. Boehnke, G.R. Abecasis.* Univ Michigan, Ann Arbor, MI.

For complex diseases, disease-marker association studies generally are necessary to identify disease-predisposing variant(s) in a linkage candidate region. Typically, a subset of individuals from the original family sample is genotyped for these association studies. We compared 4 strategies for choosing members of affected sibships to be genotyped in follow-up association studies in terms of (a) the expected difference in disease allele frequency between cases and controls (ED) and (b) the power to detect a disease allele frequency difference between cases and controls. The 1st strategy is to choose one sib at random from each sibship. The 2nd is to choose from each sibship the sib that shows the most evidence for IBD allele sharing with the other affected sibs. Since we assume the region has been targeted due to evidence for linkage, the 3rd and 4th strategies mirror the 1st and 2nd except that sibs are chosen only from those sibships that provide evidence for linkage to the region, where we define evidence for linkage as having an S_{all} value greater than expected for that sibship size assuming no linkage. For a wide array of disease models, and for sibship sizes 2-5, we calculated ED for the 4 strategies, and the expected proportion of sibships included for the 3rd and 4th strategies. We found that for affected sibship sizes >2 , ED was always greater when the sib showing the most evidence for sharing with the other sibs was chosen compared to randomly choosing a sib, whether one sib was chosen from each sibship or only from those sibships showing evidence for linkage. For nearly all models consistent with a common complex disease, ED was greater when one sib each was chosen only from sibships showing evidence for linkage rather than from all sibships, whether sibs were randomly chosen or chosen based on sharing with other sibs. For most recessive models, the increase in ED by using the 3rd and 4th strategies resulted in equal or increased power to detect a difference between cases and controls compared to the 1st and 2nd strategies despite the smaller sample size; for other models, this generally was not the case.

A Second Generation Genomic Screen For Multiple Sclerosis. *Y. Bradford*¹, *N. Schnetz-Boutaud*¹, *J.B. Rimmler*², *J.R. Oksenberg*³, *S.L. Hauser*³, *S. Schmidt*², *L.F. Barcellos*³, *R.R. Lincoln*³, *M. Clanet*⁴, *G. Edan*⁵, *J. Yaouanq*⁵, *G. Semana*⁵, *I. Cournu-Rebeix*⁶, *M.-C. Babron*⁷, *B. Fontaine*⁶, *M.A. Pericak-Vance*², *J.L. Haines*¹. 1) Program Human Genetics, Vanderbilt Univ, Nashville, TN; 2) Duke University Medical Center, Durham, NC; 3) Univ Cal San Francisco, San Francisco, CA; 4) Centre Hospitalier Universitaire Purpan, Toulouse, France; 5) Centre Hospitalier Universitaire Pontchaillou, Rennes, France; 6) Groupe Hospitalier Pitie-Salpetriere, Paris, France; 7) INSERM Le Kremlin-Bicetre, France.

Multiple sclerosis (MS) is a chronic inflammatory disorder of the central nervous system with a complex etiology. While the contribution of the Major Histocompatibility Complex (MHC) to genetic susceptibility for MS has been long established with strong associations to the HLA-DR locus (primarily to the HLA-DR2 allele), identifying other risk genes has been problematic. Previous genomic screens have suffered from small sample sizes and have identified numerous different regions, few of which have overlapped. We have completed a genomic screen with ~360 microsatellite markers (~10 cM spacing) on 250 families with 354 affected sibpairs and 119 other affected relative pairs, one of the largest screening datasets to date. 21 markers (defining 17 regions on chromosomes 1q, 3q, 4q, 5p, 6p, 6q, 7p, 9q, 11p, 11q, 13q, 15q, 18p, 20p, and 21q) met our initial criteria of a lod score > 1.0 for the semi-parametric NPL(pairs) or parametric MLOD statistics. The strongest signals are near the HLA-DR locus in the MHC on chromosome 6p (MLOD>3) and on chromosome 1q (180 cM on the Marshfield map, MLOD=2.12). The regions on 5p, 6q, 11p, and 15q overlap with regions identified in at least one previous genomic screen. Detailed analyses of these data suggest that some regions may interact with the HLA-DR locus. This may help explain the previous inconsistencies among the genomic screens.

Sib-similarity and the 10p problem. *J.H. Edwards.* Biochemistry, Oxford University, Oxford, Oxon, England.

Mein et al (1998), working on IDDM, showed a same:different ratio of parental alleles in pairs of affected sibs of 248:167 (63% same, $\chi^2 = 15.8$, $p < 0.0001$) after selecting a subset based on prior expectations. Raw data from www.cimr.cam.ac.uk/todd Davies et al.(1994) showed a similar pattern on earlier data from the same laboratory. This segment has now been incriminated on strong evidence in leprosy, on substantial evidence in four genome trawls of schizophrenia and four other psychoses, and in Paget's disease, with a supporting cast from autism, asthma and normal families from France and Denmark. See www.medvet.angis.org.au/www/w10p Other segments showing consistent sib-similarity include 6q, with strong evidence in IDDM and schizophrenia, moderate evidence in several disorders and one normal variant, height. Chromosome 14, 19 and chromosomal arms 10q, 16p and 16q also show excess segregation. The loci inferred in autism and Crohn's disease lie between main peaks. Such similarities are to be expected in sib-pair analyses based on any sibships with two or more affected, rather than the far more numerous sibships with one or more affected, as advanced by Penrose in 1935. medvet.angis.org.au/wspr/sibpr.htm Excess sib-similarity unrelated to disease due to embryonic lethals is a likely cause of the high losses between conception and birth in humans. In addition preferential fertilisation between gametes that lack identical alleles at some loci is likely. The evolutionary advantages of this mechanism, common to most plants, is likely to be exploited in vertebrates. However the problem remains. The symmetrical segregational disturbance is more than could attributed to recessive lethals alone, and neither meiotic drive nor preferential fertilization is likely to show symmetry. There is some tendency to paternal excess. If deficiency polymorphisms are a common cause of recessive lethals this will confound SNP trawls as the ends will show complete allelic association.

Conserved noncoding sequences (CNSs) on human chromosome 5q31 and susceptibility to asthma. *J. Donfack*¹, *K. Frazer*², *C. Ober*¹. 1) Dept Human Genetics, Univ Chicago, Chicago, IL; 2) Perlegen Sciences, Santa Clara, CA.

Comparisons of DNA sequences between species can identify functional elements. A recent study comparing human, mouse, and dog sequences identified 13 CNSs on human chromosome 5q31, including the region encoding the Th2 cytokines, IL-4 and IL-13 (Dubchak et al, *Genome Res* 2000;10:1304). One of these CNSs, CNS-1, was shown to coordinately regulate expression of these genes in transgenic mice (Loots et al, *Science* 2000;288:136). This region on 5q has been linked to asthma and atopy, disorders of Th2 cytokine dysregulation, in many populations, including the Hutterites, a founder population (TDT $P = 0.0009$). The objective of this study was to survey the 13 CNSs for variation and to determine whether variation in this region was associated with asthma or atopy or could explain the evidence for linkage in the Hutterites. We identified 7 single nucleotide polymorphisms (SNPs) in 5 of the CNSs. No variation was detected in 8 CNSs, including CNS-1. Based on allele frequencies and patterns of linkage disequilibrium (LD), we genotyped 4 SNPs and evaluated their association with asthma and atopy in the Hutterites, and in case/control samples of African Americans and European Americans. None of the SNPs were individually associated with asthma or atopy in any of the populations. However, haplotypes composed of alleles in one CNS and an intronic SNP in *IL4* showed nonrandom transmission to children with atopy (Global TDT $c^2 = 12.93$; $P = 0.004$), but did not explain the original evidence for linkage in this region. These combined data suggest that although some CNSs contain important elements for the coordinate regulation of Th2 cytokines, they do not contain variation that influences disease risk among individuals, although our studies in the Hutterites suggest that they may be in LD with variation that underlies susceptibility to atopic diseases. Furthermore, the fact that the only CNS known to have regulatory properties (CNS-1) showed no variation suggests that noncoding regions that are highly conserved between species may also show reduced levels of polymorphism within humans, similar to coding regions that are also highly conserved. Supported by HL49596 and HL56399.

Significant Association of Haplotype Blocks in the Urokinase Type Plasminogen Activator Gene on Chromosome 10 with Ab42 and Late Onset Alzheimer's Disease. *N. Ertekin-Taner^{1, 2}, M. Tucker^{3,4}, J. Ronald², S. Younkin², L. Younkin², M. Hella², S. Jain², D. Fadale², A. Hackett², L. Scanlin², J. Kelly², M. Kihiko-Ehman^{3,4}, S. Edland⁵, W. Markesberry⁴, R. Petersen⁶, N. Graff-Radford⁷, M. Hutton², S. Estus^{3,4}, S.G. Younkin².* 1) Department of Neuroscience, Mayo Clinic, Rochester, MN; 2) Department of Neuroscience, Mayo Clinic, Jacksonville, FL; 3) Department of Physiology, University of Kentucky, Lexington, KY; 4) Sanders-Brown Center on Aging, University of Kentucky, Lexington, KY; 5) Department of Epidemiology, Mayo Clinic, Rochester, MN; 6) Department of Neurology, Mayo Clinic, Rochester, MN; 7) Department of Neurology, Mayo Clinic, Jacksonville, FL.

We obtained linkage to a locus on chromosome 10 at 81 cM in 10 late-onset Alzheimer's disease (LOAD) pedigrees, using plasma Ab42 levels as a quantitative surrogate phenotype. Linkage to the same locus was obtained in a genome screen of LOAD sib-pairs, providing strong evidence for a novel locus on chromosome 10 that increases the risk for LOAD by elevating Ab. The urokinase plasminogen activator gene (PLAU), located within the 1-locus support interval of our linkage peak on chromosome 10, converts plasminogen to plasmin, which degrades Ab aggregates. We tested PLAU as a candidate LOAD risk gene. We evaluated single nucleotide polymorphisms (SNP) in PLAU for association with Ab42 and LOAD in 10 extended LOAD families and 2 LOAD case-control series. There was strong linkage disequilibrium between the PLAU SNPs. PLAU SNP haplotypes were significantly associated with plasma Ab42 levels in 267 members of the AD families ($p=0.016$). PLAU SNP genotypes were also associated with AD in the first case-control series ($p=0.012$), and this result was replicated in the second series ($p=0.004$). When the two series were analyzed together there was highly significant association ($p=0.002$). Collectively, these findings implicate specific PLAU SNP haplotypes as novel risk factors for LOAD. Importantly, PLAU SNP haplotypes did not account for the Ab42 linkage at 81 cM, suggesting the presence of another LOAD risk gene on chromosome 10 (see abstract by Younkin et al.).

HLA-Cw*0602 as the primary risk factor for psoriasis accounts for all other observations of association with psoriasis in the HLA class I region. *A.M. Bowcock¹, C. Helms¹, T.M. Hsu¹, J. Daw¹, K. Cao², M.A. Fernandez-Vina², A. Menter³, J.P. Rice¹, P.-Y. Kwok⁴, N.L. Saccone¹.* 1) Washington University School of Medicine, St. Louis, MO; 2) Naval Medical Research Center, Georgetown University, Kensington, MD; 3) Baylor University Medical Center, Dallas, TX; 4) University of California San Francisco, San Francisco, CA.

Psoriasis is a complex inflammatory disease of the skin with both genetic and environmental risk factors. Associations with alleles from the HLA class I region (now known as PSORS1) were initially described. Extensive linkage disequilibrium within this region has made it difficult to identify the susceptibility allele although Cw*0602 is historically strongly associated with disease susceptibility.

To evaluate the HLA class I region more closely, we investigated both family-based association of DNA markers with psoriasis as well as linkage disequilibrium across the HLA class I region in patients and controls. HLA-Cw*0602 was the most highly associated allele with psoriasis in family-based analyses (TDT p-value = 0.000016), confirming reports from some groups that this is indeed PSORS1. However, linkage disequilibrium (LD) in case versus control chromosomes fluctuated throughout the HLA class I region, making identification of PSORS1 difficult with this approach. We thus applied two-locus logistic regression models to the case-control data, pairing HLA-C with other loci in the associated class I region. These analyses revealed that HLA-C*0602 remained significant while the effects of alleles at the other loci were explained by variation at HLA-C. This observation provides strong evidence for HLA-Cw*0602 as the primary risk factor for psoriasis in the HLA class I region.

Evidence supporting a language QTL on 7q in autism. *M. Alarcón¹, D.H. Geschwind¹, T.C. Gilliam², A.G.R.E. Consortium³, R.M. Cantor-Chiu⁴.* 1) Neurology, UCLA School of Medicine, Los Angeles, CA; 2) Columbia Genome Center, Columbia University, New York; 3) Cure Autism Now, Los Angeles, CA; 4) Human Genetics, UCLA School of Medicine, Los Angeles, CA.

Autism is a neurodevelopmental disorder typified by deficits in language and social skills, and repetitive behaviors. We previously found evidence for a quantitative trait locus for language deficits, as measured by 'age at first word' on chromosome 7q35 (Alarcón et al., 2002) in a sample of 152 families from the Autism Genetic Resource Exchange. The multipoint linkage peak of a nonparametric analysis by Genehunter first localized the putative gene between markers D7S1824 and D7S3058, a 24 cM region starting at 149.9 cM. Fine mapping with 28 flanking markers further localized it to a 10 cM region between D7S1824 and D7S2426. In the same sample, 'age at first phrase' was not linked to this region, whereas 'repetitive and stereotyped behavior' appeared linked when the flanking markers were included in the analysis ($Z = 2.48$, $p = 0.007$). Here, we report the results of adding 114 families and 9 markers to these analyses. Linkage to 'age at first word' was supported: the peak for the putative gene contributing to 'age at first word' has been narrowed and covers a 5 cM region between D7S676 and D7S2511 ($Z = 2.9$, $p < 0.002$). Consistent with our previous results, 'age at first phrase' was not linked to 7q. However, the 'repetitive and stereotyped behaviors' linkage evidence to 7q was not supported after adding these additional families. Thus, these results provide additional evidence there is a QTL for 'age at first word' in autism on chromosome 7q.

Linkage disequilibrium mapping of a type 2 diabetes susceptibility gene on chromosome 1q21-q23 in Utah Caucasians, Pima Indians, and Old Order Amish. *S.C. Elbein^{1,2}, H. Wang¹, W. Chu¹, J.K. Wolford³, R.L. Hanson³, B.D. Mitchell⁴, A.R. Shuldiner⁴.* 1) Department of Medicine, University of Arkansas for Medical Sciences, Little Rock, AR; 2) Central Arkansas Veterans Healthcare System, Little Rock, AR; 3) NIDDK, National Institutes of Health, Phoenix, AZ; 4) Department of Medicine, University of Maryland, Baltimore, MD.

Family linkage studies have implicated chromosome 1q23 as a type 2 diabetes (T2DM) susceptibility locus, with evidence for linkage in Utah Caucasians, Old Order Amish, Pima Indians, and others. To identify the susceptibility locus in this region, we initially typed 1029 SNPs over 15 Mb in pooled samples comprising approximately 100 cases (T2DM) and controls from Pima Indians, Utah Caucasians, and Old Order Amish, plus an additional Amish pool of 59 individuals with impaired glucose tolerance (IGT). Typing was performed commercially using MassARRAY MALDI-TOF mass spectrometry (Sequenom, Inc). Between 511 and 600 SNPs were both polymorphic and successfully typed in each population. Of these, 28, 39, 19, and 33 SNPs showed significant ($p < 0.01$) initial differences between controls and Pima T2DM, Utah T2DM, Amish T2DM, and Amish IGT cases, respectively. We retyped all pools in triplicate for 93 initially suggestive SNPs, and also typed 11, 26, and 19 SNPs in the individual samples comprising each Pima, Utah, and Amish pool. After retyping in pools, 5, 12, and 19 SNPs remained significant ($p < 0.05$) in Pima, Utah, and Amish pools. Individual typing generally concurred with the pooled confirmations ($r > 0.4$), but with some error. We confirmed 9 SNPs in the Utah sample ($p < 0.05$), but only 2 SNPs with $p < 0.01$. Among Amish pools, 9 SNPs were confirmed in individual samples, of which 5 had $p < 0.01$. When both ancillary candidate gene studies and SNPs from pooled typing were combined in the analysis, we found a cluster of significant SNPs in the region between 157 Mb and 158 Mb (April 2002 Santa Cruz freeze) in all 3 populations. Additional regions in one or more populations were found at 148 Mb ($p = 0.001$ in Utah Caucasians), and 168 Mb (Amish T2DM). Our results are consistent with more than one T2DM susceptibility locus on 1q21-q23.

Mapping genes influencing Type 2 diabetes risk and Body Mass Index in Japanese. *N. Iwasaki*¹, *N.J. Cox*², *Y. Wang*², *P.E.H. Schwarz*², *G.I. Bell*², *M. Saito*³, *N. Kamatani*³, *M. Honda*⁴. 1) Diabetes Ctr, Tokyo Women's Medical Univ, Tokyo, Japan; 2) Departments of Human Genetics, Medicine, and Biochemistry and Molecular Genetics, Chicago, USA; 3) Department of Rheumatology, Tokyo Women's Medical Univ, Tokyo, Japan; 4) Department of Diabetes, Shiseikai Daini Hospital, Tokyo, Japan.

We have carried out an autosomal genome scan search for genes contributing to the development of type 2 diabetes mellitus (T2DM) in Japanese. We also mapped the chromosomal location of genes affecting body mass index (BMI). The 256 affected sib pairs (368 type 2 diabetic siblings from 164 families) were used. We found 12 regions on nine different chromosomes that showed nominally significant multipoint evidence of linkage with T2DM (LOD score > 0.59, $P < 0.05$): chromosome 1, 29.9 cM from pter ($P=0.030$); chromosome 2, 169.6 ($P=0.016$) and 236.8 cM ($P=0.047$); chromosome 4, 104.9 cM ($P=0.028$); chromosome 5, 114.8 cM ($P=0.040$); chromosome 6, 42.3 cM ($P=0.037$); chromosome 8, 15.3 cM ($P=0.033$) and 93.3 ($P=0.046$); chromosome 9, 140.0 cM ($P=0.006$); chromosome 11, 131.6 cM ($P=0.035$); chromosome 17, 36.1 cM ($P=0.040$); and chromosome 21, 48.0 cM ($P=0.001$). We found 12 regions on nine chromosomes showing nominal multipoint evidence for linkage with log transformed BMI (lnBMI): chromosome 2, 167.9 cM ($P=0.008$) and 210.5 cM ($P=0.005$); chromosome 3, 185.7 cM ($P=0.018$); chromosome 4, 118.9 cM ($P=0.007$) and 145.6 cM ($P=0.022$); chromosome 5, 131.9 cM ($P=0.019$); chromosome 7, 7.4 cM ($P=0.008$); chromosome 10 ($P=0.010$); chromosome 15, 12.8 cM ($P=0.014$); chromosome 16, 30.0 ($P=0.005$); and chromosome 17, 47.8 cM ($P=0.010$) and 100.2 cM ($P=0.005$). One of the lnBMI-linked loci (chromosome 2, 167.9 cM) maps to a region showing linkage with T2DM suggesting that it may be a "diabetes/obesity" gene. Eight of the 12 regions showing linkage with T2DM have been listed as candidate regions in other genome scans. Similarly seven of the 12 regions with BMI and BMI-related traits in other studies. Thus, our results replicate findings in other studies and may indicate new regions of the genome containing genes that contribute to the development of T2DM or regulate body weight.

A genome-wide scan in 438 families with early-onset coronary artery disease. *E.R. Hauser¹, D.C. Crossman², C. Granger¹, J.L. Haines³, C.J.H. Jones⁴, V. Mooser^{5,6}, L. Middleton⁶, A.D. Roses⁶, M.A. Hauser¹, M. Pericak-Vance¹, J.M. Vance¹, W.E. Kraus¹.* 1) Duke Univ, Durham, NC; 2) Univ of Sheffield, Sheffield, UK; 3) Vanderbilt Univ, Nashville, TN; 4) Univ of Wales, Cardiff, UK; 5) Lausanne Univ, Lausanne; 6) Glaxo-Smith-Kline, Philadelphia, PA.

We performed a genome-wide scan in 1168 individuals from 438 families comprising 491 affected sibling pairs with onset of CAD before age 51 in males and age 56 in females. CAD was determined by history of MI, coronary revascularization procedure or positive functional test. To identify more homogeneous groups, we pre-defined 3 stratification variables: 1) presence of acute coronary syndrome in ≥ 2 members of the sibship; 2) absence of Type 2 diabetes in one or more affected sibs; and 3) presence of metabolic syndrome defined by the 75th%tile of age-gender specific triglyceride levels, 25th%tiles of gender-specific HDL levels and BMI <35. Genotypes were produced for 395 microsatellite markers (an approximate 10 cM map). We used a battery of single point linkage analyses, including non-parametric affected sib pair (Siblink), non-parametric nuclear family analysis (Genehunter and Genehunter-plus) and affecteds-only parametric analysis (Fastlink and Homog). We also performed multipoint linkage analysis using Siblink and Genehunter-Plus. Regions were targeted for follow-up analyses if they provided lod scores greater than 1 on at least two analyses from 1) two-point parametric analysis using Homog and Fastlink performed for each marker and 2) two-point non-parametric analyses using Genehunter-Plus (nuclear families) and Siblink (ASPs) or 3) multipoint analysis. The affected siblings had mean age of 42 for men and 46 for women, 64% had prior MI, 72% had ACS, 19% had diabetes, 18% had metabolic syndromes. We identified 3 regions in the overall genome scan (chromosomes 1 (lod=1.3), 3 (2.1) and 17 (1.6)), 4 regions for the ACS families (chr 1 (lod=2.2), 3 (2.7), 15 (1.4), 16 (1.6)), 1 region for the non-diabetic families (chr 3 (lod=1.7)) and 3 regions for the metabolic syndrome families (1 (lod=1.1), 7 (1.3), 17 (1.1)). The relevance of these findings will be discussed in context of other published genome screens for CAD.

Association and linkage analyses of rgs4 polymorphisms in schizophrenia. *V.C. Kodavali¹, M. Karoly^{1,2}, S. Prachi⁵, J. Wood¹, E. Lawrence³, T. Bhatia⁶, S.N. Deshpande^{6,7}, B.K. Thelma^{5,6}, R.E. Ferrell³, F.A. Middleton², B. Devlin^{1,3}, P. Levitt², D.A. Lewis^{1,4}, V.L. Nimgaonkar^{1,3,6}.* 1) Department of Psychiatry, University of Pittsburgh, Pittsburgh, USA; 2) Department of Neurobiology, University of Pittsburgh, Pittsburgh, USA; 3) Department of Human Genetics, University of Pittsburgh, Pittsburgh, USA; 4) Department of Neuroscience, University of Pittsburgh, Pittsburgh, USA; 5) University of Delhi South Campus, New Delhi, India; 6) Indo-US Project on Schizophrenia Genetics, New Delhi, India; 7) Dr. R.M.L. Hospital, New Delhi, India.

Gene expression analyses of postmortem cerebral cortex suggest that transcription of the Regulator of G-protein Signaling 4 (RGS4) is decreased in a diagnosis specific manner in subjects with schizophrenia (Mirnics K et al, 2001). We have shown using the TDT, significant transmission distortion in three samples ascertained independently in Pittsburgh, New Delhi and by the NIMH Collaborative Genetics Initiative at this locus (Chowdari K et al 2002). Among SNPs spanning approximately 300 kb, significant associations involved four SNPs localized to a 10 kb region at RGS4, but the associated haplotypes differed. Consistent with the TDT results, samples with affected siblings (NIMH, India) showed higher levels of allele sharing, identical by descent, at RGS4. When the US patients were contrasted to two population-based control samples, however, no significant differences were observed. We also examined US families with Bipolar I Disorder (BD1) probands. This sample showed a trend for transmission distortion and cases differed significantly from the population-based controls for the four-SNP haplotypes tested in the other samples. The transmission distortion is unlikely to be due to chance. To understand these disparate findings, we have identified several novel SNPs localized in a 30 kb region upstream to the RGS4 locus for further analysis in our sample. We are also re-sequencing genomic DNA from the post-mortem brain samples employed in the gene expression analyses.

Association and Linkage analysis of von Willebrand factor and Bipolar I Disorder. *Y. Lee¹, M. Miller¹, A. Hasset², B.Y. Lee--Kim¹, J.J. Kim¹, M. Haraczak¹, S. Ranade¹, J. Wood¹, R. Reddy¹, D.J. Kupfer¹, F. Bontempo², V.L. Nimgaonkar^{1,3}.* 1) Department of Psychiatry, University of Pittsburgh School of Medicine and Graduate School of Public Health, Western Psychiatric Institute and Clinic, Pittsburgh, PA, USA; 2) Department of Medicine(Division of Hematology), University of Pittsburgh School of Medicine and Graduate School of Public Health, Western Psychiatric Institute and Clinic, Pittsburgh, PA, USA; 3) Department of Human Genetics, University of Pittsburgh School of Medicine and Graduate School of Public Health, Pittsburgh, PA, USA.

We report on association and linkage analyses of bipolar I disorder(BD1) and schizophrenia(SZ), using three common polymorphisms of von Willebrand factor(vWF), the gene conferring susceptibility to von Willebrand disease(vWD). The polymorphisms included 1548T>C, 2365A>G and an MSP I polymorphism in intron 19. The study was motivated by observed co-segregation of vWD and a range of mood disorders in an extended pedigree. Among 91 cases with BD1 and their available parents, the Transmission Disequilibrium Test(TDT) revealed significant transmission distortion of two haplotypes, but not the individual polymorphisms. To understand the overall transmission distortion, a global test of association for all haplotypes encompassing these SNPs was conducted. This analysis suggested significant transmission distortion(TRANSMIT program chi square=9.9, 3df, p=0.019). No significant associations were detected when the cases were compared with unrelated, population-based controls. To test whether the TDT results were due to general transmission distortion, 93 cases with schizophrenia and their parents were also investigated. Significant transmission distortion was not detected. Our analyses suggest linkage and association at vWF with BD1, but the effect is small and replicate studies are required.

Genome wide screen for genes related to healthy aging (wellness) in the NAS-NRC twin panel cohort. *T. Reed¹, D.M. Dick¹, T. Foroud¹, S.K. Uniacke², W.C. Nichols²*. 1) Dept Medical & Molecular Gen, Indiana Univ Medical Ctr, Indianapolis, IN; 2) Div Human Gen, Children's Hosp Medical Ctr, Cincinnati, OH.

The National Academy of Sciences-National Research Council twin registry is comprised of white veteran male twins born between 1917 and 1927 and represents about 93% of the male twin births in the above decade. An epidemiologic/health information questionnaire (Q8) was mailed between September and November of 1998 to 4086 twin-pairs with known addresses and 908 men who had completed both previous health surveys, but whose brother had died. Eliminating those with invalid addresses or the death of the subject, 6109 of 8848 (69%) questionnaires were completed comprising 2061 complete pairs with a mean age of 74.3 years.

A trait termed wellness, defined as a lack of chronic disease (no heart attack, no coronary surgery or angioplasty, no stroke, no diabetes, and no prostate cancer), had a heritability estimate (h^2) of 0.53 (0.46-0.61). An even narrower definition (also including no hypertension) had a h^2 of 0.57 (0.52-0.63) but approximately halved the number of pairs concordant for wellness. Fraternal (DZ) twin-pairs from this cohort provide a unique population to search for genes related to healthy aging.

A 10cM genome screen was performed using DNA from 79 DZ twin-pairs concordant for either of the wellness definitions obtained from the Q8 responses. Multipoint linkage analysis identified markers on 10 different chromosomes with a maximum LOD score ³ 1.0. Some of the more interesting locations in this preliminary analysis include a region near the apolipoprotein E locus on chromosome 19, and a region on chromosome 4 in the vicinity of a locus reported to be linked in families with extreme longevity (*PNAS* 98:10505,2001). Analyses including additional concordant twin-pairs will be performed as well as more extensive genotyping within areas of interest from the genome wide scanning. (Supported by AG18736).

Evidence for Haplotype Sharing and Association in Obese Finnish Males on Chromosome Xq24. *E. Suviolahti¹, L. Oksanen^{1,2}, R.M. Cantor¹, M. Öhman^{3,4}, K. Kontula², L. Peltonen^{1,3}, P. Pajukanta¹.* 1) Dept of Human Genetics, UCLA, Los Angeles, CA; 2) Dept of Medicine, University of Helsinki, Finland; 3) Dept of Molecular Medicine, National Public Health Institute, Finland; 4) Dept of Internal Medicine, University of Michigan, Ann Arbor, MI.

Obesity has been established as a risk factor for several important health problems such as type 2 diabetes, coronary heart disease, hypertension and osteoarthritis. It has been linked to a region on chromosome Xq24 in our genome wide scan of 166 Finnish nuclear families. We fine mapped this 30 Mb region by genotyping 10 microsatellite markers and 25 single nucleotide polymorphisms (SNPs) for 8 positional candidate genes in an augmented sample of 218 obese Finnish sibpairs (BMI>30 kg/m²) and in a Finnish case-control sample of 117 obese cases and 67 controls. The SNPs were selected in genomic regions conserved between humans and mice to increase their potential functional significance. The genotyped microsatellites and SNPs were tested for linkage and used for constructing haplotypes. Analysis of marker haplotypes significantly restricted the region from the previous 30 Mb to 4 Mb, between the markers DXS8088 and DXS8067. Importantly, haplotype analyses revealed that the evidence for linkage emerged mainly from the obese male sibling pairs, suggesting a gender-specific effect for the underlying gene. We also genotyped SNPs in three additional positional candidate genes: angiotensin receptor 2, solute carrier family 6 member 14 and adenine nucleotide translocator 2 and tested them for linkage and association. Our data show preliminary evidence for an association with some of these SNPs and their haplotypes (p<0.006). To replicate these results and identify the causative variants, we are genotyping the associated SNPs in a Finnish sample of obese and lean individuals.

Restriction of the susceptibility locus for migraine with aura on 4q24. *M. Wessman¹, G. Oswell², M. Kallela³, M.A. Kaunisto¹, J.C. Papp⁴, P.J. Tikka¹, A. Korhonen⁴, E. Hämäläinen⁴, H.T. Harno³, M. Ilmavirta⁵, M. Nissilä⁶, E. Säkö⁶, H. Havanka⁷, M. Färkkilä³, L. Peltonen⁴, A. Palotie².* 1) Dept of Clinical Chemistry, University of Helsinki, Helsinki, Finland; 2) Dept of Pathology, UCLA, LA, CA; 3) Dept of Neurology, University of Helsinki, Helsinki, Finland; 4) Dept of Human Genetics, UCLA, LA, CA; 5) Dept of Neurology, Central Hospital of Central Finland, Jyväskylä, Finland; 6) Turku Headache Center, Turku, Finland; 7) Dept of Neurology, Länsi-Pohja Central Hospital, Kemi, Finland.

Migraine is a complex neurovascular headache disorder with substantial evidence supporting a genetic contribution. There are two main types of migraine: without aura, occurring in 85% of patients; and with aura (MA), occurring in 15% of patients. MA attacks are preceded or accompanied by transient focal neurological, usually visual, aura symptoms. We recently reported the first genome-wide scan showing statistically significant linkage (HLOD 4.2) with the marker D4S1647 (at 104.95 cM) for MA on 4q24 on 50 clinically well-defined Finnish MA families. In the genome scan the λ -value for HLOD was 0.23-0.5, suggesting that 23-50% of the families would be linked to this region. When analysing the next set of 30 Finnish MA families the results confirmed that about 30% of our families contribute to the linkage to this chromosomal area. This area has further been fine mapped with 31 additional multiallelic markers. Based on two-point linkage analysis, the most likely location of the putative predisposing gene is in an 8 cM region between the markers D4S2278 (at 100.75 cM) and D4S1591 (at 107.95 cM). None of the markers tested so far show evidence for association. The clinical phenotype of the 4q24 linked families is characterized by severe vascular headache preceded by typical migraine aura with multiple provoking factors and premonitory symptoms. Overall, the phenotype corresponds well with the current criteria for migraine with aura.

Further Evidence of Linkage between Parkinson Disease and Chromosome 2q. *N. Pankratz¹, W.C. Nichols², S.K. Uniacke², C. Halter¹, A. Rudolph³, C. Shults^{4,5}, P.M. Conneally¹, T. Foroud¹ and Parkinson Study Group.* 1) Indiana Univ Sch Medicine, Indianapolis, IN; 2) Children's Hospital Research Foundation, Cincinnati, OH; 3) Univ Rochester, Rochester, NY; 4) Univ California, San Diego, CA; 5) VA San Diego Healthcare System, San Diego, CA.

While a number of different chromosomal regions have been implicated in autosomal dominant or autosomal recessive Parkinson disease (PD), only the role of alpha-synuclein and parkin have been clearly delineated. Mutations in the alpha-synuclein gene appear to be limited to only a few families; however, mutations in the parkin gene have been more widely reported, particularly among individuals with earlier onset PD. To identify susceptibility genes contributing to the more common, later onset form of PD, families consisting of at least one pair of living siblings diagnosed with PD were recruited through 60 Parkinson Study Group (PSG) sites distributed throughout North America. A Diagnostic Checklist was completed by the neurologist with inclusion criteria consisting of clinical features highly associated with autopsy-confirmed PD and exclusion criteria highly associated with other non-PD pathological diagnoses. Responses on the Diagnostic Checklist were then used to classify study subjects as having verified PD or nonverified PD. A genome screen was previously completed using 400 microsatellite markers. Families with a positive lod score in the chromosome 6 region near the parkin gene were screened for parkin mutations. All families with parkin mutations were removed from the subsequent analyses that were designed to identify novel genes contributing to PD susceptibility. With this approach toward reducing genetic heterogeneity, we have previously reported a lod score of 1.9 near the marker D2S206, in a sample of 96 sibling pairs with verified PD (Pankratz et al. 2002). We have since collected an additional 54 verified PD sibpairs from 46 families. When these families were combined with the previously collected sample, the maximum lod score increased to 3.0 near the marker D2S206. Therefore, these results provided further evidence of a PD susceptibility gene at 2q35. Study supported by: NINDS NS37167.

Ordered subsets analysis in Alzheimer disease: Refined linkage to 9p and novel linkage to 2q and 15q. *W.K. Scott¹, K.K. Nicodemus¹, P.C. Gaskell¹, D.J. Hedges¹, S.N. Walters¹, G.W. Small², P.M. Conneally³, A.D. Roses⁴, E.R. Hauser¹, J.R. Gilbert¹, J.M. Vance¹, J.L. Haines⁵, M.A. Pericak-Vance¹.* 1) Duke Univ., Durham, NC; 2) UCLA, Los Angeles, CA; 3) Indiana Univ., Indianapolis, IN; 4) GlaxoSmithKline, RTP, NC; 5) Vanderbilt Univ., Nashville, TN.

Alzheimer disease (AD) is a complex disorder with a wide range of ages at onset (AAO) within and between families. Considering AAO as a covariate in genetic linkage studies may reduce genetic heterogeneity and increase the power to detect linkage. Ordered subsets analysis (OSA) includes continuous covariates in linkage analysis by rank-ordering families by covariates and summing lod scores until a maximum is found. We analyzed data from 336 markers (10 cM average spacing) from a recent genomic screen of 455 multiplex AD families. Families were ascertained by: 1) a collaboration of Duke, Vanderbilt, and UCLA; 2) the Indiana AD Cell Repository; 3) the NIMH AD Genetics Initiative. To determine if GENEHUNTER+ non-parametric linkage results varied by AAO, families were rank-ordered by increasing and decreasing mean and minimum AAO. Permutation tests were used to assess significance of changes in the lod score. Two regions identified in the previously reported genomic screen provided significantly stronger results (lod>3) when considering AAO: 1) At D19S246 (19q13, 10 cM from APOE) lod=3.4 (p=0.009) in 107 families with mean AAO<70; 2) At D9S741 (9p22), lod=3.7 (p=0.02) in 405 families with minimum AAO>60. In addition, three regions not detected in the overall genomic screen provided interesting results (lod>2): 1) At D2S1384 (2q31), lod=2.8 (p=0.015) in 35 families with a minimum AAO<60; 2) At D2S125 (2q37), lod=2.4 (p=0.025) in 47 families with mean AAO>80; 3) At D15S153 (15q22), lod=2.7 (p=0.0023) in 39 families with mean AAO>80.5 and at D15S1507 (2 cM from D15S153) lod=2.3 (p=0.0015) in 37 families with minimum AAO>79. Consistent with previous analysis, OSA identified the region around APOE as most strongly linked in families with AAO<70, and the region of linkage on 9p as a late-onset (AAO>60) locus. The identification of novel linkages on 2q and 15q in very late onset AD (AAO>80) merits further investigation.

Genomewide search for celiac disease susceptibility loci in a Finnish population confirms the role of the HLA locus and provides evidence for a locus on 2q. *J.D. Rioux¹, H. Karinen², K. Kocher¹, S. McMahon¹, P. Krätkäinen², E. Janatuinen², M. Heikkinen², R. Julkunen², J. Pihlajamäki², A. Naukkarinen², V-M. Kosma³, M.J. Daly¹, E.S. Lander¹, M. Laakso².* 1) Human Medical and Population, Genetics Center for Genome Research, Whitehead Inst, MIT, Cambridge, MA; 2) Department of Medicine, University of Kuopio, Kuopio, Finland; 3) Department of Clinical Pathology, University of Kuopio, Kuopio, Finland.

Celiac disease (CD) is strongly associated with the HLA-DQ2 alleles DQA1*0501 and DQB1*0201. However, this association only accounts for a portion of the genetic component of CD. Several non-HLA loci and a few non-HLA candidate genes (including CTLA4) that potentially contribute to CD susceptibility have been reported, but have not yet been confirmed. In this study, we aim to determine the role of the HLA locus in a CD population from Finland. We also attempt to identify non-HLA loci that contribute to disease susceptibility in this population. To accomplish these aims, we performed genomewide linkage analysis on 146 CD patients and 104 healthy relatives from 54 Finnish CD families typed for 306 microsatellite markers. Our genomewide scan identified two regions of significant linkage to CD: 6p and 2q23-32. Specific typing at the HLA locus showed significant association of the DQ2 alleles with CD, likely accounting for the linkage peak at 6p. Because the linkage peak on chromosome 2 encompasses the CTLA4 gene, we typed each individual from our CD families for the A/G polymorphism at position 49 of the CTLA4 gene, but did not detect association in this population. Our analysis confirms the HLA-DQ2 alleles play a role in CD and provides evidence that a locus on chromosome 2q, that is distinct from CTLA4, confers risk to CD.

Program Nr: 1701 from 2002 ASHG Annual Meeting

Development of a Tumor Suppressor Gene (p53, BRCA, APC, ATM, RAD51, Rb, pTEN) SNP and Mutation Panel using the Single-Base Extension ELISA (SureScore™). *P.N. Gilles, P.T. Lieu, Y. Zhang, M. Gleeson.* Dept Genomics, Invitrogen, Carlsbad, CA.

Tumor suppressor genes exhibit a crucial role in many biological functions including DNA replication, DNA repair, gene expression, apoptosis and tumor development. The aim of this study was to develop an easily accessible panel of reagents to detect polymorphisms and mutations in tumor suppressor genes without the need for specialized instrumentation. To this end, a panel of approximately 50 SNPs and mutations in the p53, BRCA1, BRCA2, ATM, APC, RAD51, Rb and pTEN tumor suppressor genes have been developed using the single-base extension ELISA. The panel consists of genetic variations, which identify common haplotypes, contribute to disease, or alter gene function. The single-base extension ELISA in 96-well format was chosen as one of the simplest and most effective means of SNP typing and does not require specialized instrumentation (SureScore™, Invitrogen). The assay relies on the inherent ability of DNA polymerase to incorporate the precise nucleotide on to a capture oligo bound to a single-stranded PCR fragment; whereby the robustness of antibody-enzyme conjugates allows for the extended reactions to be scored colorimetrically at the same reaction conditions. The SNP and mutation reagents have been validated using a publicly available panel of diverse DNA samples (Corriell Institute), cell lines and controls. The panel can determine the genotypes of tumor suppressor genes in samples with unique phenotypes and the SureScore™ kit gives flexibility to scientists to design assays to detect other genetic variations with minimal optimization. The kit includes access to a web-based primer design software and data analysis software. The format is well established in the SNP Consortium (Orchid), and has been successfully applied to a number of SNPs on blinded genomic samples. SureScore™ analysis of tumor suppressor genes will facilitate the elucidation of gene functions and complex disease processes (www.invitrogen.com/surescore).

Dense SNP map of IL1 gene cluster and end stage renal disease. *J.T. Bensen¹, C.D. Langefeld², G.A. Hawkins¹, L.E. Green², J.C. Mychaleckyj¹, C.S. Brewer¹, D.S. Kiger¹, S.M. Binford¹, C.J. Colicigno³, D. Allred¹, B.I. Freedman⁴, D.W. Bowden^{1,3}.* 1) The Center for Human Genomics; 2) Department of Public Health Science; 3) Department of Biochemistry; 4) Department of Internal Medicine, Wake Forest University School of Medicine, Winston-Salem, NC.

Evidence supporting an inflammatory component in the development of nephropathy, characterized by glomerular basement membrane thickening and mesangial expansion exists. Studies have demonstrated a significant association between variations in the interleukin-1 receptor antagonist gene (IL1RN) and diabetic nephropathy. A dense SNP map was constructed across a 360 kb region containing the interleukin-1 gene cluster (IL1A, IL1B and IL1RN) focusing on IL1RN. In total, 95 polymorphisms were confirmed or identified primarily by direct sequencing: in IL1A, 13 SNPs and 1 insertion/deletion (4 bp); in IL1B, 5 SNPs; 1 intragenic tetranucleotide repeat; in IL1F10, a novel gene, 6 SNPs; and within IL1RN, 1 VNTR (86 bp), 3 single base insertion/deletions and 65 SNPs. Polymorphisms were mapped to completed BAC and genomic sequence spanning this region. The 95 polymorphisms were typed in 443 case-control subjects; 95 Caucasian controls, 75 Caucasians with type 2 diabetes mellitus-associated end stage renal disease (DM-ESRD), 86 African American controls, 92 African Americans with DM-ESRD and 95 African Americans with non-DM-ESRD. Consecutive pairwise marker linkage disequilibrium (LD) was not strictly correlated with distance and ranged from $D=0.0079 - 1.000$ and $D=0.0521 - 1.0000$ in Caucasians and African Americans, respectively. In general however, a shorter window of LD among African American than Caucasian controls was observed (50 kb vs. 350 kb for similar levels of LD, respectively). In addition, single marker and 2 and 3-marker haplotypes (EM method) were used to identify association with ESRD in IL1A, IL1F10 and IL1RN. Among African Americans, 8 and 3 single markers were significantly associated ($P<0.05$) with non-DM and DM-ESRD, respectively. The strongest disease-associated markers were in the IL1A gene, an intron 5 SNP ($P=0.0015$) and an I/D in the 3-UTR ($P=0.0024$), among African Americans with non-DM-ESRD.

Human insertion/deletion (indel) polymorphisms. *N. Ghebraniou¹, C. Zhao¹, L. Ott¹, D. David¹, G. Marth², R. Sachidanandam³, J.L. Weber¹.* 1) Center for Medical Genetics, Marshfield Medical Research Foundation, Marshfield, WI; 2) National Center for Biotechnology Information, NLM, NIH, Bethesda, MD; 3) Cold Spring Harbor Laboratories, Cold Spring Harbor, NY.

Insertion/deletions (indels) comprise roughly 20% of all human DNA polymorphisms. Using primarily overlapping BAC sequences from public sources and The SNP Consortium sequences, we have assembled a collection of about 200,000 human candidate indel polymorphisms. The collection of indels is available from the Marshfield web site (<http://research.marshfieldclinic.org/genetics>), and includes roughly equal numbers of diallelic and multiallelic polymorphisms. The collection is searchable using sequence positions along each chromosome. To date, about 2,400 of the candidate diallelic indels and 12,000 of the candidate multiallelic indels have been confirmed and characterized to varying degrees. Recently, we have focused efforts on indels that have relatively small numbers of tandem repeats. Multiallelic indels based upon long runs of tandem repeats (STRPs or microsatellites) are relatively well known. However, polymorphisms based upon small numbers of tandem repeats have not been closely studied. We find that for any short repeat sequence, the number of sequences within the human genome increases dramatically and monotonically as the numbers of repeats within the tandem array decreases. We also find that the fraction of sequences which are polymorphic drops dramatically as the number of repeats decreases. Candidate polymorphic indel sequences with relatively few numbers of dinucleotide tandem repeats appear to largely fall into the following four categories: 1) Compound repeat sequences with adjacent runs of two different tandem repeats 2) Sequences with interruptions in the runs of tandem repeats 3) Sequences with alternating purines and pyrimidines and 4) Short but uninterrupted runs of a single tandem repeat. We have also studied a few long, uninterrupted runs of tandem repeats which show little or no polymorphism within human populations. These sequences may mark segments of the genome which have either unusually low mutation rates or which are under strong selective pressure.

Refinement of the dyslexia 3 locus (*DYX3*) on chromosome 2p15-p16 and mutation screening of candidate genes.

*T. Fagerheim*¹, *F-E. Toennesen*², *H.A. Lubs*³. 1) Dept Medical Genetics, Univ Hosp Northern-Norway, Tromsoe, Norway; 2) Center for Reading Research, Stavanger, Norway; 3) Division of Genetics, Department of Pediatrics, Miami, FL, USA.

Developmental dyslexia is defined as a specific and significant reading disability that affects children and adults who in the absence of other neurological deficits possess normal intelligence, cognitive skills and adequate schooling. There is evidence of a considerable genetic contribution to the trait, but it is likely to be complex and to involve more than one gene. Several genetic loci have been mapped on chromosomes 1,2,3,6,15 and 18. We previously identified a family in which dyslexia is inherited as an apparent monogenic, dominant trait. We used this family to map the disease gene to a small region on 2p15-p16 by linkage analysis. The *DYX3* candidate region was defined by extensive haplotyping between D2S2352 and D2S1337.

The family has been investigated further and additional family members have been genotyped for new microsatellite markers. New flanking markers defining a 3.5 cM region on the physical map are D2S2153 and D2S444. The *DYX3* locus consists of 4.3 Mb of DNA sequence and contains 17 known and putative genes. There are no obvious functional candidate genes in the region, and genes have been screened mainly based on their location. However, genes with high expression in the brain have been considered first. Analysis of three candidate genes, BC200, Neurexin and Calcineurin 3, using a combination of Southern blot and direct sequencing of exons and intron/exon boundaries have revealed evidence of polymorphisms that are common to affected and control individuals.

Identification of SNPs in the central areolar choroidal dystrophy region on 17p13.2. *H.H. Abdeen¹, G. Silvestri², A.E. Hughes¹*. 1) Medical Genetics, Queen's University Belfast, Belfast, N Ireland, UK; 2) Ophthalmology, Queen's University Belfast, Belfast, N Ireland, UK.

Central areolar choroidal dystrophy (CACD) is a macular degenerative disease causing visual loss in middle age. The causative gene maps in a large Irish family to a 2 cM interval on chromosome 17 p13.2. The region contains over 50 genes, several of which are expressed in retina and are positional candidates for CACD. Over 20 genes have been investigated so far and over 100 SNPs identified. These include an interesting cluster of genes believed to be involved in macular degeneration, including PYK2 N-terminal domain-interacting receptor 1 (NIR1), aryl hydrocarbon receptor interacting protein-like 1 (AIPL1) and two other proteins of unknown function FLJ10156 and KIAA00523. This gene cluster was particularly rich in SNPs with a few C-SNPs. No mutations were detected in the members of the CACD family. However, the SNPs we have identified may be valuable for association studies in age-related and other macular degeneration.

Association study between the polymorphism D104N of endostatin, an angiogenesis inhibitor, and diabetic retinopathy in the Brazilian population. *F.I.V. Errera¹, M.E. Rossi², D. Gianella², B. Oliveira³, V. Takahashi³, M.R. Passos-Bueno¹*. 1) Centro de Estudos do Genoma Humano-Instituto de Biociências, Universidade de São Paulo, Brazil; 2) Departamento de Endocrinologia, Faculdade de Medicina da Universidade de São Paulo, USP, Brazil; 3) Departamento de Oftalmologia, Faculdade de Medicina Universidade de São Paulo, USP, Brazil.

Retinopathy is an important microvascular complication of Diabetes and a major cause of blindness. There is a growing list of evidences suggesting that its manifestation depend both on genetic as well as environmental factors. Angiogenesis is the hallmark of retinopathy and depends on a balance between activators and inhibitory factors. Endostatin, a proteolytic fragment of collagen XVIII, has been shown to be a potent endogenous inhibitor of angiogenesis. Recently, we showed that the endostatin polymorphism D104N changes the charge of the molecule and is associated with an increased risk for development of prostate carcinoma (*Cancer Res.*, 2001, 61: 7375-7378). Collagen XVIII plays a critical role in the maintenance of the structure of the retina (*Hum Mol Genet.*, 2000, 9: 2051-2058) and is highly expressed in blood vessels; therefore, we have hypothesized that the polymorphism D104N might be associated with susceptibility to diabetic retinopathy. We analyzed this polymorphism by Single Nucleotide Primer extension (SnPe; Amersham-Biotech) genotyping in 128 diabetic patients with retinopathy (66= non-proliferative, 30=pre-proliferative and 32=proliferative). The frequency of this polymorphism in the total sample was 11,7% and in each group was 12% (8/66), 10% (3/30) and 12,5% (4/32) for non-proliferative, pre-proliferative and proliferative retinopathy, respectively. These frequencies were very similar to that previously found in our control population (12%; *Cancer Res.*, 61: 7375-7378). This is the first study with a polymorphism on angiogenesis inhibitor and these preliminary results show no evidence of association between the polymorphism D104N of endostatin and diabetic retinopathy susceptibility. Other cSNPs in endostatin or in other anti-angiogenic inhibitors should be tested. This work was supported by FAPESP, HHMI, PRONEX, CNPq.

Lack of association of a promoter polymorphism of interferon regulatory factor 2 (IRF-2) gene with psoriasis in

Japan. *N. Hosomi*¹, *K. Fukai*¹, *N. Oiso*¹, *A. Kato*¹, *T. Murakami*¹, *M. Ishii*¹, *K. Nakajima*², *S. Shibahara*³. 1) Dermatology, Osaka City University Graduate School of Medicine, Osaka, Japan; 2) Immunology, Osaka City University Graduate School of Medicine, Osaka, Japan; 3) Molecular Biology and Applied Physiology, Tohoku University School of Medicine, Sendai, Japan.

Interferon regulatory factor 2 (IRF-2) is a transcriptional regulatory protein which represses for the interferon-alpha/beta genes. In mice lacking IRF-2, the inflammatory skin disease very similar to human psoriasis develops spontaneously. In addition, IRF-2 gene is located at human chromosome 4q35 where a familial psoriasis susceptible locus has been mapped. Furthermore, intravenous injection of interferon alpha for the treatment of hepatitis C infection often cause worsening of psoriasis. Therefore, we analyzed the IRF-2 as a possible candidate gene for common psoriasis in Japanese population. The coding region of the gene was normal in 35 patients with psoriasis. Then, we analysed the promoter region of IRF-2 gene and identified a 535A/G polymorphism in the IRF-2 transcriptional promoter. Association study was done in patients with 76 cases of psoriasis vulgaris versus 102 normal controls. We also recruited 113 patients with atopic dermatitis as the second control group. The association study showed no statistical differentiation between psoriasis, atopic dermatitis and normal controls. Computer-aided transcription search predicted that upstream stimulatory factor (USF) should bind only to G allele of the promoter. In fact, supershift assays showed specific binding of both USF-1 and USF-2 to only -535G allele of the IRF-2 promoter. However, luciferase assay revealed no statistical difference of the promoter activity between allele A and allele G. Furthermore, cotransfection of the USF-1 expression vector failed to stimulate the promoter activity of our luciferase reporter system. From these results, we conclude that the 535A/G polymorphism in the IRF-2 promoter is not associated with psoriasis and atopic dermatitis.

An ancient SNP haplotype in the Fanconi anemia gene *FANCA* occurs in 5% of the human population. *O. Levrán, K. Pujara, S.D. Batish, A.D. Auerbach.* Lab. of Human Genetics & Hematology, Rockefeller Univ., New York, NY.

The Fanconi anemia (FA) proteins function in DNA damage surveillance and patients are highly predisposed to cancer. The *FANCA* gene (FA complementation group A; GenBank NM 000135; 16q24.3) is highly polymorphic with more than 100 SNPs described (<http://www.ncbi.nlm.nih.gov/SNP>; <http://www.rockefeller.edu/fanconi/mutate/>). SNP haplotypes have become promising markers for human genetic studies, with evidence for blocks of SNPs in close physical proximity that are descended from an ancient ancestral chromosome. We have studied all 43 exons and flanking regions of *FANCA*, and have identified a conserved SNP haplotype spanning at least 60 Kb of the gene. The haplotype consists of at least 24 SNPs (9 common and 15 rare), located in exons 13,14,16,22,26,30,37,38 and 40, and introns 6,8,18,19,20,21,22,23,31,32,34,39 and 42. Most of the exonic SNPs are silent changes, except for 1235C/T (A>V), 1927C/G (P>A) and 3982A/G (T>A). A "representative" SNP (e.g. IVS20+30insGT) can be used to detect the haplotype, which occurs in 5% of normal or FA chromosomes. Carriers of this haplotype represent different ethnic groups (Caucasian, Asian, Jewish and African), suggesting an ancient origin for this allele whose stability is especially surprising because of the highly polymorphic nature of *FANCA*. There was only one pathogenic mutation (3391A>G) on this variant haplotype that occurred in two patients with no known familial relationship; otherwise the pathogenic mutations on this ancestral SNP haplotype all appear to be unique mutations of independent origin. A high proportion of *FANCA* mutations are large heterozygous deletions that are not detected by PCR and sequence analysis. We have used the homozygosity for these rare SNPs to detect large genomic deletions in nine FA-A families in which only one or no mutation was originally found. Since this haplotype spans a large part of the gene, it has enabled us to identify the extent of the deletions by studying the segregation and homozygosity state of each SNP within a pedigree. This haplotype may be a part of a larger SNP block and may contribute to the current effort to describe the haplotype structure of the human genome.

Program Nr: 1709 from 2002 ASHG Annual Meeting

Association of SPINK5 gene polymorphisms with atopic dermatitis in the Japanese population. *A. Kato, K. Fukai, N. Oiso, N. Hosomi, T. Murakami, M. Ishii.* Dermatology, Osaka City University, Medical School, Osaka, Japan.

Netherton syndrome (NS) is an autosomal recessive disorder characterized by trichorrhexis invaginata (bamboo hair), congenital ichthyosiform erythroderma, and atopic diathesis. NS has recently been shown to be due to a defect in the SPINK5 gene, encoding LEKTI, a 15-domain serine protease inhibitor. SPINK5 is located on chromosome 5q31, and has been suggested to be a locus predisposing to atopy in general. Recently, coding polymorphisms in SPINK5 exons 13 and 14 have been reported to be associated with atopy, asthma, and atopic dermatitis (AD). Here, we have examined whether this is also true in Japanese AD patients. We characterized eight polymorphisms in SPINK5 exons 13 and 14 in 124 Japanese AD patients and 110 healthy controls. The polymorphisms we examined were IVS12-26C>T, IVS12-10A>G, 1103A>G (Asn368Ser, in exon13), 1156G>A (Asp386Asn, in exon13), 1188T>C (His396His, in exon13), IVS13-50G>A, 1258G>A (Glu420Lys, in exon14), and IVS14+19G>A. We found significant associations between seven of these polymorphisms and AD in Japanese patients, confirming the previous suggestion of association between SPINK5 and AD.

Relationship between endometriosis and polymorphism of detoxification enzymes *NAT2*, *GSTM1* and *CYP1A1* in a Korean Population. *H.-S. Lee*¹, *J.H. Jun*¹, *S.Y. Park*², *I.S. Kang*³, *K.S. Han*³, *M.K. Koong*³. 1) Laboratory of Reproductive Biology and Infertility; 2) Laboratory of Medical Genetics; 3) Department of Obstetrics and Gynecology, Samsung Cheil Hospital and Women's Healthcare Center, Sungkyunkwan University School of Medicine, Seoul, 100-380, Korea.

Endometriosis is a common gynecologic disorder and inherited as a complex genetic trait, related to multiple genes interacting with each other and with the environmental factors. The relationship between endometriosis and genetic polymorphism of detoxification enzymes *N-acetyl transferase 2 (NAT2)*, *glutathione S-transferase M1 (GSTM1)*, and *cytochrome P450 (CYP) 1A1* was investigated in a Korean population. DNA was extracted and analyzed in patients with minimal/mild (group I; n=23) and moderate/severe endometriosis (group II; n=30) and unaffected female controls (n=26) of Korean origin, using polymerase chain reaction and restriction fragment length polymorphism (RFLP). For *NAT2*, RFLP was used to detect the wildtype (wt) and mutant (mt) alleles, enabling classification into slow (mt/mt) or fast (wt/wt or wt/mt) acetylation genotypes. For *GSTM1*, PCR was used to distinguish active (+/- or +/+) from null (-/-) genotypes. For *CYP1A1*, *MspI* digestion was used to detect the wildtype (A1A1), heterozygote (A1A2) or mutant (A2A2) genotypes. The frequency of *NAT2* fast-acetylation genotypes in patients of endometriosis (group I and II) was significantly higher than that of controls (91.3% and 96.7% vs 76.9%; P<0.05). The frequency of *GSTM1* active genotypes was significantly greater in group II than controls (63.3% vs 38.5%; P<0.05). No significant difference was observed between patients and controls in the frequencies of the *CYP1A1 MspI* polymorphism, A1/A1, A1/A2 and A2/A2, respectively. However, the combination of the *GSTM1* null mutation and the *CYP1A1 MspI* polymorphism (A1/A2 or A2/A2) had a tendency for increased risk of endometriosis. We found an association between endometriosis and the detoxification enzyme *NAT2* fast acetylator, *GSTM1* active genotypes, and *GSTM1* null genotypes and *CYP1A1 MspI* polymorphism. These data suggest that affected detoxification enzymes activity may be related to the pathogenesis of endometriosis.

Analysis of the Defensin Gene Family for DNA Sequence Variants. *G.A. Hawkins¹, B-L. Chang¹, S.L. Zheng¹, T.D. Howard¹, A. Turner¹, S.D. Isaacs², K.E. Wiley², D.S. Postma³, E.R. Bleecker¹, P.C. Walsh², D.A. Meyers¹, W.B. Isaacs², J. Xu¹.* 1) Internal Med, Ctr Human Gen, Wake Forest Univ Sch Medicine, Winston-Salem, NC; 2) Dept. of Urology, Johns Hopkins Med. Institutions, Baltimore, MD; 3) U. of Groningen School of Med., the Netherlands.

Defensins are a family of small cationic peptides that act as antimicrobial and cytotoxic agents. Located within the 8p23.1 region, each defensin gene consists of 2 or 3 exons that encodes a 3-5 kDa arginine-rich peptide with extensive disulfide cross links. Depending on the positions of the disulfide crosslinks, defensins can be divided into two subclasses. Expression of the a subclass occurs primarily in neutrophils and intestinal Paneth cell granules, while expression of the b subclass occurs in various tissues including the gastrointestinal tract, trachea, placenta, thymus, colon, lung, epithelia cells, eye, and the genitourinary tract, including the prostate.

In two separate studies, we have evidence for linkage of two complex diseases in the 8p21-23 region: prostate cancer and asthma. In both complex diseases, inflammation caused by infectious agents has been proposed as a potential factor in disease progression and severity. Since defensins could play a role in controlling the growth of infection agents in these diseases, the defensin genes were targets for a candidate gene analysis. We sequenced six of the defensin genes, DEFA4, A5, A6 and DEFB1, B2 and B3 in two specific study panels. The first panel consisted of 96 hereditary prostate cancer (HPC) probands, and the second panel consisted of 96 individuals composed of equal numbers of American Caucasians, Dutch Caucasians, African Americans and US Hispanics, with each population divided into 16 asthma cases and 8 controls. Sequencing has identified: 25 SNPs in DEFB1, (1 non-synonymous); 17 SNPs in DEFB2, (1 non-synonymous); six SNPs in DEFB3, (no coding); 21 SNPs in DEFA4, (3 non-synonymous); 12 SNPs in DEFA5 (2 non-synonymous); and 11 SNPs in DEFA6, (no coding). The most notable non-synonymous SNP was a non-conservative amino acid change Ala19Glu in DEFA4 (2 asthma cases, 1 asthma control, 2 HPC).

Linkage and association analyses suggest the interleukin-1 receptor antagonist contributes to susceptibility of ankylosing spondylitis. *J. Luo¹, J. Akey¹, W. Maksymowych², L. Jin¹, J. McClain³, J. Reveille³.* 1) Center for Genome Information, Department of Environmental Health, University of Cincinnati, Cincinnati, OH; 2) Department of Genetics, University of Alberta, Canada; 3) University of Texas Health Sciences Center, Houston, TX.

Ankylosing Spondylitis (AS) is a common complex autoimmune disease. While approximately 90% of AS patients are HLA-B27 positive, other genes clearly contribute to AS susceptibility. We have conducted linkage and association analyses with microsatellite and SNP markers on chromosome 2q to better understand the genetic factors that contribute to AS. Specifically, three linked microsatellites spanning approximately 8 cM demonstrated significant linkage to AS in 187 affected sib-pairs (D2S160, NPL = 1.78, $p = 0.036$; D2S340, NPL = 4.09, $p = 0.00002$; D2S373, NPL = 2.37, $p = 0.009$). In silico analysis of this region led us to select the interleukin-1 receptor antagonist (IL1RA) for further study. In total, 101 cases and 48 controls were completely sequenced for all exons of IL1RA resulting in the identification of 37 SNPs. Furthermore, one SNP in exon 5 and two SNPs in exon 6 showed a significant association to AS (exon 5, $p = 0.03$; exon 6 SNP1, $p = 0.0019$; exon 6 SNP2, $p = 0.03$). Collectively, our data strongly supports the hypothesis that IL1RA contributes to AS susceptibility.

Program Nr: 1713 from 2002 ASHG Annual Meeting

A streamline method for SNP discovery. *P. McEwan, C. Fujii, J. Ziauddin, J. Malek, K. McKernan.* Agencourt Bioscience, Beverly, MA.

Discovery of a dense set of SNP markers across the genome, particularly in coding and regulatory regions, is a necessary first step in elucidating the role of genetic variation in common disease and drug efficacy. The SNP Consortium has identified and placed greater than 2 million SNPs into publicly available databases. Unfortunately, these public SNPs are randomly distributed throughout the genome, and there is a low probability of having high density SNP markers in specific regions of interest. As a result, additional directed SNP discovery is often required for pharmacogenomic studies focusing on candidate genes suspected in playing a role in a particular disease. Agencourt Biosciences SeeSNP Discovery program addresses this growing need for high throughput and directed SNP discovery in candidate regions. To address this need, we have developed a genomic alignment and amplicon modeling algorithm for the automatic generation of PCR primers across coding neighborhoods (exons and putative regulatory regions). The system utilizes an integrated Oracle LIMs system and a 384-well laboratory pipeline that relies on a high throughput-resequencing strategy. Newly discovered SNPs as well as in silico mined publically available SNPs are mapped to the candidate coding neighborhoods. Five microlitre, 384-well PCR and 1/32nd X BigDye, 384-well sequencing provide affordable high-throughput SNP discovery. Currently, 30,780 SeeSNP reads can be generated daily.

Development of a PCR based method for the determination of the BclI RFLP in the glucocorticoid receptor gene.
C. Lara-Castro, C. Song, Y. Chen, S.M. Sell. Nutrition Sciences, University of Alabama at Birmingham, Birmingham, AL, USA.

Background. Glucocorticoids have been implicated in the pathogenesis of obesity. Abnormalities in the glucocorticoid receptor gene (GCCR) such as the BclI restriction fragment length polymorphism (RFLP) in intron 1 have been associated with visceral obesity. Genotyping for this polymorphism is currently performed using the Southern blot technique. By using bio-informatics and data available through the human genome project, we were able to determine the region where this polymorphism is present, and to subsequently develop a PCR-based technique for the genotyping of this polymorphism. **Objective.** To develop a PCR-based, automated method for the determination of the GCCR BclI polymorphism. **Reagents.** DNA was amplified by PCR using standard conditions and the following primers: forward primer (5' — GGT TTG GAT GTG TGA CTA GC —3'); reverse primer (5'— CAA TGC AAT CCA TTT GCA CAG C —3'). The 317 bp product obtained was incubated with BclI restriction endonuclease (New England Biolabs), electrophoresed and analyzed. **Conclusions.** The PCR-based automated technique for the detection of the BclI RFLP in the GCCR gene described here will support faster analysis for large, population-based studies, and therefore a better understanding of the role of this polymorphism in the pathogenesis of obesity. This work was supported in part by funds from NIH grant P30DK056336.

A high throughput fluorescent assay for the detection of glutathione S-transferase polymorphic alleles. *R. Scholl¹, M. Blandford², L. Ballard¹, J.B. Magee¹, S. Williams¹, M. Robertson¹, F. Ali-Osman, D.Sc.³, R. Lemons, M.D., Ph.D², C. Keller, M.D.^{2,4}.* 1) Genomics Core Facility, University of Utah, Salt Lake City, UT; 2) Division of Pediatric Hematology-Oncology, Department of Pediatrics, University of Utah, Salt Lake City, UT; 3) Section of Molecular Therapeutics, Department of Neurosurgery, University of Texas, MD Anderson Cancer Center; 4) To whom correspondence should be addressed.

Polymorphisms of glutathione S-transferase (GST) enzymes are correlated with altered risk of selected cancers, as well as altered response and toxicity from the treatment of cancer. In this poster we demonstrate a low cost fluorescent polymerase chain reaction (PCR) based high-throughput assay that will facilitate the widespread study of how differences between GST alleles correlate with risk and with outcome of therapy for a variety of diseases, including cancer. Our assay design has three advantages over existing high-throughput assays. First, our assay design does not require restriction endonuclease digestions of PCR products in order to detect length differences between GST polymorphic alleles, as is needed for existing assays of GSTM1, GSTM3, or GSTP1. Second, our assay design allows all analyses to be performed simultaneously in the same electrophoresis gel lane. Third, our assay design is the first comprehensive, high-throughput method of assessing all four clinically-significant GST polymorphic alleles. Using an alternative genotyping method (single nucleotide extension) developed in our laboratory, we have determined the sensitivity and specificity of our assay to be 85 - 90% and 97 - 100%, respectively, depending on the source of genomic DNA.

Submicroliter genotyping of diallelic polymorphisms in microtape. A. Yu¹, J. Chen¹, T. Rusch¹, K. Fieweger¹, J. Chudyk¹, M. Doktycz², S. Hicks², W. Dickinson¹, N. Ghebraniou¹, J.L. Weber¹. 1) Center for Medical Genetics, Marshfield Medical Research Foundation, Marshfield, WI; 2) Life Sciences Division, Oak Ridge National Laboratory, Oak Ridge, TN.

Using a homogeneous assay with allele-specific PCR and fluorescently-labeled molecular beacons, we have developed a simple, two-step genotyping process for human diallelic polymorphisms. Reaction mixtures within sealed microtape are first amplified via thermal cycling, and then scanned for fluorescence without further manipulation. We have applied this assay to both substitution and insertion/deletion (indel) polymorphisms. For the indels, it is relatively easy to select robust allele-specific PCR primers. Microtape is a continuous thin strip of plastic embossed with an array of wells. It is an attractive substrate for genotyping and for many other chemical reactions. Microtape is manufactured by transiently heating a section of the plastic strip and then punching the wells using a metal tool. Because these tools are relatively inexpensive, many different versions of the microtape with varying well density, spacing, and geometry can easily be produced and tested. Our latest version of microtape (v.8) has shallow, conical wells with total volume of 1.1 l. Version 8 has 384-well arrays with dimensions that match standard 384-well microtiter plates. Microtape also has a series of indexing holes along each edge which allow the tape to be easily translated through pipetting, sealing, and scanning instruments. We have built a series of instruments to transfer liquid into the microtape using metal pins, syringes, and especially jetting of liquid droplets. A fluorescent scanner has also been developed along with software for analyzing the resulting signals. With v.8 microtape, reaction volumes are 400-800 nl; it may ultimately be possible to reduce reaction volumes to 100-200 nl leading to additional savings in reagent costs.

Significant Association of Five Candidate Gene Polymorphisms with Type 2 Diabetes in the Samoans. *D.T. Smelser¹, G. Sun¹, X. He¹, R. Indugula¹, M. Wolujewicz¹, H-J. Tsai², J. Tufa³, S. Viali⁴, S.T. McGarvey⁵, D.E. Weeks², R. Deka¹.* 1) Dept of Environmental Health, University of Cincinnati, Cincinnati, OH; 2) Human Genetics and Biostatistics, University of Pittsburgh, Pittsburgh, PA; 3) Department of Health, Pago Pago, American Samoa; 4) Department of Health, Apia, Samoa; 5) International Health Institute, Brown University, Providence, RI.

Type 2 diabetes is a complex disorder involving an intricate interaction between numerous environmental and genetic factors. The trademark of type 2 diabetes is hyperglycemia, resulting from impaired insulin secretion and utilization. Genes involved in the pathway of glucose metabolism are prime candidates in diabetes research. We identified 15 candidate genes and genotyped a single nucleotide polymorphism (SNP) within each one to test for an association with type 2 diabetes. We studied: *PC-1*, *PPARG2*, *FABP2*, *HNF-1b*, *GCK*, *NPY*, *GYS-1*, *ADRB3*, *UCP1*, *ADRB2*, *IGF1R*, *UCP3*, *LEP*, *ACE*, *IAPP*. We also genotyped 3 polymorphisms within the *Calpain-10* (*CAPN10*) locus, which had been identified as a susceptibility gene in a Mexican-American population (Horikawa et al. 2000 *Nat Genet* (26) 163-175). The Samoan islands are divided into American Samoa (AS) and Samoa (S). The independent nation of Samoa maintains a traditional Polynesian lifestyle, while AS has been culturally influenced by the U. S. Our cases consisted of 299 affected putative sib pairs and 1 half-sib pair from AS. The 96 unrelated controls were drawn from both AS and S. Five of the SNPs were found to be significantly associated using Fisher's exact test: *HNF-1b*, *IGF1R*, *UCP1*, *GCK*, and *ADRB3*. The locus *IGF1R* was in Hardy-Weinberg disequilibrium for the cases and controls, and for the cases only for *FABP2* and *ADRB2*. Haplotype frequencies and odds ratios were estimated for the *CAPN10* SNPs. No significant difference between cases and controls was found. Nonparametric linkage analysis was performed utilizing the *CAPN10* SNPs as well as 30 microsatellite markers spanning chromosome 2; the LOD score was 0. We are testing other candidate genes as well as additional SNPs in the above loci. (Supported by NIH grants AG09375, HL52611, DK55406 and DK59642).

A Genome-wide SNP Panel for use in Mapping and Association Studies. *K.E. Scott¹, J.F. Studebaker¹, F. Kuo¹, M.S. Phillips¹, P. Bauer¹, W.A. Ankeney¹, M.A. Donaldson¹, L. Cardon², M.T. Boyce-Jacino¹.* 1) Orchid BioSciences, Inc., Princeton, NJ; 2) Oxford University, Oxford, England.

Common diseases such as heart disease, cancer, diabetes, or asthma believed to be the result of complex polygenic phenotypes rather than a single gene variation. The “common variant — common disease” theory proposes that patterns of genetic variations frequently found in the human genome probably contribute to these common diseases. Therefore, identification of these patterns of variation may allow us to uncover the genetic factors of common diseases.

We have compiled a low-density panel of SNP markers that can be used to scan the genome for common genetic variants. The panel was designed for use with tag-array SNP-IT primer extension technology. The SNP-IT system provides a robust and highly reproducible assay with a more simple protocol for collecting genome-wide genotypes than the commonly used microsatellite mapping process. Automated SNP-IT technology using the SNPstream UHT instrumentation allows for more than 100 unique genome-wide scans to be collected in a single day. Additionally, the entire scan can be conducted using as little as 500 ng of genomic DNA. By comparison, microsatellite scans require microgram quantities of DNA, take weeks to run, and achieve spacing of only approximately 10 Mb.

The panel of SNPs provides coverage of all characterized regions of the human genome at an average of 1 Mb spacing. SNPs were selected based on map location and allele frequency in three diverse populations in order to achieve this coverage. We will present data demonstrating the utility of our genome-wide panel by comparing the data we have collected from the panel to that of the microsatellite set.

Sequence Variation in the *WFS1* Gene. T.A. Sivakumaran¹, J.C. Long^{2,3}, M.M. Lesperance¹. 1) Otolaryngology-Head & Neck Surgery, University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 3) Center for Statistical Genetics, University of Michigan, Ann Arbor, MI.

Mutations in the Wolfram syndrome 1 gene (*WFS1*) cause both autosomal recessive Wolfram syndrome and autosomal dominant low frequency sensorineural hearing loss (LFSNHL) linked to DFNA6/14/38. Several different heterozygous missense mutations in *WFS1* have been reported to underlie LFSNHL, whereas the majority of the mutations in Wolfram syndrome are homozygous inactivating mutations. In addition, several polymorphic variants in *WFS1* have been reported, some of which are associated with diabetes mellitus and/or psychiatric disorders. With a large number of nonsynonymous variants, it becomes difficult to determine if any given variant is disease-causing versus a benign polymorphism. No study to date has attempted to look at the entire coding sequence in a large number of controls reflective of the U.S. population. We sequenced the entire coding (2673 bp) and the flanking intronic region (463 bp) of *WFS1* in 96 control individuals, of which 90 were from the DNA Polymorphism Discovery Resource. A total of 49 simple sequence variations were found. 42 were in the coding region, and most (35/42) were in exon 8, by far the largest exon in *WFS1*. 41/42 were base substitutions (53.6% synonymous). About half of the variations were found only once in 192 chromosomes screened. The observed genotype frequencies of these variants were within Hardy-Weinberg equilibrium (HWE), except for R611H. The deviation ($p < 0.05$) from HWE for R611H is due to a lack of heterozygotes, which is not surprising in an admixed population. The nucleotide diversity coefficients (p) were 13.37×10^{-4} and 10.28×10^{-4} for the coding and non-coding regions, respectively. Tentative haplotype assignments constructed from 13 single nucleotide polymorphisms (SNPs) revealed 23 different haplotypes, with five haplotypes accounting for 83% of chromosomes. Linkage disequilibrium analysis of *WFS1* showed strong disequilibrium over the entire genomic sequence. The results have important implications for the use of these SNPs in the genetic analysis of families with LFSNHL as well as for association studies of other disorders.

Evidence for an association between IL-9 polymorphism and susceptibility to Visceral Leishmaniasis. *H. Elloumi Zghal¹, S. Abdelhak¹, A. Ben Salah², M.R. Barbouche¹, M. Ben Fadhel¹, A. Garnaoui¹, K. Dellagi¹.* 1) Immunology, Pasteur Institute, Tunis, Tunisia; 2) Ecology and Parasitic Epidemiology, Pasteur Institute, Tunis, Tunisia.

Mediterranean Visceral Leishmaniasis (MVL) is caused by *L. infantum*, an obligate intracellular parasite of mononuclear phagocytes that mainly affects children under 5 years old. Experimental Leishmaniasis in inbred mouse strains as well as segregation studies have shown that genetic factors may affect the susceptibility to Visceral Leishmaniasis but no specific human genes have been identified. Ten candidate genes have been selected on the basis of their relevance to disease pathogenesis and the presence of intragenic polymorphisms of possible biological significance. To investigate the role of these polymorphisms in susceptibility to MVL, we have carried out a case control study in a sample of 103 patients with MVL and 105 ethnically matched unrelated healthy controls, selected on the basis of a positive Leishmanin Skin Test, from an endemic region in central Tunisia. Allele frequencies were compared with the use of a two by- two chi-square test. We have not observed any evidence of association between susceptibility to MVL and the NRAMP1 gene, which has been reported to regulate the early resistance and susceptibility infection with *Leishmania* in mouse strains. Analysis of an intragenic IL-9 polymorphism showed a strong association of the allelic variant 124 and susceptibility to MVL ($\chi^2=9.79$ with 1 df; $p=0.0017$). In the other hand, a protective effect of the 142 allele of a polymorphism in the IL-10 promoter was noted in the studied sample ($\chi^2=4.04$ with 1 df; $p=0.044$). This is to our knowledge, the first description of an association between IL-9 gene and Visceral Leishmaniasis. IL-9 is a member of the Th2 cytokine family that has recently been involved in the pathology of human asthma as well as in the response to parasitic infections, and inflammatory processes. Our results indicated that IL-9 may be directly involved in LVM susceptibility, although, the association observed may be the result of strong linkage disequilibrium between IL-9 gene and another nearby susceptibility gene.

Genetic of bitter taste: identification of a Ch 7q35 locus in a Sardinian genetic isolate. *D.A. Prodi¹, D. Drayna², A. Angius¹, P. Forabosco¹, D. Piras¹, M.A. Palmas³, M. Pirastu¹.* 1) Istituto di Genetica delle Popolazioni, CNR, Alghero, SS, Italy; 2) National Institute of Deafness and Other Communication Disorders, Rockville, USA; 3) Sharda, Cagliari, Italy.

The inability to taste phenylthiocarbamide (PTC) is one of the best studied simple inherited traits in humans, but genetic linkage studies of this trait have produced inconsistent and conflicting results. Recently, a linkage study found a major locus on chromosome 5p15 and evidence for an additional locus on chromosome 7q. We sought to clarify these studies by using an exceptional genetic isolate residing on the island of Sardinia. This population consists of approximately 1200 individuals, 85% of which are descended from fewer than 20 founder couples. Phenotypes were determined using six scalar solutions of PTC with scores corrected for age and sex. Qualitative PTC taste threshold assignment in 280 individuals gave 75% tasters and 25% non tasters in this population. We tested for linkage at 400 microsatellite markers spaced across the genome using 110 selected informative individuals. Parametric and non-parametric analysis, performed with LINKAGE and GENEHUNTER, showed significant values at 7q35 (peak two-point lodscore of 3.03 at D7S661 and multipoint lodscore of 2.77). Phenotype was also analyzed as a quantitative trait using SOLAR which confirmed localization on chromosome 7: we obtained a two-point lodscore of 4.31 and a multipoint lod score of 4.73 in the same region. No strong evidence for linkage was obtained on chromosome 5p (multipoint lod score of 1.36) These results support previous studies assigning linkage of PTC tasting to the region surrounding the Kel blood group antigen on 7q.

Allele frequency determination of a 10 cM clustered set of SNPs for the TSC Linkage Map project. *J.D. Winick, A. Silbergleit, W. Lee, B. Chui, M.R. Bonner, P. Gwynne, M. Gaskin, A. Gandhi, T. Perez, M. Hernandez, J. Zdunek, A. Ledesma, S. Lew, R. Shippy, P. Stafford, J. Goldsmith, K. McWeeny, C.T. Yamashiro.* Motorola Life Sciences, Tempe, AZ.

In collaboration with The SNP Consortium (TSC), we have determined allele frequencies for a 10 cM SNP cluster map set using the CodeLink SNP genotyping platform. A SNP cluster is defined as a selection of SNPs from the total content contained in a 100 kb genomic region. Each SNP cluster is linked to a Marshfield microsatellite, which was used to determine an approximate average of 10 cM spacing. The TSC Linkage Map project was set up in two phases. The first phase was to determine the allele frequencies of candidate SNPs within three diverse population sample sets. The second was to use this data to select SNPs to be used to genotype 50 CEPH pedigrees to produce a SNP based linkage map. In all 2222 SNPs from 335 SNP clusters were evaluated for Phase I. Of these, 1517 passed the CodeLink primer and probe design process. One to four SNPs (1024 total SNPs) within 331 of the 335 SNP clusters were selected for evaluation on the 90 individuals from the TSC diversity panel (30 Caucasians, 30 African-Americans and 30 Asians). Minor allele frequency was determined for 851 of the 1024 SNPs evaluated, of which 740 or 87% of SNPs analyzed were polymorphic in at least one population and 606 SNPs were polymorphic in at least 2 out of 3 populations tested. It was found that in 2 of 3 of the test populations, 62.9% of SNPs had a minor allele frequency of >10% and 49.6% >20%. 106 SNPs proved to be monomorphic in all 3 populations tested. Each SNP was sequence confirmed for accuracy against three diverse DNA samples and only accurately performing SNPs progressed in the analysis. A total of 76,590 genotypes were reported in the minor allele frequency determination phase of the project. All 797 successfully designed and functioning SNPs, regardless of polymorphic state, were genotyped in 50 CEPH pedigrees (~640 samples and ~510,000 genotypes) for phase II of the TSC linkage-mapping project and all informative SNPs were included in the map.

Program Nr: 1723 from 2002 ASHG Annual Meeting

Do we need to correct for population stratification in the UK BioBank initiative? *M.P.H. Stumpf, N. Soranzo, D.B. Goldstein.* Department of Biology, University College London, London, UK.

We present the results of a large-scale study of population stratification in Northern Europe. We have genotyped over 1 000 males from throughout the British Isles and other parts of Northern Europe at 20 completely unlinked, autosomal SNPs to establish how population stratification in the UK is likely to affect the MRC/Wellcome Trust BioBank program. The SNPs were chosen to be at least 80kb from the nearest known gene or EST; thus we also expect them to be selectively neutral. With this set of SNPs it became possible to (i) assess the likely extent of stratification in North-European population samples and (ii) develop adequate methods for correcting for spurious association resulting from admixture in the UK. The experimental study was complemented by extensive use of coalescent simulations of an N-island demography with migration. This allows us to directly assess divergence of populations in the UK that may cause problems in large-scale case-control studies. We find that spurious associations can be a concern in the UK, especially in extremely admixed population samples (generated, for example, by pooling the geographically most separated sub-populations in our study). Even if there are detectable levels of stratification they are not always high enough to reliably group population samples into distinct sub-populations for further analysis. Thus we believe that standard methods of genomic control offer the most convenient method to correct for cryptic population structure in the UK. We were also able to confirm the statistical significance of the experimental results through computer simulations. In particular we show that the UK data is incompatible with high levels of population divergence between the regions in the British Isles. Moreover we provide evidence that the present set of 20 unlinked SNPs will be sufficient to keep the rate of false positives below the 5% level using standard methods of genomic control.

Association of GABA receptor rho1 gene polymorphisms with severe myopia. *E.C. Tan¹, S.H. Ng¹, S.H. Yap¹, L. Gan¹, U. Karupathivan¹, H.M. Wu¹, E.P.H Yap^{1,2}.* 1) Defence Medical Research Institute, Defence Science and Technology Agency, Singapore; 2) Singapore Eye Research Institute.

The etiology of human myopia is unknown. While environmental factors such as near work and educational attainment are important, family history and ethnic background are established risk factors suggesting a genetic predisposition to the development of severe myopia. In our ongoing study to identify susceptibility genes for myopia, we target retinally expressed genes as functional candidates. Among molecules involved in the retinal signaling process, GABA (gamma-aminobutyric acid) is the primary inhibitory neurotransmitter in the adult mammalian retina. There are at least three types of GABA receptors in the retina. For the r1 subunit which is one of the components of the GABA_A receptors, expression is primarily confined to retinal bipolar cells and cerebellum and is also developmentally regulated. In this study, we genotyped 2 single nucleotide polymorphisms in the r1 gene and carried out initial association analysis using 87 controls and 85 subjects with refractive errors of between -8.5 and -18.25D. Controls are ethnically, gender and age-matched subjects with refractive errors of less than -0.5D. For the T99C polymorphism, which involved an amino acid substitution, there was some difference in the distribution of the genotypes between the two groups but it did not reach statistical significance. The difference in genotype distribution was marginally significant for the C457T polymorphism ($\chi^2=3.73$, $p=0.053$). Difference in allele frequency was also marginally significant between cases and controls ($\chi^2=3.47$, $p=0.063$) with the odds ratio at 3.3 (95% CI: 0.88-12.04). Haplotype analysis was performed to obtain estimated haplotype frequencies by diagnosis group separately and for all subjects combined. There was no significant linkage disequilibrium between the 2 single nucleotide polymorphisms. There was also no significant difference in the distribution of the 4 possible haplotypes between cases and controls. We will confirm the positive association with a larger set of samples and also investigate other polymorphisms within this gene.

Fine Mapping Linkage Analysis of COPD-related Phenotypes on Chromosome 19. *J.C. Celedon^{1,2}, L.J. Palmer^{1,2}, B. Raby^{1,2}, J.M. Senter¹, J.M. Drazen^{1,2}, D.J. Kwiatkowski^{1,2}, H.A. Chapman³, M. Hernandez¹, F.E. Speizer^{1, 2}, S.T. Weiss^{1, 2}, E.K. Silverman^{1, 2}.* 1) Channing Laboratory, Brigham and Women's Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) University of California at San Francisco, San Francisco, CA.

Severe alpha 1-antitrypsin (AAT) deficiency is the only proven genetic risk factor for chronic obstructive pulmonary disease (COPD). To study novel genetic determinants of COPD, we enrolled 72 pedigrees ascertained through severe, early-onset COPD probands (FEV1 < 40% pred., age <53 yrs, without severe AAT deficiency). Results of a 10 cM genome scan with short-tandem repeat (STR) markers have been previously reported (AJHG 2002;70:1229-39). Following the genome scan, we conducted linkage analysis of 15 STR markers (5 from the original scan and 10 additional markers) on chromosome 19 (range, 33 to 68 cM) with COPD-related phenotypes in 585 members of families of the severe, early-onset COPD probands. We used SOLAR for variance component linkage analysis of quantitative traits (FEV1 and FEV1/FVC), and the NPL all statistic (in MERLIN) for the analysis of qualitative traits (chronic bronchitis, mild airflow obstruction [FEV1 <80% pred. and FEV1/FVC <90% pred], and moderate airflow obstruction [FEV1 <60% pred. and FEV1/FVC <90% pred). Compared with the genome-wide scan, there was increased evidence for linkage on chromosome 19 for FEV1, FEV1/FVC, and moderate airflow obstruction. In the original genome scan, the maximum multipoint LOD scores were: 1.40 (at 59 cM) for FEV1; 1.47 (at 61 cM) for FEV1/FVC; and 1.54 (at 42 cM) for moderate airflow obstruction. In the current analysis, the maximum multipoint LOD scores were: 1.73 (at 61 cM) for FEV1; 1.64 (at 62 cM) for FEV1/FVC; and 2.31 (at 36.2 cM) for moderate airflow obstruction. These results provide further suggestive evidence that there is a locus on chromosome 19 that contributes to airflow obstruction, an important COPD-related phenotype. This abstract is funded by NIH Grants: HL61575 (EKS) and NIH HL04370 (JCC).

Common functional polymorphisms in Toll-like Receptor 4 (TLR4) are not associated with asthma or atopy-related phenotypes. *B.A. Raby^{1, 2}, W.T. Klimecki³, C. Laprise⁴, Y. Renaud², J. Faith², M. Lemire², C. Greenwood², C. Lange⁵, L.J. Palmer¹, R. Lazarus¹, D. Vercelli³, D.J. Kwiatkowski¹, E.K. Silverman¹, F. Martinez³, T.J. Hudson², S.T. Weiss¹.* 1) Channing Laboratory, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 2) Montreal Genome Centre, McGill University Health Centre, Montreal, QC, Canada; 3) Arizona Respiratory Center, University of Arizona, Tucson, AZ; 4) University of Quebec at Chicoutimi, Departments of Fundamental Sciences and Human Sciences, Chicoutimi, QC, Canada; 5) Department of Biostatistics, Harvard School of Public Health, Boston, MA.

Toll-like receptor 4 (TLR4) is the principal receptor for bacterial endotoxin recognition. Functional variants in the gene confer endotoxin-hyporesponsiveness. There is also evidence that endotoxin exposure during early life protects against the development of atopy and asthma. It is therefore possible that genetic variation in TLR4 contributes to asthma susceptibility. The purpose of this study is to characterize the genetic diversity in TLR4 and test for association between the common genetic variants and asthma-related phenotypes. In a cohort of 90 ethnically diverse subjects, we resequenced the TLR4 locus, identified a total of 29 single nucleotide polymorphisms (17 of which are novel) and inferred the haplotype structure. We assessed five common polymorphisms for evidence of association with asthma in two large family-based cohorts: a North-American cohort (589 families), and a founder population from northeastern Quebec, Canada (167 families). Using the transmission-disequilibrium test (GENEHUNTER 2.0) we found no evidence of association with asthma for any of the polymorphisms tested, including two functional variants D259G and T359I. We also found no evidence of association with the common TLR4 haplotypes. Furthermore, using FBAT, we found no evidence for association between the TLR4 variants and four quantitative intermediate asthma- and atopy-related phenotypes (FEV1, PC20, total serum IgE and serum eosinophils). Based on these results, we find no evidence that genetic variation in TLR4 contributes to asthma susceptibility. Grants: NIH HL07427 HR16049 HL66386 HL66795 CIHR: MC1-40745.

ASSOCIATION BETWEEN THE CA POLYMORPHISM IN INTRON 13 OF THE ENDOTHELIAL NITRIC OXIDE SYNTHASE GENE (eNOS) IN ISCHEMIC HEART DISEASE PATIENTS OF MEXICAN

POPULATION. *R.P. Mariaud¹, M.P. Gallegos¹, L. Arnaud¹, T.J. Beltran², M.R. Arechavaleta², G.M. Zuniga¹.* 1) Medicina Molecular, IMSS, Guadalajara, Jalisco, Mexico; 2) Departamento de Endocrinologia, HE, CMNO, IMSS, Guadalajara, Jalisco, Mexico.

INTRODUCTION. Recently several polymorphisms of the endothelial synthase gene have been associated as risk factors for ischemic heart disease. However, in different studies around the world, the results have been not conclusive. In Mexico, we unknown this polymorphism frequency in patients with ischemic heart disease and controls. **OBJETIVE:** Determination of the CA-13 polymorphism of the endothelial nitric oxide synthase gene frequency in ischemic heart disease patients. **MATERIAL AND METHODS:** We studied 108 patients with ischemic heart disease of the Mexican population and 49 controls. For the entire participant the lipid profile was quantified. For the endothelial nitric oxide synthase gene VNTR polymorphism analysis, we amplified a 130pb segment of intron 13 of the eNOS gene, which consists of 2 pb (CA) repetitions, with 23 different alleles identified. **RESULTS AND CONCLUSION.** The 43 allele was more frequently in patients (32%) vs. controls (10.3%), immediately the 45 allele (30% in patients vs. 1% in controls), however the sample number is not similar and we just conclude the association of this alleles with the ischemic heart disease, this association should be confirm with a wide sample.

Candidate loci linkage analysis in dominantly inherited cataract with microcornea. *C.E. Willoughby^{1,2,3}, A.E. Shafiq⁶, S.B. Kaye⁴, G. Billingsley¹, A. Chandna⁵, E. Heon^{1,2}.* 1) Dept of Ophthalmology/Visual Science Research Program, Toronto Western Hospital Reserach Institute, Toronto, ON, Canada; 2) Dept of Ophthalmology, Hospital for Sick Children, Toronto, ON, Canada; 3) Dept of Medicine, University of Liverpool, Liverpool, UK; 4) Royal Liverpool University Hospital, Liverpool, UK; 5) Royal Liverpool Children's Hospital, Liverpool, UK; 6) Royal Victoria Infirmary, Newcastle-upon-Tyne, UK.

The genetic basis of dominantly inherited cataract with microcornea has not been fully elucidated and is a good model for eye development. To date, the molecular characterization has been limited to one family in whom a mutation in alpha-A-crystallin (CRYAA) was described. The aim of this study is to document the ocular phenotype, and map a genetic locus for dominantly inherited cataract with microcornea, using a three generation family. Seventeen family members (11 affected and 6 unaffected) had a full ocular assessment to document the phenotype. The affected status (presence of cataracts) was determined before the genetic analysis. A panel of 10 candidate loci was selected for preliminary linkage analysis. Microsatellite markers were selected for each locus and genotyping was performed on a Pharmacia automated sequencer. Two-point linkage analysis used the MLINK program of the LINKAGE package v5.2. All affected individuals had congenital cataracts requiring surgery in infancy and 10 individuals also had microcornea. The cataract morphology of one individual was assessed at birth. Linkage analysis of 10 candidate loci (CRYAA, CRYAB, CRYBB2, PAX6, PITX2, PITX3, FOXC1, CHX10, MAF, Nance-Horan syndrome) is reported and provides evidence for another candidate loci in this family. The analysis of this family further outlines the genetic heterogeneity of anterior segment malformation disorders.

Mitochondrial Myopathies in the South African population: implications for diagnosis - lessons from the first four years. A. Olckers^{1,2}, D. Prosser¹, F. Maree^{1,2}, M. Brown³, D. Wallace³, I. Smuts⁴. 1) Centre for Genome Research, Potchefstroom University for CHE, Pretoria, South Africa; 2) DNAbiotec, Pretoria, South Africa; 3) Emory University, USA; 4) University of Pretoria, South Africa.

A Mitochondrial Myopathy (MM) research programme was initiated to investigate the genetic basis of MM in the South African population. This study represents the first extensive investigation of MM in our population and focuses on the most frequent MMs presenting in childhood: MERRF, MELAS and LS. A clinically well characterised group of 53 patients was included: 10 patients indicative of LS, 12 for MELAS and 3 for MERRF. The remaining patients were classified as displaying various non-specific symptoms associated with MMs. Initially our investigative approach included only patients that have been well characterised on the clinical and biochemical level. This remains our approach today, however our molecular investigative strategy has changed dramatically. Initially we screened for the 10 most common MM mutations (3 MERRF, 6 MELAS, 2 LS) in the mt genome via RFLP. After finding that only 1 patient harboured a reported mutation we embarked on an extensive sequencing strategy. Currently our molecular approach is to sequence the 3000, 8000 and 9000 regions. This strategy allows the detection of 13 additional MM mutations. In addition evidence is gathered on the polymorphisms in the region, some of which are African specific, which makes it highly relevant in our population. Failing detection of any causative changes in these 3 regions, we include the individual in our full mt DNA sequencing screening study. The screening of 6 patients has been completed on this level and several known and novel changes have been reported. LS referrals are also subjected to additional analysis of the SURF1 gene via SSCP/HEX. To date 4 patients referred for LS have been identified with aberrant conformers, via SSCP, in exons 3,4,8 and 9 of the SURF1 gene. Diagnosis of MM in the South African population has been challenging, mainly due to the fact that the reported mutations causing MMs in the European population are for the most part not responsible for the MM phenotypes observed in our Caucasian or African populations.

Isolation and characterization of the putative nuclear modifier gene MTO1 involved in the pathogenesis of deafness-associated mitochondrial 12S rRNA A1555G mutation. *M.X. guan*¹, *X.M. LI*², *R.H. Li*³. 1) Div Human Genetics, Children's Hosp Medical Ctr, Cincinnati, OH; 2) same as 1; 3) same as 2.

The human mitochondrial 12S rRNA A1555G mutation has been found to be associated with aminoglycoside-induced and non-syndromic deafness. However, putative nuclear modifier gene(s) has been proposed to regulate the phenotypic expression of this mutation. In yeast, the mutant alleles of MTO1, encoding a mitochondrial protein, manifest respiratory-deficient phenotype only when coupled with the mitochondrial 15S rRNA PR454 mutation corresponding to human A1555G mutation. This suggests that the MTO1-like modifier gene may influence the phenotypic expression of human A1555G mutation. Here we report the identification of full-length cDNA and elucidation of genomic organization of the human MTO1 homolog. Human Mto1 is an evolutionarily conserved protein that implicates a role in the mitochondrial tRNA modification. Functional conservation of this protein is supported by the observation that isolated human MTO1 cDNA can complement the respiratory deficient phenotype of yeast *mto1* cells carrying PR454 mutation. MTO1 is ubiquitously expressed in various tissues, but with a markedly elevated expression in tissues of high metabolic rates including cochlea. These observations suggest that human MTO1 is a structural and functional homolog of yeast MTO1. Thus, it may play an important role in the pathogenesis of deafness-associated A1555G mutation in 12S rRNA gene or mutations in tRNA genes.

(GJB2)Connexin 26 and 30(GJB6) mutations in a South African population with nonsyndromic deafness of probable autosomal recessive origin. *G. De Jong*¹, *C. Whitehead*², *L. Muller*³, *L. Du Plessis*¹, *M.J. Kotze*¹, *L. Warnich*². 1) Dept Human Genetics, Univ Stellenbosch, Tygerberg, South Africa; 2) Dept Genetics, Univ Stellenbosch, South Africa; 3) Department Audiology, Speech and Language, Univ Stellenbosch.

GJB2 And GJB6 gene mutations are common in patients with nonsyndromic autosomal recessive deafness. The most common mutation in the Mediterranean European population with hereditary nonsyndromic deafness is the 35del G mutation in GJB2. Mutations differ in frequency in different countries. A 342kb deletion found within GJB6 has recently been described as a very common in the Spanish population in nonsyndromic autosomal recessive deafness. A second deletion of 140kb was identified in an Ashkenazi Jewish population. In this study we are screening parents with normal hearing and 1 or 2 children with unexplained deafness possibly autosomal recessive ie the deaf children and parents with normal siblings (if available)- at least 50 families. Consent is obtained together with a history as well as blood for DNA analysis. A basic PCR technique was used together with sequencing to detect known and novel mutations. The 35 delG mutation in GJB2 was found at a frequency of ~22% whereas a second mutation, 312del(14) was seen at a frequency of ~16%. In the case of GJB6 the deletion of 140kb has been observed at a frequency of ~21%. The 342kb deletion has not been observed. Further analysis is ongoing.

Large deletion of GJB6 gene in deaf patients heterozygous for GJB2 gene : genotype and phenotype analysis. *S.*

Marlin¹, F. Denoyelle², D. Feldmann³, I. Del Castillo⁴, S. Odent⁵, A. Joannard⁶, F. Moreno⁴, R. Couderc³, E.N. Garabedian², C. Petit⁷. 1) Unite de Genetique, Hopital A Trousseau, AP-HP, Paris, France; 2) Service d'ORL, Hopital A Trousseau, AP-HP, Paris, France; 3) Laboratoire de Biochimie, Hopital A Trousseau, AP-HP, Paris, France; 4) Unidad de Genetica Molecular, Hospital Jamon y Cajal, Madrid, Spain; 5) Unite de Genetique, Hopital de Pontchaillou, Rennes, France; 6) Service de Pediatrie, CHU, Grenoble, France; 7) Unite de genétique des deficts Sensoriels, Institut Pasteur, Paris, France.

Hearing loss is the most frequent sensorial defect. At birth, 1/1000 child presents with a severe or profound hearing loss. 60% of the prelingual hearing loss are presumed to have a genetic origin. GJB2 gene represents the major genetic form of prelingual deafness as it accounts for 40% of the congenital hearing loss. GJB2 gene has been analysed in 255 independant patients with non syndromic prelingual hearing loss. 81 of them have a biallelic mutation in GJB2 (35delG 76% ,L90P 4.1%, 167delT2.6%, 312del14, E47X,Q57X 2%) of all mutated alleles. Of the 29 deaf patients heterozygous for a mutation in GJB2 ,16 carry a deletion in trans implicating GJB6 (14 patients 35delG/+, one V37I/+, one Q57X/+). In all families, the molecular anomalies in GJB2 and GJB6 segregate with the hearing impairment. No difference of genotypes between sporadic and familial cases is observed. The phenotype of the 16 composite GJB2/GJB6 heterozygous patients have been compared with the phenotype of patients homozygous for GJB2 mutations or without GJB2 mutations. In profound deafness, the percentage of patients heterozygous composite GJB2/GJB6 and homozygous for GJB2 mutations was significantly higher than in moderate or mild deafness.

A human mitochondrial GTP binding protein related to tRNA modification has an implication for modulating the phenotypic expression of the deafness-associated mitochondrial 12S rRNA mutation. X. Li, M.X. Guan. Div Human Genetics, Children's Hosp Medical Ctr, Cincinnati, OH.

A variety of mitochondrial DNA (mtDNA) mutations have been found to be associated with many clinical abnormalities, including neuromuscular disorders, hearing loss, and diabetes. However, the nuclear backgrounds modulate the phenotypic expression of pathogenic mtDNA mutations, specifically in the deafness-associated A1555G mutation. In yeast, mutant alleles of *MSS1*, encoding a mitochondrial GTP binding protein, manifest a respiratory-deficient phenotype only when coupled with mitochondrial 15S rRNA PR454 mutation corresponding to the human A1555G mutation. This suggests that *MSS1*-like modifier gene may influence the phenotypic expression of the human A1555G mutation. Here we report the identification and characterization of the human *MSS1* homolog, *GTPBP3*. This is the first identified vertebrate gene related to mitochondrial tRNA modification, which plays a pivotal role in the fidelity of translational process. The *Gtpbp3* is the mitochondrial GTPase evolutionarily conserved from bacteria to mammal. Functional conservation of this protein is supported by the observation that isolated human *GTPBP3* cDNA can complement the respiratory deficient phenotype of yeast *mss1* cells carrying the mitochondrial PR454 mutation. *GTPBP3* is ubiquitously expressed in various tissues as multiple transcripts, but with a markedly elevated expression in tissues of high metabolic rates. We also showed that *Gtpbp3* localizes in the mitochondrion by immuno-staining with the specific antibodies and analyzing with a confocal microscope system. These observations strongly suggest that the human *GTPBP3* is a structural and functional homolog of the yeast *MSS1*. Thus, it may modulate the phenotypic manifestation of mitochondrial A1555G mutation.

Molecular and clinical characterization of a large Chinese pedigree with maternally inherited hearing loss. *R. Li¹, X. Bu², M. Yan², M.X. Guan¹*. 1) Dept Human Genetics, Cincinnati Children's Hosp, Cincinnati, OH; 2) Department of Otolaryngology, People's Hospital of Jiangsu Province, Nanjing Medical University, Nanjing, Jiangsu, China 210097.

Mutations in the mitochondrial DNA has been shown to be one of the important causes of non-syndromic sensorineural hearing loss. We reported here the molecular and audiological characterization of a large Chinese family (507 members in six generations) with maternally inherited non-syndromic hearing loss. In particular, 41 subjects in the kernel pedigree in the family were intensively evaluated by audiological approaches and screening for mutations in mtDNA. Audiological results showed symmetrical bilateral progressive sensorineural hearing loss in 17 of 41 individuals with a highly variable age of onset. Sequence analysis of complete mitochondrial genome in this pedigree revealed the presence of a homoplasmic A1555G mutation and other sixteen-nucleotide changes. These are the A663G, and 959 insC in the 12S rRNA gene, five polymorphisms in protein encoding genes, including the A4824G in the ND2 gene, C8794T and A8860G in the A6 gene, A15426G in the cytob gene, and 11 polymorphisms in D-loop region. Of these changes, the novel 959 insC is of special important as the homologous position is the very conserved tRNA and streptomycin-binding region of P-site in the bacterial 16S rRNA. In addition, the 515 CA deletion is the novel mutation in the mitochondrial genome. These data suggests that the A1555G mutation is the primary factor for the deafness phenotype, while other mtDNA mutations, specifically in the 959 insC, acting as the secondary mutation(s), play a synergic role in the deafness phenotype. In addition, the genetic evidence of this pedigree clearly points out that the nuclear modifier gene(s) modulates the phenotypic variability associated with the A1555G mutation. This pedigree is certainly an excellent system for investigating the role of nuclear modifier gene(s) in the development of deafness phenotype related to the A1555G mutation.

Gene expression alterations in tau-deficient mice. *F. Oyama*^{1,2}, *S.E. Kotliarova*², *A. Harada*^{3,4}, *M. Ito*⁵, *Y. Ueyama*^{5,6}, *N. Hirokawa*⁴, *N. Nukina*², *Y. Ihara*¹. 1) Department of Neuropathology, Graduate School of Medicine, the University of Tokyo, Tokyo, Japan; 2) Laboratory for CAG Repeat Diseases, RIKEN Brain Science Institute, Saitama, Japan; 3) Laboratory of Cellular and Molecular Morphology, Institute for Molecular and Cellular Regulation, Gunma University, Gunma, Japan; 4) Department of Cell Biology and Anatomy, Graduate School of Medicine, the University of Tokyo, Tokyo, Japan; 5) Central Institute for Experimental Animals, Kanagawa, Japan; 6) Department of Pathology, School of Medicine, Tokai University, Kanagawa, Japan.

Tau, a microtubule-associated phosphoprotein, plays an important role in determining and maintaining neuronal morphology. Its hyperphosphorylated form is the major constituent of paired helical filaments in Alzheimers disease. A number of exonic and intronic mutations in the tau gene were identified in the patients affected by frontotemporal dementia and parkinsonism linked to chromosome 17 (FTDP-17). The affected brain is characterized by extensive neuronal loss most dominantly in the frontotemporal region and PHF-like fibril formation. Thus, this is definite genetic evidence that tau can kill the neuron. To find an as yet unidentified role of tau in vivo, we used oligonucleotide DNA arrays profiling ~11000 mRNAs to see how the gene expression is altered in the brain of tau-deficient mice, as compared with control mice at the same ages. This microarray screening suggested that the expression of Gem GTPase, a member of Ras-related GTP-binding proteins, is significantly increased at 8 week aged tau-deficient mice. This was confirmed by quantitative RT-PCR. These results indicate that tau-deficiency leads to overexpression of Gem GTPase at 8 weeks of age.

A Behavioral and Correlated Neurochemical Mouse Phenotype Related to the Absence of *Snrpn*, a Locus Associated with Prader-Willi Syndrome. R.A. White¹, E. Vorontosova², R. Chen², S.M. Lunte², M.I. Davies², K.E. Heppert², S.G. McNulty¹, K.N. Young¹, M.G. Butler¹, C.I. Brannan³, T. Thompson⁴, S.C. Fowler². 1) Children's Mercy Hospital and UMKC School of Medicine, Kansas City, MO; 2) University of Kansas, Lawrence, KS; 3) University of Florida, Gainesville, FL; 4) University of Kansas Medical Center, Kansas City, KS.

The bicistronic *Snrpn* gene is involved in mRNA production for two different proteins (SNURF and SmN), and localized in the area that regulates imprinting in the Prader-Willi syndrome chromosomal 15q11-q13 region. Adult homozygous (-/-) and paternally derived (+/-) *Snrpn* knockout mice and adult littermate controls were subjected to three behavioral assays (rotarod, grip strength test, and force-plate actometer). Although the rotarod and grip tests detected no behavioral consequence in the *Snrpn*-deficient mice, the actometer indicated a significant tendency ($p=0.009$) for the *Snrpn*-null mice ($n=6$) to rotate to the right compared to no rotational bias in the controls ($n=12$). The rotational bias suggested possible imbalances in striatal dopamine (DA) levels. Accordingly, the striata of individual mouse brains were dissected into right and left halves and analyzed by HPLC with electrochemical detection for DA content and dopamine metabolites, DOPAC and HVA. The *Snrpn*-deficient mice had lower DA in the left than in the right striatum ($p=0.027$), while the left and right DA levels of controls were similar and at the same level as the right side in the *Snrpn*-deficient knockout mice. The DA metabolites, DOPAC and HVA, also displayed similar *Snrpn*-status-by-side interactions, suggesting that the DA imbalances had not been overcome by compensatory increases in turnover of DA. These neurochemical and behavioral data in the *Snrpn*-null mice, when considered in the context of right striatal overactivity in human Obsessive Compulsive Disorder (OCD), raise the possibility that the *Snrpn*-null mice may model aspects of OCD seen in Prader-Willi syndrome. These findings also suggest that the *Snrpn* knockout mouse may be more relevant to developing an understanding of PWS than had previously been suspected.

Identification of Candidate Genes for Parkinson Disease (PD) by the Convergence of Genetic Linkage and Association Data with Gene Expression in the Substantia Nigra. *M.A. Hauser¹, J.W. Walter¹, R.W. Walters¹, M. Maready¹, S. Takeuchi¹, W.P. Segars¹, C.M. Hulette³, D.E. Schmechel², M.L. Bembé¹, J.M. Stajich¹, E.R. Hauser¹, E.R. Martin¹, B.L. Scott², J. Stenger¹, Y.J. Li¹, F. Beato⁴, R. Jensen⁵, C. Scherzer⁴, S. Gullans⁴, J.M. Vance^{1,2}.* 1) Ctr Human Genetics, Duke Univ Med Ctr, Durham, NC; 2) Dept of Med, Duke Univ Med Ctr, Durham, NC; 3) Dept of Pathology, Duke Univ, Durham, NC; 4) Brigham and Women's Hosp, Harvard Med Sch, Boston, MA; 5) Dept of Physics, Wesleyan University.

Parkinsons Disease (PD) is characterized by the loss of dopaminergic neurons in the substantia nigra. We have reported 5 large linkage peaks in 174 multiplex PD families. Concurrently, we are performing gene expression profiling in the substantia nigra of 3 PD patients (aged 79, 83, and 87) and 2 controls (aged 81 and 72). Expression data often presents so many candidates that it is difficult to interpret. Likewise, linkage analysis of complex disorders yields large regions with many candidate genes. Combining our genetic and expression data allows us to identify critical genes and pathways in the disease, specifically: 1) to assist in the prioritization of candidate genes within linkage peaks and 2) to provide high priority candidate genes for testing of genetic association in our large PD data set. Expression profiling was performed with the Affymetrix U133A gene chip, and by serial analysis of gene expression (SAGE), generating over 200,000 SAGE tags. Genes whose expression levels are significantly up or down regulated in affected individuals constitute candidate susceptibility genes. Of special interest, heat shock protein 90kD (HSP90) protein 1 is up 15-fold ($p=0.000015$), HSP70 protein 4 is up 8-fold ($p=0.003$), and HSP70 protein 5 is up 3-fold ($p=0.0007$) in PD cases vs controls. These results are confirmed by microarray analysis. This is the first report in human tissue corroborating the observation that HSP70 can prevent dopaminergic neuron loss in a *Drosophila* model of PD (Auluck et al. *Science* 295:865). All differentially expressed genes mapping to regions of linkage are being analyzed for their role in the etiology of Parkinson disease.

IDENTIFICATION AND GENOMIC STRUCTURE OF A HUMAN DTNBP1 GENE FROM A PUTATIVE SCHIZOPHRENIA SUSCEPTIBILITY LOCUS ON 6P22.3 IN SILICO. *Y. Jiang¹, R.E. Straub¹, P.F. Sullivan¹, C. Harris-Kerr¹, B.T. Webb¹, B. Wormley¹, X. Wang¹, A. Gibberman¹, A.J. Cesare¹, X. Chen¹, F.A. O'Neill², D. Walsh³, K.S. Kendler¹, B. Riley¹ and I.* 1) Dept Psychiatry, Virginia Inst Psych/Behav Gen, Richmond, VA; 2) Department of Psychiatry, Queens University, Belfast, Northern Ireland; 3) The Health Research Board, Dublin, Ireland.

Schizophrenia is a relatively common, chronic and debilitating psychiatric disorder. It is highly heritable but the genetics are complex. Human chromosome 6p22.3 has previously been linked to schizophrenia in several studies. However, genes present in this region have not yet been investigated in detail. Here we report a full-length cDNA and genomic structure of the human dystrobrevin binding protein 1 gene (DTNBP1) identified between markers D6S260 and D6S1676 by an in silico pipeline and PCR from human brain cDNA libraries. Genome annotation revealed that human DTNBP1 spans 140kb and has a putative promoter with features characteristic of housekeeping gene. We verified 10 exons in our transcript by direct sequencing. The corresponding cDNA is 1349 bp. The open reading frame encodes a 351-amino-acid protein that contains several conserved features: a coiled-coil region, a leucine-rich repeat and several protein kinase phosphorylation sites, which may indicate a role in intracellular signal transduction. It is a promising positional candidate gene for schizophrenia given its genomic localization and interaction with the dystrophin-associated protein complex (DPC) in brain. Three simple sequence repeats and 24 SNPs identified by database hunting and sequencing on pooled ISHDSF DNA samples are useful resources for further evaluating the candidate gene status.

***COL1A1* polymorphism (a four-base-pair insertion polymorphism in 3'UTR) in young male Greek army recruits with lumbar disk disease.** *T.A. Bei*¹, *C. Tilkeridis*², *S. Garatziotis*², *E. Kortetas*^{2,3}, *C.A. Stratakis*^{1,2}. 1) Unit on Genetics & Endocrinology, DEB, NICHD, NIH, Bethesda, MD 20892-1862; 2) Greek Army Medical Center, Arta, Greece; 3) Department of Defense, Greek Army Medical Service, Athens, Greece.

Lumbar disk disease (LLD), one of the most frequent conditions for which patients seek medical care, has been associated with various polymorphisms and/or mutations of the COL genes. *COL1A1*, in particular, has been linked to LLD with a number of genetic changes. In the present study we collected DNA from Greek army young recruits (19-38 years old) and their relatives with LLD. These young soldiers, at the time of their presentation to a military medical training site, were diagnosed with early LLD. All patients had radiological confirmation of their disease; a control group was also studied. A four base-pair insertion polymorphism in the 3' untranslated region (3'UTR) of the *COL1A1* was tested: it is highly polymorphic producing a fragment of 430bp (allele A1) or a fragment of 434bp (allele A2) by simple PCR-amplification. In a total of 30 patients, 10 showed heterozygosity for one of the two alleles; 5 (16.7%) were A1A1, whereas only one of the control subjects had this genotype. Overall, there was a tendency for the shorter allele (A1) to be more frequent in patients with LLD ($p=0.096$). In both groups, there was no deviation from the Hardy-Weinberg equilibrium for this polymorphism of the *COL1A1* gene. We conclude that a previously not studied in LLD polymorphism of the *COL1A1* gene shows a tendency of association with this condition in young soldiers and their relatives; it is unclear whether it is this genetic change that is responsible for a functional effect on the COLA1 protein or whether it is in close association with another COLA1 alteration that is directly responsible. Ongoing studies are aimed at clarifying this question in our patients with LLD.

Program Nr: 1740 from 2002 ASHG Annual Meeting

Molecular Genetic Dissection of Attention Network Efficiency. *J.A. Fossella, J. Fan, T. Sommer, Y. Wu, D. Pfaff, M.I. Posner.* Sackler Institute, Weill Medical College of Cornell University, New York, NY.

Attention can be viewed in terms of neural networks that carry out specific functions of maintaining the alert state, orienting to sensory input, and coping with stimulus and response conflict. The alerting network shows a dependence on right frontal and parietal areas as well as the effects of noradrenaline; the orienting network involves the posterior parietal lobe and is sensitive to acetylcholine, while the executive network involves frontal areas including the anterior cingulate and lateral prefrontal cortex which are sensitive to dopamine. Our genetic analysis seeks to determine the contributions of noradrenergic and dopaminergic genetic variation to the efficiency of alerting and executive networks, respectively. As a first step, the heritability of each network was gauged using the Attention Network Task (ANT) on 26 pairs of MZ twins and 26 pairs of age matched DZ twins. The highest heritability ($h^2 = 0.89$) was observed for the executive network while alerting showed a lesser heritability ($h^2 = 0.18$) and RT's, while highly correlated among MZ twins (0.74) and DZ twins (0.66), showed modest heritability ($h^2 = 0.16$). ANT efficiency scores have been collected for a mixed population of normal subjects ($N = 400$). PCR-RFLP analysis of buccal swab DNA is used to assay sequence variation in genes involved in dopaminergic and noradrenergic signaling. Statistical associations performed using ANOVA as well as control tests for population stratification using unlinked loci are reported. Sponsored by an NRSA postdoctoral fellowship #1 F32 MH64360-01A1 and NARSAD Young Investigator Award to JAF.

Analysis of Reelin in autism. E. BONORA¹, K.S. BEYER², J.A. LAMB¹, S.M. KLAUCK², A. POUSTKA², A.J. BAILEY³, A.P. MONACO¹, *International Molecular Genetic Study of Autism Consortium (IMGSAC)*⁴. 1) WTCHG, University of Oxford, UK; 2) Department of Molecular Genome Analysis, Deutsches Krebsforschungszentrum, Heidelberg, Germany; 3) Centre for Social, Genetic and Developmental Psychiatry and Department of Child and Adolescent Psychiatry, Institute of Psychiatry, London; 4) <http://www.well.ox.ac.uk/~maestrin/iat.html>.

Autism is a complex neurodevelopmental disorder. Genetic studies indicate that chromosome 7q is likely to contain an autism susceptibility locus. We have used a positional candidate gene approach to identify relevant gene(s) and report here the analysis of Reelin (RELN), a gene located under the peak of linkage. Analysis of a previously reported polymorphic triplet repeat at the 5'UTR and of two intragenic single nucleotide polymorphisms using the transmission disequilibrium test provided no evidence for association with autism in IMGSAC families. The results obtained in the German sample for the triplet repeat showed no evidence of association. Screening the coding regions of RELN in 55 autistic individuals led to the identification of ten missense variants. The exons in which the variants were found were screened in all 169 IMGSAC families and 192 controls. In total, twelve missense variants were identified, five of which were found with similar frequency in controls. Seven variants were not found in controls, three of which did not cosegregate in the affected sibs. Four missense variants were found only in the IMGSAC families and did cosegregate with the disorder in the affected sibs. The four exons in which these variants were identified were screened in an independent sample of 146 German families and 197 German controls. A new missense variant was found and three families carrying two of the four previously identified substitutions were identified. It is difficult to assess the significance of these results in term of contribution to autism susceptibility. The frequency of variants identified is too low to explain the relatively strong linkage results on chromosome 7q. The analysis of RELN suggests that it does not play a major role in autism aetiology, although further analysis is warranted in additional affected individuals.

A genome-wide association study of sporadic amyotrophic lateral sclerosis in Japan. *T. Fukushima*¹, *R. Nakano*¹, *K. Kikugawa*², *T. Inuzuka*³, *A. Miyashita*⁴, *R. Kuwano*⁴, *S. Tsuji*¹. 1) Department of Neurology, Brain Research institute Niigata University, Niigata, Niigata, Japan; 2) Department of Neurology, West Niigata Central Hospital, Niigata, Niigata, Japan; 3) Department of Neurology and Geriatrics, Gifu University, Gifu, Gifu, Japan; 4) Research Laboratory for Molecular Genetics, Niigata University, Niigata, Niigata, Japan.

Purpose: Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disease characterized by a selective loss of upper and lower motor neurons. Approximately 10% of cases are familial, and 15-20% of familial cases have mutations of copper-zinc superoxide dismutase gene. The gene causing an autosomal recessive form of juvenile ALS (ALS2) has also recently been identified. On the other hand, genetic backgrounds of sporadic ALS (SALS), which may be a multifactorial disease, still remains unknown. To find susceptibility loci for SALS, we conducted a genome-wide scan using 811 microsatellite markers. Methods: A total of 84 unrelated Japanese patients with SALS and 95 controls were investigated in this study. Informed consent was obtained from all the subjects. A genome-wide set of 811 microsatellite markers were analyzed using ABI PRISM 3100 Genetic Analyzers. An average distance of each marker is 4.6cM (ABI PRISM Linkage Mapping Set HD-5). The genotyping results were analyzed by the Chi-Square test. For the loci showing the low p value ($p < 0.01$), we conducted detailed association studies using densely distributed microsatellite loci. Results: Among the 811 markers analyzed, we identified one locus with p value < 0.001 on chromosome 18 ($p = 0.00042$) and 8 loci with $0.001 < p < 0.01$. From the detailed association studies, we identified the loci on chromosomes 2 and X with two neighboring loci that gave $0.001 < p < 0.01$. The present study suggests possible SALS susceptibility loci. To further characterize these loci, we are currently conducting a genome scan using more closely distributed markers.

CITED2 is not a major determinant of human NTDs. V. Capra¹, P. De Marco¹, A. Moroni¹, E. Merello¹, A. Raso¹, S. Dunwoodie², A. Cama¹. 1) Lab Servizio Di Neurochirurgia, Inst Scientifico G Gaslini, Genova, Italy; 2) Developmental Biology Unit, Victor Chang Cardiac Research Institute, St Vincent's Hospital, Darlinghurst, NSW 2010, Australia.

Defects of embryonic neural tube closure (NTDs), anencephaly and Spina Bifida, are among the most common human birth defects. Their causes are at least in part genetic, but the genes contributing to human NTDs have not been identified. Maternal periconceptional folate supplementation can reduce risk of NTDs, even if the mechanisms for such preventive effect are until now unknown. Most genetic understanding of neural tube closure is derived from studies of animal models. Gene knock-out technology and spontaneous mutations in mice have produced a series of mutants exhibiting exencephaly or spina bifida, but they differ from the human NTDs in having mendelian, highly penetrant genetic transmission pattern and in having a syndrome of multiple developmental defects. Among them, the Cited2 mutant mouse represents the first genetic model in which folic acid treatment significantly reduces the exencephalic phenotype and prevents a defect in neural tube closure by a mechanism other than compensation of an intrinsic folate related defect in the embryo. In particular, the Cited2^{-/-} mutants died at late gestation and exhibited heart defects and exencephaly, arising from defective closure of the midbrain and hindbrain. Cited2 is a member of a new conserved gene family that comprises genes that bind transcriptional coactivators. It is expressed during mouse development and in adult tissues. In this study we explored the possible involvement of the homologous gene CITED2 in human NTDs malformations by SSCP analysis of 32 patients with myelomeningocele and Chiari II malformation and 31 individuals affected by Chiari I malformation. No crucial shift could be detected in any of the exons examined. Anyway, a possible role of CITED2 in NTDs etiology cannot be excluded because variations in the promoter region and in the introns have not yet been studied. In conclusion, our data, although preliminary, provide evidence that CITED2 does not play a major role in the etiology of human NTDs.

Specific BACE1 Genotypes Provide Additional Risk for Late-Onset Alzheimer Disease in APOE-e4 Carriers. J.-L. Blouin¹, G. Gold², F.R. Herrmann², A. Michon², R. Mulligan², G. Duriaux Saïl¹, C. Bouras², P. Giannakopoulos², S.E. Antonarakis¹. 1) Medical Genetics, University of Geneva School of Medicine and University Hospitals, Geneva, Switzerland; 2) Departments of Psychiatry and Geriatrics, University Hospitals, Geneva, Switzerland.

Alzheimer's disease (AD) is characterized neuropathologically by neurofibrillary tangles and senile plaques in brain. A key component of plaques is Ab, a 40-42 residue polypeptide derived from Ab-precursor-protein (APP) through cleavage catalyzed by secretases (b,g). b-secretase is the rate-limiting enzyme, which represents an alternate to normal a-secretase cleavage. Sequence variation in genes BACE1 (chromosome 11q23.3) and BACE2 (21q22.3), which encode two closely related proteases that appear to act as b-secretase, may represent a strong genetic risk factor for AD. To address this issue, we analyzed the frequencies of 2 SNPs in BACE1 (V262, dbSNP rs#638405) and BACE2 (chr.21-cSNP #hc21s00169, dbSNP rs#12149) respectively in a community-based sample of 96 individuals with late-onset AD followed in geriatric and psychiatric clinics (mean age = 79.9; SD 9.3 ; 45% men) and 170 controls randomly selected among residents of the same community who underwent extensive mental status testing (Epidemiological study of dementia, mean age = 74.7 ; SD 7.4 ; 48% men). Genotype and allele distribution analysis in both groups did not demonstrate any association between AD and BACE1 or BACE2 (Fisher's exact test) in agreement with the recently published studies (Nowotny et al., 2001, Murphy et al., 2001). However, after stratification for APOE status, an association between a BACE1 SNP in codon V262 (genotype GG) and AD in APOE-e4 carriers was observed (p=0.03). Furthermore, when our results are combined with those of Nowotny et al. (2001), the described association becomes highly significant (p=0.003). These results strongly suggest that specific BACE1 haplotypes further increase AD risk in APOE-e4 carrier, possibly through a linkage disequilibrium with other undetected variants in BACE1 which may have a functional effect. (Authors J.-L.B. and G.G. have equal contribution).

Mutation analysis of genes regulating the hypothalamo-pituitary adrenal (HPA) axis in patients with depressive syndrome. *E.B. Binder*¹, *P. Lichtner*², *M. Uhr*¹, *Th. Bettecken*², *T.M. Strom*², *T. Meitinger*², *S. Modell*¹, *F. Holsboer*¹. 1) Max-Planck Institute of Psychiatry, Munich, Germany; 2) Institute of Human Genetics, GSF National Research Center, Munich-Neuherg, Germany.

A series of clinical and preclinical data indicate that a hyperactivity of the HPA-axis may underlie depressive symptomatology. We have shown that depressed patients can be divided into two groups: one showing a drastical hyperactivity of the HPA-axis that normalizes with remission; the other not displaying an increased activity of the HPA-axis. HPA-axis activity was measured using the Dexamethasone suppression/corticotropin releasing hormone-stimulation (Dex-CRH) test within 10 days of admission to the psychiatric ward. Hamilton Depression Rating Scale scores at the time of the test were above 18 in all patients and did not differ between the groups. These two subgroups may thus represent two biologically and possibly genetically distinct subtypes of depressed patients. To investigate whether these subtypes differ with respect to polymorphisms in genes regulating the HPA-axis, we screened the following seven genes for polymorphisms: CRH and vasopressin (AVP), which regulate the axis at the hypothalamic level, and BAG1, STUB1, P23, FKBP4, FKBP5, which are chaperones of the glucocorticoid receptor that have been shown to regulate glucocorticoid receptor function in *in vitro* experiments. Polymorphism screening was performed using capillary electrophoresis SSCP analysis and subsequent sequencing in 47 depressed patients with hyperactive HPA axis vs. 47 patients with normal HPA-axis activity. Up to 1000 bp of the 5 untranslated region and all exons, including exon/intron junctions were analyzed. Several rare and novel polymorphisms could be identified. Some of these polymorphisms will be tested for association with HPA-axis activity in depressed patients as well as for association with depressive symptomatology in a case/control sample. To that aim genotyping will be performed in 188 patients with Dex-CRH test and 188 healthy age- and sex-matched controls.

PICK1, a gene on chromosome 22q13: a putative regulator of serine racemase and D-serine. *K. Fujii^{1,2}, J. Xia¹, P. Dulloor¹, Y. Ozeki¹, N. Yamada², M. Ohkawa², C.A. Ross¹, S.H. Snyder¹, R.L. Huganir¹, A.E. Pulver¹, A. Sawa¹.* 1) Depts. of Psychiatry and Neuroscience, Johns Hopkins Univ. Sch. of Med. Baltimore, MD; 2) Shiga Univ. of Med.Sci. Otsu, Japan.

There has been growing evidence suggesting that dysfunction or down-regulation of NMDA neurotransmission may contribute to the manifestations of schizophrenia. D-serine is a putative endogenous co-agonist for the glycine site of NMDA receptor, and clinical trials of D-serine with classical neuroleptics can improve part of the symptoms in schizophrenic patients, suggesting a role of D-serine in schizophrenia. We have evaluated roles of serine racemase (SR), an enzyme synthesizing D-serine, in the pathogenesis of schizophrenia. Through yeast two-hybrid screenings, we have identified protein interacting with C kinase (PICK1) as a potential interacting molecule with SR. By yeast two-hybrid assay and in vitro protein binding assay, we confirmed that the PICK1/SR binding requires PDZ domain and coiled-coil domain in PICK1. In cellular models, PICK1 can contribute to re-distribution of SR; this redistribution is specifically augmented by the addition of TPA, a protein C kinase activator. The gene for PICK1 is located on chromosome 22q11-13, a schizophrenia susceptibility locus in linkage analyses. Based on our hypothesis that genetic variations (mutations, polymorphisms) in the PICK1 gene may interfere with SR enzymatic activity, D-serine production, and NMDA neurotransmission in schizophrenia, we have analyzed the PICK1 gene in schizophrenic probands whose families demonstrated excess allele sharing among the affecteds in this region. We have found a couple of novel polymorphisms in PICK1 gene through sequence analyses in the patient samples. The polymorphisms examined thus far are located in intronic regions just adjacent to exon-intron boundaries. We are extending the sequencing analyses to normal populations and sporadic schizophrenics. We are also analyzing whether these novel intronic polymorphisms influence exon usages as well as functions of PICK1 and SR proteins.

Evidence for allelic association between three chromosome 8p21.3-22 markers and schizophrenia points to the brain expressed microtubule associated protein gene, Pericentriolar Material (PCM1) as a candidate for increasing genetic liability to schizophrenia. *H.M.D. Gurling¹, E. Blaveri¹, S. Datta¹, G. Kalsi¹, J. Lawrence¹, D. Quested⁵, H. Moorey³, G. Lamb³, U. Chowdhury³, D.H. Blackwood⁴, W.J Muir⁴, D. Curtis².* 1) Molecular Psychiatry Lab. Windeyer Inst, University College London Med Sch, London, England; 2) City and East London Mental Health Trust, Royal London Hospital, Whitechapel, London, UK; 3) Camden and Islington Mental Health and Social Care Trust, St Pancras Hospital, London, UK; 4) Department of Psychiatry, University of Edinburgh, Royal Edinburgh Hospital, Morningside Park, Scotland, UK; 5) West London Mental Health Trust, St Bernards Hospital, Ealing, London, UK.

Three linkages to a chromosome 8p21-22 schizophrenia locus with lods above 3.00 have been reported (Blouin 1999, Brzustowicz 1999, Gurling 2001). In a case control study of 137 schizophrenics of UK ancestry and 316 matched controls, 3 markers; D8S2615, D8S2616 and D8S261, all within 108 kb, showed allelic association with schizophrenia with p values of 0.004, 0.024 and 0.01, respectively, after Monte Carlo correction for multiple alleles. Replication in a 2nd sample of 100 Scottish cases and 100 controls was found with D8S2616 ($p < 0.04$ after MC correction) but not in the 3rd sample of 100 cases and 100 controls. The combined UK and Scottish cases (N 337) and controls (N 516) showed significant association for all three markers after correction. We have identified a narrow region of 8p22, containing only the PCM1 gene, as being involved in the cause of schizophrenia. We sequenced the PCM1 gene in chromosome 8p22 associated schizophrenic cases and found several exonic base pair variants and insertion/deletions which still need to be investigated fully in relation to schizophrenia. If confirmed, better methods for diagnosis and prognosis can be created. The pinpointing of a new protein target and its neurochemical pathway will lead on to better prevention and new drug treatments for schizophrenia. Blouin JL 1999 *Nature Genetics*, 20, 70-73. Brzustowicz LM 1999 *Am J Hum Genet* 65,1096-1103. Gurling HM 2001 *Am J Hum Genet* 68, 661-673.

Genetic markers showing linkage disequilibrium with a chromosome 8p22 schizophrenia susceptibility locus near the pericentriolar material gene (PCM1) are associated with reduced left orbitofrontal cortex grey matter volume and other cerebral morphology changes at MRI compared to non chromosome 8p22 associated schizophrenics. *E. Blaveri¹, H.D. Critchley², H.M.D Gurling¹, O. O'Daly¹, G. Kalsi¹, S.R. Datta¹, A. McQuillin¹, H. Moorey³, D. Quested⁴, D. Curtis⁵, J. Lawrence¹, N. Bass¹, C.D. Good², R.S. Frackowiak², R. Dolan².* 1) Molecular Psychiatry Lab. University College London, London, England, UK; 2) Functional Imaging Laboratory, Wellcome Department of Imaging Neuroscience, Institute of Neurology, University College London, England, UK; 3) Camden and Islington Mental Health and Social Care Trust, St Pancras Hospital, London, UK; 4) West London Mental Health Trust, St Bernards Hospital, Ealing, London, UK; 5) City and East London Mental Health Trust, Royal London Hospital, Whitechapel, London, UK.

In 137 unrelated UK cases of schizophrenia and 316 matched controls we found three markers showing significant allelic association with schizophrenia at or near the PCM1 gene locus after correction for multiple alleles. PCM1 is a microtubular associated protein and could increase liability to schizophrenia. Fourteen schizophrenic patients who had inherited the chromosome 8 alleles associated with schizophrenia at two out of the three loci volunteered for brain morphology studies using MRI. They were compared to a sample of non chromosome 8 associated schizophrenics and two matched normal control groups. MRI data was analysed with age and gender as confounding covariates and corrected for total intracranial volume. A region of left orbito-frontal cortex showed significantly reduced grey matter in chromosome 8 associated schizophrenics (SZ8) compared to non chromosome 8 associated schizophrenics (SZ0) or controls ($p=0.003$). Differences in combined grey plus white matter and grey matter volumes between SZ8 patients and normal controls reached significance whereas no differences were found for these volumes between SZ0 cases and normal controls. SZ8 cases also demonstrated significant reductions in inferior and anterior thalamic grey matter volume and total brain volume compared to SZ0 cases.

Saturation mapping of bipolar affective disorder (BPAD) susceptibility locus on chromosome 20p11.2-q11.2. A.N. Akarsu¹, S. Kara-Ozer², Z. Yuncu³, B. Girgin¹, H. Okur¹, A. Sir⁴, H. Herken⁵, S. Senol⁶, U. Radhakrishna⁷, J.L Blouin⁷, R. Lyle⁷, S. Vahip³, A. Gogus², A. Ulusahin², S. Antonarakis⁷ and Bipolar Genetics Study Group of Turkey. 1) Gene Mapping Laboratory, Ped. Res. Cent. Hacettepe Univ. Ankara and Psychiatry Departments of; 2) Hacettepe; 3) Ege; 4) Dicle; 5) Gaziantep; 6) Gazi Universities, Turkey; 7) University of Geneva Medical School, Switzerland.

We have previously identified a strong linkage to chromosome 20p11.2-q11.2 in a large autosomal dominant Turkish family with BPAD (*Eur J Hum Genet* 9: 39-44, 2001). We have further initiated a systematic sample collection strategy which targets large families, sib pairs, parent offspring trios as well as sporadic cases and controls to reduce the critical interval. We have also updated the original pedigree (BP-TU1) by adding new members and reexamined younger generation (not affected by the time of the study). We have now over 600 samples from 254 index cases including 90 parent-offspring trios and 26 multiplex families. Suspicious segregation between the disease allele and the DNA markers from 20p region was observed only in 2 out of 26 families. Since we have observed common alleles for the markers D20S880 and D20S481 in these families a case control study has been performed in 158 affected samples and 130 controls (age and ethnically matched). Marker D20S481 gave 11 alleles and allele 5 (237 bp) was the most frequent allele in Turkish population with an allele frequency of 0.335. A significant association between the allele 4 (241 bp) and BPAD phenotype was observed ($p=0.042$). Furthermore, several affected individuals ascertained from the vicinity of BP-TU1 pedigree demonstrated partial haplotype association between the DNA markers D20S911, D20S880, D20S119, D20S481, D20S1151 harbouring D20S119 and D20S481 core. KCNS1 is a member of voltage gated potassium channels and is expressed only in the brain. This gene was also physically mapped to the same region with markers D20S119 and D20S481. Mutation screening in the coding region of KCNS1 gene is in progress. Support: Hacettepe University Research Foundation(Grant:01 01 101 001). nakarsu@hacettepe.edu.tr.

Association between DRD4 VNTR allele-length and the amplitude of event related potentials (ERP) during a visual attention task in attention deficit/hyperactivity disorder (ADHD) children. A. Birca, I. Fortier, L.R. Simard, P. Robaey. Hôpital Sainte-Justine, Montral, Qc, Canada.

Both genomewide and candidate gene screens have been used to identify susceptibility genes of ADHD, a complex trait with a strong genetic component. The best candidates to date are the dopamine transporter (DAT1) and D4 receptor (DRD4) genes but these associations have not always been replicated. There are a number of methodological reasons for this discordance including extensive clinical heterogeneity. Therefore, we hypothesized that more consistent associations could be revealed within ADHD children by using behavioural and brain electrical responses obtained during a visual attention task. To this end, 31 ADHD children from 6 to 9 years of age (22 boys and 9 girls) undertook a selective visual attention task during which EEGs were recorded and blood samples drawn to genotype the 48-bp VNTR in exon 3 of the DRD4 gene. ADHD children were divided into 2 groups: those with long alleles (³⁷R) and those without (<7R). Association between the DRD4 genotype and performance measures (mean reaction time, intra-subject variability and number of correct responses) or the amplitude of two ERP components: P450 (parietal sites) and N530 (anterior frontal sites) over the left and right hemispheres to target and non-target stimuli was assessed by ANOVA. No group differences were found for performance measures. On the other hand, there was a significant main effect of genotype on the P450 amplitude ($F=4.49$, $p=0.043$). This effect was greatest over the right hemisphere in response to non-targets (21.6 ± 9 mV vs. 13.5 ± 11.1 mV in ³⁷R vs. <7R groups, respectively; $t=-2.14$, $p=0.041$). We also observed a positive correlation between VNTR allele length and P450 amplitude ($R^2=0.418$, $p=0.019$). No group differences were observed for N530; however, we did detect a tendency towards higher N530 amplitudes over anterior frontal sites in the ³⁷R group, especially in response to non-target stimuli. This pilot study represents the first step towards linking sequence variants in potential ADHD susceptibility genes and specific phenotypes of brain function. Funded by FRSQ and HSJ.

CYP26A1 and RALDH2 are not implicated in the development of human neural tube defects. *M. Dickerson¹, J. Joseph¹, T.M. George², D.S. Enterline³, E.C. Melvin¹, J.R. Gilbert¹, E. Linney⁴, M.C. Speer¹ and NTD Collaborative Group.* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Department of Surgery, Duke University Medical Center, Durham, NC; 3) Department of Radiology, Duke University Medical Center, Durham, NC; 4) Department of Molecular Genetics and Microbiology, Duke University Medical Center, Durham, NC.

Retinoids (vitamin A and its derivatives) are necessary for normal growth and development of the embryo. CYP26A1 and RALDH2, genes whose products are responsible for positioning and limiting the influence of retinoic acid in the developing embryo, have a synergistic relationship. RALDH2 helps metabolize Vitamin A into retinoic acid so it can be used by the cells; CYP26A1 serves to degrade or confine retinoic acid in order to protect the cells from exposure to excess amounts particularly in the caudal end. Mis-regulation of retinoic acid exposure to the developing embryo is responsible for a variety of birth defects, including neural tube defects. This relationship has been identified through studies both in mouse and zebrafish. We investigated these genes using denaturing high performance liquid chromatography (DHPLC) as candidate genes for neural tube defects (NTD)s. The screen included 477 cases with NTD, organized into 95 pools with approximately 5 cases each. Coding sequences for the 13 exons in RALDH2 and 7 exons in CYP26A1 have been evaluated. SNPs have been identified in intron 8 and exon 11 of RALDH2 and, to date, no variation has been identified in CYP26A1. Thus, these results suggest that RALDH2 and CYP26A1 are unlikely to represent major genes that influence the development of neural tube defects in humans.

APOE- e4 in association with persistent neurocognitive impairment after traumatic brain injury. D.B.

Arciniegas^{1,2}, J.L. Topkoff¹, C.M. Filley^{1,2}, L.E. Adler¹, K.A. Ricketts³, E.B. Spector³. 1) Psychiatry, Univ. CO School of Medicine, Denver, CO; 2) Neurology, Univ. Co School of Medicine, Denver, CO; 3) Pediatrics, Univ. CO School of Medicine, Denver, CO.

Neuroimaging, neurophysiologic, and neurogenetic studies may improve understanding of the neurobiological bases of impaired cognition due to mild TBI, and may be of service in the development of rationale therapies for persistently impaired TBI survivors. We reported convergent evidence of structural and functional hippocampal abnormalities among persons with chronically impaired sensory gating, attention, and memory following TBI at all levels of initial severity. While we interpreted the comparable neurobiological findings in these groups as a reflection of our subject selection methods (relatively unfavorable outcome following mild TBI and relatively good outcome following severe TBI), the observation of comparable structural and functional abnormalities between groups with disparate initial injury severity requires further explanation. The APOE-e4 genotype has been associated with relatively poor cognitive, motor, and functional outcome following repetitive injury or severe TBI. Our subject selection procedures produced a relatively "poor outcome" mild TBI group and a relatively "good outcome" moderate/severe TBI group; we hypothesized that the frequency of the APOE-e4 genotype would be highest in the former group. APO-e4 genotypes of 26 subjects with mild or moderate/severe TBI participating in our previous studies were determined. 11/26(42%) TBI subjects are carriers of one APOE-e4 allele. Among those with mild TBI, 9/18 (50%) are APOE-e4 carriers, while only 2/8 (25%) with moderate-severe TBI are APOE-e4 carriers. Binomial statistical comparison of the frequency of APOE-e4 status in the mild TBI group differs significantly ($p < .03$) from the APOE-e4 expected frequency (28%) in a demographically comparable normal population. These preliminary results suggest that the APOE-e4 genotype may be an important factor in outcome following mild TBI, and may be useful in the effort to understand the basis of relatively poor cognitive outcome experienced some ostensibly "mildly" injured patients.

Modifier effects in autism at the DBH and MAO-A loci. *M.B. Jones¹, R. Palmour², L. Zwaigenbaum³, P. Szatmari⁴.*
1) Dept. of Behavioral Sciences, Penn State Univ College of Med, Hershey, PA; 2) Dept of Psychiatry, McGill Univ, Montreal Canada; 3) Dept. of Pediatrics, McMaster Univ, Hamilton, On, Canada; 4) Dept of Psychiatry, McMaster Univ, Hamilton, On, Canada.

Autism is a neuropsychiatric disorder that presents with marked variation in symptoms and adaptive functioning. The disorder is caused in large part by genetic mechanisms though no disease genes have yet been identified. The objective of this study was to investigate the role of the DBH and MAO-A genes in increasing risk for the disorder and in modifying the severity of the phenotype, specifically IQ. We assembled 67 sib pairs and 45 singletons with an autism spectrum disorder as determined by the ADI-R, ADOS and best-estimate diagnosis. Two different markers were genotyped in the DBH gene and one in the MAO-A gene. Allele frequencies among affected children and first degree relatives were determined and susceptibility effects through both the maternal and fetal genotypes were estimated using log linear models. Modifier effects were assessed by comparing the number of autistic symptoms and IQ of the affected children as a function of the maternal and fetal genotypes. Sizeable and significant modifier effects on IQ in affected children were found at both the DBH and MAO-A loci. For example, the low activity alleles at the DBH locus were associated with higher IQ among affected children. No modifier effects were found when autistic symptoms were compared as a function of maternal or fetal genotype. Susceptibility effects were also found but fewer, weaker and more open to question. DBH appears to act both in the mother (via the intra-uterine environment) and in the fetus to modify level of functioning whereas MAO-A acts only in the mother. The results are consistent with the hypothesis that in children at risk for autism, high levels of dopamine in utero are associated with higher IQ and low levels with lower IQ. The results have implications for the role of dopamine in autism and for the detection of modifier genes in other complex genetic disorders.

***PRODH* mutations and hyperprolinemia in schizophrenic patients.** H. Jacquet¹, G. Raux¹, F. Thibaut^{1, 2}, B. Hecketsweiler³, E. Houy^{1, 2}, C. Demilly², S. Haouzir², G. Allio², V. Drouin⁴, J. Bou¹, M. Petit^{1, 2}, D. Champion^{1, 2}, T. Frebourg^{1, 4}. 1) INSERM EMI 9906, Faculty of Medicine, Rouen; 2) Department of Psychiatry; 3) Department of Biochemistry; 4) Department of Genetics, CHU de Rouen, 76031 Rouen, France.

The increased prevalence of schizophrenia among patients with the 22q11 interstitial deletion associated with the DiGeorge syndrome has suggested the existence of a susceptibility gene for schizophrenia within the DiGeorge syndrome chromosomal region (DGCR) on 22q11. Screening for genomic rearrangements of 23 genes within or at the boundaries of the DGCR in 63 unrelated schizophrenic patients and 68 unaffected controls, using Quantitative Multiplex PCR of Short Fluorescent Fragments (QMPSF), led us to identify, in a family including two schizophrenic subjects, an heterozygous deletion of the entire *PRODH* gene encoding the proline deshydrogenase. This deletion was associated with hyperprolinemia in the schizophrenic patients. In addition, two heterozygous *PRODH* missense mutations (L441P and L289M), detected in 3/63 schizophrenic patients but in none among 68 controls, were also associated with increased plasma proline levels. Segregation analysis within the two families harboring respectively the *PRODH* deletion and the L441P mutation showed that the presence of a second *PRODH* nucleotide variation resulted into higher levels of prolinemia. In a patient suffering from type I hyperprolinemia with severe neurological manifestations, we identified an homozygous L441P and an heterozygous R453C mutation of the *PRODH* gene. These observations suggest that the genetic determinism of type I hyperprolinemia, characterized by a deficiency of proline deshydrogenase enzyme, is complex, the severity of hyperprolinemia depending on the number of hits affecting the *PRODH* locus and demonstrate that type I hyperprolinemia is present in a subset of schizophrenic patients.

Allelic variation at genes encoding NRCAM and NrCAM ligands and possible associations with substance abuse vulnerability. *H. Ishiguro, G. Uhl.* Molecular Neurobiology, NIDA, NIH, Baltimore, MD.

NrCAM is a single-TM domain protein that binds to ligands expressed on other cells in ways that alter cell contacts and are likely to change tyrosine kinase activities. In initial association-based scans for drug abuse vulnerability alleles in a chromosome seven region linked to alcoholism by COGA investigators, we have identified an NrCAM haplotype that includes 3 silent or missense SNPs which is present at lower frequencies in several samples of Caucasian substance abusers and higher frequency in a sample of African-American polysubstance abusers. We have separately identified NrCAM as a morphine- regulated gene in subtracted hybridization/PCR differential display studies, and found that it is expressed by neurons in brain regions that could play important roles in memory and addiction. To help elucidate possible roles for NrCAM locus variation in addiction vulnerability, we have examined association of markers at the loci of the genes for NrCAM ligands expressed in brain including: CHL1, contactins 2(axonin/TAG-1) and 5, receptor protein tyrosine phosphatase beta (RPTPbeta)and RPTPbeta homolog. We have compared marker frequencies in 177 unrelated Caucasian alcoholics and controls from the COGA study. Markers that displayed nominal significant differences were tested using Caucasian and African American abuser and control individuals recruited at the NIDA-IRP. An RPTPbeta gene haplotype was defined by SNP variants that were 1.3-1.4-fold more abundant in abusers. Abusers who displayed both the Pro526 NrCAM and 127G RPTPbeta alleles were 1.5-3 fold more frequent than controls. These data provide additional evidence that now tentatively implicate several NrCAM gene family members in substance abuse vulnerability.

Search for genetic contribution to the neurotoxic effects of thimerosal (ethylmercury) in mouse strains. *D.Y. Kim, J. Gitschier.* HHMI, University of California, San Francisco, CA.

Thimerosal, a commonly used preservative that is 49.6% ethylmercury by weight, has been implicated as a potential cause of autism. We hypothesize that genetic susceptibility to mercury toxicity could underlie the development of autism in some cases. To assess genetic influences in an animal model, we have begun to investigate the effects of thimerosal on the inbred mouse strains C57BL/6, FVB/N, BALB/cBy, 129S1/SvIm, and the outbred strain CD1. Mice from these different strains have been given a one-time subcutaneous injection between postnatal days 7 to 16. They have been observed and followed weekly using the SHIRPA protocol, an assessment used for general behavioral and functional testing. Preliminary results have shown that death typically occurs at a dose of 100mg/kg. At 50mg/kg, the C57BL/6 strain test group demonstrates hyperarousal and delayed eye opening compared a buffer-injected C57BL/6 group at approximately 2 weeks post-injection. However, by post-injection week 5, the experimental and control groups appear to perform comparably upon testing. In addition, within the CD1 outbred strain we may have identified several mice that display unusual resistance to thimerosal's effects. One CD1 mouse out of 16 survived a 300mg/kg dose of thimerosal and 5 out of 15 mice have survived a dose of 200mg/kg. On SHIRPA testing, the survivors perform as well as control animals even at 70 days post-injection, which suggests that these mice may represent a thimerosal-resistant strain. We are in the process of breeding these mice and will be observing the progeny for their response to thimerosal. Also, we are testing other inbred strains at a dose of 75mg/kg, a sublethal dose that is likely to elicit some neurologic effect based on our preliminary data.

DISC-1: Its function and possible implication for mental illnesses. *Y. Ozeki¹, K. Fujii^{1,2}, J. Kleiderlein¹, U. Park¹, X. Luo¹, A. Kamiya², N. Yamada², M. Ohkawa², S.H. Snyder¹, C.A. Ross¹, A. Sawa¹.* 1) Department of Psychiatry and Neuroscience, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Psychiatry, Shiga University of Medical Science, Otsu, Shiga, Japan.

DISC-1 (Disrupted-in-Schizophrenia-1) was identified as a transcript with an open reading frame that is disrupted as a result of translocation in a large Scottish family with major mental illness including schizophrenia and mood disorders. There has been growing evidence that DISC-1 may be a candidate gene for such psychiatric illnesses. We have investigated expression of DISC-1 protein in the brain using several antibodies we have raised. DISC-1 protein expression was more prominent in developing brains when compared with adult brains. In cellular models, DISC-1 protein was induced in PC12 cells upon their differentiation by NGF. To clarify physiological roles of DISC-1, we have performed the yeast two-hybrid screen. Most of the DISC-1 interactors have roles in neural development. We have already confirmed the interaction and co-distribution of NUDEL and DISC-1 with biochemical and immunofluorescent methods. To analyze DISC-1 functions further, we have also tried overexpression or knocking-down expression of DISC-1 in cellular models. We have found that DISC-1 self-dimerizes (or oligomerizes) in cells, which was addressed by co-immunoprecipitation experiments. Such self-dimerization occurred not only between full-length DISC-1 proteins, but also between the C-terminal truncated DISC-1 proteins (the putative disease protein resulting from the chromosomal translocation and the subsequent DISC-1 gene disruption) as well as the combination of full-length and C-terminal truncated DISC-1. These results are consistent with gain of function or dominant negative models in dominant genetic transmission, although we do not exclude the possibility of a haploinsufficiency model.

Polyglutamine Binding Peptide 1 (QBP1) inhibits polyglutamine aggregation and rescues neurological phenotypes in *Drosophila* polyglutamine disease models. Y. Nagai¹, N. Fujikake², K. Ohno⁴, H. Higashiyama², T. Inui³, H.A. Popiel¹, Y. Urade³, M. Yamaguchi⁴, W.J. Strittmatter⁵, J.R. Burke⁵, T. Toda¹. 1) Div Functional Genomics, Dept Post-Genomics&Diseases, Osaka University Graduate School of Medicine, Suita, Japan; 2) The Fourth Dept; 3) The Second Dept, Osaka Bioscience Institute, Suita, Japan; 4) Chr Tech Group, Div Biotechnology, Kyoto Institute of Technology, Kyoto, Japan; 5) Dept Medicine (Neurology), Duke University Medical Center, Durham, NC.

Polyglutamine (polyQ) diseases are a growing class of at least nine inherited neurodegenerative diseases including Huntingtons disease, various types of spinocerebellar ataxia, and spinobulbar muscular atrophy. They are caused by abnormal expansions of the polyQ stretch in each unrelated disease protein. Expansion of the polyQ stretch is considered to confer toxic properties on the disease proteins through alterations in their conformation, leading to pathogenic protein-protein interactions including aggregate formation. By phage display screening, we previously identified Polyglutamine Binding Peptide 1 (QBP1), a peptide sequence that preferentially binds the expanded polyQ stretch and is expected to interfere with the pathogenic properties of the expanded polyQ stretch. We showed the ability of QBP1 to inhibit polyQ protein aggregation *in vitro* and to suppress polyQ-induced cell death in cell culture. Using *Drosophila* polyQ disease models, we show here that QBP1 inhibits polyQ aggregation, suppresses polyQ-induced compound eye degeneration, and most importantly rescues polyQ-induced premature death. Structural analysis using circular dichroism suggests that QBP1 inhibits aggregation of the expanded polyQ protein by masking its binding surface rather than by affecting its conformation. Selective inhibition of the pathogenic interactions of expanded polyQ stretches by QBP1 is a useful strategy for developing potential therapies for the currently untreatable polyQ diseases.

The 5HT1Db Receptor Gene in Autism: Case-Control Study and Genotype-Phenotype Correlation Analysis in Multiplex Families. *X. Liu¹, E. Mundo², C. Zhang¹, JJA. Holden¹.* 1) Department of Psychiatry & Physiology, Queen's University, Cytogenetics & DNA Research Lab, Ongwanada Resource Centre, Kingston, ON, Canada; 2) Centre for Addiction and Mental Health, Clarke Site, University of Toronto, ON, Toronto, Canada.

Autism is a severe neurodevelopmental disorder with a complex genetic etiology, likely involving multiple genes. Increased blood and urinary serotonin (5HT) levels, the positive effects of 5HT re-uptake inhibitors on symptoms in autistic patients, and the proven role of 5HT in neurodevelopment have prompted extensive investigations of the serotonin system genes in autism. 5HT1Db gene has earned increased attention because of its essential role in the regulation of 5HT release and the use of 5-HT1Db receptor agonists to ameliorate autism-related symptoms in other psychiatric disorders. We therefore genotyped the G861C SNP in the 5-HT1Db gene in two sets of multiplex autistic families: 47 Canadian families and 81 US families (the latter were from AGRE). Case-Control comparison showed: Allele C, genotype GC and genotype CC have significantly higher frequencies in affected children from Canadian families compared to Canadian controls ($\chi^2 = 5.081$, $p = 0.024$, $df = 1$ for allele; $\chi^2 = 6.890$, $p = 0.032$, $df = 2$ for genotype; if GC and CC combined, $\chi^2 = 5.941$, $p = 0.015$, $df = 1$). A similar, non-significant trend was seen in the AGRE families. Genotype-phenotype correlation analysis using ADI-R data, showed that children with one or two copies of the C allele have significantly more severe impairment in communication ($F = 10.546$, $p = 0.002$) and social interaction ($F = 4.266$, $p = 0.04$) compared to children without the C allele. Strikingly, almost all (98%) autistic children with one copy of the C-allele had severe communication problems compared to only 80% of those homozygous for the G-allele ($\chi^2 = 7.411$, $p = 0.006$, $df = 1$). Taken together, either the G861C polymorphism in the 5HT1Db gene or a closely linked variation in 5HT1Db or another adjacent gene, appears to be a risk factor that modifies symptoms in persons with autism. (Supported by grants to JJAH from the CIHR and the OMHF).

APOE Promoter Region SNPs, APOE Genotype, and risk of Alzheimer Disease (AD) in Cases, Controls, and Families. *K.K. Nicodemus¹, C. Allen¹, A.D. Roses², A.M. Saunders¹, G. Small³, D. Schmechel¹, P.M. Conneally⁴, J.L. Haines⁵, J.G. Gilbert¹, J.M. Vance¹, M.A. Pericak-Vance¹.* 1) Ctr Human Genetics, Duke Univ Med Ctr, Durham, NC; 2) GlaxoSmithKline, Research Triangle Park, NC; 3) Univ of CA at LA; 4) IN Univ, Indianapolis IN; 5) Prgrm Human Genetics, Vanderbilt Univ Med Ctr, Nashville TN.

APOE is the only identified genetic risk factor for late-onset AD, although the presence of the APOE-4 allele is neither necessary nor sufficient. It may be that SNPs in the promoter region (PR) of AD modulate transcription of APOE4. Although several have considered individual SNPs (A491T, C427T, G219T, and C113G) and 2-SNP haplotypes in case/control studies, ours is the first to assess the risk associated with these SNPs and combinations of these SNPs in families as well as in cases/controls. We also typed an additional SNP (C5361T) with an unknown effect on risk of AD. Because the PR SNPs are physically close to the SNPs that are used to determine APOE genotype, we expected strong linkage disequilibrium between the PR SNPs and APOE genotype, and thus all analyses were stratified by APOE genotype. In a sample of 45 discordant sibship families where all individuals were APOE 3/4, association results with individual SNPs showed increased risk with 491A ($p=0.02$) and 427T ($p=0.03$). Global tests for 2-SNP haplotypes revealed a positive association between 491A-427T haplotype and AD (single haplotype $p=0.008$; global $p=0.06$). However, in families where all individuals were APOE 4 negative ($n=26$), single SNP and 2-SNP haplotype analysis revealed no association between APOE PR SNPs or haplotypes and risk of AD. Confirming a previous study, in APOE 3/3 cases versus controls ($n=378$) we observed an increase in risk of AD in individuals who carried the 113G allele (OR=1.77; 95% CI 1.07, 2.92; $p=0.03$), and we also found an increased risk associated with the 113G-5361T haplotype in this group (haplotype $p=0.004$; global $p=0.04$). In conclusion, we found evidence that APOE PR SNPs may play a small role in increasing the risk of AD in individuals who have one or no APOE-4 alleles.

Association between catechol-O-methyl transferase gene polymorphism and wearing-off and dyskinesia in Parkinson's disease. *M. Watanabe*¹, *S. Harada*², *T. Nakamura*², *N. Ohkoshi*¹, *K. Yoshizawa*³, *A. Hayashi*¹, *S. Shoji*¹. 1) Neurology/Inst Clinical Sci, Tsukuba Univ, Tsukuba, Japan; 2) Legal Medicine/Inst Community med, Tsukuba Univ, Tsukuba, Japan; 3) Neurology National Mito Hospital, Mito, Japan.

Catechol-O-methyl transferase (COMT) is an enzyme that inactivate catecholamines, including levodopa. An amino acid change (Val-108-Met) in the COMT protein has been found to result in a change from high to low enzyme activity. In the present study we genotyped 121 Japanese patients with Parkinson's disease (PD) and 100 controls. Comparison of the allele frequencies revealed that homozygosity for the low-activity allele was significantly more common among PD patients than the control ($P=0.047$, odds ratio=3.23). In addition, homozygosity for the low-activity allele was over-represented in PD patients that exhibited the "wearing-off" phenomenon ($P=0.045$, odds ratio=3.82) or dyskinesia ($P=0.030$, odds ratio=4.80) compared to controls, although these differences were not significant after Bonferroni's correction. Our results may help in the understanding of the mechanism that cause complication of levodopa therapy in PD patients.

High resolution haplotype analysis of the PSEN1 gene. *H. Yamagata*^{1, 2}, *M. Matsubara-Tsutsui*², *K. Kamino*³, *J. Nakura*², *A. Morishima*⁴, *N. Mitsuda*⁴, *I. Kondo*¹, *T. Miki*². 1) Dept Hygiene, Ehime Univ Sch Medicine, Ehime, Japan; 2) Dept Geriatric Medicine, Ehime Univ, Ehime, Japan; 3) Dept Clin Neuroscience, Osaka Univ, Osaka, Japan; 4) 2nd Dept Human Physiology, Ehime Univ, Ehime, Japan.

We sought to establish an association between sporadic Alzheimer disease (AD) and presenilin 1 (PSEN1) gene polymorphisms in the Japanese population. A total of 189 AD cases (NINCDS-ADRDA criteria) and 240 controls were studied. A 5kb fragment containing the putative promoter of the PSEN1 gene for randomly selected control subjects was subcloned into plasmid and sequenced to screen novel polymorphisms on this region. Patients and controls were genotyped for five polymorphic markers in the PSEN1 region. We then constructed haplotypes using the computer program HAPLO and compared the frequencies between cases and controls. We discovered a novel polymorphism with high heterozygosity on -4752 of the PSEN1 promoter region. A significant association was observed between the -4752C/T polymorphism and late-onset AD. The odds ratio for AD associated with the CC vs non-CC genotype was 1.59 (95% CI= 1.01-2.51), while that of E4 vs non-E4 in APOE gene was 4.41 (95% CI= 2.72-7.16). The C allele was associated with a further increase in the risk of AD in APOE E4 carriers. We found the 12 major haplotypes using five polymorphisms. The distribution pattern was significantly different between cases and controls. The data suggest that genetic variants within the PSEN1 regulatory region might be implicated in the pathogenesis of AD.

Gender differences in the genetic determinants to alcohol dependence. *M. Zatz¹, C. Guindalini¹, S. Scivoletto², RGM. Ferreira¹, A. Nishimura¹, M. Zilberman³, MA. Peluso².* 1) Human Genome Research Center; Dept of Biology, Cidade Univ, Univ of Sao Paulo, Sao Paulo, Brazil; 2) GREA Interdisciplinary Group of Studies on Alcohol and Drugs; Institute and Department of Psychiatry, Medicine Faculty, Univ of Sao Paulo, Sao Paulo, Brazil; 3) Addiction Centre; Foothills Medical Centre, University of Calgary. Calgary, AB, Canada.

Twin and adoption studies suggest that alcoholism is a multifactorial disorder caused by genetic and environmental factors. Among the different possible genes involved in the alcoholism etiology, the X-linked Monoamine Oxidase (MAO) gene, previously reported as involved in the regulation of the central nervous system represents a good candidate. The aim of the present study was to assess whether a functional polymorphism in the promoter region of the MAOA gene was related to alcoholism, comparing patients of both sexes. Ninety alcohol-dependent patients (51 males, 39 females) were selected according to CID 10 criteria. A group of 90 volunteers with a similar ethnic background, sex and age, submitted to the CAGE questionnaire, were selected as the control group. For analysis of the MAO gene genomic DNA was extracted from whole blood and submitted to PCR (polymerase chain reaction) amplification. Genotypic frequencies were compared between the two groups analyzed together and separated according to gender. When the sample was assembled, the allele 1 was significantly more frequent among alcohol-dependent individuals than controls ($p < 0.05$). However, when the two genders were analyzed separately this association was statistically significant only for females ($p < 0.05$). Among males although the allele 1 frequency was still higher, the difference was not statistically significant ($p > 0.05$). The results of the present investigation suggest that there is a greater association between the MAO A promoter polymorphism and susceptibility to alcoholism in Brazilian females than males. In order to validate this hypothesis it will be very important to replicate this study in other populations with similar gender differences in drinking habits.

Epilepsy and Pervasive Developmental Disorders due to a deletion within the AS/PWS critical region. *L. Russo¹, F. Gurrieri¹, C.T. Giordano¹, D. Battaglia², F. Guzzetta², G. Neri¹.* 1) medical genetics, Catholic University, Rome, Rome, Italy; 2) Child Neuropsychiatry, Catholic University, Rome, Rome, Italy.

The 15q11-q13 region is one of the most important candidate regions for epilepsy and PDD. In fact, both cytogenetic and cryptic rearrangements have been found in association with PDD. We screened 180 patients by microsatellite markers analysis in order to identify the real prevalence of duplications or deletions in PDD population. Here we report on a patient with PDD and partial epilepsy: he had an unremarkable prenatal period, normal measurements at birth and marked hypotonia. He had absence of speech, walking disability, seizures, mild dysmorphisms, stereotyped movements and autistic features. Chromosomes and FMR-1 test were normal; parents were consanguineous. These phenotypic features together with the specific pattern of myoclonia seizures prompted us to rule out the Angelman syndrome. Methylation test gave normal results. The analysis with microsatellite markers from the 15q11-q13 genomic region revealed a maternal deletion including the D15S113 and GABRB3 loci. The latter maps in a more centromeric position with respect to the GABRB3 gene; the D15S97 marker, which is intragenic to the GABRB3 gene, was not deleted. In order to define the extension of this deletion we performed Fluorescence in situ hybridisation (FISH) by using BAC-probes mapping between UBE3A and GABRB3 genes. FISH results confirmed the data obtained with microsatellites and showed that UBE3A and GABRB3 genes are not deleted; however, the deletion included ATP10C, a maternally imprinted gene, encoding a putative protein homologous to the mouse aminophospholipid-transporting ATPase Atp10c. These findings suggest that this gene may contribute to the Angelman syndrome phenotype as well as to PDD. In addition, ATP10C isolated deletions or point mutations might be responsible for Angelman-like features in patients who have normal methylation test and no mutation of the UBE3A gene.

Prevalence of *parkin* gene mutations and deletions in idiopathic parkinson's disease. R. Sinha¹, B. Racette², J. Perlmutter², A. Parsian¹. 1) Birth Defects Center, Univ Louisville Hlth Sci Ctr, Louisville, KY; 2) Dept of Neurology, Washington Univ Med Sch, St. Louis, MO.

Mutations in *parkin* gene are a common cause of autosomal recessive young onset parkinsonism (AR-JP) but their role in idiopathic Parkinson's disease (PD) is not clear. Recent studies demonstrate that most young onset PD without family history is not due to mutations in *parkin* but there is less information about the role of this gene in typical onset PD. To determine the frequency of *parkin* gene mutations and deletions in the general population of patients with PD categorized based on family history and age of onset, we screened a sample of PD patients (N= 433) with the age of onset of 22-82 years and normal controls (N= 115) for the previously reported mutations, single nucleotide polymorphisms (SNPs), and deletions in exons 2-12 of the *parkin* gene. A total of 10 mutations in exon 4 (1%) and 2 in exon 7 (0.2%) in the form of heterozygotes were detected in the PD group but none in controls. The SNPs in exon 10 and 11 that cause amino acid changes (arg366trp and asp394asn, respectively) are very rare (1- 5%) and have similar frequencies in PD and normal controls. No mutation was observed in exons 2, 3, 5, 6, 8, 9 or 12. No deletion in exon 3, 4, 5, and 9 were detected in PD or control samples. There was no correspondence between any mutation and family history in any group. We also analyzed the data based on the age of onset of the disease but no correlation was found. Our study is a much larger series than previously published. Therefore, we conclude that these mutations or polymorphisms are not common in idiopathic PD and are not playing any direct role in the development of PD in our patient sample.

Mutations in *LGII* in an Australian family with familial temporal lobe epilepsy with auditory features. R.H.

*Wallace*¹, *P. Izzillo*², *A.M. MacIntosh*³, *J.C. Mulley*², *S.F. Berkovic*³. 1) Department of Anatomy and Neurobiology, University of Tennessee, Memphis, TN; 2) Department of Cytogenetics and Molecular Genetics, Womens and Childrens Hospital, North Adelaide, SA, Australia; 3) Epilepsy Research Institute, The University of Melbourne, Austin and Repatriation Medical Centre, West Heidelberg, Victoria, Australia.

Epilepsy is one of the most common neurological disorders, affecting approximately 2% of the population. Identification of families with inherited epilepsies has led to the discovery of several genes involved in both generalized and partial epilepsies. Temporal lobe epilepsy (TLE) is a partial epilepsy syndrome, characterized by seizures that originate in the temporal lobe(s) of the brain. Although TLE is generally considered an acquired disorder, genetics also play a role in the etiology. Several families have now been described with autosomal dominant inheritance of TLE and mutations in the gene *LGII* have recently been reported in seven families with TLE and auditory features. We studied a four generation Australian family with TLE with auditory features, in which five members had epilepsy. Direct sequencing of *LGII* in this family revealed a single base substitution in exon 8 (c.1418C>T). The nucleotide substitution led to a missense mutation at residue 473 of the *LGII* protein (S473L). The S473L mutation was not observed in 96 healthy control subjects. Of the 8 reported mutations in *LGII*, this is only the second missense mutation, all others resulted in truncation of the protein. The serine at residue 473 is highly conserved among all known homologues of *LGII* and is likely to be phosphorylated, according to computer prediction programs. The function of *LGII* remains largely unknown. Further studies in animal models will aid in our understanding of the role of *LGII* in familial temporal lobe epilepsy.

DNA polymorphisms in Oxytocin and 7B2 (SGNE1): evidence for association between polymorphisms and autism spectrum disorder. A. Woodroffe¹, P. Flodman¹, L. Mays¹, J. Lord², S. Holguin¹, C. Modahl¹, K. Osann¹, M.A. Spence¹, D. Fein², M. Smith¹. 1) Pediatrics, University of California-Irvine, Irvine, CA; 2) Psychology, University of Connecticut, Storrs, CT.

Autism spectrum disorder (ASD) is a developmental disorder characterized by impaired communication and social interactions and stereotypic patterns of interest and activity. ASD occurs with a frequency of 1 in 150. Animal studies revealed that Oxytocin (OT) plays a role in species typical communication and social behavior (Insel et al., 1999). Modahl et al., 1998 and Green et al., 2001, reported decreased OT levels and evidence of altered OT processing in autistic males. 7B2 (SGNE1) controls proteolytic cleavage of OT by PC2 and its transportation through and release from secretory granules. Exon 1 encodes a long 5'UTR (Mbikay 2001). We sequenced OT in genomic DNA from 67 ASD subjects and 42 controls. We identified 3 single nucleotide polymorphisms (SNPs) within intron 1 and an insertion/deletion polymorphism (extra A) in intron 2, but no polymorphisms in OT exons. The OT intron 2 sequence represents a potential open reading frame. The insertion of the extra A disrupts this reading frame. Using a Fisher exact test, we showed that the ASD subjects have a genotype with the inserted A less frequently than controls, $p=0.026$ (Fisher's exact test). We found highly significant linkage disequilibrium between the insertion/deletion polymorphism in intron 2 and one of the SNPs in intron 1. The three SNPs in intron 1 were not in linkage disequilibrium with each other. We analyzed the 7B2 gene in 68 ASD subjects and 53 controls. We identified 5 common SNPs: one located in exon 1 (A/T), one in intron 1, two in intron 2 and one in intron 5. A Fisher exact test revealed statistically significant association between ASD status and a genotype that included a T allele in 7B2 exon 1, $p=0.009$. The presence of a T allele in the exon 1 A/T SNP increases the risk of ASD 4-fold. 7B2 maps in 15q12-q13, a region that has been previously reported to play a role in autism. Our current data indicate that 7B2 and OT represent ASD susceptibility loci. [Supported by March of Dimes, Dr. Fein PI and NICHD-HD35458, Dr. Spence PI].

Human substance abuse substance vulnerability loci: identification and initial fine mapping studies. *G.R. Uhl, Q.R. Liu, H. Ishiguro, J.P. Gong, X. Zhu, T. Drgon, J. Draganova, P.W. Zhang, Z. Lin, O. Polesskaya, D. Walther.* Molecular Neurobiology Branch, NIH/NIDA/IRP, Baltimore, MD. 21224.

Convergence of results from association and linkage based genome scans now reveal 12 human rSA chromosomal regions that each contain markers associated with and linked to substance abuse (Uhl, *Trends Genetics*, 2002). These convergent results are very unlikely to have arisen by chance alone. Interesting candidate genes and striking LD are found in several of these regions. rSA1 on chr 3 30Mb has a core region which contains 11 candidate genes including NIMA kinase 6. The core 1Mb region of rSA2 on Chr 3, 175 Mb contains 4 genes including a TRAF2 homolog and PLD1. The rSA3 core contains 6 genes including LEPA and repressor of protein kinase inhibitor genes, while flanking sequences include GABAR genes. rSA7 displays paired SNPs 29 bp apart that both reveal association 4q 125Mb. 12 putative genes lie within a core region, including a putative channel protein. The rSA 8 region contains 8 genes in a core region including PLA2 activating protein and TEK kinase. The rSA 9 region of Chr 10, 106Mb contains a core region with a sortilin-receptor related protein. The 11p rSA10 region near D11S1984 includes a cluster of phosphorylation pathway genes with substantial brain expression, including DUSP8 whose intron 3 variant participates in the abuse-associated haplotypes. The 11p 26 Mb rSA11 region contains >24 genes, including BDNF and GPCR48. The rSA 12 region of 12, 123-24 Mb includes a 2Mb core of high LD with 24 genes including TJ6 and an orphan GPCR. The 13, 94 Mb rSA13 region has a core region of 18 genes including glypican 5, HNRPA1-related protein, and rap2A, several with brain expression. The rSA 14 region of chr 13, centered at 113Mb contains a core of nine genes including phospholipid/ATPase and guanine nucleotide exchange factor genes. The rSA15 region of X, 142 Mb contains 62 genes that include several zinc finger, channel and rab proteins. These features, and the results of initial fine-mapping studies, add to evidence from linkage, association, and linkage disequilibrium patterns to indicate that these regions are strong candidates for substance abuse vulnerability variants.

Tumor necrosis factor α (TNFA) haplotypes modify susceptibility to schizophrenia. *V. Saviouk*¹, *E.W.C. Chow*², *A.S. Bassett*², *L.M. Brzustowicz*^{1,3}. 1) Department of Genetics, Rutgers University, New Brunswick, NJ; 2) Department of Psychiatry, University of Toronto, and Schizophrenia Research Program, Queen Street Division, Centre for Addiction and Mental Health, Toronto; 3) Department of Psychiatry, University of Medicine and Dentistry of New Jersey, New Jersey Medical School, Newark.

The HLA region has been implicated in the etiology of schizophrenia. TNFA is a gene located in the HLA III complex, between HLA I and II, a region known for tight linkage disequilibrium. 337 subjects from 24 Canadian families of Celtic (n=23) and German (n=1) origin were genotyped for two TNFA promoter polymorphisms, G-308A and G-238A. Three families with branches separated by multiple unavailable individuals were divided, producing a total of 27 pedigrees for analysis. Analysis with SIMWALK2 revealed three segregating haplotypes: H1 (-308G, -238G; .04), H2 (-308A, -238G; .78), and H3 (-308G, -238A; .18). Analysis with TRIMHAP revealed association of the H2 haplotype with schizophrenia ($p < 0.01$ with narrow disease definition/dominant inheritance). Pedigrees were stratified into two groups, with and without H2. LOD scores from our prior genome scan were available on 25 pedigrees, and were re-analyzed using these two subsets. The subset with H2 (n=17 pedigrees) produced larger 2-point heterogeneity LOD scores than the total data set at D1S1679 (HLOD=5.9), D3S3045 (3.3), D8S136 (2.4), D9S925 (2.0), and D13S779 (2.7). While most of the increases in the HLODs were small (< 0.3), the HLODs at D3S3045 and D9S925 increased by 0.9 and 1.6, respectively. The subset without H2 (n=8) produced larger HLODs at D1S1609 (2.5), D2S297 (2.3), D5S148 (2.4), and D14S608 (2.2). The magnitude of the average increase in HLOD was larger for this group, ranging from an increase of 1.2 for D1S1609 to an increase of 2.1 for D5S148. While none of the HLODs from this subset reached significance, the magnitude of the scores are noteworthy as this subset represents only 30% of the total sample. These results suggest that TNFA or other loci in the HLA region can modify the susceptibility to schizophrenia caused by other loci in the genome.

Comparing region specific mRNA expression profiles in Progressive Supranuclear Palsy. *P. Rizzu*¹, *V. Bonifati*^{1,2}, *A.H. Rajput*³, *R. Ravid*⁴, *P. Heutink*¹. 1) Clinical Genetics, Erasmus University, Rotterdam, The Netherlands; 2) Department of Neurological Sciences, La Sapienza University, Rome, Italy; 3) University of Saskatchewan, Canada; 4) The Dutch Brain Bank, Amsterdam, The Netherlands.

PSP is a neurodegenerative movement disorder of unknown etiology, neuropathologically characterized by abundant neurofibrillary tangles (NFTs) and neuropil threads consisting of hyperphosphorylated protein tau. To determine whether there are consistent gene expression changes in brain regions of patients affected by Progressive Supranuclear Palsy (PSP) compared to non-affected controls, we isolated total RNA from four brain regions (globus pallidus, caudate, frontal and occipital cortices) from pathologically confirmed PSP cases and controls matched for age and gender. Labeled cRNAs were hybridized to Affymetrix U95 oligo-arrays to determine which genes in the PSP samples show increased or decreased expression level compared to control samples. Conventional molecular biology techniques were applied to confirm findings for individual genes, such as RT-PCR, but also immunohistochemistry and immunoblot with antibodies to investigate protein expression and localization. Approximately half of the total number of genes was expressed in at least one of the four brain regions tested. The overall pattern of gene expression is dissimilar between the PSP and control groups. According to expectations the expression of some of the heat shock proteins, HSP 70 in particular, is increased and genes encoding neurofilament proteins are decreased especially in the globus pallidus. Among the different areas investigated, signal transduction and transcription factors are constantly reported as differentially expressed across PSP and controls. Synaptic, proteolytic and mitochondrial genes account for most of the genes whose expression pattern changes in the globus pallidus. Other differentially expressed genes with unknown function are currently being investigated in more detail. Comparison of gene expression profiles with mouse and cell biological models will allow to identify and characterize cellular pathways/networks that might be potentially involved and play causative roles in PSP.

Family-based association studies of trace amine receptor genes on 6q23.3 in bipolar affective disorder. J.

Schumacher¹, C. Diaconou², R. Abou Jamra¹, R. Kaneva¹, Y. Hua¹, T.G. Schulze³, D.J. Müller⁴, M. Gross⁵, S. Ohlraun⁶, A. Golla⁷, M. Rietschel⁶, S. Cichon⁸, M.M. Nöthen⁸, P. Propping¹. 1) Institute of Human Genetics, University of Bonn, Bonn, Germany; 2) Inst Virology, Univ Bucharest, Bucharest, Romania; 3) Dept Psychiatry, Univ Chicago, Chicago; 4) Mental State Hospital Bonn, Bonn; 5) Dept Psychiatry, Univ Bonn, Bonn; 6) Central Inst Mental Health, Mannheim, Germany; 7) Inst Medical Biometry, Informatics, Epidemiology, Univ Bonn, Bonn; 8) Dept Medical Genetics, Univ Antwerp, Antwerp, Belgium.

There is evidence suggesting a role of trace amines (TA) in the etiology of bipolar affective disorders (BPAD). A functional deficiency of TA has been proposed as a potential etiological factor in depression, increased levels of TA were found to be associated with manic phases of BPAD. The genes for two trace amine receptors, TA-1 and TA-4, are both located on chromosome 6q23.2. Interestingly, this particular chromosomal region has shown evidence for linkage to BPAD in a genome-wide screen (Cichon et al., 2001). This prompted us to search for genetic variants in the TA-1 and TA-4 genes and test them for association with BPAD. Systematic sequencing of the TA-1 and TA-4 genes in 96 control individuals identified two common SNPs in the TA-4 receptor gene (914A/G and 993A/G) and one in the TA-1 receptor gene (1212A/G). TDT analysis of the three SNPs was performed in 118 parent-offspring triads that were partially derived from the genome screen sample. No association between the SNP in the TA-1 receptor gene and BPAD was found. However, we observed a preferential transmission of the 914G allele of the TA-4 receptor gene ($p=0.014$) and a non-significant trend of the 993G allele ($p=0.06$). Replication is clearly necessary to support a possible role of the TA-4 receptor gene in BPAD.

The high-activity catechol-O-methyltransferase *val* allele is a risk factor for autism spectrum disorder. *H. Zhang*¹, *X. Liu*², *C. Zhang*², *E. Mundo*³, *F. Macciardi*³, *C.E. Schwartz*⁴, *R. Michaelis*⁴, *J.J.A. Holden*^{1,2}. 1) Physiology; 2) Psychiatry, Queen's University, Kingston, ON, Canada; 3) CAMH, University of Toronto, Toronto, Ontario, Canada; 4) Center for Molecular Studies, J.C. Self Research Institute, Greenwood Genetic Center, Greenwood, SC, U.S.A.

Autism is a neurodevelopmental disorder characterized by deficits in reciprocal social interaction, verbal and non-verbal communication, and displays of repetitive behaviours. Many of the behavioural problems associated with autism, including hyperactivity and stereotypies, are modulated by catecholamine levels. Since one of the main routes for the breakdown of catecholamines is via catechol-O-methyltransferase (COMT), we examined the COMT gene in autistic families with two or more affected children. The initial test group consisted of 45 families, and a replication set consisted of 81 families. We found an increased frequency of the high-activity *val* allele in autistic individuals randomly selected from both groups of families (1 affected/family) (Set I: $c^2=4.130$, $df=1$, $p=0.042$; Set II: $c^2=9.795$, $df=1$, $p=0.002$), as well as in all affected children (Set I: $c^2=4.797$, $df=1$, $p=0.029$; Set II: $c^2=5.844$, $df=1$, $p=0.016$). This increased *val* allele frequency resulted from a larger frequency of *val/val* children than in the comparison group (*val/val*=24.6%, *val/met*=51.6%, *met/met*=23.8% compared to 16.0%, 52.2%, and 31.8%, $c^2=9.266$, $df=2$, $p=0.010$). Similar increased *val* allele frequencies were seen in both parents (mothers: $c^2=4.301$, $df=1$, $p=0.038$; fathers: $c^2=4.035$, $df=1$, $p=0.045$). To determine whether there were differences in some of the core symptoms of autism in individuals with the different COMT genotypes, information from the ADI-R was used. Although mean ADI-R scores did not differ for individuals with the different COMT genotypes in any of the three domains characterizing autism, there was a tendency for children with at least one *val* allele to have later age of first word ($c^2=3.705$, $df=1$, $p=0.054$). The above results suggest that the COMT gene may play a role in the etiology of autistic spectrum disorders. (Supported by a scholarship to HZ from OMHF and research grants to JJAH from CIHR and OMHF).

Autoantibody repertoires against brain tissue in autism nuclear families. *S.C. Silva¹, C. Fesel¹, A.M. Coutinho¹, M. Barreto¹, C. Marques², T. Miguel², A. Ataíde², C. Bento², G. Oliveira², A.M. Vicente¹.* 1) Instituto Gulbenkian Ciência, Oeiras, Portugal; 2) Hospital Pediátrico de Coimbra, Coimbra, Portugal.

The hypothesis of an autoimmune dysfunction in autism has previously been put forward without, however, compelling evidence of a direct relation to its etiology or pathogenesis. The objective of this study was the identification of immunological traits associated with autism, presenting with a simpler genetic transmission pattern, for subsequent genetic mapping. For this purpose, we have analyzed autoantibody repertoires against brain tissue extract in the serum of 126 autism spectrum disorder (ASD) children, their parents, and 54 controls in the same age range, using a quantitative immunoblotting technique. Multiparametric principal component analysis (PCA) was used for comparison of patients and controls, and the relevant PCA factors were used for heritability estimates in the sample of nuclear families. The results obtained show a significant difference in autoantibody repertoires between ASD children and controls ($p=0.0013$ for both PCA factor 1 and PCA factor 4). For PCA factor 4, analysis of the blot sections revealed a major antigenic contributor with a molecular weight in the range of Myelin Basic Protein (MBP). The correlation coefficients established for this antigenic band between parent/offspring (0.041) and spouse (-0.018) pairs and the heritability estimates ($h^2=0.082$) clearly show the absence of a genetic component for this autoantibody reactivity. Recent studies demonstrate that an autoimmune reaction directed against MBP is a protective physiological response to neuronal injury. We therefore hypothesize that the autoantibody reactivities here described, specifically in ASD patients, are not an etiological factor for autism. Instead, they may represent the immune systems protective response to a previous brain injury, which, in agreement with prevalent hypothesis for autism, might have occurred during neurodevelopment.

Genetic analysis of the Nurr1 transcription factor in Attention Deficit Hyperactivity Disorder. *K.M. Smith¹, R. Mankoski¹, M. Fischer², R. Barkley³, B.A. Navia^{1,4}.* 1) Gen Prog/Sackler Sch GBS, Tufts Univ, Boston, MA; 2) Neuropsych. Sec., Medical College of Wisconsin, Milwaukee, WI; 3) Dept. of Psychiatry, UMass Worcester Med. Cent., Worcester, MA; 4) Neurology, NEMC/Tufts. Univ. School of Medicine, Boston, MA.

Attention Deficit Hyperactivity Disorder (ADHD) is a highly heritable and common disorder that partly reflects alterations in dopamine function. Various studies have shown that genes involved in dopamine signaling and metabolism, including the 7 repeat allele of the D4 dopamine receptor (DRD4) exon 3 VNTR and the 10 repeat allele of the dopamine transporter (SLC6A3) VNTR, contribute to ADHD susceptibility. NR4A2, or Nurr1, is an orphan nuclear receptor implicated in the development of dopaminergic cells of the ventral midbrain. Mice lacking Nurr1 fail to develop dopaminergic cells of the ventral tegmental area (VTA) and the substantia nigra (SN). The dopaminergic cells of the VTA provide innervation to the prefrontal cortex, a signaling system believed to be of major importance to ADHD, suggesting that Nurr1, or one of its targets is a potential candidate gene for ADHD susceptibility. The goals of this study were to identify polymorphisms in Nurr1, and to test their association to ADHD. Database analysis revealed a CA microsatellite repeat polymorphism in the 3' UTR of this gene, which was confirmed by PCR. Two alleles were identified, differing by one repeat length. SSCP screening in 90 individuals revealed rare polymorphisms in intron 5 and the 5'UTR, each present in one individual, and a more common polymorphism -254DC in the promoter region. The CA repeat and -254DC polymorphisms were tested for an association with ADHD in both a case control study of individuals from the Milwaukee Longitudinal Study of ADHD (103 cases and 66 controls), and in 35 sib pairs with ADHD. No association was observed between either polymorphism by case control association or by TDT. Identification of these polymorphisms may aid future candidate gene studies in disorders with altered dopamine signaling, such as Schizophrenia and Parkinson's Disease.

Program Nr: 1775 from 2002 ASHG Annual Meeting

Mutation in GABA receptor gamma 2 gene is not a frequent cause of idiopathic generalized epilepsies. P.A.

Tabares¹, O.V. Evgrafov², M. Durner¹, F. Zhang¹, D. Pal¹, D.A. Greenberg¹. 1) Div. of Statistical Genetics, Columbia University, New York, NY; 2) Columbia Genome Center, Columbia University, New York, NY.

Recently, two mutations in coding regions in the GABRG2 gene were found in two families with a new epilepsy syndrome called generalized epilepsy with febrile seizures plus (GEFS+) (Baulac et al., 2001) and childhood absence epilepsy (CAE) and febrile seizures (FS) (Wallace et al., 2001). There is remarkable intrafamilial phenotypic variation in these families and some of the phenotypes are also found in common forms of idiopathic generalized epilepsy (IGE). This suggested to us that mutations in the same gene could be responsible for other types of IGE. We examined the GABRG2 gene to check whether it could be responsible for other types of common forms of IGE, with and without febrile seizures. We sequenced the whole coding sequence including splice sites of the GABRG2 gene in 44 patients with different forms of IGE, including CAE (with and without febrile seizures) and Juvenile Absence Epilepsy. No mutation was found. It indicates that GABRG2 gene is not a frequent cause of idiopathic generalized epilepsies. [Support: DK31775, NS27941, MH48858].

Linkage disequilibrium analysis of 6q13-q26 schizophrenia candidate genes. A.R. Sanders¹, M. Martinez², L. Martinolich¹, E.B. Carpenter¹, J. Duan¹, B.J. Mowry³, D.F. Levinson⁴, R.R. Crowe⁵, J.M. Silverman⁶, P.V. Gejman¹. 1) Schizophrenia Genetics Research Program, Univ of Chicago, Chicago, IL; 2) INSERM EMI6, Méthodologie Statistique et Epidémiologie Génétique des Maladies Multifactorielles, Evry, France; 3) Queensland Centre for Schizophrenia Research, Wolston Park Hospital, Univ of Queensland, Brisbane, Queensland, Australia; 4) Dept of Psychiatry, Univ of Pennsylvania School of Med, Philadelphia, PA; 5) Dept of Psychiatry, Univ of Iowa College of Med, Iowa City, IA; 6) Dept of Psychiatry, Mount Sinai School of Med, New York, NY.

We report generation of polymorphisms of chromosome 6q13-q26 candidate genes and linkage disequilibrium (LD) analysis thereof to schizophrenia. The chromosome 6q13-q26 region has been implicated as harboring a schizophrenia susceptibility gene (SCZD5) in multiple independent family collections, and most recently, in an over 1,000 affected sibling pair (ASP) replication effort. We have examined *in silico* over 1,000 positional candidate genes mapping to chromosome 6q13-q26 to prioritize their examination, based upon their known functions and putative relationships to schizophrenia etiology. Thereby, we have selected 18 of these genes (ACAT2, CNR1, ESR1, GABRR1, GABRR2, GRIK2, GRM1, HTR1B, HTR1E, IGF2R, LPA, NMBR, NR2E1, PARK2, SLC22A3, SLT, SOD2, and TCP1) to: (1) scan for several informative SNPs by published scans, database comparisons, and denaturing gradient gel electrophoresis (DGGE); (2) genotype these SNPs in the National Institute of Mental Health (NIMH) Genetics Initiative I schizophrenia families by means of DGGE, RFLP, or fluorescence polarization (FP) methods (55 SNPs examined to date); (3) examine for evidence of LD to schizophrenia; (4) increase the statistical power for SNPs yielding promising LD test results by additionally genotyping other available schizophrenia families (for a total of 837 individuals genotyped); and (5) generate additional SNPs to then examine for LD with the more promising positional/etiological candidate genes. We have obtained in our preliminary results nominally significant LD for marker(s) of the following genes: GRIK2, HTR1B, HTR1E, and SOD2.

Mutation screening and association study of LIMK1 in Autism. *M. Shinya*¹, *A. Yamamoto*², *A. Oka*^{1,2}, *M. Uchida*¹, *E. Tokubo*¹, *R. Sato*¹, *H. Inoko*^{1,2}. 1) Sch Medicine, Tokai Univ, Isehara, Japan; 2) JBIRC, Tokyo, Japan.

Autism is a neurodevelopmental disorder that characterized by marked social deficits, delay and deviance in language development and communication skills, and a restricted range of stereotypical, repetitive behaviors and limited interests. Autism is considered to arise on the basis of complex genetic predisposition. Several studies have indicated the presence of an autistic disorder susceptibility locus within the distal long arm of Chromosome 7. LIMK1, located on 7q11.23, encodes a protein tyrosine kinase with two repeats of the LIM/double zinc finger motif, and it is highly expressed in brain. LIMK1 regulates actin cytoskeletal reorganization through phosphorylation and inactivation of cofilin, a protein that is required for turnover of actin filaments. Thus, we expected that LIMK1 may prevent neurons from making their proper connections and is linked to the neurological disorder of Autism. We have screened LIMK1 coding region for sequence variants. Several polymorphic makers were identified. To further investigate transmission disequilibrium between LIMK1 and autism, a family based association study was performed for these markers in 100 AGRE autism trios.

Genomic Structure and Mutation Analysis of Semaphorin 3C. *W. Gong*², *M.L. Colavincenzo*², *E. Goldmuntz*³, *D.A. Driscoll*^{1, 2}. 1) Dept Obstetrics/Gynecology, University of Pennsylvania; 2) Div. Human Genetics and Molecular Biology and; 3) Div. Cardiology, The Children's Hospital of Philadelphia, Philadelphia, PA.

Semaphorin 3C (SEMA3C), a secreted glycoprotein involved in neuronal guidance, is expressed in the cardiac outflow tract in mice. Mice deficient in *Sema3C* display interrupted aortic arch (IAA) and persistent truncus arteriosus (PTA). The cardiac defects observed in *Sema3c* mutant mice are strikingly similar to that seen in the 22q11 deletion syndrome. However, SEMA3C maps to 7q21-q31 and therefore, is considered a promising new candidate gene for IAA and PTA, prompting us to investigate the role of SEMA3C in humans. Northern blot analysis demonstrated a unique 5.2 Kb transcript in fetal and adult heart, especially in the aorta. To determine the genomic structure of SEMA3C we compared the human cDNA sequence and the corresponding genomic sequence of human chromosome 7q31. This revealed that SEMA3C consists of 18 exons spanning 5,177bp cDNA sequence. We identified a gap between exons 4 and 5. The fragment spanning the gap was amplified and sequenced, which completed the genomic sequence of SEMA3C and allowed us to begin mutational studies to examine the role of SEMA3C in human cardiac development. Twenty sets of primers flanking all coding regions, exon-intron junctions, 5'UTR and partial 3'UTR were designed. Mutation screening was performed by confirmation-sensitive gel electrophoresis (CSGE) followed by direct sequencing. For the initial screening, we analyzed genomic DNA from 11 probands with IAA and up to 70 normal controls. We identified 12 base changes including one deletion and 11 base substitutions. Five are single nucleotide polymorphisms (SNPs). The most interesting change is an A/G substitution at 44 bp 3' to the splice donor site of exon 1, found in one patient, but not 140 normal chromosomes. This variant is located in a conserved region and predicted to create a potential splice donor site GT. Further experiments are in progress to determine the consequence of this change and to determine if SEMA3C mutations are associated with PTA in humans.

Association study of MTHFR polymorphisms and congenital heart defects. *D.A. Driscoll^{1,2,5}, T.A. Boland⁵, J.A. Campanile⁵, E. Levin², K. Brown³, E. Goldmuntz², L. Mitchell^{4,5}.* 1) Depts Obstetrics/Gynecology; 2) Pediatrics; 3) Pharmacology; 4) Clinical Epidemiology & Biostatistics, Univ Pennsylvania; 5) Division Human Genetics & Molecular Biology, Children's Hospital Philadelphia, Philadelphia, PA.

Two small case-control studies have reported an association between CHD and the MTHFR C677T polymorphism. We sought to further investigate the association between MTHFR and CHD, in families ascertained through a child with either a conotruncal (CT) or a left-sided (LS) cardiac defect. Here, we report on our analyses of data from 349 families (253 CT, 96 LS), which represents the largest family-based genetic association study of CHD, to date. The transmission disequilibrium test (TDT) was used to assess the association between CT and LS, and these two polymorphisms.

MTHFR Polymorphisms	C677T	A1298C*
#Informative transmissions	265	273
#Transmissions of T and C*	145 (54.7%)	130 (47.6%)
p-value	0.12	0.43

Analysis of the data from CT and LS families combined, shown in table, provided no evidence that either the C677T or A1298C polymorphisms were significantly related to the risk of these cardiac malformations. Analysis of data from each subgroup, CT and LS alone, also provided no evidence that either MTHFR polymorphism was significantly related to these specific cardiac defects. These results are in contrast to previous reports. However, our study has the advantage of a relatively large study population that allowed for subgroup analyses, and employed the TDT which, unlike case-control studies, is not subject to bias arising from population stratification.

Hemochromatosis-associated genotypes are not associated with early markers of atherosclerosis. *P.J. Bridge¹, L.M. Yunker¹, M.E. Hyndman², M. Fung², J.S. Parboosingh¹, T.J. Anderson².* 1) Molecular Diagnostic Lab, Alberta Children's Hospital, Calgary, AB, Canada; 2) Medicine, University of Calgary, AB, Canada.

Background: Patients with hereditary hemochromatosis (HH) suffer from iron accumulation and may be at increased risk of cardiovascular disease. The majority of HH patients are homozygous for the C282Y mutation in the HFE gene while a small number have some other combination of C282Y, H63D, S65C or unidentified mutations. Excess iron is known to result in increased oxidative stress and lipid peroxidation. Increased oxidative stress is thought to play a role in development of atherosclerosis and endothelial dysfunction, and some studies have shown an association between HFE genotype and cardiovascular disease. In an attempt to investigate how early such an effect might occur, we investigated the effect of three HFE mutations on presymptomatic atherosclerosis markers, brachial artery endothelial function measured by flow-mediated vasodilation (FMD) and carotid intima medial thickness (CIMT).

Methods and Results: We examined the association of the C282Y, H63D and S65C mutations with FMD and CIMT in 484 healthy middle-aged Caucasian men participating in a prospective study of endothelial function (mean age 45 yrs). Significant differences in ferritin saturation versus genotype indicated that the HFE mutations were penetrant in these subjects. The distribution of genotypes for each of the mutations were in Hardy-Weinberg equilibrium. No significant difference in the clinical markers was observed between the different HFE genotypes, however, there was a significant association between increased ferritin saturation and increased CIMT ($p=0.002$).

Conclusion: These results suggest that cardiovascular risk may be greater in individuals with greater ferritin saturation (and that mutant HFE genotypes are one, but not the only, contributor to absolute ferritin saturation levels). The effect of these mutations on atherosclerosis requires further investigation.

LOX-1 polymorphism as a susceptibility genetic marker for atherosclerosis. *R. Mango¹, G. Contino¹, F. Clementi², P. Borgiani¹, A. Botta¹, G.B. Forleo², A.M. Nardone¹, G. Chiricolo², S. Guarino¹, M.R. D'Apice¹, A. Romeo¹, M. Federici², R. Lauro², J.L. Mehta³, F. Romeo², G. Novelli¹.* 1) Dept Biopathology, University Tor Vergata, Rome, Italy; 2) Dept Internal Medicine, University Tor Vergata, Rome, Italy; 3) Dept Internal Medicine, University of Arkansas for Medical Sciences, Little Rock, USA.

Atherosclerosis is the leading cause of mortality in industrialized countries accounting for up to 50% of deaths. Atherosclerosis is the principal process contributing to the pathogenesis of coronary artery disease (CAD), cerebral infarction, and peripheral vascular disease. A large number of risk factors such as hypertension, hypercholesterolemia, diabetes, obesity, smoking and shear stress leads to endothelial activation and/or dysfunction, which elicit a series of cellular interactions that culminate in atherogenesis. Several biochemical and functional studies suggest that a lectin-like receptor for oxidized low-density-lipoprotein (ox-DL), termed LOX-1, and may be involved in atherogenesis. LOX-1 is a type-II membrane protein belonging to the C-type lectin family. A recent linkage study performed in a mouse model, identified LOX-1 as candidate susceptibility gene for human atherosclerosis. In order to investigate the role of LOX-1 in human atherosclerosis susceptibility, we screened a group of 164 Italian individuals with angiographic CAD phenotype (CAD; n=88) or without any angiographically demonstrable disease (CAD-free; n=76). We characterized five different SNPs (SNP 1-5) at the LOX-1 locus in this population. We demonstrated that SNP4 (A to G transition) correlates with CAD with a high degree of specificity ($X^2 = 7,37$; $P, 0.007$; 1df). This is the first report of LOX-1 SNPs and atherosclerosis. We believe that LOX-1 may be a candidate gene for atherosclerosis and endothelial dysfunction in response to ox-LDL. Work supported by the Italian Ministry of University and Research (MIUR).

GENOMIC STRUCTURE OF THE HUMAN GAS6 GENE AND IDENTIFICATION OF ALLELIC

VARIANTS. X. Munyoz¹, L. Sumoy², P. García de Frutos³, N. Sala¹. 1) Molecular Genetics, CGMM-IRO, Barcelona, Spain; 2) Centre de Regulació Genòmica, Laboratori de Microarrays, Barcelona, Spain; 3) Laboratorio de Investigaciones Biomédicas, Hospital Universitario Virgen del Rocío, Sevilla, Spain.

Gas6 (growth arrest-specific gene 6 product) is a new vitamin K dependent protein, structurally related to the blood anticoagulant protein S. Characterization of the *gas6* knockout mice confirms the importance of this protein in hemostasis and thrombosis, through its role in platelet aggregation and secretion pathways. Since little is known about the human *GAS6* gene, the purpose of the present study was to determine its intron-exon structure and to analyze it for the presence of allelic variants that could be associated with cardiovascular disease. **Methods:** The localization and sequence of *GAS6* exons and introns has been determined *in silico* by comparing the *GAS6* cDNA sequence with the whole human genome sequence using BLASTn program. Characterization of the *GAS6* exons and their intron flanking sequences allowed us to design oligonucleotides for their specific amplification by PCR. *GAS6* amplified fragments from a minimum of 10 control DNA samples were analyzed for the presence of sequence variants by Single Strand Conformation Polymorphisms (SSCPs) analysis and DNA sequencing. **Results:** Comparison of the *GAS6* cDNA with the recently reported human genome sequence allowed us to localize 15 *GAS6* exons and 14 introns in approximately 45 Kb of DNA. SSCP analysis allowed the identification of 6 different polymorphic single nucleotide substitutions (SNPs). Three of them are localized in exons 11, 12 and 14 and appear to be neutral since they do not modify the encoded amino acid. The other SNPs are in introns 7 and 8 and their effect has not yet been analyzed. **Conclusions:** The homology between protein S and *GAS6* is maintained at the genomic level with *GAS6* having, like PROS1, 15 exons. The identification of 6 different SNPs in *GAS6* will be very useful in future association studies aimed to analyze the role of *GAS6* in human disease. **We thank ISCIII 01/1468 and SAF 2001-1059-C02 for grants.**

Genetic factors of stroke with hyperhomocystinemia of young population in Taiwan. *J. Hou.* Medical Genetics, Chang Gung Children's Hospital, Taoyuan, Taiwan.

From the natural history in typical homocystinuria, high plasma homocystine (HCY) levels in such patients constitute a significant risk factor for vascular disease, such as thrombo-embolic complications at an early age. Similar findings also exist in young population with moderate or secondary hyperhomocystinemia (HH). The defective methylenetetrahydrofolate reductase (MTHFR) activity due to the homozygous presence of a thermolabile variant (t-MTHFR) of the enzyme has been recently described as a major cause of moderate HH. To evaluate the role of the t-MTHFR allele as a predisposing factor for early-onset stroke in HH children and young adult, we compare the prevalence of homozygosity and compound heterozygosity of this gene (C677T, A1298C, and T1317C) in young stroke patients (after excluding other etiologies of stroke) with reference populations. Totally 120 young patients (ranged from 6 years to 45 years) were evaluated, 30 % were homozygous for the t-MTHFR allele (C677T: 22%, and A1298C: 8%), compared with 6 % (3% and 2%, respectively) of the reference population ($p < 0.005$); 15 % were compound heterozygous for the allele (C677T plus A1298C), compared with 2 % of a reference population ($p < 0.005$). There was a significant increment of plasma total HCY concentration in subjects with homozygotes and compound heterozygotes compared with those with heterozygotes or negatives (homozygous for the wild-type allele), and controls with no history of stroke. These data suggest that homozygosity or compound heterozygosity for the t-MTHFR allele is associated with raised HCY levels in children and young adult, and is a risk factor for early-onset stroke. MTHFR gene mutation has been documented as an important cause of HH in vascular diseases, and the impact to general health care of this unconventional risk factor of vascular disease has been met. These patients can be treated with folic acid, vitamin B6 and vitamin B12, thus the early diagnosis and early prevention are beneficial for this special population.

Longitudinal Expression Profiling and Analysis of Exercise-Responsive Genes in Type-2 Diabetics. *D.S. Hittel¹, W.E. Kraus², E.P. Hoffman¹*. 1) Center for Genetic Medicine, Children's National Medical Center, 111 Michigan Ave, NW Washington DC 20010; 2) Center for Living, Duke University Medical Center, 1300 Morreene Road Durham, NC 27710.

Aerobic exercise is an important adjunct to the treatment and prevention of the many negative physiological outcomes of type-2 diabetes. While there is substantial anecdotal evidence in support of a favorable relationship between cardiovascular fitness and physical activity there are few consistent models of the molecular mechanisms which underlay this relationship. The Studies of a Targeted Risk Reduction Intervention through Defined Exercise (STRRIDE), is a randomized controlled clinical trial of different doses and intensities of exercise in a structured exercise program. The goal of this study is to more clearly define the relationship between the amount and intensity of exercise and improvements in cardiovascular health. Participants (equal numbers of men and women; 30% minority) are typically 40-65 years of age, moderately overweight with fasting hyperinsulinemia. We hypothesize that the physiological adaptations of skeletal muscle to exercise are primarily responsible for the benefits of exercise training on cardiovascular health and that the differential expression of genes and their protein products in is largely responsible for these changes. Skeletal muscle biopsies were obtained from STRRIDE participants upon entry into the study, after 6 months of exercise training and after 2-weeks of de-training. Expression profiles for several thousand genes were obtained from these biopsies using the Affymetrix DNChip platform. These expression profiles were filtered for genes whose transcript levels which changed consistently and significantly ($P < 0.05$) more than two fold after training and/or de-training relative to the control. These genes were subsequently grouped into functional classes and representative genes selected for confirmation by QMF-RT-PCR, western blot and immuno-staining. Many of these exercise-responsive genes participate in glucose metabolism, insulin signaling, fibrinolysis and other physiological processes that are negatively affected in type 2 diabetics.

Large-scale comparison of SNP and haplotype frequencies in 100 genes between 590 candidates for lipid-lowering therapy and 21 individuals from the general population. *C.J. Messer, J.A. Schneider, M. Pungliya, J.Y. Choi, A.E. Anastasio, K. Parks, R. Jiang, J.C. Stephens.* Genaissance Pharmaceuticals, New Haven, CT.

We compared SNP and haplotype frequencies in ~100 candidate genes relating to cholesterol, energy and drug metabolism and inflammation in two population groups. The first group included 590 individuals of European ancestry who are candidates for lipid-lowering therapy based on National Cholesterol Education Program guidelines for LDL-cholesterol, and the second group included 21 unrelated individuals of European ancestry from the general population. We have conducted high-throughput SNP and haplotype discovery on the 21 individuals from the general population, and are currently investigating the 590 individuals as part of a separate pharmacogenetic study of statin response. DNA sequencing was performed on several functional gene regions, and haplotypes were inferred on non-singleton SNPs using an Expectation-Maximization algorithm. Within the ~100 candidate genes, we found over 1000 SNPs in the 21 individuals from the general population, and nearly 3000 SNPs in the 590 individuals considered in the statin study. The number of haplotypes inferred was slightly less than the number of non-singleton SNPs for the group of 21 individuals from the general population, and slightly more than the number of non-singleton SNPs in the 590 candidates for lipid-lowering therapy. Five of the genes considered contained SNPs with more than 20% frequency difference between the two population groups. In addition, two of these genes also showed haplotypes with comparable frequency differences. A more detailed analysis of the association between SNPs and haplotypes with baseline clinical measurements is required to confirm these results; however, these genes are potential candidates for influencing susceptibility to high LDL-cholesterol.

Dilated Cardiomyopathy and the Microsatellite Polymorphism of Heme Oxygenase 1. *J.M. Pohorence Ferguson, Y. Liu-Stratton, G. Cooke, P.F. Binkley.* Davis Heart and Lung Research Institute, The Ohio State University, Columbus, OH.

Heme oxygenase 1 (HO-1) is upregulated by stimuli that produce reactive oxygen species, and plays a protective role in cardiovascular diseases involving oxidative stress. Oxidative stress is a major source of damage in both ischemic cardiomyopathy (ICM) and dilated cardiomyopathy (DCM). Because a loss of HO-1 activity increases tissue susceptibility to oxidative damage, the hypothesis of this study was that protective actions of HO-1 are inhibited in patients with cardiomyopathy due to a microsatellite polymorphism in the promoter region of HO-1 that reduces transcriptional activity. Accordingly, sequence analysis was performed using DNA extracted from 24 patients with ICM and 24 patients with DCM to identify the presence of this microsatellite polymorphism (L) which consists of ³ 29 dinucleotide repeats. The frequency distribution for the presence of at least one L allele is shown below. These data indicate that patients with DCM possess the L allele in a significantly (Chi square $p = 0.04$) higher proportion than ICM patients. Therefore, despite the absence of significant coronary disease, patients with DCM may be susceptible to progressive ventricular dysfunction due in part to an inability to protect against myocardial oxidative stress.

Frequency Distribution for L

Allele

Etiology	No L	L Present
ICM Number	17	7
ICM Percent	71%	29%
DCM Number	10	14
DCM Percent	42%	58%

Methionine Synthase SNP and functional assays of cardiovascular risk. *L.M. Yunker¹, M.E. Hyndman², M. Fung², T.J. Anderson², J.S. Parboosingh¹, P.J. Bridge¹.* 1) Medical Genetics, University of Calgary, Alberta, Canada; 2) Medicine, University of Calgary, Alberta, Canada.

Background: Functional variations in folate metabolism alter total homocysteine and folate levels, independent risk factors for developing cardiovascular disease. Methionine Synthase (MTR), a key enzyme in folate metabolism, catalyzes the conversion of homocysteine to methionine. An A>G SNP at nucleotide 2756 results in a Gly to Asp change. The exact physiological effect of this variant on cardiovascular risk and folate metabolism is yet to be elucidated. Hyndman et al. (*Am J Cardiol* 86:1144-6, 2000) showed that of 109 individuals who had previously suffered a cardiac event, those carrying the MTR 2756 G allele were 3.4 times less likely to suffer a recurrent event suggesting that this variation is somehow protective. **Methods/Results:** We analyzed the effect of the MS 2756 SNP (A>G) on folate levels and surrogate markers of atherosclerosis. These included brachial artery endothelial function (flow-mediated vasodilation, FMD) and carotid intima-medial thickness (CIMT). We studied 360 middle-aged males (mean age 45 years) without overt atherosclerosis participating in the FATE study (Firefighters And Their Endothelium). Using an internal primer extension method 262 individuals were found to be A/A, 90 A/G and 8 G/G giving allele frequencies of 0.85A and 0.15G. Preliminary analysis showed no association between the MS2756 genotypes and folate levels. There appears to be a trend towards decreased CIMT thickening (beneficial) in individuals who are either carriers or homozygous for the G allele (A/A .628mm, A/G .606mm, G/G .583mm) however the difference between the average mean CIMT in A/A versus A/G and G/G individuals is currently not significant (p=0.126). **Conclusion:** We are unable to demonstrate a clear relationship between MTR2756 and atherosclerosis as assessed by brachial endothelial function and CIMT. Given the allele frequency, and that we have a further 850 participants already available to study, we will continue to try to clarify the relationship between the MS2756 genotype and presymptomatic cardiovascular markers.

Folate resistant Neural Tube defects associated to MTHFR A1298C mutation. *M.A. Orera¹, A. Zuniga², J. Ubeda³, N. Villanueva³, E. Dulin³, M.D. Lillo¹, C. Lostau¹.* 1) Genetics, H. Gregorio Maranon, Madrid, Spain; 2) B. Molecular. H de la Ribera, Alzira Valencia; 3) Biochemistry. H. Gregorio Maranon.

INTRODUCTION: Neural tube defects are thought to be of multifactorial origin involving a number of genetic and environmental factors. It is not clear which is the contribution of each risk factor that is being investigated and it appears that their impact could be different among the populations studied. The prevalence of NTD shows wide regional and ethnical variation and the recurrence rate is somehow related to the basal rate. In Spain NTD prevalence is 0.7-1.2 per 1000, and the recurrence rate is 1-2 %. Periconceptional folate administration reduces both the occurrence and recurrence risks, indicating a potential role of folate metabolism genes in the development of NTD. There are two mutations of the Methylene tetrahydrofolate reductase gene, C677T and A1298C that are generally considered risk factors in the development of NTD. **MATERIAL AND METHODS:** We have followed the gestational outcome of 83 women with a previous pregnancy complicated with a NTD. All of them were treated preconceptionally with 5 mg/day of Folic Acid. Two non related patients had a NTD in the following pregnancy: Patient 1 is 36 years old and had a first pregnancy not treated with Folic Acid complicated with open spina bifida. She had preconceptional prophylaxis with Folic Acid in the second pregnancy, but the gestation produced a fetus with anencephalia. Patient 2 is 34 years old and she has a history of two pregnancies treated preconceptionally with 5mg/day Folic Acid, with open spina bifida ascertained by ultrasound. Basal plasma Homocysteine and Folic Acid levels were within normal limits for both patients. MTHFR mutation analysis revealed that patient 1 was homozygous for the A1298C mutation and patient 2 was heterozygous. **DISCUSSION:** We present two patients with folate resistant DTN and both of them have the A1298C mutation in the MTHFR, without apparent disruption of folate metabolism. We suggest that this mutation might be related to an independent risk factor that is not modulated by Folate.

Deletions in only one of the two variants of the 4q subtelomere cause Facioscapulohumeral muscular dystrophy: b-satellite the culprit? *R.J.L.F. Lemmers¹, P. de Kievit¹, L. Sandkuijl¹, G.W. Padberg², G.J.B. van Ommen¹, R.R. Frants¹, S.M. van der Maarel¹.* 1) Human & Clinical Genetics, LUMC, Leiden, The Netherlands; 2) Department of Neurology, UMCN, Nijmegen, The Netherlands.

Subtelomeres define the proterminal ends of chromosomes and are composed of patchworks of large polymorphic segments of DNA that are present on many chromosomes. Ectopic recombination between subtelomeres serves interindividual gene family diversity, but may also underlie human disease and mental retardation. Probably the best-studied human subtelomeres are 4qter and 10qter, which are almost identical over a distance of 100-500kb. Partial deletions in the subtelomeric D4Z4 repeat array on 4qter cause Facioscapulohumeral muscular dystrophy (FSHD), while identical deletions when affecting the 10qter repeat are non-pathogenic. Likely, the partial deletion on chromosome 4 results in a transcriptional deregulation of critical genes on 4qter, similar to position effect variegation. Recently, we identified two distinct 4q alleles, 4qA and 4qB, based on a 10kb polymorphic segment directly distal to D4Z4. While both alleles are equally frequent in the population, we find that FSHD is uniquely associated with partial D4Z4 repeat array deletions on 4qA alleles. Recombination is suppressed between 4qA and 4qB in the DNA segment proximal and distal to D4Z4, but not within D4Z4 repeat array proper. Moreover, since 4qA and 4qB alleles are equally susceptible to rearrangements, a functional difference must underlie the association of 4qA with FSHD. The most prominent feature that may explain this functional difference is the presence of a 6.2kb-sized b-satellite repeat array, which is absent on 4qB. The 4qter region is the first example of an intrinsically benign subtelomeric allelic variation predisposing to disease.

Hypomethylation of the D4Z4 repeat array in Facioscapulohumeral muscular dystrophy alleles. *P.G.M. van Overveld¹, L. Sandkuijl¹, L. Enthoven², G.W. Padberg³, R.R. Frants¹, S.M. van der Maarel¹*. 1) Human Genetics, LUMC, Leiden, Netherlands; 2) LACDR, Division of Medical Pharmacology, Leiden University, Leiden, The Netherlands; 3) Department of Neurology, UMCN, Nijmegen, The Netherlands.

Autosomal dominant Facioscapulohumeral muscular dystrophy (FSHD) progressively affects the facial, shoulder and upper arm muscles. FSHD is associated with partial deletion of the polymorphic D4Z4 repeat array residing in the subtelomere of chromosome 4q. Normally, the array varies between 11-150 units, while FSHD patients carry alleles of 1-10 units. A highly homologous array on chromosome 10qter is not associated with disease. The heterochromatic properties of D4Z4 have led to the hypothesis that FSHD is caused by a position effect variegation (PEV)-like mechanism in which partial deletion of the D4Z4 repeats results in a local change in chromatin structure and consequently in a transcriptional deregulation of one or more genes on 4qter. To obtain evidence for a PEV-mediated pathology, we studied the methylation of the D4Z4 repeat array applying a CpG methylation-sensitive chromosome 4-specific DNA digestion assay on DNA isolated from peripheral blood lymphocytes and skeletal muscle tissue. In those individuals with a translocated 10-type array on chromosome 4 and thus carrying only one 4-type and three 10-type D4Z4 repeat arrays, we were able to quantify the methylation of a single healthy or disease allele. We showed that some, but not all CpG methylation-sensitive restriction sites were significantly hypomethylated in FSHD alleles compared to control alleles. Although FSHD patients carry hypomethylated disease alleles, we did not observe a linear relation between the methylation and the length of the D4Z4 repeat. Apparently, a considerable variation in methylation is tolerated but, if upon partial deletion of the D4Z4 repeat array the methylation decreases below a critical threshold, the disease develops. The observed hypomethylation strongly supports a model for FSHD in which a deletion-mediated local chromatin decondensation alters gene expression of 4qter.

Ethnic differences in the expression of neurodegenerative disease: Machado-Joseph disease in Africans and Caucasians. A.A. Singleton¹, S.H. Subramony³, D. Hernandez², S. Smith-Jefferson⁵, J. Hussey⁴, K. Gwinn-Hardy¹, T. Lynch^{6,7}, O. McDaniel⁸, J. Hardy^{2,9}, M. Farrer⁴, A. Singleton². 1) Neurogenetics, NIH/NINDS, Bethesda, MD, USA; 2) Neurogenetics, NIH/NIA, Bethesda, MD, USA; 3) University of Mississippi Medical Center, Neurology Department, Jackson, Mississippi, USA; 4) Laboratories of Neurogenetics, Department of Neuroscience, Mayo Clinic, Jacksonville, Florida, USA; 5) Division of Medical Genetics, Department of Preventive Medicine, University of Mississippi Medical Center, Jackson, Mississippi, USA; 6) Department of Neurology, Columbia University, New York, USA; 7) Department of Neurology, Mater Misericordiae Hospital, Dublin, Ireland; 8) University of Mississippi Medical Center, Surgery Department, Jackson, Mississippi, USA; 9) Department of Neurology, Reta Lila Weston Institute of Neurological Studies Royal Free And University College London Medical School London, United Kingdom.

We describe several families of African origin with SCA3/Machado-Joseph disease gene expansions. In these cases, the phenotype ranges from ataxia with parkinsonian signs to a syndrome clinically almost indistinguishable from idiopathic, L-dopa-responsive Parkinson's disease. In contrast, these parkinsonian phenotypes are rare in those of European descent. Haplotype analysis shows that these African families do not share a common founder, thus a cis-acting element in the promoter is unlikely to be responsible for these unusual presentations. We suggest that trans-acting factors are responsible for the variable phenotype and discuss the implications of diseases showing racially different expressivities.

Genetic factors studied in a family with autosomal dominant autoimmune disease. *C. Spangenberg, T. Trost, S. Fees, E. Lausch, D. Prawitt, F. Zepp, J. Spranger, B. Zabel.* Dept Pediatrics, Univ Mainz, Mainz, Germany.

Systemic lupus erythematosus (SLE) and LE-like conditions are part of a heterogeneous group of chronic disorders involving the immune system. The spectrum of clinical symptoms include organ specific changes of skin and kidneys. It is believed that the disease results from a failure of regulatory mechanisms of the immune system. In this respect the conditions are often associated with the production of autoantibodies which are directed against several nuclear antigens like double-stranded DNA, RNA, and nucleic acid-binding proteins such as histones and Sm. Several genes and chromosomal loci have been linked to different forms of LE. For some of these genes - e.g. DNase1, the complement components C1q, C2, and C4 - mutations could be found in LE patients. However, due to the multifactorial nature of the disease genetic events resulting in development of LE are not yet understood in most cases. Genetic linkage studies in large families as well as the study of LE conditions in animal models have led to the identification of disease-associated candidate genes, thus helping to dissect the role of single genes in complex human diseases. We present a three-generation LE family showing autosomal dominant inheritance of the disease phenotype. A genetic linkage analysis of this family is in progress. We have started to look for co-segregating haplotypes in four affected and several unaffected family members. Highly polymorphic markers were chosen for their proximity to genes that have previously been shown to be mutated in SLE patients (like DNase1) or that have been associated with SLE in genetically engineered mice (like serum amyloid protein, SAP). Genes identified by our linkage studies will be subject of mutational analysis.

Genetics of Autism: Identification of Chromosomal Abnormalities and Susceptibility Loci on Chromosome 15q in Autism Families. *C.D. Kashork, D.W. Stockton, T. Sahoo, D. Bercovich, L.G. Shaffer, A.L. Beaudet.* Human & Molecular Genetics, Baylor College of Medicine, Houston, TX.

Classic autism or autistic disorder is a neuro-developmental disorder characterized by early childhood onset of: impaired social interaction and communication capabilities, deficits in language development, and patterns of stereotypical-repetitive behavior. A high concordance in identical twins has been interpreted to imply a strong genetic component in the etiology of autism, although we suggest that de novo epigenetic defects might equally well underlie this concordance. Numerous studies suggest that a number of chromosomal regions harbor susceptibility loci for autism, and the imprinted domain on chromosome 15q11-q13 remains a significant one. Abnormalities of chromosome 15 and fragile X mutations have been the most frequent genetic abnormality in autistic patients. To assess the frequency of chromosome aberrations involving the Prader-Willi/Angelman syndrome critical region on 15q11-q13, we carried out interphase FISH on lymphoblastoid cell lines from 56 probands with autism [obtained from the Autism Genetic Research Exchange (AGRE) resource]. To determine linkage and allele sharing for loci in the 15q11-q13 interval, we are genotyping all 56 of these families for six polymorphic microsatellite markers near the *UBE3A* gene in the PWS/AS critical interval. We detected an interstitial duplication of the chromosome 15q11-q13 region using FISH in two affected sibs in one family. The duplication was present in the phenotypically normal mother, presumably on her paternal chromosome. The authenticity of this duplication event was confirmed by microsatellite marker analysis. Preliminary analysis of linkage data for loci in this interval is underway. We are examining the hypothesis that a substantial fraction of autism might be caused by paternal or maternal epigenetic defects of 15q11-q13.

Neurocognitive Function in Williams Syndrome (WMS): Evidence for Genetic Imprinting. *H.J. Antoine¹, H. Wijesuriya¹, F. Rose², U. Bellugi², D. Mills³, J.R. Korenberg¹*. 1) Med Gen, Cedars-Sinai, LA, CA; 2) Salk Inst., San Diego, CA; 3) Emory Univ., Atlanta, GA.

WMS is caused by the deletion of 18 genes on chromosome band 7q11.23. Individuals with WMS exhibit global cognitive deficits with striking dissociations characterized by relative strengths within the verbal domain and weaknesses within the visual-spatial domain. Despite a rather uniform pattern of cognitive functioning in WMS, there is considerable variability in the range of cognitive abilities observed. Our data suggest that genetic imprinting may be a source of this phenotypic variability. Genetic, cognitive, and electrophysiological data from 65 individuals diagnosed with WMS were analyzed with 11 polymorphic markers within the deleted region. These same subjects completed a battery of neurocognitive tests measuring general intelligence, receptive and expressive language (including measures of social and spatial components of language), visuospatial skills, and face/object processing. Finally, event-related potentials (ERP) were recorded while subjects completed a face recognition task which has been previously shown to be atypical in WMS (Mills et al., 2000). Results identified 36 maternal deletions (21 female, 15 male) and 25 paternal deletions (16 female, 9 male). Analyses uncovered a few significant differences and several trends with sample sizes ranging from 17 to 34 for a given task. The evidence suggested that individuals carrying maternal deletions obtained lower scores in the K-ABC Gestalt Closure ($p=0.019$), WAIS-R Block Design ($p=0.024$), and Benton Judgment of Line Orientation ($p=0.037$). Furthermore, trends in the same direction were also found in the DAS GCA ($p=0.091$) and WAIS-R Performance IQ ($p=0.088$). No gender or age-related differences were found between groups. Analysis of the ERP data in a face-processing paradigm revealed greater abnormality in the maternal than the paternal group, suggesting that imprinting may also play a role in the neural organization of face processing. We propose that the expression of genes in WMS may be affected by genetic imprinting, which contributes to cognitive variation in WMS and possibly in the normal population.

Analysis of candidate genes for non-syndromic craniosynostosis. *S.A.B. Boyd¹, G. Zhang¹, R. Ingersoll¹, N. Isaac¹, L. Kasch¹, D. Hur¹, E.W. Jabs¹, T. Beaty², A.F. Scott¹.* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine; 2) Dept Epidemiology, Johns Hopkins School of Public Health.

While significant progress has been made in understanding the genetic basis of syndromic craniosynostosis, the causes of non-syndromic craniosynostosis remain to be elucidated. We have initiated a candidate gene based association study, identifying and verifying single nucleotide polymorphisms (SNPs) in a set of case-parent trios with non-syndromic craniosynostosis. The candidate genes were selected based on phenotypes caused by known mutations (i.e. syndromic craniosynostosis, animal models) and demonstrated biological function. As a first step, we performed sequencing analysis of the hot-spots for syndromic craniosynostosis: FGFR1 exon 7, FGFR2 exons 8 and 10, FGFR3 exon 7, and the entire coding sequence of TWIST. Analysis of 93 patients with non-syndromic craniosynostosis identified two FGFR3 P250R mutations in patients with coronal craniosynostosis, one of them familial. No mutations were identified in the other 91 individuals (64 sagittal, 8 coronal, 7 lambdoid, 5 metopic and 7 with multiple suture involvement). We are currently performing sequencing analysis on a group of 20 patients with isolated sagittal craniosynostosis for the entire coding sequence of the following candidate genes: FGFR1, FGFR2, FGFR3, FGFR1, SNAIL, SLUG, TWIST, and MSX2. No mutations have been identified so far in over 53 kb of genomic sequence (93 amplicons, 11.7 kb coding, 42 kb non-coding sequence) completed on 14 patients. A total of 93 SNPs [46 previously reported (as of 5/14/02) and 47 unique] have been identified. Of these, 19 SNPs occur in exons and 6 were non-synonymous (nsSNPs). The nsSNPs are being evaluated as possible disease causing variants. An additional twenty candidate genes have been selected for SNP identification. Allele frequencies will be determined and selected SNPs will be used in a large scale genotyping effort to detect evidence of linkage and disequilibrium or to identify possible mutations in families with non-syndromic craniosynostosis.

Genetic Analysis of Candidate genes in Nonsyndromic Cleft Lip Families. *L. Moreno*¹, *M. Marazita*³, *M. Arcos-Burgos*², *K. Krahn*¹, *B.S. Maher*³, *M.E. Cooper*³, *C. Valencia*⁴, *A.C. Lidral*¹. 1) Orthodontics and Dows Institute for Dental Research, University of Iowa, Iowa City, IA; 2) Department of Biology, University of Antioquia, Medellin, Colombia, SA; 3) Cleft Palate-Craniofacial Center And Department of Human Genetics, University of Pittsburgh; 4) College of Dentistry, University of Antioquia, Medellin, Colombia, SA.

Nonsyndromic cleft lip with or without palate (NSCL/P) is a common genetically, complex birth defect, with prevalence from 1/500 to 1/1000 live births. Evidence from linkage, linkage disequilibrium and mouse models studies is contradictory suggesting that heterogeneity between study populations may exist. A recent report of a genome wide scan in 92 sib pairs from the United Kingdom revealed suggestive linkage to 10 loci (Prescott et al. 2000). The purpose of this study is to replicate these results and evaluate additional candidate genes in 49 Colombian and 13 Ohio families. Genotypes were obtained for STRPs at 1p36, 2p13 (TGFA), 4p16 (MSX1), 6p23-25, 6q25-27, 8q23-24, 11p12-q13, 12q13, 14q24 (TGFB3), 16q22-24, 17q12-21 (RARA) and Xcen-q21. Linkage was performed using parametric (dominant and recessive models) and nonparametric (GENEHUNTERnpl and SimIBD) analyses. In addition, heterogeneity was analyzed using GENEHUNTER HLOD and association determined by the TDT. The Colombian families showed significant SimIBD results for 11p12-q13 ($p=0.034$), 12q13 ($p=0.015$), 16q22-24 (0.01) and 17q12-21 (0.009), while the Ohio families showed significant SimIBD results for TGFA ($p=0.005$), 6p23 ($p=0.004$) and 11p12-q13 ($p=0.025$) and a significant NPL result for 4p16 ($p=0.03$). Several families yielded LOD scores ranging from 1.09 to 1.73, for loci at 4p16, 6p23-25, 16q22-24 and 17q13. Efforts are ongoing to genotype more densely spaced markers for these loci to verify the results. In addition, candidate genes in the positive loci are being sequenced in families yielding positive results.

No association between *MTHFR* alleles and non-syndromic cleft lip/palate (nsCL/P) in three South/ Central American populations. *M.A. Sozen*¹, *M. Tolarova*², *R.A. Spritz*¹. 1) Human Medical Genetics Prog, Univ Colorado Health Sci Ctr, Denver, CO; 2) Dept Orthodontics, Univ Pacific, San Francisco, CA.

Non-syndromic cleft lip with or without cleft palate (nsCL/P) is among the most common major birth defects, occurring with a frequency of 1/500-1/2500 in most populations. The inheritance of nsCL/P is complex, with likely involvement of numerous genetic and environmental risk factors in a multifactorial interaction. Several candidate genes for nsCL/P have been studied in various human populations by linkage and association analyses, including *MTHFR*, encoding methylenetetrahydrofolate reductase, a key enzyme in folic acid metabolism. These studies have yielded conflicting results, some showing apparent allelic association between *MTHFR* polymorphisms and nsCL/P, and others finding no such association.

Recently, it has been suggested that increased maternal frequency of the *MTHFR* 665T allele, which results in reduced catalytic activity, and TT genotype in the offspring, contributes to the risk of non-syndromic cleft lip and palate. We carried out a case-control allelic association study of the two common functionally significant *MTHFR* variants, C665T and A1286C, in 408 patients with nsCL/P, 304 mothers, and 299 normal controls from three different regions of South and Central America: the Santiago del Estero region of Argentina, the Cumana region of northern Venezuela, and Guatemala. We found no consistent allelic associations for these variants between cases and controls in any of these regions. The frequency of the 665C allele was increased among mothers of nsCL/P patients in Venezuela ($p=.023$) and Argentina ($p=.052$) versus in population-matched controls, but was reduced among mothers of nsCL/P patients in Guatemala ($p=.035$). We observed no significant differences in *MTHFR* allele frequencies between nsCL/P cases versus controls. Overall, we found no consistent significant associations between these *MTHFR* alleles and nsCL/P in any of these three South / Central American populations, suggesting that these variants do not play a major role in the pathogenesis of nsCL/P in these groups.

Calpain-10 Gene Polymorphisms and Type 2 Diabetes in West Africans. *Y. Chen¹, R. Kittles¹, J. Zhou¹, G. Chen¹, K. Panguluri¹, W. Chen¹, A. Amoah², V. Opoku Acheampong², B. Eghan³, A. Nyantay³, E. Ofoegbu⁴, J. Oli⁴, F. Abbiyesuku⁵, M. Kuti⁵, T. Johnson⁶, T. Rufus⁶, H. Daniel¹, G. Dunston¹, F. Collins⁷, C. Rotimi¹ and Africa America Diabetes Mellitus (AADM) Study.* 1) National Human Genome Ctr, Howard Univ, Washington, DC; 2) University of Ghana, Accra; 3) University of Science and Technology, Ghana; 4) University of Nigeria, Enugu; 5) UCH, Ibadan, Nigeria; 6) University of Lagos, Nigeria; 7) NHGRI, NIH, Bethesda.

Recently, a number of studies in different populations reported association between genetic variations in the calpain 10 gene (CAPN10) and type 2 diabetes. In this report, we investigated whether genetic variations of CAPN10 are associated with type 2 diabetes in a cohort of siblings from four major ethnic groups in West Africa (Ghana: Akans and Ga; Nigeria: Ibos and Yorubas). Three single nucleotide polymorphisms (SNPs), SNP-43, -56 and -63 in CAPN10 gene were genotyped in 840 sibpairs and 190 controls. We observed a significant twofold increase in the risk (Odds Ratio [OR] = 2.1; 95% CI=1.12 3.77) of developing type 2 diabetes for carriers of the 221 haplotype compared to controls. The 221 haplotype is however rare in these populations with a frequency of 9% in cases and 5% in controls. All the OR associated with the haplogenotypes containing the 221 haplotype were greater than the null value of 1.0; none reached statistical significance however. We did not observe any association between type 2 diabetes and individual alleles or genotypes. In conclusion, we report a significant association between a haplotype (221) of the calpain 10 and type diabetes in our cohort of diabetes patients from West Africa. The low frequency of the at risk haplotype (221) and the lack of allelic or genotypic associations detracts from a causal interpretation.

Cladistic analysis of MAOA haplotypes and association with the risk for substance use disorders. M.M.

Vanyukov^{1,2,3,5}, *B.S. Maher*^{1,4,5}, *B. Devlin*^{1,3,5}, *R.E. Tarter*^{1,3,5}, *G.P. Kirillova*^{1,5}, *R.E. Ferrell*^{1,2,5}. 1) Center for Education and Drug Abuse Research (CEDAR), Dept. of Pharmaceutical Sciences; 2) Dept. of Human Genetics; 3) Dept. of Psychiatry; 4) School of Dental Medicine; 5) University of Pittsburgh, Pittsburgh, PA.

Monoamine oxidase A (MAO-A) locus is an attractive candidate for exploring genetic contribution to variation in the risk for substance use disorders, because of its important role in the metabolism of neurotransmitters, including dopamine and serotonin. Our preliminary findings (Vanyukov et al., *Am J Med Genet* 60:122-126, 1995), since supported by others, have suggested an association of the MAOA gene with the risk for early onset substance use disorders (SUD). To extend this research, we genotyped four MAOA markers (two VNTR polymorphisms and two SNPs) spanning the gene to build a cladogram reflecting the evolutionary history of MAOA haplotypes (Devlin et al., in preparation). Following the ideas of Templeton et al. (*Genetics* 117:343-351, 1987), the cladogram served as the framework for nested logit and measured haplotype (nested ANOVA) analyses of association between MAOA and indices of liability to SUD (diagnosis, age of onset, and a dimensional index of substance use related problems [DUSI; Tarter, *Am J Drug Alcohol Abuse* 16:1-46, 1990]) in a sample of adult males of European ancestry. To replicate the original association finding (Vanyukov et al. 1995), we also tested in adult probands and their adolescent sons SUD liability association with a MAOA intron 2 (CA)_n repeat (STRP). Whereas no association was found in adults for the categorical diagnosis, a significant relationship was detected between the dimensional liability indices and MAOA haplotypes. Consistent with our prior results, the STRP was associated with the risk for SUD in adolescents (i.e., early onset disorder), but not in adults. Combined with our other findings reported herein (Maher B.S. et al.), these data suggest the relationship between the MAOA gene and SUD risk, possibly mediated by liability to early onset behavioral problems.

Paternal Uniparental Disomy of 11p15 is Associated with Isolated Hemihyperplasia and Expands the Beckwith-Wiedemann Syndrome Spectrum. *C. Shuman*^{1,2,3}, *L. Steele*^{2,4}, *Y.L. Fei*³, *P.N. Ray*^{2,3,4}, *E. Zackai*⁵, *M. Parisi*⁶, *J. Squire*^{7,8}, *R. Weksberg*^{1,2,3,9}. 1) Div Clin & Metabol Genetics, Hosp Sick Children, Toronto; 2) Dept Molec & Med Genetics, Univ Toronto, Toronto; 3) Research Institute, Hosp Sick Children, Toronto; 4) Dept Paediatr Lab Med, Hosp Sick Children, Toronto; 5) Div Human Genetics & Molecular Biology, Children's Hosp of Philadelphia; 6) Dept Medical Genetics, Univ Washington, Seattle; 7) Ontario Cancer Institute, Toronto; 8) Dept Lab Medicine & Pathobiology, and Dept Med Biophysics, Univ Toronto, Toronto; 9) Dept of Paediatrics, Hosp Sick Children, Toronto.

It has long been recognized that isolated hemihyperplasia (IH) is a clinically heterogeneous condition. A subset of these individuals have features in common with Beckwith-Wiedemann syndrome (BWS). These features include high birth weight, renal anomalies and embryonal tumor predisposition. Unlike BWS, however, the underlying molecular etiologies for IH has not been elucidated, with the exception of one report of a child with IH and adrenal carcinoma who subsequently developed Wilms tumor and who was found to have paternal uniparental isodisomy (UPD) for chromosome 11p. We report here paternal UPD for chromosome 11p in five patients with IH. On closer evaluation, some of these children had some features of BWS but did not meet the clinical diagnostic criteria for this disorder. Two of these five children developed hepatoblastoma; two others were macrosomic; and two had organomegaly. Thus, somatic mosaicism, which leads to abnormal expression of imprinted genes on 11p15, forms the molecular basis for IH in some individuals. UPD may be the cause of IH in other patients but may have gone undetected due to low level mosaicism, although other molecular etiologies may exist within this clinical diagnosis. The clinical findings in our five patients with a clinical spectrum including IH, together with UPD for 11p15, supports the concept of "mild" or "incomplete" BWS and expands the clinical spectrum of mosaicism for 11p15 UPD.

The HOXA1 G allele may be associated with dysmorphism in autism. *A.M. Persico¹, C. Stodgell², L. D'Agruma³, L. Zelante³, R. Militerni⁴, C. Bravaccio⁴, S. Trillo⁵, F. Montecchi⁵, C. Schneider⁶, R. Melmed⁶, M. Elia⁷, T. Pascucci⁸, S. Puglisi-Allegra⁸, K.L. Reichelt⁹, L.A. Muscarella³, V. Guarnieri³, M. Conciatori¹, P. Rodier².* 1) Mol Psychiatry & Neurogenet, UCBM, Rome, Italy; 2) OB/GYN, Univ of Rochester Sch of Med, Rochester, NY; 3) Med Genet Serv, IRCCS Casa Sollievo dalla Sofferenza, S.Giovanni Rotondo (FG), Italy; 4) Child Neuropsychiatry, II Univ of Naples, Italy; 5) Child Neuropsychiatry, IRCCS Osp Bambino-Gesù, Rome, Italy; 6) SARC, Phoenix, AZ; 7) Neurology Serv, IRCCS Oasi Maria SS, Troina (EN), Italy; 8) Dept of Psychology, Univ La Sapienza, Rome, Italy; 9) Dept of Pediatric Res, Rikshospitalet, Univ of Oslo, Norway.

The HOXA1 G allele has been associated with autism (Ingram et al 2000). This study attempts to replicate and extend these findings in 127 autistic probands from simplex Italian families, yielding 114 complete and 13 incomplete trios, and in 101 complete trios from 46 simplex and 55 multiplex Caucasian-American families. The A, and not the G allele, displays a significantly higher frequency in 127 Italian autistics contrasted with 173 ethnically-matched population controls ($\chi^2=6.41$ and 3.87 for genotypes and alleles, respectively, 1df, $P<0.05$). Transmission of the A allele from heterozygote parents to affected offspring is significantly favored over the G allele in 215 complete trios (TDT $\chi^2=6.05$, 1df, $P<0.05$), especially in simplex, but not in multiplex families, and to a larger extent in Italian than in Caucasian-American trios. Several individuals carrying one- or three-histidine deletions were also identified. Histidine deletions were consistently found in A/G individuals, more frequently on A than on G alleles, and were not associated with autism. Since 32/57 (56.1%) autistic probands assessed by Ingram et al (2000) displayed mild-to-moderate dysmorphic features, a cause for exclusion from the current study, we hypothesize that the HOXA1 G allele may be associated with dysmorphic features seen in autism-spectrum disorders. Supported by Telethon-Italy (E.0858), Italian Min. Health (ICS.190.1.RF99/90), CNR (99.00555.PF33), and N.A.A.R.

Liver pyruvate kinase polymorphisms are associated with type 2 diabetes in Northern European Caucasians. *S.K. Das¹, H. Wang¹, Q. Ren¹, W. Chu¹, S.J. Hasstedt³, S.C. Elbein^{1,2}.* 1) Medicine, University of Arkansas for Medical Sciences, Little Rock, AR; 2) Central Arkansas Veterans Healthcare System, Little Rock, AR; 3) Department of Human Genetics, University of Utah Health Sciences Center, Salt Lake City, UT.

Pyruvate kinase is a key glycolytic enzyme. Isoforms that are expressed in the red cell, liver, pancreatic β cells, small intestine, and proximal renal tubule are encoded by the 12 exons of the PKLR gene, which maps to chromosome 1q23. We hypothesized that common variants of the PKLR gene could account for the linkage of diabetes to this region. We screened the promoter regions, exons and surrounding introns, and the 3' untranslated region for mutations. We identified 5 single nucleotide polymorphisms (SNPs); only one (V506I, exon 11) altered the coding sequence. We tested the 5 SNPs, a poly-T insertion-deletion polymorphism, and an ATT triplet repeat in 131 unrelated diabetic individuals and 118 non-diabetic control individuals. The V506I variant was rare and not associated with type 2 diabetes. The 4 SNPs and the insertion deletion polymorphism were associated with diabetes with a 10% difference in allele frequency between individuals with diabetes and nondiabetic individuals (p 0.001 to 0.011; relative risk for minor allele 1.85). The same trend was found for the ATT repeat ($p=0.029$). The 5 diallelic variants, spanning 9.4 kb, were in strong linkage disequilibrium. Thus, 98.4% of all haplotypes fell into two classes. We next determined these two haplotypes in 698 individuals (283 affected) from 63 kindreds. No excess transmission to affected offspring was found, and neither haplotype was associated with glucose or insulin levels, nor with measures of insulin secretion. Common variants in the PKLR are associated with increased risk of type 2 diabetes, but because of strong linkage disequilibrium between variants, the actual susceptibility allele may be in a different gene. Additional studies are required to reconcile the lack of association on transmission disequilibrium testing and the lack of effect on measured phenotypes with apparent the population association.

A role of hereditary hemochromatosis HFE gene mutations in susceptibility to type 2 diabetes mellitus in a Polish population. *M.T. Malecki¹, T. Klupa¹, M. Walus¹, W. Czogala¹, J. Bochenski², P. Greenlaw¹, J. Sieradzki¹.* 1) Dept. of Metabolic Diseases, Jagiellonian University, Krakow, Poland; 2) Joslin Diabetes Center, Boston, MA, USA.

Hereditary hemochromatosis (HH) is a frequent, autosomal recessive metabolic disorder characterised by excess iron deposition in various organs. Two mutations in the HFE gene are associated with HH. Due to the high prevalence of type 2 diabetes mellitus (T2DM) in HH, a hypothesis exists that heterozygous carriers of HFE mutations may be at a higher risk of developing T2DM. Aims: 1) To identify the frequency of C282Y and H63D mutations in a population of from the Malopolska region in southeastern Poland; 2) To search for an association of HFE mutations with T2DM in this population. Methods: We included 391 individuals in this study: 222 T2DM patients and 169 controls. The fragments of HFE were amplified by PCR. Alleles and genotypes were determined by gel electrophoresis of the DNA digestion products from SnaBI and DpnII, respectively. Differences in distributions were examined by χ^2 test. Results: At codon 282 the frequency of C/Y alleles was 98.2%/1.8% in T2DM patients and 96.7%/3.2% in controls ($p=0.19$). At codon 63 the frequency of H/D alleles were 85.6%/14.4% and 88.8%/11.2% ($p=0.19$), respectively. The distribution of genotypes was not statistically different between the two groups, although a trend of higher frequency of HD and DD genotypes was observed in T2DM group (27.4% vs. 20.1%, $p=0.09$). However, in the stratified analyses based on T2DM age of onset and gender, we observed a higher prevalence of HD and DD genotypes among T2DM patients diagnosed at > 49 years of age, the mean age for the entire group, ($p=0.018$) and among male T2DM individuals ($p=0.005$) than in the controls. Conclusion: 1) The frequency of HH associated mutations in this population from southeastern Poland is similar to other Caucasians; 2) We did not find evidence for the recently reported association of C282Y mutation with T2DM in a Polish population. However, the results of our study suggest that the H63D mutation may play a role in the pathogenesis of late onset T2DM and in males in a Polish population.

Mutation scan of the human Interleukin-18 Binding Protein: A candidate gene for type 1 (insulin dependent) diabetes. *R. Nolsoe¹, F. Pociot¹, D. Novick², M. Rubinstein², S.-H. Kim², C.A. Dinarello³, T. Mandrup-Poulsen¹.* 1) Steno Diabetes Ctr, Gentofte, Denmark; 2) Weizmann Institute, Rehovot, Israel; 3) University of Colorado Health Sciences Ctr, Denver, CO.

Background/Aims. Type 1 (insulin dependent) diabetes, T1D, is the result of an immune mediated destruction of the pancreatic beta cells dependent mainly on T helper cells and macrophages. Interleukin-18, IL-18, is a proinflammatory cytokine produced mainly by macrophages. IL-18 is capable of inducing T lymphocyte synthesis of IFN γ thereby skewing the T helper response toward a T helper type 1 profile. Interleukin-18 binding protein, IL18BP, neutralizes interleukin 18 and leads to a reduced T helper type 1 response. Polymorphisms in *IL18BP* may affect IL18 activity and the magnitude of the T1 helper response and may play a role in the pathogenesis of T1D. The aim of the study was therefore to identify polymorphisms in *IL18BP* and to test these for association to T1D. **Methods.** We evaluated the human IL18BP gene on chromosome 11q13 as a candidate susceptibility gene for T1D and scanned the entire *IL18BP* (promoter, exons 1-4 and 3'UTR) for polymorphisms using single strand conformational polymorphism analysis and direct sequencing. **Results.** We identified a total of eleven polymorphisms, all having allele frequencies ranging between 0.05 and 0.10. Four were in the promoter region; -257G>T, -78C>T, -65G>A and -59Gins. Three were in intron 2; 1869A>C, 2226G>T and 2314G>T and the last four; 3071A>T, 3081T>A, 3421C>G and 3474Gins were in the 3'UTR of *IL18BP*. **Conclusion.** We identified eleven polymorphisms in *IL18BP*. However, none of these were frequent enough to permit association studies in T1D, and we conclude that *IL18BP* does not contribute to the overall genetic susceptibility to type 1 diabetes.

A high resolution SNP association scan for IDDM1. *M. Wjst*¹, *N. Herbon*¹, *M. Werner*¹, *E. Bonifacio*², *A. Ziegler*². 1) Inst fuer Epidemiologie, GSF Forsch Umwelt & Gesundh, Munich, Germany; 2) Diabetes Research Institute, Munich, Germany.

Type 1 diabetes (T1D) is an autoimmune disease which is highly associated with HLA class II genes in the major histocompatibility complex (MHC) on chromosome 6p21. Association analysis of the MHC region reveal certain highly predisposing or protective haplotypes designed as IDDM1. Although the contribution of additional susceptible loci with minor effects is likely they could not be identified because of strong linkage disequilibrium in this region.

We tested in a case-control approach study 534 SNPs selected from an initial set of 1,435 SNPs covering 25 Mb around the HLA complex. We compared the allele frequencies between DNA pools of 192 German late onset T1D patients and 288 healthy individuals from a South German population-based survey using MALDI-TOF.

The already known association with the haplotypes DR3 and DR4 could be confirmed by highly significant allele differences of four SNPs located between DQB1 and DRB1 genes. Additionally, association of T1D with DOB and TNF as risk modifiers could be reproduced. We found three further potential disease loci in the HLA-class I respectively class III region which remain to be confirmed in individual haplotypes.

These findings suggest that allele frequency analysis of randomly selected markers even with low polymorphism information content is a promising method to identify disease associated loci in large linkage regions.

Association Study of *Fas* and *FasL* Polymorphisms with Multiple Sclerosis. *B.G. Weinshenker*¹, *D.D. Hebrink*¹, *O.H. Kantarci*¹, *S.J. Achenbach*², *E.J. Atkinson*², *C.T. McMurray*³. 1) Department of Neurology, Mayo Clinic and Foundation, Rochester, MN; 2) Department of Health Sciences Research, Mayo Clinic and Foundation, Rochester, MN; 3) Departments of Pharmacology, Biochemistry and Molecular Biology, Mayo Clinic and Foundation, Rochester, MN.

Fas and *FasL* expression leads to antigen activation-induced apoptosis of T-cells. Mutations in *Fas* and *FasL* cause autoimmunity and lymphoproliferation in mice and humans. Others have reported association of polymorphisms adjacent to or in *Fas* and *FasL* with multiple sclerosis (MS) susceptibility. We studied the association of *Fas* and *FasL* polymorphisms with susceptibility to, gender bias, age at onset, course and disability indexed to time of MS. Three SNPs per gene were selected to establish haplotypes that span the genes. We genotyped a population-based sample of 122 cases and 244 gender, age and ethnicity-matched controls using PCR-RFLP. Results were not corrected for multiple comparisons in this preliminary analysis. There was linkage disequilibrium (LD) between 5'(-670) and Exon7(74) SNPs of *Fas* ($p < 0.00001$). MS was more frequent in women, but not in men, who were homozygous for 5'(-670)*A ($p = 0.034$; OR:1.78, 95% CI:1.04-3.03) and for Exon7(74)*C ($p = 0.019$; OR:1.84, 95% CI:1.10-3.07), the specific alleles in LD, and for the haplotype defined by these alleles ($p = 0.053$; OR:1.66, 95% CI:0.99-2.78). Homozygotes for Exon7(74)*C more frequently had a primary progressive versus bout onset course ($p = 0.057$; OR:3.92, 95% CI:0.88-14.43). None of the *Fas* polymorphisms was associated with disease severity or age at onset. There was LD between 5'(-663), Intron2(1153) and Intron2(2776) SNPs of *FasL* ($p < 0.00001$). Carriers of 5'(-663)*T had increased susceptibility to MS ($p = 0.005$; OR:2.02, 95% CI:1.23-3.32), the effect being primarily due to a difference in the frequency of heterozygotes. None of the *FasL* polymorphisms was associated with age of onset, severity or course.

Two SNPs of *Fas* in LD with one another and a 5' region SNP of *FasL* may be associated with susceptibility to MS. For the *Fas* SNPs, the effect was evident only in homozygous women.

Cladistic analysis of MAOA haplotypes and association with the risk for attention deficit hyperactivity disorder.

B.S. Maher, B. Devlin, M.L. Marazita, M.M. Vanyukov, R.E. Ferrell. Univ Pittsburgh, Pittsburgh, PA.

The monoamine oxidases (MAO-A and MAO-B) are of interest in the study of many behavioral traits and disorders because of their role in the nervous system. Prior findings suggested contribution of the MAOA gene to variation in impulsivity, aggression and the risk for substance use disorder (SUD). SUD is frequently preceded by attention deficit hyperactivity disorder (ADHD). In turn, the highly heritable dimensional traits of hyperactivity-impulsivity and inattention underlie the risk for ADHD. We hypothesized that hyperactivity-impulsivity is associated with the MAOA gene, possibly mediating the MAOA association with the risk for ADHD. As part of an ongoing study, we inferred a cladogram representing the evolutionary relationship of MAOA haplotypes based on four markers (two VNTR polymorphisms and two SNPs) spanning the gene. Based on this cladogram, we tested for association between MAOA haplotypes and ADHD-related traits (hyperactivity-impulsivity and inattention), using measured haplotype analysis. We also tested for association between an STRP in intron 2 of MAOA ([CA]_n repeat), previously shown to be related to the risk for SUD, and the ADHD-related traits. ADHD was quantified in 163 10-12 year old Caucasian males using DSM-III-R criteria. Hyperactivity-impulsivity and inattention scores used in the study were derived via factor analysis. No association was found between the haplotypes and ADHD risk dimensions. However, moderate association (without Bonferroni correction) was detected between the MAO STRP and hyperactivity-impulsivity ($p=0.02$). This finding supports the hypothesis that variants in MAOA affect liability to ADHD, albeit weakly. Further research into this apparent association is required.

Association analysis guided by the evolution of haplotypes. *H. Seltman*¹, *K. Roeder*¹, *B. Devlin*². 1) Department of Statistics, Carnegie Mellon University, Pittsburgh, PA., USA; 2) Department of Psychiatry, University of Pittsburgh School of Medicine.

Association studies, both family-based and population-based, are a powerful means of detecting disease-liability alleles. To increase the information of the test, various researchers have proposed targeting haplotypes. Haplotypes indeed produce more definitive transmissions than the alleles comprising them, and this tends to increase power. However, the larger number of haplotypes, relative to alleles at individual loci, tends to decrease power because of the additional degrees of freedom required for the test. An optimal strategy would focus the test on particular haplotypes or groups of haplotypes much as has been done with measured haplotype analysis (MHA). First suggested by Templeton and colleagues, MHA uses the evolutionary relationships among haplotypes to produce a limited set of hypothesis tests and to increase the interpretability of these tests. To fully utilize the information contained in the evolutionary relationships among haplotypes, we propose a number of methodological extensions for the analysis of data from family-based and population-based studies. These extensions account for haplotype phase ambiguity; detect likely recombinants; incorporate covariates as needed; model correlation among siblings when they are available; and can detect likely errors in genotyping and paternity assignment. While not all of the methods are new, they are integrated into a software package that allows for exploratory data analysis and tests for association in samples of multilocus genotypes around candidate genes.

Triplet repeat sizes in candidate genes for Spinocerebellar Ataxia. *C. Homem¹, P. Magalhães¹, J. Sequeiros^{1,2}, I. Silveira¹*. 1) UnIGENE, IBMC, Porto, Portugal; 2) Laboratório Genética Médica, ICBAS; University of Porto, Portugal.

Spinocerebellar ataxias (SCAs) are a heterogeneous group of neurodegenerative disorders with a large range of clinical manifestations. At least fifteen genes are implicated in autosomal dominant SCAs: SCA1, SCA2, SCA3/MJD, SCA4, SCA5, SCA6, SCA7, SCA8, SCA10, SCA11, SCA12, SCA13, SCA14, SCA17 and the dentatorubropallidoluysian atrophy (DRPLA) gene. A triplet repeat expansion is responsible for 10 of these types of SCAs, but there are still many affected families not assigned to any of them. To identify additional genes implicated in these disorders, we selected nine expressed brain genes with triplet repeat tracts, which thus are good functional candidates for these neurodegenerative diseases. Repeat sizes were assessed for CALM1, MAB21L1, STC1, CBP, NUMBL, GRIK2, KCNN3, RAI1 and Clone 2.70 in 73 unrelated patients with SCA. All these patients were previously excluded for SCA1, SCA2, SCA3/MJD, SCA6, SCA7, SCA8, SCA12, SCA17 and DRPLA. Two genes that account for a significant number of expansions found by RED analysis were also studied, ERDA1 and SEF2-1. Large alleles were not found at any of the nine candidate genes. The ERDA1 gene showed CAG/CTG alleles of 50 to 81 repeats in 20 patients, including two affecteds from one SCA family with dementia and chorea associated. A large allele with 86 CTGs was also found at the SEF2-1 gene. In conclusion, the functional candidate genes selected do not seem to be responsible for SCA in our families.

Regions of Instability and Mutability at the *SCA8* locus. *S. Martins*¹, *P. Magalhães*¹, *I. Alonso*^{1,2}, *J. Sequeiros*^{1,2}, *I. Silveira*¹. 1) UnIGENE, IBMC, Porto, Portugal; 2) Laboratório Genética Médica, ICBAS, Universidade do Porto, Portugal.

Spinocerebellar ataxia type 8 (SCA8) is a form of late-onset neurodegenerative disorder characterized by gait, limb and speech incoordination, in addition to other variable signs. An untranslated (CTG)_n expansion on chromosome 13q21, preceded by a polymorphic stable CTA tract, has been described as being responsible for this disease. However, its pathogenic role remains controversial as very large alleles have been observed, not only in SCA8 patients, but also in patients with psychiatric disorders and in healthy control subjects. Therefore, reduced penetrance, as well as genetic instability and a maternal bias towards expansion are still a matter of debate. We have previously reported a high instability in spermatogenesis of both expanded and normal alleles, suggesting a high mutational rate at the *SCA8* locus. In order to gain insight into the biological role of the *SCA8* locus, we 1) performed a haplotype analysis, including the CTA-CTG polymorphism and eight SNPs flanking the repeat, and 2) looked for intergenerational instability and mutability in this region, in five SCA8 families and 20 control families. The analysis of two exonic SNPs (a A/G and a T/del) and an intronic C/T, upstream from the repeat, showed a common haplotype associated to the disease in all SCA8 families. In the control families, the most frequent allele had 24 CTA-CTG repeats. Interestingly all the possible haplotypes resulting from the A/G and C/T polymorphisms were seen with this allele, which suggests a higher instability rate for the 24 CTA-CTG repeat. We are completing haplotypes with the additional SNPs to identify the entire region shared by our SCA8 patients, as well as the mutability region.

A rigorous test of the CAG trinucleotide repeat expansion hypothesis of schizophrenia. *T. Tsutsumi¹, S.E. Holmes¹, A. Sawa¹, C. Callahan¹, M.G. McInnis¹, C.A. Ross¹, L. DeLisi², R.L. Margolis¹.* 1) Dept of Psychiatry, Johns Hopkins University, Baltimore, MD; 2) Dept of Psychiatry, New York University, New York, USA.

We and others have proposed that the genetic risk for schizophrenia and other psychiatric disorders could at least partly stem from expansion of trinucleotide repeats, particularly of the CAG/CTG type. To search for novel CAG/CTG repeat expansions, we examined 100 unrelated probands with familial schizophrenia using the Repeat Expansion Detection (RED) technique, an assay that detects the presence of CAG/CTG repeats larger than about 50 triplets in length in genomic DNA. 28 subjects with CAG/CTG expansions were detected using the RED assay. Using PCR and genomic Southern blots, we tested each RED positive sample for all known pathogenic and nonpathogenic repeat expansions. The expansion in 20 subjects could be accounted for by the nonpathogenic expansion at the Dir1 locus on 17q21. 7 of the 8 remaining subjects had expansions of the CTG repeat in SEF2-1 on 18q21, another expansion with no known consequences. The remaining subject had an expansion of the spinocerebellar ataxia type 8 (SCA8) locus on 13q21; this expansion may cause spinocerebellar ataxia type 8, but also occurs in the normal population. In conclusion, all RED positive cases could be explained by expansion of one of three loci known to undergo CAG/CTG repeat expansion in the normal population. While none of the repeat expansions that we detected were novel, we cannot exclude the possibility that the SEF2-1 repeat, expanded in 7% of our patients vs. 3% of the general population, could contribute to the risk for schizophrenia. This analysis also does not address CAG/CTG expansions below the threshold of detection for RED or other types of repeats, several of which have been associated with CNS disease.

Bipolar and Panic Disorder: Common and Syndrome-Specific Genes? *M. Durner*¹, *AJ. Fyer*², *SE. Hodge*^{1,2}, *SP. Hamilton*², *JA. Knowles*^{2,3}, *MM. Weissman*^{2, 4}. 1) Biostatistics; 2) Psychiatry; 3) Genome Center; 4) Epidemiology, Columbia University, New York.

A high comorbidity of bipolar disease (BP) and panic disorder (PD) has been noted in epidemiological studies. Additionally, genetic studies in BP have indicated also a genetic connection between BP and PD. We hypothesize that there may be two types of genes for BP and PD - some genes shared by both diseases, but also syndrome specific genes and it will be the interaction of both that will produce the particular phenotype. We tested this hypothesis in a dataset of 120 multiplex PD families, of whom 37 also had ≥ 1 member affected with BP. A complete genome scan was performed in all 120 families by CIDR. To search for a common gene for BP and PD, we first analyzed all families together, treating any family member with either PD or BP as affected. Secondly we analyzed families separately, depending on whether they had at least one BP member (PD+BP) or none (PD-BP). We calculated 2-point lodscores, allowing for independent male and female recombination fractions $q = (q_m, q_f)$, and assuming dominant (DOM) and recessive (REC) inheritance with an arbitrary penetrance of 50%. Search for common genes: The highest maxlod (Z_{\max}) of 4.9 at $q = .1, .3$ occurred at D2S125 (under DOM). When we considered only PD, but not BP as affected, the lod dropped to 4.5. Another peak occurred on chr.12. At PAH, Z_{\max} was 4.3 ($q = .1, .3$). Assuming REC, we found a $Z_{\max} = 4.3$ ($q = .1, .01$) at D17S1298. . Both PD-BP and PD+BP families contributed proportionally to these lods indicating that these loci are involved in both types of families. Search for syndrome specific genes: Analyzing PD+BP and PD-BP families separately, we found evidence for linkage in PD-BP families at D4S1644 with $Z_{\max} = 3.1$ and at D5S211 with $Z_{\max} = 3.3$. The PD+BP families had negative lods at these locations. The Predivided-Sample Test showed a significant difference between these two groups ($p < 0.5$). In PD+BP families, Z_{\max} was 3.0 at D13S779, vs. 0.9 in PD-BP families. Our findings might indicate genes common for PD and BP on chr.2, 12 and 17 interacting with genes on chr.4, 5 or 13 to produce the bipolar or panic phenotype.

Genetic Contribution to Uric acid in hypertension families : The Korean Cardiovascular Genome Study. *E.Y*

Cho^{1,2}, *C.M Park*^{1,5}, *S.J Bae*^{1,4}, *H.Y. Park*^{1,2}, *S.H. Baek*^{1,6}, *S.H. Jee*^{1,3}, *J.H. Lee*^{1,4}, *D.H Choi*^{1,2}, *Y. Jang*^{1,2}. 1) Cardiovascular Genome Center, Yonsei University, Seoul, Korea; 2) Yonsei Cardiovascular Research Institute, Division of Cardiology, Department of Internal Medicine, Yonsei University, College of Medicine, Seoul, Korea; 3) Department of Epidemiology and Disease Control, Graduate School of Health Science and Management, Yonsei University, Seoul, Korea; 4) Department of Food and Nutrition, College of Human Ecology, Yonsei University, Seoul, Korea; 5) Graduate Program in Biostatistics and Computing; 6) Division of Cardiovascular Medicine St. Vincent's Hospital The Catholic University of Korea.

Hyperuricemia is predictive for the development of hypertension and is associated with increased cardiovascular morbidity and mortality. Serum uric acid level is affected by multiple factors which is known to be a coronary artery risk factor and genetic factors. To address this issue, we investigated environmental, familial, and genetic influences on uric acid in 635 members of 136 families who had participated in the Korean Cardiovascular Proband Study. Proband was diagnosed essential hypertension and had not nephropathy. Maximum likelihood methods were used to fit several genetic and nongenetic models of inheritance. Adjustments for age, BMI, blood pressure, lipid levels, smoking and drink status were carried out separately for males and females by multiple regression procedures for uric acid phenotypes prior to segregation analysis. Uric acid was normally distributed and ranged from 2.00 to 11.00, with a mean of 4.86 (male, 5.68 and females, 4.09) in the entire samples. Serum uric acid levels had positive correlation with BMI, systolic blood pressure in males and with age, BMI in females. Adjusted uric acid showed weak spouse correlation (0.27) and showed stronger parent-offspring correlation and sibling correlation (0.32, 0.45) respectively. The most parsimonious model was a dominant model and estimated heritability of the uric acid was 0.681. Our results showed the major gene effect determining the uric acid in the Korean population, and linkage analyses using the genetic markers should be followed for identification of candidate genes.

ANOTHER LOCUS FOR AUTOSOMAL DOMINANT LATE ONSET ALZHEIMERS DISEASE IN BRAZILIAN FAMILIES ? *A.L. Nishimura¹, J.R.M. Oliveira², P.R. Brito-Marques³, R. Nitrini⁴, P.H. Bertolucci⁵, I.H. Okamoto⁵, M. Zatz¹.* 1) Dept. Biologia, Universidade de So Paulo, São Paulo, São Paulo, Brasil; 2) Department of Neurology, UCLA, USA; 3) Centro de Neurologia Cognitiva e do Comportamento da Universidade de Pernambuco, Pernambuco, Brasil; 4) Departamento de Neurologia da Faculdade de Medicina, USP, Brasil; 5) Departamento de Neurologia e Neurocirurgia da UNIFESP, Brasil.

Alzheimers disease(AD), the most common form of dementia in elderly, is characterized by a progressive deterioration in memory, language and others cognitive functions. Three autosomal dominant genes (the Amyloid Precursor Protein - APP, Presenilin 1 - PSEN1 and Presenilin 2 - PSEN2) responsible for early onset familial AD (AD-FAD) have been identified. However, familial AD accounts for less than 1% of all cases. Among the several susceptibility loci responsible for late onset AD (LOAD), the APOEε4 allele is the most important risk factor worldwide. Moreover, a functional polymorphism on the serotonin transporter promoter (5-HTTLPR) has been reported as a susceptibility gene to AD. We have ascertained four families with patients affected by AD displaying an autosomal dominant pattern of inheritance. A total of 10 patients were personally examined in these families and the diagnosis criteria was based on NINCDS-ADRDA. Linkage analysis allowed to exclude the autosomal dominant APP, PSEN1, PSEN2 genes as responsible for AD in three of these families. In addition, the association with the Apoe4 allele or the 5-HTTLPR polymorphic locus and AD was not found in all patients, although these markers represent only susceptibility loci. Based on these results, we suggest the existence of another gene, or more genes for autosomal dominant Alzheimer Disease in Brazilian patients. Supported by FAPESP, PRONEX and CNPq.

Familial Parkinsonism in an Ohio Amish Pedigree. *S.L. Lee^{1,2}, A. Crunk², L. McFarland², Y. Bradford², T.L. Davis¹, J.L. Haines²*. 1) Department of Neurology, Vanderbilt University Medical Center, Nashville, TN; 2) Program in Human Genetics, Department of Molecular Physiology and Biophysics, Vanderbilt University Medical Center, Nashville, TN.

Genetic analysis in rare familial cases of Parkinson disease (PD) have identified three genes, alpha-synuclein, parkin, ubiquitin carboxy-terminal hydrolase-L1, and several chromosomal regions as being involved in PD. The discovery of additional hereditary causes may further elucidate the underlying pathogenesis and provide new pharmacological targets. From 1998 to 2002, individuals from an Amish community near Holmes County Ohio were interviewed and examined for parkinsonism and/or dementia. Fifteen affected individuals from 13 nuclear families were evaluated and identified as having PD. Genealogical research revealed a common ancestor through seven generations, generating a very large and complex single pedigree. The age range of affected individuals is 46 to 85 years. The average age of onset is 53 years with a range of 39 to 74 years. Clinical characteristics were typical for idiopathic PD, including rest tremor of asymmetric onset, bradykinesia and rigidity without early postural instability. Those who were treated with levodopa were responsive to medications. In addition, there was one family member who appeared to have essential tremor, and another with progressive supranuclear palsy. Initial genetic analysis with markers in existing regions suggest that this family has a novel gene. A genomic screen with approximately 350 microsatellite markers is underway. Preliminary analyses suggest possible locations on chromosomes 5 and 3.

Absence of linkage to the chromosome 4q24 Finnish migraine locus among 78 migraine families of European descent. *T. Wieser*¹, *J. Pascual*², *M. Barmada*³, *M. Soso*⁴, *A. Oterino*², *K. Gardner*⁴. 1) Martin-Luther-University Halle, Dept. of Neurology, Germany; 2) University Marques de Valdecilla, Dept. of Neurology, Spain; 3) University of Pittsburgh, Dept. of Human Genetics, USA; 4) University of Pittsburgh, Dept. of Neurology, USA.

Objective: Investigate 78 migraine families for linkage to the Finnish migraine with aura locus on Chromosome 4q24. **Background:** Migraine with and without aura is thought to be a genetically complex disorder. A genome scan for familial migraine with aura recently found a single locus of significance (LOD 4.2) on 4q24 among 50 Finnish families. Significant migraine loci had previously been found only for rare highly penetrant autosomal dominant hemiplegic migraine families. Replication of linkage data in broader ethnic groups is necessary to establish the importance of a locus identified in a genetic isolate. **Methods:** We ascertained 78 families (average size 7 member/family) with probands identified in headache clinics using International Headache Society criteria for headache type and genotyped markers D4S1560, D4S1647 and D4S250 using a 3700 ABI PRISM DNA Analyser. Alleles were assigned using the GeneScan Analysis software. Analysis for affected relative allele sharing and linkage was performed using ALLEGRO, VITESSE 1.1 programs and the maximized maximum LOD score (MMLS) method using several models. **Results:** Seventy-eight multi-generational families were ascertained from North America (33), Spain (27), and Germany (18). 135 individuals had migraine without aura (35 families), 74 migraine with aura (25 families), 68 hemiplegic migraine (18 families), 6 of other type (mixed 5, acephalgic migraine 1) and 79 unknown (not fulfilling diagnostic criteria). More than 50% of affected individuals and 55% of families had migraine aura (including 23% hemiplegic) compared with the Finnish families. The combined two point as well as multipoint LOD scores were below 2 for all three markers. **Conclusion:** Exclusion of the chromosome 4q24 migraine aura locus among 78 families of European descent suggests the finding may be restricted to the Finnish population and correlates with expected genetic heterogeneity.

SCREENING OF SPINK1 MUTATIONS INDICATE FURTHER HETEROGENEITY FOR CHRONIC

PANCREATITIS. *A.L. Bernardino¹, D.R. Guarita², C.B. Mott², M.R.A. Pedroso², M.C.C. Machado², A.A. Laudanna², C.M. Tani², F.L. Almeida¹, M. Zatz¹.* 1) Centro de Estudos do Genoma Humano, Dept Biologia, Universidade de São Paulo, São Paulo, Brazil; 2) Setor de Gastroenterologia, Faculdade de Medicina, Universidade de São Paulo, São Paulo, Brasil.

Chronic Pancreatitis is defined as a continuing inflammatory disease of the pancreas, characterized by irreversible morphological change and/or permanent impairment of function. Recent studies have indicated that mutations in the serine protease inhibitor, Kazal type 1 (SPINK1) gene are associated with chronic pancreatitis. However, the significance and inheritance pattern of SPINK1 mutations has been differently interpreted by different groups. We have screened 87 Brazilian unrelated patients with chronic pancreatitis (alcohol-related disease in 64, idiopathic disease in 16 and hereditary disease in 2) and 5 patients with acute idiopathic pancreatitis for mutations in the SPINK1 gene and also for the CFTR and PRSS1 genes. Five alterations were identified in the SPINK1 gene (-253T>C, -164G>C, 1-7T>G, c75C>T, +32C>T). It is important to emphasize that the missense mutation N34S, which has been associated with chronic pancreatitis among Caucasians, was not found in our patients. The same samples were tested in another study with CFTR and PRSS1 genes. Mutations in the CFTR gene were found in 8 patients (~9%) with chronic pancreatitis. In the PRSS1 gene only the E79K change was found in a patient with alcohol-related chronic pancreatitis. These results, in Brazilian patients, reinforce the importance of the molecular analysis of the CFTR gene in chronic pancreatitis. Moreover our study indicates the existence of at least one more gene responsible for hereditary and idiopathic chronic pancreatitis. Supported by FAPESP, PRONEX, CNPq.

Sequence variation in the CARD15 (NOD2) gene and susceptibility to Crohn's disease. *K. KING, M.M. MIRZA, S.A. FISHER, A.P. CUTHBERT, C.M. LEWIS, C.G. MATHEW.* Div of Med and Mol Genetics, GKT School of Medicine, LONDON, UK.

Crohn's disease (CD), a subtype of inflammatory bowel disease (IBD), is a complex disorder, with both genetic and environmental aetiology. Three sequence variants (R702W, G908R and 1007fs) in the CARD15 gene have been shown to be associated with susceptibility to CD. Genotype relative risks (GRRs) for these disease susceptibility alleles (DSAs) in our cohort of 688 unrelated cases of CD were 3.0 for heterozygotes and 24 for homozygotes/compound heterozygotes. There is also evidence of an excess of rare CARD15 variants in CD, but whether these are true DSAs is unknown. In order to investigate the contribution of rare variants to CD we have selected a panel of 192 British CD patients who are heterozygous for either R702W, G908R or 1007fs for comprehensive mutation screening. The 12 exons and 5' and 3' UTRs of CARD15 were screened for mutations using the WAVE® System, and amplicons containing heteroduplexes sequenced to identify both common polymorphisms and rare potential DSAs. Screening of the first panel of 31 heterozygous CD patients revealed four rare variants. The parents of these patients were genotyped to determine whether the rare variant was cis or trans to their known DSA. Three of the four rare variants (A612T, N852S, V955I) were in trans i.e. inherited from the parent who did not carry the known DSA, and one (M863V) was transmitted on the same haplotype as 1007fs. All four rare variants are located in sequence that encodes the functional leucine-rich repeat region of CARD15. Rare variants that are candidate DSAs are being genotyped using the TaqMan allelic discrimination assay in a cohort of 1000 CD cases and 1000 controls to determine whether they have a significantly elevated frequency in CD. The results of this study may clarify whether the genetic model for CARD15 mutations best fits: (i) a gene dosage model with a lower risk for heterozygotes than homozygotes or compound heterozygotes, or (ii) a fully recessive model with no increased risk for heterozygotes and high genotype relative risk in homozygotes.

Identification and characterization of *BBS2L1*, a paralog of the Bardet-Biedl syndrome gene 2. *J.L. Badano*^{1,3}, *S.J. Ansley*¹, *R.A. Lewis*^{3,4,5,6,7}, *J.R. Lupski*^{3,5,7}, *N. Katsanis*^{1,2}. 1) Institute of Genetic Medicine, Johns Hopkins University; 2) Wilmer Eye Institute, Baltimore, MD; 3) Departments of Molecular and Human Genetics; 4) Ophthalmology; 5) Pediatrics; 6) Medicine; 7) The Texas Children's Hospital, Baylor College of Medicine, Houston, TX.

Bardet-Biedl Syndrome (BBS) is a genetically heterogeneous disease characterized by obesity, retinal dystrophy, polydactyly, hypogenitalism, learning difficulties and renal malformations. Based on an autosomal recessive mode of inheritance six loci have been mapped (*BBS1-6*), three of which have been cloned and shown to cause disease independently and in various combinations. While the predicted protein sequence of *BBS4* and *BBS6* have provided some clues about their biological role, the amino acid sequence of *BBS2* does not reveal any biological information as it does not exhibit any similarity to genes of known function nor does it contain any recognizable motifs, with the exception of a coiled-coil domain at the amino terminus of the protein. Since the orthologs of *BBS2* exhibit substantial conservation across the entire protein, we sought to identify non-orthologous members of the *BBS2* family in humans and other organisms and thereby identify regions of *BBS2* with elevated evolutionary conservation that likely represent novel domains. We report the cloning and characterization of a novel gene in human and mouse, *BBS2L1* (*BBS2* Like 1). *BBS2L1* maps to chromosome 4q23 and encodes a predicted protein of 672 amino acids. *BBS2* and *BBS2L1* show 37% similarity and 26% identity over a specific 260 amino-acid region, which encodes a putative six-blade propeller structure with similarity to the integrin protein family. This represents the first recognizable *BBS2* domain and is likely to be important in the elucidation of the cellular role(s) of this protein family. Although mutation analysis of *BBS2L1* on a cohort of 80 BBS families did not reveal any clear pathogenic alterations, the possibility that *BBS2L1* shares some functional role with *BBS2* cannot be excluded.

KCNAB1 is not responsible for predisposition to a subgroup of juvenile myoclonic epilepsy. *O.V. Evgrafov¹, F.L. Zheng^{1,2}, P. Tabares^{1,2}, M. Durner², D. Pal², C. Gilliam¹, D.A. Greenberg^{1,2}.* 1) Genome Center, Columbia University; 2) Div of Statistical Genetics, Columbia University, NY NY.

Idiopathic generalized epilepsy (IGE) is a set of syndromes with little if any involvement of environmental factors, suggesting a completely genetic, and likely oligogenic, origin. Several gene locations have been suggested in different studies, one of which is on chromosome 3 (Sander et al, 2000). Interestingly, in our data, we found evidence for linkage in a subgroup of IGE in that area of chr. 3: juvenile myoclonic epilepsy (JME) without absence in the family. The multipoint lodscore maximized around D3S1614 (178 cM) with a value of 2.3. There is an obvious candidate gene in the region, KCNAB1, which codes for a beta 1 subunit of the potassium voltage gated channel. This gene is expressed in brain and the corresponding protein modulates gating properties of the channel. It is a suggested counterpart of the alpha subunit coded by the KCNA5 gene. Some of the known genes responsible for rare mendelian epilepsies are potassium channels. We have sequenced the coding and promoter regions of KCNAB1 in probands from 5 families with the strongest linkage evidence in this region. We detected no mutation in KCNAB1, minimizing the probability that the gene is involved in etiology of JME. [Support: NIH NS27941, DK31775, MH48858].

Primary Open-Angle Glaucoma (POAG) Candidate Gene Analysis. *K.R. LaRocque¹, M.A. Hauser¹, J.L. Wiggs², B. Broomer¹, E.A. del Bono², F.L. Graham¹, M.A. Pericak-Vance¹, J.L. Haines³, R.R. Allingham¹.* 1) Duke Univ Medical Ctr, Durham, NC; 2) Massachusetts Eye and Ear Infirmary, Boston, MA; 3) Vanderbilt University, Nashville, TN.

We have previously reported linkage analysis of 86 POAG pedigrees to identify the chromosomal locations of POAG susceptibility genes (Wiggs et al, *Hum. Mol. Genet.*, 9(7); 1109-1117). For these studies, POAG was defined as age of diagnosis >35, intraocular pressure greater than 22mm Hg in both eyes, glaucomatous optic nerve damage, and corresponding visual field loss in a least one eye. Phenotypic stratification gave increased evidence for linkage in individuals with an age of diagnosis \geq 45 in four adjacent markers (GABRB3, d15s822, d15s217, d15s165) spanning chromosome 15q11.2-15q13.2, (Allingham, et al 2001). Candidate genes were selected throughout this region based on position, function and availability of completed sequence data from the UCSC genomic assembly. The coding regions of these genes (ATP10C, GABRA5, GABRB3, GABRG3, APBA2, Kiaa0574, TJP1) were sequenced to identify mutations and polymorphisms. A sample set of 14 individuals from 11 families and 2 control samples, were included in the screen. Intron/exon boundaries were determined by BLAT comparison of the cDNA sequence and the UCSC genomic assembly (<http://genome.cse.ucsc.edu>). Primers were designed flanking each exon, PCR amplification was performed, and the sequence reactions were run on an ABI3700, following standard protocols. Sequences were assembled into contigs and analyzed using Sequencher (Gene Codes Co., Ann Arbor, MI). Several SNPs, silent mutations, and missense mutations were identified throughout the genes. None of the missense mutations identified clearly segregated with disease in the families screened, indicating that none of these genes play a primary causative role in POAG. Further association studies, utilizing the SNPs and mutations we have identified, are underway.

Are Single-Nucleotide Polymorphisms of N-acetyltransferase Genes (NAT1 and NAT2) associated with Parkinson Disease? *F. Zhang^{1,2}, J. van der Walt^{1,2}, E. Martin^{1,2}, B. Scott^{1,2}, J. Haines², M. Nance², J. Hubble², W. Koller², R. Pahwa², M. Stern², B. Hiner², J. Jankovic², C. Goetz², F. Small², R. Gibson², L. Middleton², M. Perikak-Vance^{1,2}, J. Vance^{1,2}.* 1) Duke University, Durham, NC; 2) Duke CHG/GlaxoSmithKline PD Genetics Collaboration.

Parkinson Disease (PD) is a common neurodegenerative disease. There is evidence that the development of PD may be affected by multiple environmental and genetic factors. Reports on the association of N-acetyltransferase 2 with PD are inconsistent. Recently, our results from a complete genomic screen have shown a linkage of late-onset PD to a region of chromosome 8p, where the N-acetyltransferase genes NAT1 and NAT2 are located. To provide further evidence for the role of NAT1 and NAT2 in PD, we conducted a family-based association study on these two genes. We studied 1580 individuals from 397 families with at least one affected. Families were stratified as family history positive versus negative, and late age of onset (>40 years) versus early age of onset. Single nucleotide polymorphisms (SNPs) were genotyped for NAT1 (positions 445, 560, 640, 1088, and 1095) and NAT2 (positions 282, 341, 481, 590, 857). Hardy-Weinberg equilibrium (HWE) and pairwise linkage disequilibrium (LD) tests were examined for SNPs in each gene. Data were analyzed using the pedigree disequilibrium test (PDT) and the likelihood ratio test of Transmit. SNP haplotypes within and across NAT1 and NAT2 were tested for association using haplotypes with frequency > 2%. No evidence for deviation from HWE was found. In each gene the pattern of LD between affected and unaffected people is similar. In overall and stratified data sets, both PDT and Transmit failed to show any statistical significance for single loci. Neither did five-SNP haplotypes for either gene or six-SNP haplotypes across NAT1 and NAT2. This represents one of the most comprehensive investigations of these genes in PD in a very large family data set. Based on the results, we conclude that NAT1 and NAT2 are not significant genetic risk factors in PD.

Program Nr: 1823 from 2002 ASHG Annual Meeting

Functional Analysis of the Regulation of Dopamine Transporter Gene Expression. *T.A. Greenwood, J.R. Kelsoe.*
Department of Psychiatry, University of California, San Diego, La Jolla, CA.

A role for the human dopamine transporter (DAT) gene in bipolar disorder is implicated by several lines of pharmacological evidence, as well as suggestive evidence of linkage at this locus. TDT analysis of a sample of 50 parent-proband triads from our UCSD/UBC/UC family collection revealed a particular haplotyped marker deriving from the 3' region of the DAT gene (exon 9 through exon 15) to be in strong linkage disequilibrium (LD) with bipolar disorder ($p=0.0004$). Subsequent analysis of an additional 70 triads from the NIMH Genetics Initiative for Bipolar Disorder collection revealed more modest evidence for association to a region slightly 5' of that originally implicated (intron 2 through intron 10). As these two regions exhibit an overlap defined by four polymorphisms deriving from exon 9, intron 9, and intron 10, it is possible that a functional variant contributing a susceptibility to bipolar disorder exists within or near this region. However, LD analyses did not enable us to more precisely localize the putative functional variant. In order to more definitively identify the region containing the putative regulatory element, we have analyzed the effect on expression of a number of the potential regulatory and intronic regions within the DAT gene. These analyses indicate a strong core promoter and potential repressor elements in both the proximal 5' flanking region and intron 1. A 1.5-fold difference in regulatory activity was also observed between the different haplotypes of these promoter segments, representing the two 5' clades. We found no effect on transcription with inclusion of the 9- and 10-repeat alleles of the 3' VNTR. However, introns 9, 12, and 14 appear to contain enhancer elements capable of increasing expression approximately 2-fold with respect to the promoter constructs. There also appear to be differences in expression between the two alleles of intron 14, as well as between haplotypes comprised of different alleles of the promoter and exon 9/intron 9. These results thus indicate that it may be the particular combination of polymorphisms in a haplotype across the gene that ultimately effect DAT gene expression.

Pseudo-dominant mode of inheritance in Thomsen's myotonia congenita. *N.H. Mao, F. Lehmann-Horn, K. Jurkat-Rott.* Applied physiology, University of Ulm, Ulm, Germany.

Myotonia is skeletal muscle stiffness due to delayed muscle relaxation. Two entities of myotonia have been described : Thomsen's myotonia with dominant inheritance (dominant myotonia congenita, DMC) and Becker's myotonia with recessive inheritance (recessive generalized myotonia, RGM). Mutations in the gene *CLCN1* encoding the skeletal muscle chloride channel are responsible for both DMC and RGM. To date, more than 60 mutations have been identified. Because of the clinical similarities and lack of information on other family members among DMC, RGM and other diseases, it is useful to develop a simple method for mass screening of mutations in *CLCN1* to facilitate genetic diagnosis. By single strand conformation analysis (SSCA), we identified 11 novel mutations. Then by multiplex allele-specific PCR (ASPCR), we screened for these 11 novel mutations and other 43 known mutations in 82 unrelated families with DMC and 167 unrelated families with RGM. In RGM families, 24% of all families were clarified on both alleles and additional 37% on one allele. In the German population, the most frequent mutations were R894X, fs503X and F413C with prevalences of 35%, 16% and 8.9% respectively. Comparatively, F167L, R894X and T268M were most three frequent mutations in the Turkish population with prevalences of 13%, 9% and 4.5% respectively. One frequent mutation A531V found in Finnish population wasn't present in our sample set. In DMC families, 14.6% of all families had dominant mutations and 15.8% had recessive mutations in *CLCN1*. The reason for this may be because some recessive mutations in *CLCN1* are so frequent that heterozygous spouses occur in several subsequent generations resulting in a pseudo-dominant inheritance. With the technique ASPCR, fifty four mutations can be tested for in only 14 PCR reactions for 192 samples in 14 working days, which is at least required 32 working days by SSCA. From the point of view of time and money, ASPCR is a powerful method for mass screening.

Sequence variation in 3 human homologs of the *C. elegans daf-16* gene: candidate genes for human longevity.

*D.L. Lind*¹, *E. Ziv*², *W.-C. Hsueh*², *C. Kenyon*³, *A.J. Kahn*⁴, *W.S. Browner*⁵, *S.R. Cummings*^{1,6}, *P.-Y. Kwok*¹. 1) Cardiovascular Research Institute, UCSF, San Francisco, CA; 2) Department of Medicine, UCSF, San Francisco, CA; 3) Department of Biochemistry, UCSF, San Francisco, CA; 4) Department of Growth and Development, UCSF, San Francisco, CA; 5) California Pacific Medical Center, San Francisco, CA; 6) Department of Epidemiology and Biostatistics, UCSF, San Francisco, CA.

It has been estimated that 25% of the variance in human longevity is attributable to genetic components. In model organisms such as the worm *C. elegans*, the insulin/IGF1 signaling pathway has been shown to be important in determining life span. In worms, the insulin receptor is encoded by the *daf-2* gene and mutations in this gene have been associated with increased longevity in worms. This increase in longevity has been shown to require the forkhead transcriptional protein, encoded by the *daf-16* gene. In humans, there are three homologs of the *daf-16* gene: FKHRL1, FOXO1A, and AFX1. There is currently no comprehensive polymorphism information for any of these three genes. In order to determine whether mutations in these genes might underlie some of the variation in longevity in humans, we are scanning these three genes for polymorphisms in a sample of 100 individuals. A minimal set of polymorphic sites representing the maximum amount of information will be chosen to use for case-control studies where cases are individuals who are exceptionally long-lived, and controls are individuals who died at or earlier than the median age of death of non-traumatic causes.

Mice lacking podocin develop a severe glomerular phenotype. *S. Roselli*¹, *M. Sich*¹, *M.C. Gubler*¹, *C. Antignac*^{1,2}. 1) Inserm U423, Necker Hospital, Paris, France; 2) Department of Genetics, Paris 5 University, Necker Hospital, Paris, France.

NPHS2, encoding the slit diaphragm associated protein podocin, is implicated in one form of autosomal recessive steroid-resistant nephrotic syndrome characterized by early childhood onset of proteinuria, rapid progression to end stage renal disease and focal segmental glomerulosclerosis (FSGS). In order to study the exact podocin function and to better understand the pathophysiology of nephrotic syndrome, we generated a mouse model by inactivating *Nphs2* in embryonic stem cells by homologous recombination. A 4 kb genomic region spanning exons 1 and 2 and including the predicted transcription start site was replaced by a PGKHyg cassette containing the hygromycin resistance gene. Here we show preliminary results based on the analysis of 2 litters born from heterozygote matings. Three out of 12 newborn mice were homozygous for the inactivated *Nphs2* allele indicating that the *Nphs2* ^{-/-} genotype does not lead to massive embryonic lethality. Although seemingly normal at birth, the 3 *Nphs2* ^{-/-} mice rapidly present with growth retardation in the first days of life and died at 4, 7 and 10 days respectively. Massive proteinuria was found in the urine collected in the bladder of the 7 day-old mouse. In this mouse, glomerular lesions were severe and diffuse, involving not only the mature glomeruli but also the immature ones in the subcapsular region. They consist in diffuse enlargement of the mesangial matrix without cell proliferation resulting focally in segmental or global sclerosis of the tuft. No capsular adhesion was seen. Altogether, these data show that *Nphs2* ^{-/-} mice develop a severe glomerular disease with early occurrence of diffuse mesangial sclerosis. This phenotype is far more severe than the one observed in humans with *NPHS2* mutations. These results confirm the essential role of podocin in the maintenance of a functional kidney filter.

Program Nr: 1827 from 2002 ASHG Annual Meeting

The murine *klotho* gene coding sequence is completely conserved in laboratory-derived inbred strains. A. Bektas, C.A. Francomano. Laboratory of Genetics, National Inst on Aging/NIH, Baltimore, MD.

The *klotho* gene is involved in the suppression of several aging phenotypes, based on the *klotho* mutant mouse. A defect in *klotho* gene expression in the mouse results in a syndrome that resembles human aging, with premature death, osteoporosis, atherosclerosis, diabetes, and emphysema. In an effort to find functional murine variants of *klotho*, we sequenced the gene from genomic DNA of 20 different mouse strains from the Jackson Laboratory phenome project. The panel includes 16 laboratory-derived inbred strains, and 4 wild-derived inbred strains. Among the 16 laboratory derived strains, no sequence variation was found in any of the exons or intron-exon boundaries. Among the 4 wild-derived strains on the panel, we found 43 sequence variants in the coding region as well as in the introns. Only 5 variations resulted in amino acid substitutions. These included: P11Q, S117L, A446G (SPRET/Ei); A567V, H615Y (CAST/Ei); and H615Y (MOLF/Ei). We also found a deletion in intron 1 in SPRET/Ei and an insertion in intron 4 in CAST/Ei and MOLF/Ei. These observations suggest a very high degree of selection against sequence variation in the *klotho* gene. The functional consequences of sequence variation in the wild-derived strains are under investigation.

Identification of novel variations within IL-4 and association with asthma and associated phenotypes in a Dutch population. *M.J.M. Basehore¹, E.R. Bleecker¹, T.D. Howard¹, H. Jongepier², D.A. Meyers¹, D.S. Postma².* 1) Center for Human Genomics, Wake Forest Univ Sch of Med, Winston-Salem, NC; 2) Dept of Pulm, Univ Hospital, Groningen, the Netherlands.

Asthma is a common respiratory disease characterized by acute and chronic bronchial inflammation and intermittent airway obstruction. Findings closely associated with the asthma phenotype include bronchial hyperresponsiveness (BHR) and total serum IgE levels, both of which have a strong genetic component. Asthma and/or atopy susceptibility genes have been mapped to a region on chromosome 5q31-q33 in multiple populations. There is strong evidence that one or more loci within this region is closely associated with BHR and elevated serum IgE levels, the two most characteristic clinical phenotypes of asthma. A cluster of proinflammatory cytokine genes important in immune regulation resides within this candidate locus, including interleukin (IL)4 and IL-13. In the present study, we identified 21 new sequence variants in the IL-4 gene by re-sequencing 8 Dutch probands with asthma and 8 Dutch controls. We performed association studies with 12 of these polymorphisms in a Dutch population (originally ascertained by a proband with asthma) that has previously shown evidence for linkage to chromosome 5q31 for BHR and total serum IgE levels. We have also evaluated the interaction of IL-4 polymorphisms with other previously identified polymorphisms in both IL-13 and IL-4 receptor alpha. Five of the identified novel IL-4 polymorphisms showed significant association with asthma or an asthma-related phenotype. Significant associations were observed with % predicted FEV1, change in post-bronchodilator FEV1 over an extended time period and skin test positivity. These data suggest that variations within the IL-4 gene may contribute to both asthma susceptibility as well as disease severity.

Sequence analysis of promoter region of the brain-derived neurotrophic factor gene in parkinson's disease. A. Parsian¹, R. Sinha¹, B. Racette², J. Perlmutter². 1) Birth Defects Ctr, Univ Louisville Hlth Sci Ctr, Louisville, KY; 2) Dept of Neurology, Washington Univ Med Sch, St. Louis, MO.

Idiopathic PD is one of the most common neurodegenerative disorders affecting about 1% of people over the age of 60 year. Most cases of PD are sporadic but approximately 20% have a positive family history suggesting a hereditary component. Although most of the genetic factors are unknown, genes coding for nerve growth factors involved in dopamine receptor and cellular regulation such as Brain-derived neurotrophic factor (BDNF) are logical candidate genes. To determine the role of the BDNF gene in the development of familial and sporadic Parkinson's disease (PD), we sequenced the promoter region of the gene using genomic DNA from 45 patients with familial PD to identify unique mutation or variation. Two single nucleotide polymorphisms (SNPs) at positions C-1331T and C270T were identified. There was no sign of linkage disequilibrium between these two SNPs. We screened our entire sample of PD with the SNP at C270T in the 5' non-coding region of the gene. The sample comprised of 146 patients with and 208 without a positive family history for PD and 195 matched controls. The allele frequencies in the familial PD subjects were significantly different compared to normal controls ($p < 0.0006$) but not significantly different between sporadic PD and normal controls. Both PD groups (familial and sporadic) were categorized based on age of onset (AON) of 45 years into two subgroups of young (<45) and typical (>45). The allele frequencies of the familial group with AON of >45 were significantly different than normal controls but not the sporadic groups or familial with AON of <45. In addition, there were only three patients who were homozygous for the T allele. Our data indicate the possibility of linkage disequilibrium between this variation and a mutation in coding region of BDNF gene. Our findings suggest that BDNF may play a role in familial PD with typical AON and warrant further study.

Program Nr: 1830 from 2002 ASHG Annual Meeting

Differential screening of gene initiation sequences using polymerase chain reaction. *X. Ni, J. Trakalo, G. Wong, J. Kennedy.* Neurogenetics Section, Ctr Addiction & Mental Health, Toronto, ON, Canada.

Purpose: Gene initiation sequences (GIS) contribute significantly to gene expression both in vivo and in vitro. Effective methods are needed to identify variation in the GIS that can lead to differential expression of coding sequences. This report describes a method to screen for GIS differences between patients with major psychoses versus controls using the polymerase chain reaction (PCR). **Methods:** The key element is to use the consensus Kozak sequences with the addition of one or two 3 bases as the forward anchoring primers for gene initiation sites. We designed 40 anchoring primers; 32 primers for downstream sequences and 8 for upstream sequences. Reverse primers were chosen at random from a set of arbitrary primers. Individual samples and pooled DNAs were used to screen for variants. After amplification with an optimal protocol, products were separated using polyacrylamide gel electrophoresis. Differential DNA bands were excised from the gel and sequenced. **Results:** We have identified 201 DNA bands which show either different frequencies between patients with schizophrenia or bipolar disorder and controls in individual samples, or differing banding patterns in pooled DNAs. Fifty-four DNAs have been sequenced and 5 candidate genes, 36 clones, and 13 unknown sequences from the human genome have been identified. **Conclusions:** Our results demonstrate the potential of this technique to identify variations in the GIS. It should be possible to detect most of the GIS variants in an individual by use of multiple primer sets. Thus our GIS methods should be quite valuable for testing gene expression hypotheses in schizophrenia and bipolar disorder. **Key words:** gene initiation sequence, gene expression, differential screening, polymerase chain reaction *This work is supported by CIHR/CPRF partnered Fellowships.

Bardet-Biedl Syndrome and its relationship to QTL for obesity in the Newfoundland population. *Y. Fan¹, E. Dicks², J.S. Green², P.S. Parfrey², W.S. Davidson¹.* 1) Dept Molecular Biol, Biochem, Simon Fraser Univ, Burnaby, BC, Canada; 2) Faculty of Medicine, Health Sciences Centre, Memorial University, St. John's, NF, Canada.

Bardet-Biedl Syndrome (BBS) is characterized by retinal dystrophy, polydactyly, hypogonadism, learning difficulties, renal dysplasia, and obesity. Although it has traditionally been considered that BBS is inherited in an autosomal recessive fashion, there is evidence for triallelism and it may serve as a bridge between Mendelian and multifactorial inheritance. There is a high incidence of BBS in the Newfoundland population that cannot be explained by a single ancestral founder event. We considered the possibility that the increased incidence of BBS is due to an underlying common modifier gene in this population. It has been suggested that there is a link between BBS and obesity in the general public. Therefore, we examined the relationship between QTL that have been shown to influence obesity and BBS loci in 13 families. Genotypes were constructed for the obesity-related QTL on chromosome 13q14 and chromosome 7q32.3. Comparisons of the haplotypes of the obesity-related QTL revealed a few groups of partially related chromosomes among the different families. However, there was no obvious relationship between any of the obesity-related QTL haplotypes and the five BBS loci represented in the 13 families. This suggests that the molecular basis of obesity in BBS individuals in the Newfoundland population is unrelated to the mechanism resulting from the obesity-related QTL on chromosomes 7 and 13. (Supported by the Canadian Institutes of Health Research).

Dinucleotide Repeat Expansion and Clonal Selection of Mesangial Cells in Diabetic Nephropathy. *A. Fornoni, O. Lenz, A. Banerjee, G.E. Striker, L.J. Striker.* Vascular Biology Institute, Department of Medicine, University of Miami School of Medicine, Miami, FL.

Clonal expansion of cells with a disease phenotype characterizes chronic diseases such as atherosclerosis and systemic sclerosis. We propose that a similar pathogenetic mechanism occurs for progressive diabetic glomerulosclerosis. We used the ROP mouse strain prone to progressive glomerulosclerosis to investigate the influence of 25 mM glucose in vitro and diabetes in vivo on dinucleotide repeat instability and clonal selection of mesangial cells. We used the length of the dinucleotide repeat of the matrix metalloproteinase-9 (MMP-9) promoter as a marker to discriminate different mesangial cell clones. We found that mesangial cells (MC) isolated from ROP mice consisted of clones that are heterogeneous in the length of the d(CA) repeat in the MMP-9 promoter. Using PCR and automated sequencing we detected sub-populations with either 20 or 24 d(CA) repeats. No such heterogeneity could be detected in MC isolated from sclerosis-resistant C57BL/6 mice. 25 mM glucose and diabetes selected for clones with 24 d(CA) repeats only. Analysis of single cell clones showed that two mechanisms were responsible for induction of clones with 24 d(CA) repeats: d(CA) repeat expansion and clonal selection. The mesangial cell changes induced by 25 mM glucose in vitro were reversible, whereas those induced by diabetes in vivo were not. We conclude that the presence of heterogeneous clones of MC may be a marker for the susceptibility to develop progressive glomerulosclerosis. Genomic changes induced by elevated glucose concentrations suggest a novel mechanism for the pathogenesis of diabetic nephropathy.

Comprehensive Detection of CFTR Mutations in Idiopathic Chronic Pancreatitis. *J. Feng¹, J.A. Cohn^{2,3}, J.P. Neoptolemus⁴, Z. Jiang¹, W. Greenhalf⁴, I. Ellis⁵, S.S. Sommer¹.* 1) Dept of Molecular Genetics, City of Hope National Med Ctr, Duarte, CA; 2) Dept of Medicine, Duke Univ, Durham, NC; 3) V.A. Med Ctr, Durham, NC; 4) Dept of Surgery, Univ of Liverpool, Liverpool, UK; 5) Alder Hey Children's Hosp, Liverpool, UK.

BACKGROUND: Idiopathic chronic pancreatitis (ICP) accounts for most chronic pancreatitis in children and nonalcoholic adults. Some ICP patients are CFTR compound heterozygotes who have a CF-causing mutation plus a milder mutation (*Gastroenterology* 121:1310-1319, 2001). This study examined a large series of ICP patients for rare CFTR mutations to determine whether ICP risk is increased by CF carrier genotypes containing one normal CFTR allele. **METHODS:** Fifty-five sporadic cases of ICP were recruited by the European Registry of Hereditary Pancreatic Diseases (EUROPAC). Most cases (75%) were British and patients with cationic trypsinogen mutations (causing hereditary pancreatitis) were excluded. DNA was tested for CFTR mutations by DOVAM-S, a highly multiplexed and robotically enhanced form of SSCP that detects virtually all mutations in the tested regions, as validated by blinded analyses of samples containing 250+ different mutations in other genes. DNA sequencing was used to confirm the presence of one normal CFTR allele in selected CF carriers. **RESULTS:** At least one abnormal CFTR allele was detected in 21/55 tested ICP patients. In this series, ICP risk was strongly associated with CFTR compound heterozygosity and it was also associated with CF carrier genotypes and with the R75Q mutation. **SUMMARY:** Comprehensive testing of a large series of ICP patients confirmed the strong association of ICP with CFTR compound heterozygosity and it also associated ICP with CF carriers who have one normal CFTR allele. The latter finding is unexpected because it implies that 50% loss of CFTR function is sufficient to increase the risk of ICP. (Supported in part by a V.A. Merit Review Grant).

Polymorphism of interleukin ligands and receptors genes and variability of quantitative asthma-associated traits.

M.B. Freidin¹, L.M. Ogorodova², V.P. Puzyrev^{1,2}. 1) Institute for Medical Genetics, Tomsk, Russia; 2) Siberian State Medical University, Tomsk, Russia.

In 323 Russian patients with atopic bronchial asthma and their relatives, inhabitants of Tomsk, Russia, a contribution of eight single nucleotide polymorphisms of interleukin ligands and receptors genes (IL4, IL5, IL9, IL4RA, IL5RA, IL5RB) in a variation of quantitative asthma-associated traits (lung volumes, bronchial reactivity, common serum immunoglobulins levels) was investigated. It was established, that polymorphisms of the genes of study have a significant contribution to variability of the given complex of the traits and this effect differs by force and direction for different genes and attributes. The mean percent of general phenotypic variance of the quantitative traits explained by a genetic variety on the set of genetic loci was 1.63-5.54% in men and 1.03-2.15% in women. The percent of the contribution of variability on analyzed loci to general polygenic variance of the traits was 3.96-32.11% and 2.60-12.23% in men and women, respectively. The obtained data testify, that interleukin ligands and receptors genes polymorphisms are only a part of a hereditary diversity determining a variability of quantitative risk factors for atopic bronchial asthma.

Multiple sclerosis (MS) in DR2 homozygotes: dose effect of HLA genes on susceptibility and influence on disease course. *L.F. Barcellos¹, J.R. Oksenberg¹, R.R. Lincoln¹, S. Schmidt², P. Bucher¹, A. Swerdlin¹, A.B. Begovich³, E. Vittinghoff¹, M.A. Pericak-Vance², J.L. Haines⁴, S.L. Hauser¹ and Multiple Sclerosis Genetics Group.* 1) University of California, San Francisco, CA; 2) Duke University Medical Center, Durham, NC; 3) Roche Molecular Systems, Alameda, CA; 4) Vanderbilt University, Nashville, TN.

The etiology of MS is complex, involving both genetic and environmental components. Linkage to the HLA-DR locus, and association with the DR2 haplotype (DRB1*1501-DQB1*0602) within the MHC on ch.6p21 have been consistently demonstrated. Approximately 70% of familial and 50% of sporadic MS cases have at least one DR2 allele compared to 28% of control subjects. This finding implicates DR2 as an important genetic factor in the majority of MS cases. We examined the effect of DR2 gene dose in 549 stringently ascertained Caucasian MS families (187 multicase and 362 singleton families; total n=2382 comprised of 808 patients and 1574 unaffected family members) and show that it is correlated with increased risk and disease course. All individuals were stratified by HLA-DR2 genotype (DR2/DR2, DR2/DRX and DRX/DRX, where X denotes other DR alleles). 52.8% (n=94) DR2/DR2 individuals were affected, in contrast to 38.7% (n=395) DR2/DRX and 26.9% (n=319) DRX/DRX individuals. Using DRX/DRX individuals as the reference group, significant results were obtained from conditional logistic regression modeling when patients were compared to unaffected family members for both DR2/DR2 and DR2/DRX genotypes (OR=6.7, $p < 10^{-6}$ and OR=2.7, $p < 10^{-6}$, respectively). Significant evidence for a dose effect was present and suggests that two copies of DR2 confer an even greater disease risk relative to one copy (OR=2.5, $p < 10^{-5}$, OR=2.4, $p < 10^{-3}$, OR=2.7, $p < 0.01$ for all families, multicase, and singleton families, respectively). DR2 homozygotes were significantly less frequent in patients with a more benign disease course (EDSS <3 after 10 or more years; 5.4% vs. 17.3%, OR = 0.3, $p = 0.037$), providing evidence to support a disease modifying role for HLA-DR2. These important findings shed new light on our understanding of the complex molecular mechanisms that underlie MS pathogenesis.

Role of serotonin transporter variants in the determination of platelet serotonin levels in Autism Spectrum

Disorders. *A.M. Coutinho¹, S. Silva¹, C. Fesel¹, T. Morgadinho³, T.R. Macedo³, C. Bento², C. Marques², A. Ataíde², T. Miguel², G. Oliveira², A.M. Vicente¹.* 1) Instituto Gulbenkian Ciência, Oeiras, Oeiras, Portugal; 2) Hospital Pediátrico de Coimbra, Coimbra, Portugal; 3) Faculdade de Medicina da Universidade de Coimbra, Coimbra, Portugal.

The role of the serotonin system in the etiology and pathogenesis of autism spectrum disorders (ASD) is not clearly defined. High levels of platelet serotonin (5-HT) are found in a proportion of patients, and the serotonin transporter (5-HTT) has been associated to autism in some studies. The relation between these two findings and with autism etiology is still not clear. We have examined the association of platelet serotonin levels with two 5-HTT polymorphisms (5-HTTLPR in the promoter and Stin2 in intron2) in a sample of 106 ASD patients, their parents, and 52 age-matched controls. The heritability of 5-HT levels was estimated at 83%, although a positive father/mother correlation shows that a nuclear environment effect is present. The association of this trait with 5-HTT was tested using the quantitative transmission disequilibrium test (QTDT), and a significant association was found with the long/Stin2.10 haplotype ($p=0.0012$). The association between this 5-HTT haplotype and 5-HT levels was confirmed using ANOVA, and emphasized in long/Stin2.10 homozygous individuals ($p=0.0049$). 70% of the alleles in hyperserotonemic patients were long/Stin2.10, against 25% in normal 5-HT level patients ($p=0.006$, OR 7.1). This study clearly shows a role of 5-HTT alleles in the determination of 5-HT levels. A direct relation of 5-HT levels with ASD could not be established since its distribution in patients was not significantly different from controls, although a trend towards higher levels was observed in the patients sample. We found no transmission disequilibrium of any of the 5-HTT variants with ASD. However, the excess of the long/Stin2.10 haplotype in hyperserotonemic patients suggests that these may represent a separate etiological group. Given the heterogeneity of ASD, further exploration of this question is warranted.

Crohn's Disease: Role of CARD15/NOD2 Gene Mutations in Clinical Heterogeneity. *S.R. Brant¹, M.F. Picco², J.P. Achkar³, S. Kane⁴, T.M. Bayless¹, F. Nouvet¹, D. Bonen⁴, A. Brzezinski³, A. Karban¹, T. Dassopoulos¹, R. Karaliukas⁴, D. Vogel³, T.H. Beaty⁵, S.B. Hanauer⁴, R.H. Duerr⁶, J.H. Cho⁴.* 1) Dept Med, Johns Hopkins Univ, Baltimore, MD; 2) Dept Med, Mayo Clinic, Jacksonville, FL; 3) Dept Gastro, Cleveland Clinic Foundation, Cleveland, OH; 4) Dept Med, Univ of Chicago, Chicago, IL; 5) Dept Gen Epidemiology, JHU Sch Pub Hlth, Baltimore, MD; 6) Dept Med, Human Genetics, Univ of Pittsburgh, Pittsburgh, PA.

Crohn's disease (CD) is a chronic intestinal inflammatory disorder, highly variable in phenotypes of age at diagnosis, intestinal site, fistulizing or stricturing behavior, and need for surgery. CARD15 gene mutations L1007fsinsC, G908R, and R702W are established molecular genetic CD risk factors. We examined effect of CARD15 mutations on phenotype in context of other established CD risk factors. **METHODS:** Age at diagnosis, family history, Jewish ethnicity, tobacco use, surgery, disease site and behavior were determined by questionnaires, interviews and case-record reviews in 275 unrelated patients with CD. The 3 CARD15 mutations were genotyped by ARMS assay. Correlations were analyzed by univariate (chi-sq. or Fishers) and multivariate (linear regression and Cox proportional hazards) methods. **RESULTS:** There were 32 homozygotes or compound heterozygotes (MM), 76 heterozygotes (MW), and 167 wildtype patients (WW). MM patients had a younger age at diagnosis than MW or WW patients (mean 21.4 vs. 24.4; $p=0.03$), more ileal disease involvement (MM 97%, MW/WW 77%; $p=0.01$), and more complications of strictures (Odds Ratio, OR 4.1; $p=0.03$) and non-perianal fistulas (OR 5.0; $p=0.004$) (relative to patients with neither complication). By logistic regression MM genotype was the strongest significant risk factor for ileal disease (OR 10.1) followed by smoking at diagnosis (OR 2.25) and age at diagnosis (OR 0.97 per increased year). Ileal sites (OR 4.8) and carrying CARD15 mutations (OR 1.9 MW and 3.5 MM) were independent risk factors for stricturing or fistulizing behavior. Ileal disease, youthful onset and smoking at diagnosis (but not CARD15 mutations) were risk factors for early surgery. Therefore, CARD15 mutations are important determinants of CD phenotypic heterogeneity.

MUTATIONS IN THE COL4A4 GENE IN RELATION TO FAMILIAL HEMATURIA. *D. Glavac¹, M. Slajpah¹, A. Meglic², M. Ravnik-Glavac^{1,3}.* 1) Department of Molecular Genetics, Medical Faculty, Institute of Pathology, Korytkova 2, 1000, Ljubljana, Slovenia; 2) Department of Paediatrics, University Medical Centre, Ljubljana, Slovenia; 3) Institute of Biochemistry, Medical Faculty, Ljubljana, Slovenia.

Mutations in COL4A4 gene located at 2q35, have been reported in autosomal recessive and dominant type of Alport syndrome (AS), as well as benign familial hematuria (BHF) or thin basement membrane disease (TBMD). BHF probably affects at least 1% of the population and is characterized by persistent microscopic glomerular hematuria, sometimes with proteinuria or hypertension, thinning of the glomerular basement membrane (GBM) and normal renal function. Considering the similarities in GBM abnormalities, TBMD cannot be clinically differentiated from the initial stages of AS. It has recently been suggested that TBMD represents a carrier state of autosomal recessive or X-linked AS. We analyzed 22 patients with confirmed BHF and 12 AS patients who had tested negative in COL4A5 gene screening also for COL4A4 mutations. Non-isotopic single stranded conformation analysis (SSCA) after amplification of each exon with boundary intronic sequences by the polymerase chain reaction (PCR) was used for all 51 exons of COL4A5 and 47 exons of COL4A4 gene. While no mutation was identified in COL4A5 gene in all 34 patients COL4A4 mutation screening disclosed eleven common polymorphisms that are shared in part with other populations and six novel mutations: G774R (GGT>CGT), G789G (GGA>GGT), 2860+2T>G, R908W (CGG>GGG), D1049H (GAC>CAC)+del 5 bp, 3506-8T>G and 4081-8G>C comprising three missense mutations, one frameshift and two potentially splice site mutations. Furthermore, we found one silent mutation, one rare variant in a non-coding region, and several polymorphism with a very low heterozygosity. This study confirms the importance of the COL4A4 gene in the pathogenesis of benign familial hematuria.

A novel C597A polymorphism of Norrie disease gene is associated with Retinopathy of prematurity in Kuwaiti Arabs. *M.Z. Haider¹, L.V. Devarajan¹, M. AlEssa¹, H. Kumar²*. 1) Dept Pediatrics, Fac Medicine, Kuwait Univ, Safat, Kuwait; 2) Dept Ophthalmology, Ibn Sina Hosp, Sulaibikhat, Kuwait.

Retinopathy of prematurity (ROP) is a retinal vascular disease which occurs in infants with a short gestational age and low birth weight and may lead to retinal detachment and blindness. In some premature infants, ROP progresses to advanced stages despite rigorous intervention, but in the majority, it spontaneously regresses before the threshold stage. Genetic factors, e.g., mutations in the Norrie disease (ND) gene have been implicated in determining the progression of ROP to advanced stages. We have identified a novel C597A polymorphism and screened this in 210 Kuwaiti premature infants using PCR-RFLP and DNA sequence analysis, to investigate an association with ROP. In our Kuwaiti premature newborn cohort, 115 of 210 babies had no eye problems and served as controls while 95 were found to have ROP. In 71 of the 95 ROP cases, the disease spontaneously regressed at or before stage 3, while in 24 of 95 ROP cases, the disease progressed to advanced stages 4 or 5. The incidence of the AA genotype of the C597A polymorphism was considerably higher in advanced stage ROP cases (83.3%) compared to 0 in spontaneously regressing ROP cases and 10.4% in the normal controls ($p < 0.0001$). For other genotypes, no significant difference was detected between the controls and ROP cases. The data show a strong association of this novel C597A polymorphism of the ND gene, with progression of ROP to advanced stages.

Maternal DBH levels modulate obsessive-compulsive behaviors in autistic probands. *R. Mankoski^{1,2}, M. Dowd¹, K. Smith², S. Folstein^{1,2}.* 1) Psychiatry, New England Medical Center, Boston, MA; 2) Genetics Program, Sackler School of Graduate Biomedical Sciences, Tufts University, Boston, MA.

Autism is a neurodevelopmental disorder characterized by abnormal social interactions, abnormal language, and restricted and repetitive behaviors. Dopamine beta-hydroxylase (DBH) converts dopamine (DA) to norepinephrine (NE) and is postulated to play an epigenetic role in the etiology of autism by modulating prenatal intrauterine concentrations of DA and NE. DBH levels are thought to be controlled in part by two promoter polymorphisms: a 19 base-pair insertion/deletion (D19) and a c/t transition (-1021 c/t). The D19 +/+ and -1021 c/c alleles are associated with high DBH activity. 100 mothers and 94 fathers of autistic subjects were genotyped for each polymorphism. Genotype distributions were evaluated with a chi-square test using the fathers as controls. 6 Autism Diagnostic Interview-based factors (each scored 0-1) were compared between children of D19 +/+ vs. D19 +/- and -1021 c/c vs. -1021 t/t mothers using two-tailed t-tests. The genotype distribution of the D19 alleles (+/+, +/-, -/-) is different in mothers compared to fathers ($p = 0.02$). This appears to be due to an increased prevalence of the +/+ allele (+/+ vs. +/- and -/-, $p = 0.005$). There is no difference in the distribution of the -1021 c/t alleles (c/c, c/t, t/t) in mothers compared to fathers ($p = 0.09$). Autistic children of D19 +/+ mothers score 1.6 times worse on measures of obsessive-compulsive behaviors than children of D19 +/- mothers (0.33 vs. 0.21, $p = 0.001$). Children of -1021 c/c mothers score 1.6 times worse on measures of abnormal spoken language than children of -1021 t/t mothers (0.45 vs. 0.28, $p = 0.02$), although this is not significant after correction for multiple tests. We conclude that DBH promoter alleles associated with high maternal DBH activity lead to worse outcomes with respect to obsessive-compulsive behaviors and possibly spoken language. The D19 +/+ allele appears to have a higher prevalence than expected in mothers of autistic probands. Low intrauterine DA may be a risk factor or low NE may be a protective factor for aspects of the autism phenotype.

Possible association of serotonin 1B receptor and cholecystokinin 1 receptor gene polymorphisms in bipolar and unipolar affective disorder cases in Estonia. A. Kurg¹, T. Nikopensius¹, P. Hallast¹, M. Laan¹, S. Kõks², J. Slik³, E. Maron³, E. Vasar², A. Metspalu¹. 1) Dept. of Biotechnology, Inst. of Molecular & Cell Biol, Univ. of Tartu / Estonian Biocentre Tartu, Estonia; 2) Dept. of Physiology, University of Tartu, Tartu, Estonia; 3) Clinic of Psychiatry, University of Tartu, Tartu, Estonia.

Human mood disorders have complex inheritance, involving the interaction of multiple genes in combination with environmental factors. So far linkage and association studies searching candidate genes for mood disorders have yielded controversial results, leading to multiple nonreplications in second-generation genomic screens. Many studies have focused on relationship of polymorphisms in genes related to two major - serotonergic and dopaminergic - neurotransmission systems, expected to play an important role in the genetic predisposition to neuropsychiatric disorders. We have performed a scan of single nucleotide polymorphisms (SNPs) selected from a total of 24 candidate genes including majority of serotonin-, dopamine- and cholecystokinin-related genes, endogenous opioid system genes and wolframin gene. In a subsequent pilot association study we genotyped 212 polymorphisms with Arrayed Primer EXTension (APEX) technology in a sample of 73 unrelated patients with unipolar or bipolar (DSM-IV) disorder and 72 matched controls from Estonian population. Case-control comparison of allelic and genotypic distribution demonstrated significantly higher frequencies of mutant alleles and enriched fraction of minor allele homozygotes in patient group with polymorphisms 129C-T in serotonin 1B receptor gene (29% vs 18%, $P=0.05$) and 1266T-C in cholecystokinin 1 receptor gene (20% vs 9%, $P=0.01$). Further studies with larger sample size should provide evidence, if these associations are true positives. We will investigate whether these markers present real functional polymorphisms, or they are in LD with a true functional polymorphisms in the same gene or nearby allelic variant playing role in determining susceptibility to depressive illnesses.

NOD2 genotype-phenotype correlations in Canadian Crohns Disease families. *W.G. Newman^{1,2,4}, A.H. Steinhart^{1,4}, R. McLeod^{3,4}, G. Greenberg^{1,4}, Z. Cohen^{3,4}, M. Silverberg^{1,2,4}, K.A. Siminovitch^{1,2,4}.* 1) Dept of Medicine, University of Toronto, Canada; 2) Dept of Immunology, Medical Genetics and Microbiology, University of Toronto, Canada; 3) Dept of Surgery, University of Toronto, Canada; 4) Mount Sinai Hospital, Toronto, ON, Canada.

Variants in the NOD2 gene (IBD1) have been associated with susceptibility to Crohns disease (CD). However, in a previous genome wide scan of 158 Canadian affected sibling pairs linkage to the IBD1 locus was not detected(1). To determine whether NOD2 mutation is etiologically relevant in this CD population, the frequency and phenotypic consequences of the three major CD-associated NOD2 variants, R702W, G908R and 1007fs, were studied in 507 (238 familial and 269 sporadic) unrelated CD patients. At least one of the three NOD2 variants studied was present in 31.5% of the CD patients compared to 20% of unrelated controls. The frequency of these variant alleles was similar in familial versus sporadic cases. No significant association was found between the presence of a NOD2 variant and age of diagnosis, gender, smoking status, ethnicity (non Jewish Caucasian versus Ashkenazi Jewish) or disease severity. However, the R702W variant occurred more frequently in non-Jewish versus Jewish CD patients (10.2% vs 4.5%, $p=0.005$), whereas the G908R variant was more common in Jewish patients (6.8% vs 3.8%, $p=0.04$). A significant positive association was also detected between the presence of NOD2 variant(s) and distal ileal involvement ($p=0.001$), while NOD2 variant(s) were negatively associated with involvement of the colon ($p=0.002$). These data thus reveal a significant influence of NOD2 mutation on the site of bowel involvement in CD and indicate the frequency of NOD2 variants to be similar in Canadian relative to other reported CD populations. The data also reveal NOD2 variants occur more frequently in the controls studied here than reported in other studies, an observation which may account for the failure to detect the IBD1 locus in our genome wide scan. NOTCH4 gene haplotypes are associated with schizophrenia in African-Americans. X. Luo¹, T.A. Klempan², J. Lappalainen¹, R.A. Rosenheck¹, D.S. Charney³, J. Erdos¹, D.P. van Kammen⁴, H.R. Kranzler⁵, J.L. Kennedy², J. Gelernter¹. 1) Dept Psychiatry, Yale Univ Sch Medicine, New Haven, CT; and VA CT Healthcare Center, West Haven, CT; 2) Neurogenetics, CAMH, Toronto, ON, Canada; 3) NIMH, Bethesda, MD; 4) J&J Pharm R&D, Raritan, NJ; and Univ Penn, Philadelphia, PA; 5) Univ Conn Sch of Medicine, ARC, Dept Psychiatry, Farmington, CT.

As an important locus within the HLA region, NOTCH4 is both a positional and a functional candidate for influencing susceptibility to schizophrenia. A recent study (Wei et al., 2000) reported associations between polymorphisms at NOTCH4 and schizophrenia in trios of British descent. Several subsequent studies failed to replicate the association. To evaluate a possible association in African-American (AA) and European-American (EA) subjects, two SNPs at the NOTCH4 locus were genotyped in 123 AA schizophrenics, 223 EA schizophrenics, 87 AA normal controls and 212 EA normal controls. The specific polymorphisms studied were "SNP1" (-1725T/G) and "SNP2" (-25T/C). Comparisons of allele and haplotype frequencies between cases and controls were performed with the Chi-square test or Fisher's Exact Test. Linkage disequilibrium (LD) between these two SNPs was evaluated with 3LOCUS (Long et al., 1995). We found that haplotype -1725G/-25T associates with schizophrenia ($p=0.0012$) in the AA sample. There was no such association in the EA sample. Alleles -1725T and -25C are in positive LD in AA schizophrenics, EA normal controls and EA schizophrenics. We conclude that the haplotype -1725G/-25T at the NOTCH4 locus, which results from SNPs of NOTCH4 that are in LD, may increase susceptibility to schizophrenia in AAs, and that any effect of this locus on risk for schizophrenia is population-specific. (1. Wei J, et al. Nat Genet 2000; 25: 376-377; 2. Long JC, et al. Am J Hum Genet 1995; 56: 799-810).

Deficient alleles (S and Z) of alpha-1 antitrypsin gene among patients with intracranial aneurysm in Japanese population. *T. YONEYAMA*^{1,2}, *H. ONDA*², *H. KASUYA*², *T. NAKAJIMA*¹, *T. HORI*², *I. INOUE*¹. 1) GENETIC DIAGNOSIS, IMS UNIV.OF TOKYO, TOKYO, JAPAN; 2) NEUROSURGERY, TOKYO WOMEN'S MEDICAL UNIV. , TOKYO, JAPAN.

Background and Purpose- We have already performed a genome-wide linkage study of intracranial aneurysm (IA) and detected positive evidence of linkage at chromosome 5, 7 and 14. The follow-up investigations were continued to identify the susceptibilities of IA from the three loci. Previously, it was reported that possible association could exist between the formation of intracranial aneurysm (IA) and deficiency alleles (S and Z) of alpha-1 antitrypsin (AAT) gene, which encodes a major circulating protease inhibitor. Because AAT is locating chromosome 14 near D14S280, the gene was extensively screened in Japanese IA. **Methods-** Genomic DNAs were obtained from 260 IA patients and 293 controls. The seven allelic variants including S and Z alleles were genotyped by direct sequencing. The haplotype in phase-unknown samples was constructed with the expectation-maximization method. Differences in allelic and haplotype frequencies between patients and controls were evaluated by chi-square statistics. **Results-** Significant differences in allelic frequencies were not observed at all seven variants between IA patients and controls. **Conclusions-** We could not detect S and Z alleles of AAT gene in our Japanese samples. The other allelic variants that result in AAT deficiency were not associated with the development of IA. Taken together, AAT may not constitute the susceptibility of IA among Japanese. Possible involvement of other candidate genes for IA could be discussed.

Sequence alterations in the lipoprotein lipase gene in type 2 diabetes patients with hypertriglyceridemia. P.M.K.

*Poon*¹, *T. Yang*^{1, 4}, *M.W. Tsang*³, *C.W. Lam*¹, *Y.S. Chan*¹, *C.P. Pang*². 1) Chemical Pathology, Chinese Univ Hong Kong, Hong Kong, China; 2) Ophthalmology & Visual Sciences, Chinese Univ Hong Kong, Hong Kong, China; 3) Medicine, United Christian Hospital, Hong Kong; 4) Medical Genetics, Institute of Basic Medical Sciences, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, China.

The purpose of this study was to investigate the role of LPL gene variants on patients with hypertriglyceridemic type 2 diabetes with a view to detect genetic factors contributing to most patients with type 2 diabetes. 200 type 2 diabetes patients and 198 healthy control subjects were recruited for the study. We screened for sequence changes in LPL with polymerase chain reaction, single-strand conformation polymorphism, restriction analysis and direct DNA sequencing. LPL mass and activity in post-heparin plasma and in in vitro expression were investigated. Four missense mutations were detected in patients but not controls. Ser447Ter was detected in both patients and controls with no significant difference in the frequencies. The four missense mutations were located in the highly conserved exon 3, 5, and 6 regions and in highly conserved amino acid sites. They led to reduced LPL mass and enzyme activities in post-heparin plasma and in in vitro expression. These results indicated that the 4 missense mutations lead to LPL deficiency and subsequent hypertriglyceridemia. Based on our study and published data, a putative pathogenic pathway was suggested: LPL enzyme deficiency causes elevated plasma triglyceride level and subsequent insulin resistance.

CCR2 and CCR5 gene polymorphisms and susceptibility to sarcoidosis. *T.A. Wischmeijer¹, C. Bombieri¹, C. Agostini², G.P. Semenzato², M. Luisetti³, P.F. Pignatti¹.* 1) Sec. Biology & Genetics, DMIBG, University of Verona; 2) Clin. Immunology, Dpt. of Clinical and Experimental Medicine, University of Padova; 3) Inst. Respiratory Diseases, IRCCS, S.Matteo, University of Pavia; Italy.

Sarcoidosis is a multisystem granulomatous disorder of unknown etiology, that is characterised by high activity of macrophages and CD4+ helper T cells, and by the formation of noncaseating granulomas in a variety of organs, predominantly the lung. A number of chemokines are produced by alveolar cells in the course of inflammatory reactions of sarcoidosis. Interplay between chemokines and their receptors is considered to be crucial for transmigration of lymphocytes and monocytes from the circulation to the bronchoalveolar space. Polymorphisms resulting in a non functional product expression were described in two chemokine receptor genes: a Val to Ile substitution in the CCR2 gene (CCR2-V64I) and a 32 bp deletion in the CCR5 gene (CCR5-del32). Different distribution of these alleles between sarcoidosis patients and controls were described for both the polymorphisms in the Czech population (*Am J Resp Crit Care Med* 162, 1000; 2000) and for CCR2-V64I in the Japanese populations (*Am J Resp Crit Care Med* 159, 2021, 1999). On the basis of these findings a role in disease susceptibility for CCR5 gene polymorphism and a protective role for CCR2-64I allele were suggested. We performed a case-control association study in 75 sarcoidosis patients and 86 control subjects in order to elucidate the role of these polymorphisms in the Italian population. CCR5-del32 allele was present in 10/150 (6.7%) chromosomes of sarcoidosis patients and in 8/172 (4.7%) of controls (NS). CCR2-64I allele was present in 13/126 (10.3%) chromosomes of sarcoidosis patients and in 17/164 (10.4%) of controls (NS). In contrast with the studies on the Czech and Japanese populations, our results show that in an Italian population sample, CCR2-V64I and CCR5-del32 polymorphisms did not seem to play a role in the pathogenesis of sarcoidosis.

DNA sequence variants in optineurin in patients with primary open angle glaucoma and low tension glaucoma.

J.L. Wiggs¹, J.D. Flor², R.R. Allingham³, M.A. Pericak-Vance², J. Augustine¹, K. Rodgers¹, B. Broomer³, E.A. DelBono¹, J.L. Haines⁴, M.A. Hauser². 1) Dept Ophthalmology, Harvard Medical School, MEEI, Boston, MA; 2) Center for Human Genetics, Duke University School of Medicine, Durham, NC; 3) Department of Ophthalmology, Duke University School of Medicine, Durham, NC; 4) Program in Human Genetics, Vanderbilt School of Medicine, Nashville, TN.

Glaucoma is an important cause of blindness worldwide. Of the various forms of glaucoma, adult primary open angle glaucoma (adult POAG) is most common. Typically adult POAG is associated with an elevation of intraocular pressure and a characteristic degeneration of the optic nerve. Patients may have deterioration of the optic nerve without an increase in intraocular pressure, and this is called 'low tension' glaucoma (LTG). Recently, mutations in a novel gene, optineurin, have been described in patients with LTG. The purpose of this study is to determine the frequency of mutations in optineurin in patients with adult POAG and in patients with LTG. Using dHPLC and direct sequencing, we screened all 13 coding exons of the optineurin gene in 86 patients with adult POAG, 38 patients with LTG, and 80 ethnically and age-matched control patients for DNA sequence changes. Two amino acid changes were identified: Met98Lys in 8/86 adult POAG probands, 8/80 control patients and in 6/38 LTG patients; and, E50K in one LTG patient. For the eight POAG individuals with the Met98Lys variant, all available pedigree members were screened. We found that 14 of the 25 affected individuals (56%) and 9 of the 13 unaffected individuals (59%) carried the mutation. Consistent segregation of the mutation with the disease was not demonstrated in any of the eight families. Our results indicate that DNA sequence variants in optineurin are not associated with disease in patients with adult POAG. Alterations of the optineurin gene may be a rare cause of low tension glaucoma. Collectively these results suggest that low tension glaucoma is a genetically distinct disease that is not a major component of the phenotypic spectrum of adult POAG.

CANDIDATE GENE SCREENING OF THE VCFS DELETED REGION FOR MUTATIONS ASSOCIATED WITH SCHIZOPHRENIA. *N.M. Williams¹, N. Norton¹, A. Preece¹, G. Spurlock¹, H. Williams¹, S. Zammit¹, K.C. Murphy², M.C. O'Donovan¹, M.J. Owen¹.* 1) Department of Psychological Medicine, University of Wales College of Medicine, Cardiff, UK; 2) Department of Psychiatry, Royal College of Surgeons, Dublin, Eire.

The df1 murine model of VCFS (del 22q11) displays phenotypic characteristics considered by some to model certain neuro-psychological features of schizophrenia. The df1 deletion spans 22 genes with human orthologs in the 22q11 (ES2, Gscl, Ctp, Vpreb2, Dgcr6, Prodh, ym24d07, Op53c05, Ranbp1, Htf9C, Vo59c07, T10, Arvcf, Comt, TrxR2, Wdr14, Tbx1, Gp1bb, Pnutl, TmVCF, Cdc45l, Ufd1l). In light of the association between VCFS and psychosis, and also the neuro-psychological findings in the df1 mice, these 22 genes are positional candidate genes for schizophrenia. We have examined whether variation within any of these genes confers susceptibility to schizophrenia. We screened the exons and flanking intronic sequence of each gene for sequence variation in 14 individuals with DSM-IV. All polymorphisms identified were genotyped using DNA pooling in a sample of 368 schizophrenics and matched controls. Evidence for association has been found for 1 of the df1 genes, a finding that has been confirmed by individual genotyping of the 368 subjects. We are currently examining this finding in our extended sample of more than 700 schizophrenic cases and controls, in family based association samples, and in VCFS subjects with and without psychosis.

A polymorphism in the C-reactive protein (CRP) promoter is associated with increased prevalence of type 2 diabetes mellitus in Pima Indians. *J.K. Wolford, R.L. Hanson, J.D. Gruber, B. Vozarova, V.M. Ossowski, C. Bogardus.* NIDDK/PECRB, NIH, Phoenix, AZ.

Chronic activation of the immune system may play an etiologic role in the development of type 2 diabetes mellitus (T2DM). Results from recent longitudinal studies report that higher baseline levels of C-reactive protein (CRP), a humoral marker of inflammation, predict the development of T2DM independent of adiposity in Caucasians. In addition, plasma CRP levels are substantially increased in diabetic subjects. It is known that plasma CRP levels are heritable and interestingly, the CRP gene is located on chromosome 1q21 where we have reported linkage to T2DM in Pima Indians. We therefore evaluated CRP as a candidate T2DM susceptibility gene. We screened the CRP locus, including 2 kb of flanking sequence in both the 5' and 3' directions, to identify allelic variants and test them for association with T2DM in Pimas. We also investigated the adjacent amyloid P component, serum (APCS) gene, which is located within 124 kb of CRP. APCS is structurally similar to CRP and increased serum protein levels are also increased in subjects with diabetes. We identified 27 informative polymorphisms, including 26 single nucleotide polymorphisms (SNPs) and 1 insertion/deletion, which were assigned to 7 linkage disequilibrium clusters. We genotyped representative SNPs in ~1300 Pima samples and found one C/T polymorphism (SNP-133552) in the CRP promoter that was significantly associated with T2DM ($P=0.006$). In addition, the variant TT genotype was associated with lower insulin secretory function as measured by 25 g IVGTT ($p=0.05$, adjusted for age, sex, percent body fat, and insulin sensitivity), indicating that CRP might increase the risk of T2DM by decreasing insulin secretory function. These findings suggest that variation within the CRP locus may play a role in diabetes susceptibility in Pima Indians.

CORRELATION OF CLINICAL FEATURES OF WILLIAMS SYNDROME WITH PARENT OF ORIGIN TO IDENTIFY THE POSSIBLE ROLE OF IMPRINTING. *H.K. Wijesuriya¹, H.J. Antoine¹, G. Mohapathra¹, U. Bellugi², F. Rose², J.R. Korenberg¹.* 1) Med Genet, Cedars-Sinai Med Ctr, UCLA, Los Angeles, CA; 2) Salk Institute, San Diego, CA.

Williams Syndrome (WMS) is a neurodevelopmental disorder with variable phenotypes. Phenotypic variability in WMS subjects could be due to differences in the size of deletion, however approximately 95% of WMS subjects carry a deletion of the same 18 known genes located on 7q11.23. We have considered the hypothesis that phenotypic variability could be due to the alteration of gene expression due to the parent of origin of the remaining alleles. Genomic imprinting is defined as the total or partial inactivation of an allele as a consequence of having passed through gametogenesis in one parent. To identify the possible role of imprinting in WMS clinical phenotypes we determined the parent of origin of 62 subjects (47 Trios & 15 single parent families) with confirmed elastin deletion status. To do this we genotyped patients and available parents using 11 microsatellite markers covering the deletion and flanking regions. Of the 62 families tested 61 cases were informative, of which 36 were maternally derived and 25 were paternally derived. This is consistent with increased number of maternal over paternal deletions found in previous data. A deletion was detected at D7S489U locus in 33.3% of cases, D7S2476 in 52.4% cases, ELN1 in 61.1% of cases, and D7S1870 in 38.7% of cases. A deletion was detected at locus D7S489L (larger deletion) in 2 of 59 cases (3.4%), and 19 of 59 cases (32.2%) were not deleted (normal) at the D7S489L locus. A X² analysis was used to assess the influence of parent of origin status on historical, clinical and physical criteria for WMS (Am. Acad. of Ped., 2001) revealed no significant correlation between the degree of clinical phenotypes and the parent of origin. However significant trends were seen in hypertension ($p=0.073$), joint limitation ($p=0.134$), strong attraction to music ($p=0.066$), language delay ($p=0.093$) and short nose ($p=0.109$). The present data support a trend for the presence of imprinted genes in the deleted regions that may contribute to some of the clinical findings of WMS. A larger sample size may be necessary to obtain significance.

Carboxypeptidase A5: an imprinted member of the CPA gene family. *L. Bentley*¹, *K. Nakabayashi*², *Z. Montamedi*¹, *M. Preece*³, *S. Scherer*², *P. Stanier*¹, *G.E. Moore*¹. 1) Maternal and Fetal Medicine, IRDB, London, United Kingdom; 2) Hospital for Sick Children, Toronto Canada; 3) Institute of Child Health, University College London, London, United Kingdom.

Identification of segmental maternal uniparental disomy (mUPD) of 7q31 to the telomere in a Silver-Russell (SRS) patient emphasises this domain as a candidate region for the syndrome (1). Since mUPD7 has been found in approximately 10% of SRS patients, the causative gene is expected to behave in an imprinted way. The human homologue (*MEST*) of mesoderm-specific transcript (*Mest*) was the first imprinted gene to be identified on chromosome 7. It has been localised to chromosome 7q32 and is flanked by biallelically expressed genes, *TSGA14* (testis-specific protein A14) in a centromeric direction and *COPG2* (nonclathrin coat protein) in a telomeric direction (2). Subsequently, *CIT1* (*COPG2* antisense) and *MESTIT1* (*MEST* intronic transcript 1) at 7q32 have been described with imprinting effects (3). Since biallelically expressed genes can occur within a cluster of imprinted genes, the search for further imprinted genes was continued beyond *TSGA14* to the carboxypeptidase (*CPA*) group of genes. At least three transcripts of *CPA5* have been identified by RT-PCR, two of which are expressed in a range of fetal tissues. Single nucleotide imprinting analysis of these isoforms in fetal tissues has revealed tissue specific monoallelic expression. We also report the results of a mutation screening on non mUPD7 SRS patient DNAs. 1. Hannula et al. 2001 Am. J. Hum. Genet. 68:247-253 2. Yamada et al. 2002 Gene. 288:57-63 3. Association study of neurotrophic tyrosine kinase receptor type 2 (NTRK2) and childhood-onset depression. *J. Adams*¹, *K. Wigg*¹, *N. King*², *M. Kovacs*³, *J.L. Kennedy*², *C.L. Barr*^{1,4}. 1) Molecular & Cellular Division, The Toronto Western Hospital, Toronto, ON, Canada; 2) Centre for Addiction and Mental Health, Toronto, ON, Canada; 3) University of Pittsburgh, Pittsburgh, PA; 4) The Hospital for Sick Children, Toronto, ON, Canada.

Childhood-onset depression (COD) is a particularly serious form of affective illness. Extensive evidence suggests that depressive disorders are familial and twin studies suggest a substantial genetic component with increased genetic risk for relatives of childhood-onset probands. Several lines of evidence suggest a relationship of depression to neurotrophic factors. Brain derived neurotrophic factor (BDNF) is believed to be a key component of neural plasticity as it promotes neuronal survival and differentiation during development and encourages neuron growth during adulthood. Moreover, stress has been shown to reduce BDNF expression whereas chronic anti-depressant treatment increases expression. Also, administration of BDNF in both cellular and animal models has anti-depressant like effects. BDNF acts through its high-affinity receptor tyrosine kinase B (Trkb) which is encoded by the gene NTRK2. We hypothesize that DNA variations in NTRK2 relate to an individual's vulnerability to developing COD. We tested for association of NTRK2 with COD by comparing the distribution of a 2 allele polymorphism in NTRK2 in 104 cases that met DSM-IV criteria for a major depressive disorder before the age of 14 to a representative control sample balanced for ethnicity and gender. We found that the allele frequency between the two groups did not differ (chi square = 1.184, 1 df, p=0.277) and that the COD group showed no significant difference in genotype distribution compared to controls (chi square = 3.014, 2 df, p=0.222). Additional markers in this gene are currently under investigation.

***GABRA2* is associated with alcohol dependence and brain oscillations in a large family-based sample from the Collaborative Study on the Genetics of Alcoholism.** *H.J. Edenberg*¹, *D.M. Dick*¹, *B. Porjesz*², *X. Xuei*¹, *T. Foroud*¹, *H. Begleiter*² and *COGA Collaborators*. 1) Indiana Univ Sch Medicine, Indianapolis, IN; 2) SUNY HSC, Brooklyn, NY.

Linkage analyses using microsatellite markers identified a region of chromosome 4p that contained genes affecting the risk for alcoholism and affecting brain oscillations in the beta frequency (13-28 Hz). Within this region is a cluster of genes encoding GABA(A) receptors; these are excellent candidates for affecting brain oscillations through their role in mediating fast synaptic inhibition, and for affecting risk of alcoholism. We pursued these candidate genes by genotyping and analyzing multiple SNPs in *GABRA2*, *GABRA4*, and *GABRB1* in more than 2200 individuals from 262 families containing multiple alcoholics systematically ascertained by the Collaborative Study on the Genetics of Alcoholism. Linkage disequilibrium (LD) between markers within each gene was high; LD between genes was lower. Analyses of these SNPs provide evidence that variations in the *GABRA2* gene, encoding the alpha subunit of the GABA(A) receptor, affect brain oscillations. LD analyses performed using the Pedigree Disequilibrium Test provide strong evidence that the same gene, *GABRA2*, affects the risk for alcoholism, defined as DSM-IV alcohol dependence. SNPs throughout the *GABRA2* gene were significantly associated with alcohol dependence. The analyzed SNPs do not affect the amino acid sequence of the receptor subunit, but might be related to subtle differences in gene expression. The convergence of evidence from different analyses and phenotypes on this gene provides strong evidence that *GABRA2* is a key gene affecting the risk for alcoholism, and provides a plausible biological hypothesis that its effect is mediated by alterations in brain oscillations that affect the level of excitation.

A polymorphism in ENPP-1 that is associated with ectopic ossification is also associated with diabetic end-stage renal disease. *J.P. Bochenski, P.P. Wolkow, L.H. Canani, A. Smiles, M.G. Pezzolesi, J.H. Warram, A.S. Krolewski.*
Genetics and Epidemiology, Joslin Diabetes Center, Harvard Medical School, Boston, MA.

A polymorphism in exon 4 of the ecto-nucleotide pyrophosphatase/phosphodiesterase 1 (ENPP-1) gene resulting in an amino acid change (K@Q) is associated with insulin resistance and recently has been shown to be associated with end-stage renal disease (ESRD) in patients with diabetes. A different polymorphism in the ENPP-1 gene, a T insertion/deletion in intron 20 (T ins/del) has been shown to be associated with the ossification of the posterior longitudinal ligament of the spine. This suggested the hypothesis that mechanisms involved in calcification of connective tissue may also be involved in glomerulosclerosis in kidneys. We examined this hypothesis in a case-control study of 144 cases with diabetic ESRD and 281 controls with normoalbuminuria despite more than 15 years duration of type 1 diabetes. DNA from cases and controls, which had already been genotyped for the exon 4 polymorphism, was genotyped for the T ins/del in intron 20. The deletion was significantly more frequent in ESRD cases than controls ($p=0.02$) and the odds ratio for ESRD among carriers of the deletion was 1.7 ($p=0.01$). This association is almost identical in magnitude to that shown previously for carriers of the Q allele at exon 4. However, linkage disequilibrium between the polymorphisms in exon 4 and intron 20 is only modest ($D=0.55$). Two other polymorphisms have been identified and in preliminary analyses the odds ratios for ESRD range from 2 to 4. The critical haplotype for ESRD is being searched for using a family-based study design (TDT). Our data indicate that sequence differences in the ENPP-1 locus contribute to genetic susceptibility to ESRD in diabetes. Pathways involved in ectopic ossification may underlie glomerulosclerosis leading to ESRD in diabetes.

The expression pattern of 119 genes from the region of 18q21-22 that has shown linkage to bipolar disorder. *H. Chen*¹, *Y. Huo*¹, *N. Wang*¹, *D.F. MacKinnon*¹, *J.B. Potash*¹, *P. Sklar*³, *R. DePaulo, Jr.*¹, *C.A. Ross*^{1,2}, *M.G. McInnis*¹.

Linkage evidence of a locus on chromosome 18q21-22 to bipolar disorder has led to the effort to identify novel genes expressed in brain from this region for mutation study. We selected all 119 genes (35 known and 84 predicted) in the region annotated at the Celera databases, and created a gene array for expression analysis. To test the genes whether they are expressed in brain, we amplified one exon of each gene by PCR and made dot blot filters using 20 ng of PCR products for each gene. The filters in duplicate were then hybridized with ³²P labeled probes derived from 2 mg of normal brain polyA+ RNA (Clontech). We used a PhosphorImager scanner (Molecular Dynamics) to scan the hybridization images, and the ImageQuant software (Molecular Dynamics) to analyze data. In this study, we identified 22 known and 2 novel genes expressed in brain with various levels. We observed that 3 genes showed expression reduction of at least two fold when the array was hybridized with a probe derived from RNA isolated from a postmortem brain of bipolar disorder. This observation is being tested on additional postmortem brain samples of bipolar disorder, and being verified with RT-PCR amplification. The fact that few predicted genes were detected on the array then lead us to test by use of Northern blot analysis the genes for expression. We selected 20 such genes and performed expression analysis using a commercial Northern blot (Clontech #7760-1). None of the genes tested showed detectable hybridization signal. It is possible that these genes are expressed at very low levels hardly to be detected by Northern blot assay, or that a substantial number of predicted genes are not expressed in the tissues examined, or false prediction.

No evidence for linkage or linkage disequilibrium to nine circadian clock genes in bipolar disorder. *C.M. Nievergelt, D.F. Kripke, N.J. Schork, J.R. Kelsoe.* Department of Psychiatry, University of California, San Diego, CA.

Bipolar disease is suspected to be associated with malfunctions of the circadian system, which regulates individual circadian rhythms and enables the adaptation to a daily 24-hour cycle. Several human clock genes have been identified and localized and a comparison with linkage hotspots for bipolar disorder has revealed close correspondences. Linkage and linkage disequilibrium (LD) of nine clock genes (cryptochrome 1 and 2, period 1, 2, and 3, clock, *bmal1*, casein kinase 1e, and D box binding protein) to bipolar disorder were analyzed here.

Linkage analysis using 18 microsatellites in 52 affected families showed suggestive evidence for linkage to one (CK1e) of the nine genes. Because of the complex nature of bipolar disease, heterogeneity tests and multi-locus analysis were performed. No additional evidence for linkage under single locus or multi-gene models was found.

Because of its close location to a linkage hotspot, *cry1* was further analyzed by screening for functional mutations in 25 bipolar subjects from families with suggestive linkage to this gene. 13kb of the 102kb gene were sequenced and 17 variations (16 SNPs and a insertion) were identified. Two SNPs were located in the promotor region. The only coding sequence variant identified was found to be synonymous.

Multiple polymorphic SNPs for each of the nine clock genes, identified by sequencing for cryptochrome 1 and selected from databases for the other eight genes, were genotyped in 185 affected parent proband triads. LD analyses using TDT tests for single SNPs as well as haplotype analyses did not show evidence for association to bipolar disease.

In summary, we found no significant evidence for association or linkage of any of the clock genes examined. However, we have examined only a subset of putative clock genes. Further extension of this study would include examination of other clock genes and of subforms of the bipolar phenotype that have abnormalities of circadian rhythms.

Familial Meniere's disease in Finland. *M. Männikkö*¹, *J. Kotimäki*², *E. Jakkula*¹, *M. Sorri*³, *L. Ala-Kokko*¹. 1) Collagen Research Unit, Biocenter Oulu, and Department of Medical Biochemistry and Molecular Biology; 2) Central Hospital of Kajaani; 3) University Hospital of Oulu, Finland.

Menieres disease (MD) is characterized by fluctuating sensor neural hearing loss, vertigo, and tinnitus. Its etiology still remains unknown and treatment is largely empirical. It is usually defined idiopathic, but suggested to be due to a variety of causes including trauma, viral infections and autoimmune factors. Both autosomal dominant and recessive inheritance has been documented for MD. The incidence in Finland is 43/100 000, and the estimate of hereditary MD is 5-15%. In the present study we have collected 26 Meniere-patients with positive family history from 11 families with 25 non-affected family members, and 42 patients with no family history of the disease. The mode of inheritance for MD in Finland was defined as autosomal dominant with low penetrance and anticipation in two families. The candidate gene approach was used to analyze the COCH and COL11A2 genes for sequence variations. Both genes are expressed in the inner ear with a putative role in MD. Sixty-four Meniere-patients were screened for P51S mutation in the COCH gene causing autosomal dominant non-syndromic progressive sensor neural hearing loss with MD-like symptoms. None of the patients carried this mutation. Conformative sensitive gel electrophoresis analysis (CSGE) and subsequent sequencing of the change containing exons was performed for the coding region and surrounding sequences of the COCH gene. Four polymorphic changes were found, that were also found from the control set from general population. An HLA-allele, Cw7, was reported to be more abundant in MD than in controls suggesting a linkage to HLA-region (Chr 6), where COL11A2 also locates. Mutations in the COL11A2 gene have been reported in syndromic hearing loss associated with collagen related diseases but also in non-syndromic hearing loss, DFNA13. CSGE analysis of the COL11A2 gene was performed. Nineteen polymorphic changes were found with similar incidence than observed in general population. In addition an arginine to proline change and two intronic changes were found that were not observed in general population.

Association of a single nucleotide polymorphism of the DAZL gene with susceptibility to spermatogenic failure.

*P. Kuo*¹, *Y. Lin*², *Y. Teng*³. 1) Dept OB/GYN, National Cheng-Kung Univ Hosp, Taiwan, Republic of China; 2) Dept Urology, National Cheng-Kung Univ Hosp, Taiwan, Republic of China; 3) Department of Early Childhood Education and Nursery, Chia Nan University of Pharmacy and Science, Taiwan.

Purpose: To investigate the association of DAZL gene with spermatogenic failure. **Materials and methods.** Single-strand conformation polymorphism (SSCP) analysis of exon-containing genomic DNA segments of the DAZL gene was performed in 160 infertile Taiwanese men presenting with severe oligozoospermia and non-obstructive azoospermia. Sequence analysis was used to identify the mutations or polymorphisms in the fragments with aberrant SSCP patterns. All cases also underwent PCR analysis to characterize deletion status of 15 Y-chromosome genes. **Results.** An AG transition at nucleotide 260 (260 A->G) in exon 2, and an AG transition at nucleotide 386 (386 A->G) in exon 3 were identified. The mutation in exon 2 leads to a Thr12Ala change (T12A) of the DAZL protein. There was no difference in allelic frequency in T12A polymorphism between patients with spermatogenic failure and control subjects ($P=0.542$). The mutation in exon 3 is located within the RNA-recognition motif of the DAZL protein and will lead to Thr54Ala change (T54A). The frequencies of T54A allele in patients and control group were 7.39% and 0.86%, respectively ($p=0.0003$). There was no linkage disequilibrium between T12A and T54A alleles. The phenotypes varied significantly in cases with heterozygous T54A polymorphism, ranging from hypospermatogenesis and maturation arrest to Sertoli cell-only syndrome. A combination of DAZ gene deletion and T54A polymorphism did not worsen the phenotype. **Conclusion.** Our findings provide strong evidence for the role of the autosomal DAZL gene in human spermatogenesis. Heterogeneity of phenotypes in patients with T54A variant indicates involvement of complex genetic components in spermatogenic failure.

Microarray Analysis of Postmortem Multiple Sclerosis Cortex. *J. McDonough¹, J. Peterson¹, R. Klinkosz¹, K. Mirnics², B.D. Trapp¹.* 1) Dept Neuroscience, Cleveland Clinic Foundation, Cleveland, OH; 2) University of Pittsburgh School of Medicine, Neurobiology Dept. and Pittarray, Pittsburgh, PA.

Multiple Sclerosis is an inflammatory disease of the CNS marked by loss of myelin, oligodendrocytes, and neurons. MS is a complex disease in which susceptibility is conferred by many genetic loci in combination with environmental factors. It is hypothesized to be at least in part an autoimmune disease in which an immune response is directed against myelin proteins. The cause or causes of MS, however, are unknown. A component of MS relatively overlooked until recently is the pathology involving neurons. There are several mechanisms by which neurons are destroyed in MS and the possibility that MS is a primary neurodegenerative disease with secondary inflammatory white matter lesions has been raised. We are interested in identifying genes in neurons which are involved in the neuropathology associated with MS. In this study we have identified genes differentially expressed in MS cortical lesions vs. control cortex by microarray analysis. We have 27 MS brains from rapid autopsies from the Cleveland Clinic Foundation. Control brains have been obtained from the University of Pittsburgh and are matched for age, sex, postmortem interval, race, and pH. Lesions were identified and staged in postmortem MS brains with antibodies to myelin proteins and microglia. We then isolated mRNA from these lesions and from normal cortex and made probes which were hybridized to either Incyte or Affymetrix human microarrays. We have analyzed four cortical lesions and have identified gene groups which are consistently changed. Myelin protein genes were decreased in all lesions analyzed. The expression of presynaptic genes, genes involved in calcium homeostasis, mitochondrial genes, cytoskeletal element genes, and intracellular signalling genes are also changed in the cortical lesions. More comparisons are needed however to determine which changes are significant and to identify genes that will be candidates for further study.

Linkage of the Dopamine Receptor D1 Gene to Attention-deficit/hyperactivity Disorder. *V.L. Misener¹, P. Luca¹, O. Azeke¹, R. Tannock², W. Roberts³, M. Malone³, R. Schachar², J. Crosbie², A. Ickowicz², J.L. Kennedy⁴, C.L. Barr^{1,2}.*
1) Department of Psychiatry, Toronto Western Hospital, Toronto, Ontario, Canada; 2) Department of Psychiatry, The Hospital for Sick Children and the University of Toronto, Toronto, Ontario, Canada; 3) Division of Neurology, The Hospital for Sick Children, Toronto, Ontario, Canada; 4) Neurogenetics Section, The Centre for Addictions and Mental Health, Clarke Division, University of Toronto, Toronto, Ontario, Canada.

Attention-deficit/hyperactivity disorder (ADHD) has a strong genetic component, and genes of the dopamine system are considered primary candidates because medications that are effective in the treatment of this disorder influence the dopamine system. This has been borne out by positive and replicated linkage findings for the dopamine receptor D4 (DRD4) and dopamine transporter (DAT1) genes.

Evidence from both human and animal studies, which includes hyperactivity exhibited by dopamine receptor D1 (DRD1)-knockout mice, suggests that the DRD1 gene is a strong candidate for involvement in ADHD. Here, we tested for linkage of DRD1 to ADHD, by examining the transmission of three bi-allelic DRD1 polymorphisms (D1P.5, D1P.6 and D1.7) in a sample of 157 nuclear families identified through an ADHD proband. Using the transmission disequilibrium test, we observed trends for biased transmission of alleles for each of the three markers individually (*ie.* biased towards transmission of D1P.5 Allele 1, $p=0.122$; D1P.6 Allele 1, $p=0.105$; D1.7 Allele 2, $p=0.146$), and obtained significant evidence for linkage when haplotypes for these markers were analysed. Specifically, among three haplotypes which were sufficiently informative for the analysis in our sample (*ie.* 1.2.1, 2.2.1 and 1.1.2), we observed a bias for transmission of the 1.1.2 haplotype ($p=0.011$) and for non-transmission of the 2.2.1 haplotype ($p=0.022$). These findings support the proposed involvement of the DRD1 gene in ADHD. Since none of the polymorphisms analysed here is predicted to alter DRD1 function, we are currently screening the gene, by sequencing, to identify functional DRD1 variant(s) in our ADHD sample.

Association of ADAM33 with asthma and associated phenotypes in ethnically diverse populations. *T.D. Howard¹, D.A. Meyers¹, E.A. Ampleford¹, S.L. Zheng¹, H. Jongepier², D.S. Postma², E.R. Bleeker¹.* 1) Center for Human Genomics, Wake Forest Univ Sch Med, Winston-Salem, NC; 2) Dept of Pulm, Univ Hospital, Groningen, the Netherlands.

Asthma is a common respiratory disease characterized by intermittent airways obstruction and respiratory symptoms that are caused by acute and chronic bronchial inflammation. A recent study of 483 Caucasian families from the US and UK used a positional cloning approach to identify a candidate region on chromosome 20p for susceptibility to asthma, bronchial hyperresponsiveness (BHR), and total and specific IgE levels (patent number WO 01/78894). Further investigation identified the putative candidate gene as A Disintegrin And Metalloprotease (ADAM) 33. Multiple single nucleotide polymorphisms (SNPs) within ADAM33 were significantly associated with asthma and bronchial hyperresponsiveness (BHR) phenotypes for either the US, UK, or both populations combined. The ADAM family of transmembrane proteins has been implicated in critical functions such as cell-cell and cell-matrix interactions, cell migration, cell adhesion, and signal transduction. One role of ADAM genes studied to date is the shedding of the extracellular portion of specific cytokines and growth factors, leading to soluble forms of these proteins. In an effort to further characterize the contribution of ADAM33 to asthma, we evaluated a subset of the previously described SNPs in four populations: Dutch, US Caucasian, African-American, and US Hispanic. Significant associations were observed with multiple SNPs within ADAM33 and asthma, BHR, and total serum IgE levels in one or more of the four populations. For example, for the SNP labeled Q_2, significant associations were observed with measure of skin test responsiveness in the Dutch ($p=0.01$), BHR in US Caucasians ($p=0.045$), asthma in US African-Americans and Hispanics ($p=0.04$, 03). Further studies of this gene and its role in asthma are needed.

No association of polymorphisms in the cholinergic locus with late-onset Alzheimer's disease. *D. Harold¹, T. Peirce¹, M. Hamshere¹, A. Myers², D. Turic¹, S. Lovestone³, J. Powell³, S. McIlroy⁴, D. Craig⁴, P. Passmore⁴, J. Hardy⁵, A. Goate⁶, M. Liddell¹, M. O'Donovan¹, J. Williams¹, M.J. Owen¹, L. Jones¹.* 1) Dept of Psychological Medicine, UWCM, Cardiff, United Kingdom; 2) Washington University, St Louis, United States; 3) Institute of Psychiatry, London, United Kingdom; 4) Queens University, Belfast, United Kingdom; 5) National Institute on Aging, Bethesda, United States; 6) Dept of Psychiatry, St Louis, United States.

The genes for choline acetyltransferase (CHAT) and the vesicular acetylcholine transporter (VACHT) are strong functional and positional candidates for late-onset Alzheimer's disease (AD). One of the hallmarks of AD is the widespread dysfunction of the basal forebrain cholinergic system. The activity of CHAT has been shown to be reduced by 50-90% in AD patients compared with age-matched controls and is correlated with the depth of dementia. At present, the most effective therapies in treatment of the early stages of AD target this loss of function through the action of cholinesterase inhibitors. In addition, CHAT and VACHT are transcribed from a single locus on chromosome 10, in a region showing strong evidence of linkage to AD. We used DHPLC and sequencing to identify sequence variation in all known exons plus 3kb of putative regulatory sequence 5' to the multiple transcriptional start sites of these genes. We found 17 sequence variants: 16 single nucleotide polymorphisms and one minisatellite. Of the four polymorphisms in the coding exons, three were non-synonymous. A further 12 SNPs were observed in introns, untranslated and regulatory regions. We analysed all of the variants in a UK sample of late-onset AD cases and controls, consisting of 131 cases with probable late-onset AD and 106 age-matched controls sampled from the UK population. We found no significant association with AD. Haplotype analysis revealed some positive two-marker associations with a SNP in intron 9 of CHAT, but this was not replicated in a further sample of 242 AD cases and 235 controls collected in Belfast. We conclude that there is no genetic association between variation in CHAT or VACHT and late-onset AD.

A search for CCG expansion mutations in schizophrenia linkage regions. *J.J. Kleiderlein¹, J.B. Potash¹, L. Monfredo¹, S. Pirzadeh¹, H. Hwang¹, C.A. Ross^{1,2,3}, L.E. DeLisi⁴, R.L. Margolis^{1,3}, S.E. Holmes¹.* 1) Dept of Psychiatry,; 2) Dept of Neuroscience; 3) Program in Cellular and Molecular Medicine, Johns Hopkins Univ Sch Med, Baltimore, MD; 4) Dept of Psychiatry, NYU, New York, NY.

Many investigators have searched for a causal link between CAG expansion mutations and schizophrenia, but there has not been a rigorous study of CCG repeats in this disorder. Fragile X syndrome, a neurodevelopmental disorder with phenotype including psychiatric features, is caused by a large CCG expansion mutation. Schizophrenia is also hypothesized to have a neurodevelopmental basis, and we thus undertook a systematic search for CCG expansion mutations in a set of 65 unrelated individuals with schizophrenia. This is a clinically well-characterized collection of subjects ascertained in the USA and Europe on the basis of having at least two full siblings with the diagnosis of schizophrenia or schizoaffective disorder. We have also examined CAG repeats in this sample (Tsutsumi et al., 2002). We selected linkage regions that have been confirmed in more than one sample set, those with particularly high LOD scores, and regions showing linkage in our sample set (DeLisi et al., 2002). Within these regions (1q22-1q42, 2p11-2q14, 6p25-6p21, 6q14-6q27, 8p23-8p12, 10p14-10p12, 13q31-13q34, 15q13.14-15q13.3, and 22q11.2-22q13) we identified 35 CCG repeats containing 8 or more consecutive triplets. We developed PCR assays including Southern blots to screen for expansion mutations. No expansions were detected in the initial 18 repeats tested. This evidence does not support the hypothesis that a CCG expansion mutation is involved in schizophrenia, but additional studies are underway. DeLisi, L.E. et al., *Am J. Psychiatry* 2002; 159; 803-812. Tsutsumi, T. et al., ASHG 2002.

Positive allelic association of the marker d21s171 with bipolar disorder identifies TRPC7, a calcium channel protein on chromosome 21 at 21q22.3, as being a candidate gene for increasing genetic susceptibility to bipolar and related unipolar affective disorders. A. McQuillin¹, G. Kalsi¹, J. Lawrence¹, C. Smyth¹, D. Curtis², N.J. Bass¹, H.M.D. Gurling¹. 1) Molecular Psychiatry Laboratory, Department of Psychiatry, Royal Free and University College London Medical School, Windeyer Building, 46 Cleveland Street, London W1T 4JF, UK; 2) Department of Psychological Medicine, St Bartholomew's and Royal London School of Medicine and Dentistry, Whitechapel, London E1 1BB, UK.

Linkage analysis of bipolar families from many independent investigators have identified the distal end of the long arm of chromosome 21 as a potential source of genetic susceptibility for bipolar affective disorder (Gurling 1998, Smyth et al 1997). We genotyped 22 genetic markers near the telomere of chromosome 21 at 21q22.3 in 300 cases and 300 ethnically matched controls and found one marker that gave significant evidence for allelic association with bipolar disorder after a Monte Carlo correction for multiple alleles. Flanking markers gave weaker evidence for association and were only significant without correction for multiple alleles. We found evidence for a very high rate of recombination in this region because consistent evidence for linkage disequilibrium was difficult to detect even with adjacent markers expected to show disequilibrium. Cases who inherited the D21S171 marker alleles that were associated with bipolar disorder were selected for direct genomic sequencing of the TRPC7 calcium channel gene. Several polymorphic single nucleotide base pair variants within the gene have been detected and their significance in relation to the genetic susceptibility to bipolar disorder is currently being assessed. Gurling H (1998) Chromosome 21 Workshop. *Psychiatr Genet* 8, 109-113. Smyth C, et al (1997) *Genomics* 39,271-278 The research was funded by Medical Research Council grant G9623693N and by a research lectureship from the Priory Hospital, London to Dr. J Lawrence and by the Neuroscience Research Charitable Trust. We would also like to acknowledge the help of Hamish Scott and Stylianos Antonarakis for providing unpublished mapping information and primer sequences.

Program Nr: 1865 from 2002 ASHG Annual Meeting

Allelic association study investigating GABRA3 and markers in G6PD region in a UK bipolar case-control sample. *G. Kalsi, A. Mcquillin, D. Curtis, N. Bass, H.M. Gurling and Molecular Psychiatry.* Psychiatry & Behav Sciences, Windeyer Inst of Med Sciences, London, UK.

An excess of affected females and a deficiency of male-to-male transmission has led to the proposal of an X-linked form of bipolar illness. Several studies have highlighted a possible link between Glucose-6-Phosphate Dehydrogenase (G6PD) on Xq28 and bipolar illness. The $\alpha 3$ subunit of the gamma amino butyric acid receptor gene (GABRA3) has received attention on the basis of preclinical and pharmacological studies, which suggest that a dysfunction in brain GABAergic system activity could contribute to manic depression. Thus, the $\alpha 3$ subunit localised on Xq28 represents a plausible candidate gene. Previous linkage and association studies have shown mixed results. We used microsatellite markers for GABRA3, G6PD and markers flanking this gene to test for allelic association in a stringently screened sample of 306 UK bipolar affective patients of English, Irish, Welsh or Scottish ancestry and compared allele frequencies in 310 ethnically matched normal controls. The data was analysed using the CLUMP program. Results showed statistically significant evidence in favour of a putative locus in G6PD region. The G6PD-Med polymorphism produced $p=0.005$. However, tests with GABRA3 showed lack of evidence in favour of a possible pathogenic role in our sample.

Evidence for linkage but not association to the GABRB3 region of chromosome 15 in a subset of autistic disorder (AutD) families characterized by an increase in restricted and repetitive behaviors. *M.M. Menold¹, Y. Shao¹, S.J. Kim¹, C.M. Wolpert¹, S.L. Donnelly¹, S.A. Ravan², R.K. Abramson², H.H. Wright², G.R. Delong¹, M.L. Cuccaro¹, M.A. Pericak-Vance¹, J.R. Gilbert¹.* 1) Ctr for Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) WS Hall Psychiatric Institute, Univ.of S. Carolina, Columbia, SC.

Autistic disorder (AutD) is a complex neurodevelopmental disorder with a strong genetic component. While numerous susceptibility genes probably exist for AutD, it has been difficult to detect these genes by linkage or association since each gene is presumed to contribute just a small part to the etiology of the disease. Identification of the genes is made even more complicated because of the clinical heterogeneity present in data sets. Ordered subset analysis (OSA) is a method that can be used to identify a particular set of families that are contributing to linkage or association at a given locus. Using this technique, Shao et al. (this meeting) demonstrated significantly increased LOD scores in the region of the GABRB3 gene by using a factor derived from repetitive behaviors and stereotyped patterns as the covariate for OSA. This analysis strengthened previous results of linkage and association at this locus for AutD.

Using the 23 families (107 individuals) that were identified by OSA as being a homogeneous subset of the AutD data set, we analyzed 9 single nucleotide polymorphisms (SNPs) within the GABRB3 gene and in the region located beyond the 3' end of the gene. Eight of the nine SNPs showed positive linkage with a peak LOD score of 1.673 for SNP GABRB3-3PR1 located 3.6 kb from the end of the gene. Association analysis was not significant for any of the SNPs using either the Pedigree Disequilibrium Test (PDT) or Transmit. While this result supports evidence for an autism gene in the GABRB3 region of chromosome 15, AutD does not appear to be associated with a specific SNP haplotype, and may instead be due to multiple mutation events in this region.

Transmission of SYNAPSIN3 gene variants in schizophrenia families. *T.A. Klempan¹, T. Armstrong¹, N. King¹, C. Pato², M. Pato², M.-H. Azevedo², F. Macciardi¹, J.L. Kennedy¹.* 1) Neurogenetics, CAMH, Toronto, ON, Canada; 2) Department of Psychiatry, University of Coimbra, Portugal.

The synapsins comprise a family of exocytotic vesicle membrane proteins that participate in vesicle mobilization, axon formation, and neural plasticity. The association of synapsins with actin microfilaments following phosphorylation serves to control the recruitment of vesicles, in turn regulating the kinetics of neurotransmission and synaptic strength. The synapsins are highly expressed in brain and several reports have revealed reduced expression of synapsins in the brains of schizophrenic individuals. The SYNAPSIN3 gene has been localized to chromosome 22q13, within 5 cM of D22S278, a dinucleotide repeat marker previously associated with schizophrenia. The possible role of SYNAPSIN3 in the pathogenesis of schizophrenia was investigated through analysis of two substitution polymorphisms within the promoter region (-631C/G and -196G/A) and a dinucleotide repeat (D22S280) within intron 5 of the gene. These markers were studied in a combined sample of 228 small nuclear schizophrenia families, 123 families of variable ethnicity and 105 families from mainland Portugal and the Azores islands. Transmission of alleles to affected individuals was examined using the family-based association test (FBAT). No significant differences in inheritance of these alleles was observed in these pedigrees using FBAT (multi-allelic, dominant model: -631C/G chi-squared=0.518, $p=0.772(2df)$; -196G/A chi-squared=0.246, $p=0.884(2df)$; D22S280 chi-squared=4.591, $p=0.710(7df)$). Comparison of the age at onset for affected individuals shows an effect of homozygosity for the 631G allele on early age at onset ($F=5.14$, $p=0.026$). These findings suggest that while alleles of SYNAPSIN3 are unlikely to act as major susceptibility factor for schizophrenia, they may influence the timing of symptom onset.

Program Nr: 1868 from 2002 ASHG Annual Meeting

Quantitative RT-PCR Analysis of Gene Expression Alterations in Selective Brain Regions of Patients with Mood Disorders. *J. Li¹, P.V. Choudary², S.J. Evans³, M.P. Vawter⁴, H. Tomita⁴, J. Meador-Woodruff³, E.G. Jones², W.E. Bunney⁴, S.J. Watson³, H. Akil³, R.M. Myers¹.* 1) Stanford Human Genome Center, Palo Alto, CA; 2) Center for Neuroscience, Univ. California, Davis, CA; 3) Mental Health Research Institute, Univ. Michigan, Ann Arbor, MI; 4) Department of Psychiatry, Univ. California, Irvine, CA.

We compared transcript levels for several hundred genes in *post-mortem* brain tissues between patients and controls in an effort to identify gene-expression alterations associated with mood disorders. We isolated total RNA from specific brain regions implicated in mood disorders, synthesized first-strand cDNA, and performed SYBR Green-based realtime-PCR experiments to quantitate transcript levels for each gene relative to a panel of reference genes. So far we have analyzed anterior cingulate cortex, dorsolateral prefrontal cortex and cerebellum from nine Bipolar patients, eleven Major Depressive Disorder (MDD) patients and 20 control individuals. The genes included in this study are approximately 150 carefully selected candidate genes covering a variety of functional categories, additional genes previously reported in literature as putatively associated with suicide, Bipolar and/or MDD, as well as genes that appeared to be up- or down-regulated in our cases as compared to controls according to our Affymetrix microarray analysis (reported elsewhere). This presentation will describe results of our quantitative RT-PCR analysis, as well as our methods for achieving high sensitivity and high throughput, while ensuring accuracy. *Supported by: The Pritzker Neuropsychiatric Disorders Research Consortium, Pritzker Family Philanthropic Fund and NIH CONTE Center grant #L99MH60398.*

Mutation analysis for candidate genes in Japanese autistic population. T. Yamagata, H. Li, M. Mori, K. Suwa, M.Y. Momoi. Department of Pediatrics, Jichi Medical School, Tochigi, Japan.

Mutation analysis for candidate genes in Japanese autistic population. T. Yamagata, H. Li, M. Mori, K. Suwa, and M. Y. Momoi. Department of Pediatrics, Jichi Medical School, Tochigi, Japan We are analyzing several candidate genes for possible causative mutations among Japanese autistic children. Patients diagnosed with pervasive developmental disorder or autism according to the criteria of DSM-IV were enrolled in this study after the informed consents by their parents. Up to one hundred autistic patients were enrolled. We report the results of mutation analyses of methylation-related genes, such as *MeCP2*, *MBD1*, *MBD2* and *MBD3*, and the genes located on 7q such as *FOXP2* and serotonin receptor gene (*HTR5A*). All exons and promoter regions of these genes were amplified by PCR and the mutation was detected by DHPLC, and subsequently by direct sequencing. We found two base substitutions in *MBD1* that were not found in 150 control DNA. One was G to A change in the first base of exon 2 (5UTR) in one male patient. The other was C805T that introduced R269C amino acid change in another male patient. The C805T change was also detected in the patients father with some phenotype of autism and in a normal sister. We also found repeat length polymorphism of (GGC)₄ to 5 and (GGGGCC)₂ to 3 in *MBD2*, and (CAA)₅ to 4 in *FOXP2* in some patients, however, we did not detect the difference in the frequency between patients and controls. The significance of these base substitutions with amino acid change in patients and some of their family members is not known, however, the absence of these SNPs among normal populations suggested the relevance to the disease. We also found that methylation-related genes were highly polymorphic, that also suggested the possible involvement of SNPs of these genes in the pathology of autism.

Identification of susceptible gene for the ossification of the posterior longitudinal ligament of the spine from the linkage region on chromosome 21. *T. TANAKA¹, K. IKARI², K. FURUSHIMA¹, S. TOH¹, S. HARATA¹, T.*

NAKAJIMA², I. INOUE². 1) Department of Orthopaedic Surgery, Faculty of Medicine, Hirosaki University, Hirosaki, Japan; 2) Division of Genetic Diagnosis, The Institute of Medical Science, The University of Tokyo, Tokyo, Japan.

Ossification of the posterior longitudinal ligament of the spine (OPLL) is a subset of bone former disease, characterized by ectopic ossification in the spinal ligaments by an endochondral process. OPLL is a common disorder among Japanese and other Asian populations constituting the leading cause of spinal myelopathies. The incidence of this disorder in Japan is reported to be 1.9 %-4.3 %. Although multiple etiologies for OPLL need to be considered because of the late-onset nature of the disease, it is well recognized that a certain fraction of this common disease is genetically determined. We have performed a genome-wide linkage study with 126 affected sib pairs using GENEHUNTER and SIBPAL programs to identify genetic loci related to OPLL. Positive evidence of linkage were found at limited number of loci and the best evidence of linkage was detected at D21S263 on chromosome 21q21.3-22 (maximum LOD score 3.6). In order to identify the susceptible gene for OPLL, we performed extensive association studies with SNPs (single nucleotide polymorphisms) covering the 15 Mb of linkage region. SNPs were obtained from the public database (NCBI dbSNP [<http://www.ncbi.nlm.nih.gov/SNP/>] and IMS-JST JSNP DATABASE [<http://snp.ims.u-tokyo.ac.jp/>]). We have analyzed 189 genes with 400 SNPs in the region. Thus far we have obtained positive allelic associations with 6 genes ($P < 0.05$). Linkage disequilibrium and haplotype analysis could infer that one gene could be responsible for the predisposition of OPLL. Identification of the susceptibility of OPLL by genome-wide linkage study and allelic association study could provide new insights into the pathogenesis of OPLL, which could lead to development of novel therapeutic tools.

BDNF and susceptibility to autism spectrum disorders. *S. Robitaille*¹, *X. Liu*^{1,2,3}, *M. Currie*³, *J.J.A. Holden*^{1,2,3}. 1) Department of Physiology, Queen's University, Kingston, ON, Canada; 2) Department of Psychiatry, Queen's University, Kingston, ON, Canada; 3) Cytogenetics and DNA Research Laboratory, Ongwanada, Kingston, ON, Canada.

Autism Spectrum Disorders (ASDs) are a group of neurodevelopmental disorders characterized by impairments in reciprocal social interaction and communication as well as repetitive behaviours. Nelson and colleagues¹ demonstrated significant elevation of the brain-derived neurotrophic factor (BDNF) neuropeptide in neonatal blood from individuals later diagnosed with autism and/or developmental disabilities. These findings suggest that BDNF is a good candidate gene for ASDs. Philippe and colleagues² recently reported their findings on an intragenic marker and two markers linked to BDNF in 39 multiplex autistic families, finding no evidence for an association between BDNF and autism. We investigated the same intragenic marker and a closely linked marker, D11S1301, in 123 multiplex ASD families and a comparison group (N=171). Although the allele distributions for both markers did not differ in ASD families compared to controls, we found that the D11S1301-331 allele and the BDNF-D11S1301 170-331 haplotype were transmitted more often than expected to offspring using the family-based association test (FBAT) and the Transmit program (331 allele: S=141, E(S)=122.5, p=0.013; 170-331 haplotype: $c^2=11.359$, df=1, p=0.001). Moreover, fathers transmitted the 331 allele to offspring more often than the 50% expectancy ($c^2=3.928$, df=1, p=0.047). Our findings support BDNF or a closely linked unidentified gene as a candidate gene for autism. Genotyping of another intragenic BDNF marker with an amino acid change (ie. valine-66-methionine) is in progress. (Supported by a scholarship to SR from NSERC and research grants to JJAH from CIHR and OMHF) ¹ 2001 Ann Neurol 49: 597-606. ² 2002 Am J Med Genetics 114: 125-128.

Optineurin Sequence Variants Do Not Predispose to Primary Open Angle Glaucoma. *J.W. Walter¹, R.R. Allingham¹, J.D. Flor¹, K.R. LaRocque¹, F.L. Graham¹, B. Broomer¹, E.A. del Bono², J.L. Haines³, M.A. Pericak-Vance¹, M.A. Hauser¹, J.L. Wiggs².* 1) Duke Univ Medical Ctr, Durham, NC; 2) Massachusetts Eye and Ear Infirmary, Boston, MA; 3) Vanderbilt University, Nashville, TN.

The optineurin protein, which is encoded by the OPTN gene located on chromosome 10p14-p15, is expressed in the brain and many tissues of the eye including the trabecular meshwork, retina, and non-pigmented epithelium. Recent studies have suggested that mutations and polymorphisms in optineurin may cause or increase susceptibility to normotensive glaucoma (Rezaie T et al., Science 295, 1077). To assess the influence of optineurin in the more common high-tension primary open angle glaucoma (POAG), we screened the probands from a set of 86 adult-onset POAG families. Criteria for inclusion include age of onset great than 35 years, elevated interocular pressure ³ 22mm Hg in both eyes, optic nerve damage, and corresponding visual field loss in at least one eye. Transgenomic WAVE denaturing high performance liquid chromatography (dHPLC) was used to screen for sequence variants in the optineurin gene. Pools of genomic DNA from 3 individuals were subjected to dHPLC at several different temperatures. Pools displaying altered column retention time were sequenced to confirm and identify sequence variants. Exons 4 and 5, containing the previously reported E50K and M98K variants, were sequenced in their entirety. Within this sample of 86 probands and 80 controls, we detected the M98K variant in 10% of affected individuals, as well as 10% of controls. We did not detect the E50K variant in any of the individuals tested nor did we detect any other polymorphisms within the optineurin coding sequence. However, we did detect six intronic SNP's none of which are predicted to cause splice defects. This data suggests that variations in the optineurin gene do not cause or predispose individuals to adult onset POAG.

Characterization and Analyses of AD Candidate Genes P16 and MTAP on Chromosome 9p21. *P.-T Xu¹, J.R. Gilbert¹, S.N. Walters¹, C. Browning¹, K.A. Desombre¹, K. Nicodemus¹, W.K. Scott¹, J.L. Haines², M.A. Pericak-Vance¹.* 1) Duke University Medical Center, Durham, NC; 2) Vanderbilt University Medical Center, Nashville, TN.

The Collaborative Alzheimer Project (CAP) has completed an Alzheimers disease (AD) screen using 334 microsatellite markers in the largest AD dataset to date (455 families, 726 sibpairs). A region on chromosome 9p21, using the marker D9S741, gave the highest lod score (MLOD = 3.43; MLS = 3.31 in the overall dataset and MLOD = 3.94; MLS = 4.41 in autopsy confirmed cases). We have found evidence for significant association with SNPs around the CDKNA2 (p16) [two point results (rs1042387 (p=0.0006) and rs 717326 (p=0.04)] and Methylthioadenosine Phosphorylase (MTAP) genes [multipoint results:tsc03520892/tsc0129737_1/tsc0129737_2 (p=0.003)].

The region from the p16/p15 complex to MTAP encompasses approximately 200 kb. P16, which co-localizes with nNOS and p21^{ras} in pyramidal neurons in AD brain is an approximately 7kb tumor suppressor gene that produces a 987 bp transcript and has three exons. It utilizes a different promoter but shares portions of its exon 1, exon 2, and part of exon 3 with an overlapping p14 isoform/gene.

We have analyzed the AD candidate genes P16 and MTAP by sequencing the whole p16 gene, and the coding region of MTAP gene including exons and exon/intron junctions. We have designed 34 pairs of primers that covered a region of 15,525 bp of p16 gene. We have found 6 new SNPs in several AD patients in which 2 SNPs are located about 100 bp and 4,000 bp upstream of exon 1, respectively. We have also identified 13 isolated nucleic variants in P16 gene. A poly-(T) tract with a variation from 15T to 53T in different AD patients was also detected in intron1 of P16 gene. A dinucleotide (CA) repeat was observed in intron1b ~200 bp downstream of exon1b of p14 protein gene (an isoform of p16). We have found 4 new SNPs in exon 3 and exon 8 of MTAP gene including a missense mutation (valine to isoleucine) in coding region of exon3.

The role of promoter polymorphisms in the APOE gene in progression of multiple sclerosis (MS). *S. Schmidt¹, I.C. Allen¹, R.R. Lincoln², J.B. Rimmler¹, L.F. Barcellos², A. Swerdlin², A.M. Saunders¹, J.R. Oksenberg², S.L. Hauser², J.L. Haines³, M.A. Pericak-Vance¹.* 1) Duke Univ Med Ctr, Durham, NC; 2) Univ California, San Francisco, CA; 3) Vanderbilt Univ Med Ctr, Nashville, TN.

Genes on chromosome 19q13 have been implicated in both progression and risk of MS. For risk, linkage evidence implicates a broad region, and association evidence implicates genes distal to the apolipoprotein E (APOE) locus. For progression, we have previously reported evidence that the APOE-4 allele is associated with a more severe disease course, whereas carriers of the APOE-2 allele are more likely to be affected with a mild form of MS. In addition to the functional polymorphism that produces the well-known apoE protein isoforms, we have now completed genotyping of three promoter, one intronic, and one 3' UTR polymorphism in the APOE gene (-491A/T, -427C/T, -219G/T, 113C/G, 5361C/T) in a large data set of Caucasian MS families. The 219T allele has previously been reported to increase risk of both Alzheimer disease and myocardial infarction independently of the established effect of the APOE-4 allele in these disorders. Both -219G/T and -491A/T have been shown to influence the transcriptional activity of the APOE gene. Our current MS data set consists of 189 multiplex and 410 singleton families, with a total of 872 clinically definite MS patients and 1404 unaffected family members. Preliminary analyses of the additional APOE variants indicate that none of them are associated with an increased risk of MS, and that they are not independently associated with disease course. Haplotype analyses suggest that the -219T and -491A allele in combination with APOE-4 are significantly over-represented in patients with a more severe course of MS (EDSS>6.0 within 10 years of disease onset; $p=0.01$, $p=0.01$, resp.). On the other hand, -491A in combination with APOE-2 is significantly more frequent in patients with mild MS (EDSS<3.0 after 10 or more years of disease duration; $p=0.04$). While the strength of the association is similar to that observed with APOE-4 and APOE-2 alone, the particular associated alleles of the promoter variants further support a role of the APOE gene in MS progression.

Germline mutations in angiotensinogen associated with predisposition to type 1 diabetes. *D.L. Russell¹, F. Kronenberg², K.M. Timms¹, M.T. McDermott¹, J. DeGrado¹, H.A. O'Neill¹, Y. Chen¹, M. Auinger³, C. Säly⁴, R. Sommer⁵, R. Weitgasser⁶, S.C. Hunt⁷, M. Skolnick¹, M. McGrail¹, D.M. Shattuck¹.* 1) Myriad Genetics, Salt Lake City, UT; 2) Institute of Med Biol and Human Genetics, Univ of Innsbruck, Austria; 3) Lainz Hospital, Vienna, Austria; 4) Feldkirch Hospital, Dept of Inter Med, Austria; 5) Graz Univ Hospital, Dept of Inter Med, Austria; 6) Salzburg Hospital, Dept of Inter Med, Austria; 7) Cardiovascular Genetics, Univ of Utah, Salt Lake City, UT.

Type 1 diabetes (T1D) is an autoimmune disease with both genetic and environmental contributing factors. Reportedly, >20 loci show linkage to T1D. The HLA complex (IDDM1) has the most significant association but accounts for ~50% of the familial clustering of T1D, indicating the existence of non-HLA, T1D-predisposition genes. There is significant evidence of linkage to T1D at 1q42-43, near angiotensinogen (*AGT*). To investigate whether *AGT* is the gene responsible for this linkage, we obtained 38 nuclear families, each with > 2 children affected with T1D, from the HBDI. We observed haplotype sharing across 1q42-43 in 20 families, which we used to screen for mutations in *AGT*. We detected rare novel mutations, including Cys18Arg. Next, we screened these variants in an independent set of 308 unrelated cases and 1003 population controls. Enrichment of Cys18Arg in the cases as compared to controls (3/308 vs. 1/1003, $p=0.03$) was detected. We then sequenced the promoter and coding region of *AGT* in the cases and 631 of the controls. In cases, we found novel rare missense and non-coding mutations, including three variants in a putative HNF4/MODY1 activating element. Comparison of the frequency of rare mutations in *AGT*, in both sets, showed significantly more carriers in the cases as compared to controls (18/308 vs. 17/631, $p=0.01$). These data support our hypothesis that the mutations, described here, in *AGT* are predisposing to T1D. To replicate these results in an independent study population, we are screening for Cys18Arg and the HNF4 activating element variants in a set of Austrian type 1 diabetics and a set of matched controls of the same ethnicity and from the same geographical region.

Linkage disequilibrium mapping of the serotonin transporter gene (SLC6A4) region in autism. *J.E. Vander Molen¹, S.J. Kim², E.H. Cook², N. Cox¹*. 1) Human Genetics, University of Chicago, Chicago, IL; 2) Laboratory of Developmental Neuroscience, Child and Adolescent Psychiatry, Department of Psychiatry, University of Chicago, Chicago, IL.

The serotonin transporter gene (SLC6A4) is a candidate gene in autistic disorder based on neurochemical studies and the efficacy of serotonin transporter inhibiting drugs. Previous studies have shown nominally significant over/under-transmission of alleles at this locus [Kim et al, Mol Psych, 2002]. A sample of 115 trios consisting of unaffected parents and an offspring affected with autism were typed for 27 markers in and around the SLC6A4 region, spanning 2.1 Mb. We applied the decay of haplotype sharing (DHS) method developed by McPeck and Strahs [AJHG, 1999] to these data to localize variation affecting susceptibility to autism and identify ancestral haplotypes. The 95% confidence interval obtained using the conditional coalescent model for the DHS analysis is a 0.51 Mb region including markers D17S1294 through 5-HTTLPR. The ancestral haplotype for markers in the 95% CI is largely consistent with results of the TDT for these data using individual markers, including the allele found overtransmitted for all markers except HTT SNP17 in exon 1b and a GAA repeat in intron 7. DHS analyses with control data only show a low peak for the likelihood function when compared to analyses with patient and control data, indicating that DHS adequately models background LD in this region. Pairwise LD between markers on patient chromosomes appears to be of greater magnitude than LD on the untransmitted parental chromosomes.

CARD4/NOD1 in Inflammatory Bowel Disease. *H. Zouali¹, S. Lesage¹, F. Merlin¹, JP. Cézard², JF. Colombel³, J. Belaiche⁴, S. Almer⁵, C. Tysk⁶, C. O'Morain⁷, M. Gassull⁸, R. Modigliani⁹, C. Gower-Rousseau³, M. Chamaillard¹, G. Thomas¹, JP. Hugot¹.* 1) Fondation Jean Dausset, Paris, France; 2) Hôpital Robert Debré, Paris, France; 3) Hôpital Calmette, Lille, France; 4) Department of Gastroenterology, CHU de Liège, Belgium; 5) Institutionen för Molekylär och Klinisk Medicin, Linköpings Universitet, Linköping, Sweden; 6) Department of Gastroenterology, Örebro Medical Center Hospital, Örebro, Sweden; 7) Department of Gastroenterology, Adelaide & Meath Hospital, Dublin.; 8) Department of Gastroenterology, Hospital Universitari Germans Trias i Pujol, Badalona, Spain; 9) Department of Gastroenterology, Hôpital Saint Louis, Paris, France.

Background : IBD are complex genetic disorders of unknown etiology. We have recently identified CARD15/NOD2 as being a susceptibility gene for Crohns disease (CD). Aim : Because CARD4/NOD1 shares many structural and functional similarities with CARD15/NOD2, we tested its putative role in Inflammatory Bowel Disease (IBD). Patients and methods : The IBD families were recruited through a large European consortium. The 11 exons and intron-exon boundaries of CARD4/NOD1 were screened for the presence of variants in 77 unrelated IBD patients (62 CD and 15 UC patients) using direct sequencing. The identified variant was genotyped using a PCR-RFLP procedure. The Transmission Disequilibrium Test (TDT) was computed by GENEHUNTER 2.0 program. Results : Nine sequence variations were identified in the coding sequence of the CARD4 gene. Five of them (E266K, D372N, R705Q, T787M and T787K) were non conservative variants but only one (E266K) was present in more than one IBD patient. This variant was genotyped in 291 IBD families including 235 Crohn (CD) and 56 Ulcerative Colitis (UC). TDT failed to demonstrate any association between the E266K variant and any of the three phenotypes : IBD, CD and UC ($p>0.05$). The analysis of the phenotype-genotype relationship do not show any differences between mutated E266K and wild type IBD patients. Conclusion: These results suggest that CARD4/NOD1 do not play a major role, if any, in IBD genetic susceptibility.

A Tnfr1 genotype with a protective role in familial rheumatoid arthritis. P. Dieude¹, E. Petit-Teixeira¹, S. Moreno¹, J. Osorio¹, S. Cailleau-Moindrault¹, C. Stalens¹, S. Lasbleiz², B. Prum³, T. Bardin^{1,2}, F. Cornelis^{1,2}. 1) Laboratoire ECRAF-GENHOTEL, Universites ParisVII-Evry, Evry, France; 2) Unite de Genetique Clinique, Hopital Lariboisiere, Assistance Publique des Hopitaux de Paris, France; 3) Laboratoire Statistique et Genome, Genopole, Evry, France.

Background Tumor necrosis factor alpha is involved in rheumatoid arthritis (RA) and binds TNFR1 and TNFR2 receptors. Genome scans have suggested the TNFR1 and TNFR2 loci as susceptibility loci for RA. Previous studies in a UK and French Caucasian population have shown an association between a TNFR2 genotype and familial, but not sporadic RA. Our objective was to test the TNFR1+36 A/G polymorphism for an association in RA.

Methods. To test for an association in sporadic RA, 100 families with one RA patient and both parents were genotyped for the +36 A/G polymorphism. Analysis used the transmission disequilibrium test and the haplotype relative risk (HRR). To test for an association in familial RA, RA index cases from affected sib pair (ASP) families that had been typed for two TNFR1 flanking microsatellite markers (D12S99 and D12S1625) (n = 86) were genotyped for +36 A/G polymorphism. To further explore the involvement of a particular genotype in RA ASP families, we used a subgroup more likely to have a TNFR1 putative factor : RA index cases with TNFR1 twin like RA sib (n = 19) : a TNFR1 genetically identical RA affected sib (RA cases for whom the affected sib had identical genotype at both TNFR1 flanking microsatellites).

Results. A trend of decreased number of +36 A/A genotype was observed in sporadic RA (33%) compared to controls (41%) and reached significance in familial RA (24%) (P= 0.012). This negative association was most marked in the context of TNFR1 twin-like RA sibs, 11% compared to 41% in the controls (P= 0.008).

Conclusion. This study provides evidence of the involvement of TNFR1 in RA genetic heterogeneity. Our data suggest that a TNFR1 recessive factor, in linkage disequilibrium with the +36A allele, plays a protective role in a subset of families with multiple RA cases.

Multivariate analysis of autoantibody repertoires in Systemic Lupus Erythematosus (SLE) multiplex families. C. Fesel¹, M. Barreto¹, F. Fontes¹, R. Andreia², F. Crespo², C. Vasconcelos², AM. Vicente¹, C. Ferreira². 1) Instituto Gulbenkian de Ciencia, Oeiras, Portugal; 2) Associao de Doentes com Lupus, Lisboa, Portugal.

SLE is an autoimmune disease with female predominance and demonstrated inheritable effects, though complex and most likely highly multigenic, and not yet well elucidated by genetic studies. Patients produce IgG autoantibodies to a wide variety of primarily nuclear, but also non-nuclear autoantigens, likely to include yet uncharacterized ones. In order to identify genetic factors influencing SLE, we have applied an indirect strategy to first dissect serological subtypes without respect to known antigens, expected to represent non-genetic as well as genetic effects, but with the possibility to find among them sub-phenotypes likely to be major Mendelian, thus useful for mapping. Using a standardized quantitative immunoblot method, we measured serum IgG autoantibody repertoires to 3 tissue extracts, permitting to quantify 130 separate reactivity bands in a sample of 16 multiplex families including 27 patients and 71 unaffected relatives, and 46 healthy control adults. Principal component analysis on these parameters showed that among the 10 major principal components extracted, 4 were associated with lupus, one of which was interpretable as the representation of a genetic trait. This component (factor 10), though among the 4 lupus-associated factors contributing least to the total data variance (3%), was like the other three strongly associated with lupus ($p=.003$, Mann-Whitney test), but, unlike them, had a heritability estimate of 50% ($p=.003$). Family correlations (mother-daughter .41, father-daughter .58, while parent-son and parent-parent insignificant) were most compatible with the interpretation as a trait with sex-dependent penetrance. This type of model was also the best-fitting, and non-rejectable Mendelian model for factor 10 in complex segregation analysis. Though requiring confirmation in a larger sample, this result supports the existence of subtypes characterized by autoantibody reactivity patterns, and their possible usefulness to constitute a phenotypic trait appropriate for mapping.

Paternal origin of Y-chromosome-bearing cells in microchimeric nulligravid females with autoimmune disease.
C.J. Osgood^{1,2}, L. Blanchfield¹, R.N. Slotnick³, M.W. Stacey², C. Gabriel^{2,4}, D.S. Lidwell². 1) Dept Biological Sci, Old Dominion Univ, Norfolk, VA; 2) Dept of Pediatrics, Eastern Virginia Medical School, Norfolk, VA; 3) Dept OB/GYN, Eastern Virginia Medical School; 4) Dept Internal Medicine, Eastern Virginia Medical School.

Autoimmune diseases (AID) are estimated to affect approximately 30 million people in the US, with a predominance of affected females. The etiology of autoimmune diseases is poorly understood, although several authors have noted an association between microchimerism and enhanced risk of developing disease. We have detected evidence of presumptive microchimerism in samples collected from nulligravid, juvenile females diagnosed with AID. We have detected Y-chromosome sequences in samples from patients diagnosed with juvenile rheumatoid arthritis, dermatomyositis and system lupus erythromatosis. We report here the results from DNA sequence analyses of Y-chromosome sequences detected in those females by PCR. We find that 1) the PCR-amplified sequences are not attributable to contamination, and 2) that those sequences match uniquely to the fathers of the nulligravid females. We propose that nulligravid females are likely derived from XXY zygotes with subsequent loss of the Y-chromosome in the majority cell population. Possible mechanisms by which such events promote development of AID will be discussed.

Association of a functional repeat polymorphism within the promoter of the human Nramp1 gene in familial rheumatoid arthritis. E. Petit-Teixeira¹, P. Dieude¹, V. Arbelaziz¹, J. Osorio¹, C. Pierlot¹, S. Cailleau-Moindrault¹, S. Lasbleiz², T. Bardin^{1,2}, F. Cornelis^{1,2}. 1) Laboratoire ECRAF-GENHOTEL, Universités Paris VII - Evry, Evry, France; 2) Unité de Génétique Clinique, Hôpital Lariboisière, Assistance Publique des Hôpitaux de Paris, France.

The gene Nramp1 (Natural resistance associated macrophage protein 1) encodes a protein which regulates macrophage activation in infectious and auto-immune diseases. Our objective is to test one promoter polymorphism of this gene in rheumatoid arthritis (RA).

Methods To test for an association of this functional polymorphism with sporadic RA, 100 families with one RA patient and both parents were genotyped. Analysis used the transmission disequilibrium test (TDT) and the haplotype relative risk (HRR). To test for an association in familial RA, RA index cases from 84 affected sibling pairs (ASP) families were also genotyped. To further explore the involvement of a particular genotype in RA ASP families, we used a subgroup (n = 20) more likely to have a NRAMP1 putative factor : RA index cases with NRAMP1 "twin like" RA sibling (RA cases for whom the affected sibling had identical genotype at both NRAMP1 flanking microsatellites).

Results No allelic association for the three alleles detected was observed with sporadic RA. The HRR test in sporadic RA found a trend for increase of the 2/2 genotype present 6 times in patients whereas never in the controls ($P = 0.051$). In familial RA, the suspected genotype was significantly more frequent than in controls (14% vs 0%, $P = 5.10^{-5}$). In ASP index cases with NRAMP1 "twin like" RA sibling, this genotype was also more frequent than in controls (10% vs 0%, $P = 0.026$).

Conclusion The increased frequency of the 2/2 genotype observed in familial RA cases provided evidence for a factor involved in RA genetic heterogeneity. Our data suggested that a NRAMP1 recessive factor, in linkage disequilibrium with the allele 2, would play a role in RA genetic susceptibility.

DNA methylation imprints of the maternally expressed genes differs from the paternally expressed genes in the AS/PWS region. *H.J. Dong, J.R. Khadake, D. Amidon, M.M. Whitney, D.J. Driscoll.* Pediatric Genetics, Univ. of Florida, Gainesville, FL.

Angelman syndrome (AS) and Prader-Willi syndrome (PWS) are clinically distinct imprinted gene disorders that map to the chromosome 15q11-q13 region. PWS results from paternal insufficiency while AS results from maternal insufficiency. Paternally expressed genes in the CpG islands of the "PWS region" are undermethylated in comparison to the maternally repressed alleles. Since the maternally expressed *UBE3A* and *ATP10C* genes in the "AS region" both have prominent CpG islands we looked for parent-of-origin methylation differences in various AS and PWS tissues and normal germ cells. Previous *UBE3A* analysis by our group using Southern blot hybridizations had not revealed any DNA methylation in somatic tissues and germ cells. In order to do an in-depth analysis of the 144 individual CpG dinucleotides in the 1140 bp CpG island of *UBE3A* we performed genomic sequencing by the sodium bisulfite method in fibroblast and several brain regions from AS (paternal-only allele) and PWS (maternal-only allele) deletion individuals. The *ATP10C* CpG island was analyzed in various somatic tissues, including brain, as well as in adult male germ cells and fetal ovaries using Southern blot analysis by CpG island probes.

We found that the entire CpG island for *UBE3A* is unmethylated by genomic sequencing in fibroblast and brain tissues for both the maternal and paternal alleles. For *ATP10C* there is variable DNA methylation in the CpG island of various somatic tissues and the brain, but it is not parent-of-origin specific. However, adult male germ cells are methylated in the CpG island while the fetal oocytes are unmethylated. Thus, in contrast to the paternally expressed genes in the AS/PWS region, we did not find any DNA methylation imprints in somatic tissues from the maternally expressed genes, *UBE3A* and *ATP10C*. However gametic imprints were found in *ATP10C*, but not *UBE3A*. Therefore, the imprinted expression of the genes in the "AS region" are probably regulated in somatic tissues by different mechanisms than those in the "PWS region".

Program Nr: 1883 from 2002 ASHG Annual Meeting

Strain-dependent differences in phenotype in the Prader-Willi syndrome mouse model. *S.J. Chamberlain, C.I. Brannan.* Molecular Genetics & Microbiology and the Center for Mammalian Genetics, University Florida, Gainesville, FL.

Prader-Willi syndrome (PWS) is a contiguous gene syndrome resulting from deletion or mutation of two or more imprinted genes. Previously, we described a mouse model for PWS in which paternal transmission of a 35 kb PWS Imprinting Center (PWS-IC) deletion mutation resulted in complete loss of local paternal gene expression. On the C57BL/6J genetic background, these PWS mice exhibit severe growth retardation, hypotonia, and neonatal lethality. We later found that (FVB/NJ x C57BL/6J) F1 mice harboring the PWS-IC deletion mutation are able to survive to adulthood, provided the majority of the wild-type sibs are removed within a few days after birth. Low-level expression of various genes in the PWS region that was detectable by RT-PCR was seen in the IC deletion offspring from an FVB/NJ mother, suggesting that low-level gene expression from the PWS region was allowing PWS pups to survive.

We sought to determine if either survival or low-level leaky gene expression was associated with other mouse strains, some of which were known to be non-methylators of transgenes. To this end, we tested C3H/HeJ, Balb/c, 129/Sv, and DBA/2J mice for similar leaky gene expression in the PWS region, as well as survival of PWS mice on these strain backgrounds.

Microarray analysis of gene/transcript expression in Prader-Willi syndrome: Deletion versus UPD. *D. Bittel, N. Kibiryeve, Z. Talebizadeh, M.G. Butler.* Children's Mercy Hospitals and Clinics and University of Missouri-Kansas City School of Medicine, Kansas City, MO.

Prader-Willi syndrome (PWS) is characterized by infantile hypotonia, hypogonadism, hyperphagia, early onset of childhood obesity and mental deficiency. PWS is caused by a deficiency of expression of genes located on the proximal long arm of chromosome 15. Several genes have been identified in the 15q11-q13 region which are imprinted and the lack of the paternally expressed genes contributes to PWS. A deletion of 15q11-q13 is found in about 70% of PWS subjects, maternal uniparental disomy (UPD) 15 in approximately 25% and an imprinting mutation in 2-5%. In our continuing efforts to understand the molecular genetics of PWS we have generated cDNA microarrays representing most of the genes/transcripts from the PWS critical region. We have used our custom microarrays to compare gene expression from actively growing lymphoblastoid cell lines established from nine adult males [6 with PWS (3 with deletion and 3 with UPD) and 3 controls]. There was no evidence of expression of genes previously identified as paternally expressed (e.g., SNRPN, IPW, MAGEL2, ZNF127 and NDN) in the PWS cell lines and we detected no difference in expression levels of genes with biallelic expression located outside of the 15q11-q13 region (e.g., B-ACTIN, FIBRILLIN and GAPDH) in all cell lines studied. There was no difference in expression levels of biallelically expressed genes (e.g., OCA2) from within the 15q11-q13 when comparing UPD cell lines with controls. Two genes previously identified as maternally expressed (UBE3A and ATP10C) showed an approximate 2 fold increase in expression in UPD cell lines compared with controls and PWS deletions. In addition, several transcripts (e.g., SGC32610, WI-18493 and D38449) had increased expression in UPD cell lines compared to controls, indicating maternal bias. These transcripts may also contribute to physical and behavioral differences recently observed between PWS deletion and UPD patients and/or in Angelman syndrome, an entirely different clinical disorder and also due to genomic imprinting of this chromosomal region.

Use of a marked transgene to study imprinting in the Prader-Willi syndrome region. *C. Futtner, S.J. Chamberlain, M. Elmore, C.I. Brannan.* Molecular Genetics & Microbiology and the Center for Mammalian Genetics, University of Florida, Gainesville, FL.

The Prader-Willi syndrome (PWS) candidate genes as well as the Angelman syndrome (AS) candidate gene are regulated by an Imprinting Center (IC) located 5' and including the first exon of the SNRPN gene. The elements that are necessary for the IC have been defined by means of deletion mutations that have been mapped in humans and created in mice. We then determined the minimal sequence sufficient to confer imprinting to a transgene. A single-copy transgene containing 90 kb of upstream sequence are expressed upon paternal, but not maternal transmission, while transgenes containing 8kb and 23 kb of upstream sequence do not demonstrate this imprinted expression pattern. These data suggest that the relevant sequences for single copy imprinting lie within a 90 kb region upstream of Snrpn.

To further investigate elements that are minimally sufficient to confer correct imprinted expression in single-copy transgenes, we have taken advantage of a BAC modification system based on the Red genes from lambda phage (1). We subjected a BAC, containing the necessary upstream sequences for imprinting, to two different modifications. First of all, the murine Snrpn exon 1 was replaced with human SNRPN exon 1. The purpose of this modification is to determine whether or not the murine imprinting machinery was capable of acting on human sequences. Secondly, the exons 5-7 of Snrpn were replaced with a neomycin resistance cassette. This modification was performed to allow for the analysis of transgene expression upon both paternal and maternal inheritance in a single generation.

Epimutation at KvDMR1 leads to ablation of *CDKN1C* expression in patients with Beckwith-Wiedemann syndrome. *N. Diaz-Meyer*¹, *C.D. Day*¹, *E.R. Maher*², *C. Junien*³, *G. Graham*⁴, *V. der Kaloustian*⁵, *M.J. Higgins*¹. 1) Roswell Park Cancer Institute, Buffalo, NY; 2) University of Birmingham, Birmingham, UK; 3) Inserm UR383, Hôpital Necker Enfants Malades, Paris, France; 4) Children's Hospital of Eastern Ontario, Ottawa, ON, Canada; 5) Montreal Children's Hospital, Montreal, PQ, Canada.

Imprinted genes are expressed from only one allele depending on whether it was inherited from the mother or father. An imbalance in the expression of imprinted genes in human chromosome 11p15.5 results in Beckwith-Wiedemann syndrome (BWS), an overgrowth and cancer predisposition condition. Together, uniparental disomy (UPD), duplications and translocations of 11p15.5, inactivating mutations in *CDKN1C* (*p57^{KIP2}*), and loss of imprinting of *IGF2* account for fewer than half the cases of BWS. We and others have shown that the majority of remaining cases are associated with demethylation of KvDMR1, a differentially methylated CpG island in 11p15.5. This locus has several characteristics of an imprinting control region (ICR) including the derepression in *cis* of normally silent (imprinted) genes following its deletion on the paternal chromosome, as well as methylation-modulated chromatin insulator activity in cell culture. Thus, it appears that the function of the unmethylated, paternally-inherited KvDMR1 is to silence genes under its control on the paternal chromosome, thereby giving rise to maternal-specific imprinted expression. Although direct evidence is lacking, it has been proposed that demethylation of KvDMR1 on the maternal chromosome in patients with BWS results in aberrant activation of this repressive function which leads to the pathological silencing of maternally expressed genes in 11p15.5. To test this hypothesis, we are performing real-time quantitative RT-PCR using TaqMan assays. As predicted by the model, early results show that *CDKN1C* is significantly downregulated in fibroblast cells from BWS patients that lose methylation at KvDMR1. This epigenetic repression is functionally equivalent to an inactivating mutation in *CDKN1C* and would likely lead to the syndrome. Funded by NCI/NIH Ca63333 to MJH.

***Atp10a*, the mouse homologue of the human imprinted gene, *ATP10C*, escapes genomic imprinting. T.**

Kayashima^{1,4}, *K. Yamasaki*^{1,4}, *K. Joh*³, *T. Yamada*^{1,4}, *T. Ohta*^{2,4}, *T. Kishino*^{2,4}, *T. Mukai*³, *N. Niikawa*^{1,4}. 1) Human Genetics, Nagasaki Univ Sch Med, Nagasaki, Japan; 2) Nagasaki University Gene Research Center, Nagasaki, Japan; 3) Department of Biochemistry, Saga Medical School, Saga, Japan; 4) CREST, JST, Kawaguchi, Japan.

Mouse *Atp10a* (GenBank accession No. AF156549), previously called *pfatp* gene encodes a member of the third subfamily of P-type ATPases, characterized by a putative aminophospholipid transporter. *Atp10a* is located between *Gabrb3* and *Ube3a/Ipw* on mouse chromosome 7 and is a candidate gene for increased body fat seen in mice only with deletions of the maternally derived *p*-locus. Such positional candidacy neighboring the maternally expressed gene *Ube3a* and an unusual inheritance pattern of the obese phenotype with *p*-locus deletions have suggested that *Atp10a* might be imprinted. Recently, its human homologue, *ATP10C*, was identified as a second imprinted, maternally expressed gene, 200 kb distal to *Ube3a* at 15q11-q13. Although preferential maternal expression of *ATP10C* has been demonstrated in fibroblasts and the brain, no direct evidence of *Atp10a* imprinting has been reported yet. To know the imprinting status of *Atp10a*, we performed expression analysis in various tissues from embryo and adult mice of reciprocal crosses between C57BL/6 and PWK (a divergent strain of *Mus musculus*). RT-PCR using intron-spanning primer pairs in exons 10 and 11, followed by *Hpy*CH4IV digestion, revealed that *Atp10a* was ubiquitously and biallelically expressed in all the embryonic and adult tissues examined, including various brain regions of adult mice and white adipose tissues. Although we can not completely exclude the possibility of mouse-strain-specific imprinting or brain-region-specific partial imprinting, our results suggest that mouse *Atp10a* escapes genomic imprinting, and that other maternally expressed genes in the *p*-locus deletion interval may cause the obesity phenotype.

Identification of potentially imprinted genes on human chromosome 14. *G. Macintyre, C.J. Clarke, P. Callum, D.W. Cox.* Department of Medical Genetics, University of Alberta, Edmonton, Alberta, Canada, T6G 2H7.

Genomic imprinting is the differential expression of the two alleles of a gene, predominantly from either the maternally or the paternally inherited allele. In mammals, imprinting affects many fundamental processes involved in development, growth and nurturing behaviour. Patients exhibiting paternal or maternal uniparental disomy for chromosome 14 (pat or mat UPD14) display distinct disease phenotypes, suggesting the presence of imprinted genes on chromosome 14. Reciprocally imprinted genes, *DLK1* and *GTL2*, have been identified at 14q32. It has been suggested that *DLK1* and *GTL2* constitute part of a cluster of imprinted genes. How far this imprinted region extends is unknown. Interestingly, two previously reported cases of interstitial segment matUPD14, proximal to and not including 14q32, describe a phenotype that is similar to matUPD14, suggesting that more proximal regions of chromosome 14 may also contain differentially expressed genes. We have used RNA from cell lines derived from UPD14 patients, human chromosome 14 monochromosomal hybrids and human fibroblasts in an RT-PCR assay to identify candidate genes for genomic imprinting. Our analysis has focused on the expression of genes and ESTs situated within 14q12-13, 14q22-24 and 14q32.11-32.33. The latter region is adjacent and proximal to the known imprinted region. More than 250 genes and ESTs have been analysed giving extensive coverage (approximately 50-400kb) throughout these regions. No evidence for imprinting was found in the region adjacent to the imprinted cluster. However, a number of genes and ESTs in the more proximal regions of chromosome 14 exhibit differential gene expression in some of the cell lines tested and are potentially imprinted genes. How the phenomenon of differential gene expression relates to the function of the protein products of these genes will be discussed.

Program Nr: 1889 from 2002 ASHG Annual Meeting

Species specificity of the Prader-Willi syndrome imprinting center. *K.A. Johnstone, M. Elmore, C.I. Brannan.*
Molecular Genetics & Microbiology and Center for Mammalian Genetics, University of Florida, Gainesville, FL.

Genomic imprinting is the differential expression of genes dependent on parent of origin. The majority of imprinted genes identified to date are conserved between mouse and human. Most imprinted genes reside in clusters and this appears to be key to the imprinting process. While the precise mechanism of imprinting is likely to differ between clusters, the mechanism active within a cluster is superficially conserved between species. The genes in the Prader-Willi (PWS) and Angelman syndrome (AS) region on chromosome 15q11-q13 are coordinately regulated by two imprinting centers (ICs), the PWS-IC and the AS-IC. We have previously shown using a mouse model that the PWS-IC is functionally conserved. Our recent data shows that a single-copy murine transgene is correctly imprinted and therefore defines the region likely to contain the murine AS-IC. We have previously shown that a human transgene fails to imprint in mice regardless of copy number and despite containing sequences from both the AS-SRO and the PWS-SRO. This has led us to propose that, although there is a high degree of conservation of imprinting within the region, the imprinting machinery has diverged.

In order to determine which processes have diverged, we have replaced *Snrpn* exon 1 and adjacent sequences with an equivalent human region spanning the PWS-SRO by gene targeting in ES cells. The resulting mouse model should allow us to study in more detail the sequences and factors involved in the acquisition and maintenance of imprinting in the PWS and AS region.

DNA methylation patterns in the *Snurf-Snrpn* gene 5' CpG island during embryonic and germ cell development.

*C. Mione*¹, *J.R. McCarrey*², *T.P. Yang*^{1,3}. 1) Biochem. and Molecular Biology, University of Florida College of Medicine, Gainesville, FL; 2) Department of Biology, University of Texas San Antonio; 3) Center for Mammalian Genetics, University of Florida College of Medicine, Gainesville, FL.

Differential DNA methylation plays a critical role in the epigenetic mark (imprint) that establishes and maintains allele-specific imprinted gene expression. We have analyzed the DNA methylation patterns in the 5' CpG island of the imprinted mouse *Snurf-Snrpn* gene, a paternally expressed gene in the Prader-Willi and Angelman Syndromes (PWS/AS) region of mouse chromosome 7c. This analysis utilized sodium bisulfite genomic sequencing to examine 41 CpGs within the entire length of the 1.1 kb CpG island using species-specific polymorphisms from inter-species hybrids to distinguish the parental alleles. In adult brain and spleen, the maternal allele is methylated and the paternal allele is unmethylated at all CpGs analyzed. During germ cell development, methylation imprints must be erased and reset to ensure that the zygote receives one allele of each parental epigenotype. Analysis of the same region in primordial germ cells (PGCs) from E13.5 indicates that the maternal DNA methylation imprint is completely erased (ie. unmethylated) in both male and female PGCs by this stage of germ cell development. Analysis in pachytene spermatocytes and round spermatids shows that both alleles remain unmethylated through these stages of spermatogenesis. Thus, erasure occurs before germ cells reach the genital ridge and resetting of the imprint occurs at a later stage. During embryogenesis, imprinted alleles must also maintain their parent-specific epigenotype during the global demethylation that occurs in the pre-implantation embryo. Our analysis of blastocysts (near the end of global demethylation) indicates that the entire adult somatic methylation imprint of the *Snurf-Snrpn* CpG island is retained and remains through E9.5 and E12.5 after implantation and remethylation of the genome. Thus, the overall CpG methylation pattern in the *Snurf-Snrpn* 5' CpG island escapes global demethylation and is likely to contribute to the maintenance of allele-specific imprinted gene expression during embryogenesis.

Epigenotype-phenotype relationships in patients with features of Beckwith-Wiedemann syndrome. *E.L. Niemitz^{2,3}, A.P. Feinberg^{2,4}, S. Brandenburg², V. Kanchananakhin¹, M.R. DeBaun¹.* 1) Division of Pediatric Hematology-Oncology, Department of Pediatrics, Washington University School of Medicine, St. Louis MO; 2) Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore MD; 3) Predoctoral Program in Human Genetics, Johns Hopkins University School of Medicine, Baltimore MD; 4) Departments of Medicine, Oncology, and Molecular Biology and Genetics, Johns Hopkins University School of Medicine, Baltimore MD.

Beckwith-Wiedemann syndrome (BWS) is characterized by prenatal overgrowth, macroglossia, midline abdominal-wall defects, and predisposition to Wilms and other embryonal tumors. BWS serves as a model for birth defects and cancer caused by imprinted genes, i.e. those preferentially expressed from a specific parental allele. The most common constitutional abnormalities in BWS are epigenetic, involving abnormal methylation of either *H19* or *LIT1*, which encode untranslated RNAs on 11p15. We have attempted to determine the relationship between epigenotype and phenotype in BWS by analyzing a cohort of BWS patients for these molecular abnormalities. The odds ratio for cancer in children with altered *H19* methylation was 6.0 (95% CI 1.3-26.5), while midline abdominal wall defects and macrosomia were significantly associated with altered *LIT1* methylation. These results define an epigenotype-phenotype relationship in BWS, in which distinct epigenetic alterations are strongly associated with cancer risk and specific birth defects. These epigenetic alterations were in marked contrast to patients with isolated hemihypertrophy. We are also investigating the relationship between multiple phenotypic and epigenotypic features of BWS in families.

Imprinting analysis of genes flanking *MEST* at 7q32. T. Yamada^{1,4}, K. Mitsuya², T. Kayashima^{1,4}, K. Yamasaki^{1,4}, T. Ohta^{3,4}, T. Kishino^{3,4}, M. Oshimura², N. Niikawa^{1,4}. 1) Department of Human Genetics, Nagasaki University School of Medicine, Nagasaki, Japan; 2) Molecular and Cell Genetics, School of Life science, Tottori Univ., Yonago, Japan; 3) Nagasaki University Gene Research Center, Nagasaki, Japan; 4) CREST, JST, Kawaguchi, Japan.

MEST located at 7q32 is the paternally expressed gene in the mesodermal derivatives at early embryonic stages and imprinted in both human and mouse fetal tissues. Since some imprinted genes are clustered to form an imprinted domain in a chromosomal region, it is reasonable to presume that there exists another imprinted domain at 7q32, where *MEST* and its flanking genes are involved in genomic imprinting. We previously demonstrated that *COPG2* and *TSGA14*, both neighboring on *MEST*, showed biallelic expression, whereas *COPG2IT1* (*CIT1*) was paternally expressed and *CPA3* maternally expressed. Here we report the imprinting status of nine other genes located to the *MEST*-flanking 7q32 region. Allelic expression of these genes was examined by RT-PCR in fetal samples heterozygous for nucleotide polymorphisms and also analyzed using mouse A9 somatic cell hybrids. All genes but *TSGA13* which are spanning an approximately 1.2-Mb region were evaluated. Of the eleven genes in this region, three (*MEST*, *COPG2IT1* and *CPA3*) showed imprinted expression but the remaining eight genes, i.e., *NRF1*, *UBE2H*, *HSPC216*, *KIAA0265*, *CPA2*, *CPA1*, *TSGA14* and *COPG2*, revealed not imprinted. These findings that most genes in the vicinity of *MEST* are not imprinted may suggest that the *MEST*-flanking 7q32 region is not strictly controlled as an imprinted domain.

Relative levels of the *UBE3A* sense transcript and the IC-*SNURF-SNRPN* sense/*UBE3A* antisense transcript in blood and brain. *M. Runte*¹, *P.M. Kroisel*², *C. Lich*¹, *B. Horsthemke*¹, *K. Buiting*¹. 1) Institut für Humangenetik, Universitätsklinikum Essen, Essen, Germany; 2) Institut für Medizinische Biologie und Humangenetik, Universität Graz, Graz, Austria.

The *UBE3A* gene, which is affected in Angelman syndrome, is expressed in brain from the maternal allele only. In contrast to other imprinted genes, monoallelic expression of *UBE3A* does not appear to be regulated by a differentially methylated region. It has been suggested that the paternal allele is silenced through a paternally-expressed *SNURF-SNRPN* sense/*UBE3A* antisense transcript, which starts at the imprinting center (IC). To exclude other start sites we performed real-time RT-PCR on blood RNA of IC deletion carriers. As expected, in two IC deletion patients with Prader-Willi syndrome, who have the deletion on the paternal chromosome, the deletion results in the complete loss of expression of this transcript, whereas in their fathers, who have the deletion on the maternal chromosome, an IC-deletion has no effect. To find out if and how the IC-*SNURF-SNRPN* sense/*UBE3A* antisense transcript might regulate imprinted expression of *UBE3A* in brain, we have compared the levels of both transcripts in human blood and brain by RT-PCR. In blood, where *UBE3A* is biallelically expressed, we found that the *SNURF-SNRPN* exons 1-2 and 57-58 are expressed at a level similar to *UBE3A*, but the 3'-, antisense part of the transcript was barely detectable. In fetal brain, where the paternal *UBE3A* allele is silenced, the 3' end is present at a level similar to the maternal *UBE3A* sense transcript. These findings are compatible with a model in which imprinted *UBE3A* expression is regulated by alternative 3' ends or splice variants of the *SNURF-SNRPN* sense/*UBE3A* antisense transcript.

Reactivation of imprinted genes in a Prader-Willi syndrome mouse model. *K. Takano*¹, *M. Takahashi*¹, *A. Sudo*¹, *T. Wada*¹, *T. Ohta*², *R.D. Nicholls*², *S. Saitoh*¹. 1) Dept. Pediatrics, Hokkaido Univ., Sapporo, Japan; 2) Dept. Psychiatry, Univ. Pennsylvania, Philadelphia, PA, USA.

Prader-Willi syndrome (PWS) is associated with the loss of paternal gene expression in 15q11-q13. The maternal alleles are present but inactivated by genomic imprinting, so reactivation of these genes could ameliorate PWS clinical symptoms. Previously, we demonstrated that a key imprinted gene, *SNURF-SNRPN*, could be reactivated by treatment with a methylation inhibitor, 5-azadeoxycytidine (5-aza-dC), but not by the histone deacetylase inhibitor trichostatin A (TSA). To further investigate a potential therapeutic role for these drugs, we have now used as a model mice that carry a deletion in 7C that is homologous to human 15q11-q13. We established fibroblasts from PWS and Angelman syndrome model mice (with the deletion on the paternal or maternal chromosome, respectively), and wild type controls. These cells were treated with 5-aza-dC, TSA, or both. Expression of 3 paternally-expressed genes (*Snurf-Snrpn*, *Ndn*, *Mkrn3*) and a control gene (*Gapdh*) was examined by RT-PCR, while histone acetylation at 5' CpG islands was examined by chromatin immunoprecipitation with anti-acetylated histone H3 and H4. As in human cells, the imprinted genes were reactivated by 5-azadC but not by TSA alone. While *Snurf-Snrpn* was only slightly reactivated by 5-azadC, *Ndn* and *Mkrn3* were readily reactivated. The level of reactivation correlated with increased levels of histone acetylation. These findings indicate that imprinted genes in mouse cells can be reactivated by a DNA methylation inhibitor, histone acetylation correlates with reactivation, and the reactivation pattern may differ between human and mice. Studies with PWS mice will examine further the potential use and limitations of these therapeutic agents.

Program Nr: 1895 from 2002 ASHG Annual Meeting

Role of histone methyltransferase G9a in H3 Lys9 methylation and CpG methylation of the Prader-Willi imprinting center. Z. Xin¹, M. Tachibana², Y. Shinkai², J. Wagstaff¹. 1) University of Virginia School of Medicine, Charlottesville, VA; 2) Kyoto University, Kyoto, Japan.

Imprinted genes in the Angelman/Prader-Willi (AS/PWS) region are subject to long-range regulation by cis-acting sequences known as imprinting centers (ICs). The mechanisms by which these ICs exert their effects is unknown. The PWS-IC, which overlaps the major promoter of SNRPN, is required for establishment and maintenance of the paternal pattern of gene expression of the AS/PWS region. The PWS-IC shows CpG methylation specific for the maternal chromosome, which has been hypothesized to be the gametic imprint for the AS/PWS region. In the mouse, parent-specific CpG methylation of this region is established during gametogenesis. However, a recent study has shown that the PWS-IC is completely unmethylated in human oocytes (O. El-Maarri et al., *Nature Genet.* 27:341-344). We have proposed histone H3 methylation on Lys9 as a candidate gametic imprint for the AS/PWS region (Z. Xin et al., *Am. J. Hum. Genet.* 69:1389-1394), with CpG methylation of the IC and of other promoter regions occurring as a consequence of the primary histone-based imprint. Here we show that both histone H3 Lys9 methylation and CpG methylation of the PWS-IC in mouse ES cells are dependent on the function of the G9a histone H3 Lys9/Lys27methyltransferase. Our results demonstrate a role for histone H3 methylation in the maintenance of parent-specific CpG methylation of imprinting regulatory regions. These observations suggest a possible role of histone methylation in establishment of imprints during gametogenesis.

Analysis of *cis*-acting elements in the 5' region of the *SNRPN* gene. *S. Rodriguez-Jato*¹, *D.J. Driscoll*^{2,3}, *T.P. Yang*^{1,3}. 1) Dept. of Biochem & Molec Biol; 2) Dept. of Pediatrics; 3) Center for Mammalian Genetics, University of Florida College of Medicine, Gainesville, FL.

The Prader-Willi/Angelman syndrome (PWS/AS) region on chromosome 15q11-q13 includes a cluster of imprinted genes that are coordinately regulated by an imprinting center (IC) that spans the 5' region of the *SNRPN* gene. The IC has a bipartite structure where the PWS-IC is postulated to enhance the transcription of paternally-inherited alleles, while the AS-IC is postulated to negatively regulate the PWS-IC. We are interested in analyzing *cis*-acting elements within the IC that may mediate IC function and/or *SNRPN* promoter activity. The PWS-IC contains a major nuclease hypersensitive site (HS) associated with the *SNRPN* promoter region on the paternally-inherited allele. A 2nd HS on the paternal allele is found adjacent to the PWS-IC in the 1st intron of the *SNRPN* gene. We have used transient expression assays to examine *cis*-acting elements within these HS sites. We generated constructs in which a reporter gene was driven by segments of the *SNRPN* 5' flanking region in human neuroblastoma and fibrosarcoma cells. These studies define the minimal *SNRPN* promoter and suggest the existence of a negative regulatory element in the promoter region. Introducing sequences from the intronic HS into *SNRPN* expression constructs reveals a position dependent and orientation independent activator function in the HS. These intronic sequences show the same effect on the SV40 and imprinted *MKRN3* promoters. These data suggest the intronic HS may play a role in the postulated transcriptional activation function of the PWS-IC. Previous analysis of *cis*-acting elements in the *SNRPN* promoter region by in vivo footprinting identified 4 transcription factor binding sites on the paternal allele. To examine the function of these sites, we mutated each one and determined the effects on promoter activity in transient expression assays. We found that two of the footprinted sites affect *SNRPN* promoter function, while the two other sites do not. These data suggest the 2 latter sites may have an alternate function, such as a role in IC function and/or establishing chromatin structure of the paternal *SNRPN* allele.

Chloride channel mutations in proximal myotonic myopathy: implications for disease modulating effects. *S.F. Ursu, N.H. Mao, F. Lehmann-Horn, K. Jurkat-Rott.* Applied Physiology, University of Ulm, ULM, Germany.

Proximal myotonic myopathy (PROMM) is a multisystemic disorder with similarity to myotonic dystrophy (DM) but without the abnormal (CTG) expansion in the DMPK (myotonic dystrophy protein kinase) gene. The inheritance is autosomal dominant and the clinical feature includes myotonia, proximal weakness and cataracts. Recently, the disease causing mutation, a CCTG expansion, located in intron 1 of the zinc finger protein 9 (ZNF9) gene was identified. We tested 32 families diagnosed as PROMM for the presence of expanded alleles by indirect linkage test (using the CL3N58 microsatellite marker). Because of the presence of the CCTG repeats in the marker, the mutant allele is too large to be amplified. Therefore this marker shows an abnormal segregation pattern: all affected individuals are hemizygous and seem to have only one allele (the normal one), and affected children (hemizygous also) appear not to inherit an allele from their affected parent. Using this indirect test we determined that 19 of 32 tested families (59,37%) presented this segregation pattern. The affected members of these families did not have the CTG expansion in DMPK gene either thus demonstrating genetic heterogeneity. It is known that non-dystrophic myotonia in humans may be caused by mutation in the gene coding for skeletal muscle chloride channel (CLCN1). Using multiplex allele specific PCR, all these 19 families were tested for mutation in CLCN1. We found that 6 of the 19 positive families (31,57%) have the R894X. Because the frequency of this mutation in the normal population is 1%, this is unlikely to be coincidental. Only one PROMM affected individual was homozygous for R894X and therefore additionally has Becker myotonia. All other affected families members with R894X mutation in CLCN1 were heterozygous and showed no other known CLCN1 mutation. We suggest that presence of CLCN1 mutations in PROMM may enhance myotonia, and that therefore these people seek medical aid, which ultimately leads to more frequent diagnosis of patients. Our observations imply disease-causing mutation in genes, other than the causative one to modulate the PROMM phenotype.

Analysis of six candidate genes for autism on 7q. *AHMM. Huq, H. Zhong, R. Nabi, F. Serajee.* Departments of Pediatrics and Neurology, Wayne State University, Detroit, MI.

Autism is a neurodevelopmental disorder with a complex genetic etiology. Several independent genome scans have revealed excess allele sharing in an overlapping 40 cM region of 7q21-34. However some studies show an additional linkage peak further distally on 7q. We studied single nucleotide polymorphisms (SNPs) in DLX6, PCLO, metabotropic glutamate receptor 3 (GRM3) and metabotropic glutamate receptor 8 (GRM8) genes on 7q21-32 and vasoactive intestinal peptide receptor type 2 (VIPR2) and engrailed homologue 2 (EN-2) genes on 7q36.3 for evidence of association and linkage to autism using 196 multiplex autistic disorder families. Transmission disequilibrium testing did not show any association between VIPR2, EN-2, DLX6, PCLO and GRM3 genes and autistic disorder. There was evidence for association with stereotypic behavior and parent-of-origin effects for age-of-onset for phrase-speech for a SNP in the GRM8 gene. Affected sib pair studies using SNP genotype data and publicly available genotype and phenotype data from the same Autism Genetics Resource Exchange families showed increased identity by descent sharing and a maximal multipoint NPL (GENEHUNTER) score of 2.2 on 7q36 at the VIPR2 locus. When stratified according to language development, families in which all affected sibs have useful phrase speech contributed to linkage at both 7q21 and 7q36, but the families in which at least one sib has no useful phrase speech contributed to linkage at 7q36 only. Quantitative trait linkage analysis revealed evidence of linkage to 7q21, 7q31 and 7q36 regions. Using nonparametric multipoint linkage analysis, the strongest quantitative trait locus evidence was for useful phrase speech level between markers D7S1830 and D7S2204 at 7q21 ($Z = 3.97$, one sided $p = 0.00003$) and for stereotypic behavior at GRM8 locus at 7q31 ($Z = 3.94$, one sided $p = 0.00004$). Taken together, these data may suggest the presence of more than one autism susceptibility locus at chromosome 7q.

Program Nr: 1899 from 2002 ASHG Annual Meeting

Analysis of five serotonin system genes in autism by association and linkage. *R. Nabi, H. Zhong, D.C. Chugani, F.J. Serajee, AHMM. Huq.* Departments of Pediatrics and Neurology, Wayne state University, Detroit, MI.

Although abnormalities of serotonin system have been described in autism, genetic analyses of serotonin transporter, receptors and related genes have given conflicting results. We have investigated single nucleotide polymorphisms in serotonin 1B receptor (HTR1B), serotonin 2A receptor (HTR2A), monoamine oxidase A (MAOA), tryptophan hydroxylase (TPH) and tryptophan 2, 3 dioxygenase (TDO2) genes for linkage and association in autistic disorder. 196 multiplex autistic disorder families from Autism Genetic resource Exchange (AGRE) were tested using transmission disequilibrium and two-point affected sib pair linkage analysis. We found no evidence of association with intragenic markers in HTR1B ($c2 = 0.26$; $p = 0.61$), HTR2A ($c2 = 1.45$; $p = 0.23$), MAOA ($c2 = 0.08$; $p = 0.78$) and TPH ($c2 = 0.03$; $p = 0.87$) with autism. In addition, there was also no linkage or association between language and stereotypic behavior quantitative traits in autism and single nucleotide polymorphisms. TDT studies of a SNP in TDO2 provided suggestive evidence of association ($c2 = 5$; $p = 0.02$) in an initial set of 44 autistic disorder families ascertained by referral from the local clinicians. However, additional studies in 196 multiplex AGRE families did not demonstrate any evidence of association. In conclusion, our studies suggest that these five serotonin system genes are unlikely to play a major role in autism.

Association of the metabotropic glutamate receptor 8 gene at 7q31 with quantitative traits in autism. *H. Zhong, F.J. Serajee, R. Nabi, AHMM. Huq.* Departments of Pediatrics and Neurology, Wayne State University, Detroit, MI.

Several independent genome scans have revealed linkage of autism to the chromosome 7q21-32 region. We sequenced the promoter region and exons of the metabotropic glutamate receptor 8 (GRM8) gene at 7q31 in 40 individuals and investigated several intragenic single nucleotide polymorphism (SNPs) in the GRM8 gene for evidence of association and linkage to autism using 196 multiplex autistic disorder families. Two point nonparametric linkage studies with GENEHUNTER demonstrated evidence for linkage of an intron 8 SNP to stereotypic behavior (Z score 2.95), useful phrase-speech level (Z score 1.3) and age-of-onset for phrase-speech (Z score 1.6). Multipoint linkage studies revealed a nonparametric Z score of 3.94 (one sided $p = 0.00004$) at the intron 8 SNP for stereotyped behavior. Variance component analysis using MERLIN also revealed evidence of linkage to stereotyped behavior ($p = 0.003$). Using the QTDT package, there was nominally significant association of the intron 8 SNP with stereotyped behavior ($p = 0.017$). However, when paternal and maternal alleles were modeled separately, there was highly significant association of the intron 8 SNP with age of onset for phrase-speech in autistic subjects. To further explore the parent-of-origin effects, we performed RTPCR studies which demonstrated biallelic expression of the major splice forms of the GRM8 gene in hippocampus and cerebral cortex. Transmission disequilibrium testing (TDT) did not show any association between the intron 8 SNP and autistic disorder ($p = 0.14$). However, when age-of-onset of phrase-speech was used to determine the affection status, TDT analysis showed evidence of association during maternal transmission ($c^2 = 4.35$, $p = 0.02$), but not during paternal transmission ($c^2 = 0.01$, $p = 0.92$). In addition, there was evidence of linkage disequilibrium ($p = 0.03$) between a haplotype of intron 8 and exon 10 SNP and autistic disorder. Taken together, these data suggest the presence of a susceptibility mutation in the GRM8 or a nearby gene.

Natural selection may have impact to maintain linkage disequilibrium at interleukin-4/ interleukin-13 region on chromosome 5q31-33. *T. Sakagami*^{1,2}, *T. Nakajima*¹, *N. Jinnai*¹, *T. Hasegawa*², *E. Suzuki*², *F. Gejyo*², *I. Inoue*¹. 1) Division of Genetic Diagnosis, The Institute of Medical Science, The University of Tokyo, Tokyo, Japan; 2) Division of Respiratory Medicine, Graduate School of Medical and Dental Sciences, Niigata University, Niigata, Japan.

Linkage disequilibrium (LD) has recently become the focus of interest in the mapping of complex disease loci through genotype-phenotype association studies. To better understand the pattern of LD in the human genome, the refined structure of LD in a 25.6 kb region covering the entire human interleukin 13 gene (IL13) and interleukin 4 gene (IL4) was evaluated among Africans, Caucasians, and Japanese, based on 73 single nucleotide polymorphisms (SNPs). IL13 and IL4 locate adjacently on chromosome 5q31-33 where susceptibility loci for several allergic diseases were reported. Two near-perfect LD blocks, one spanning 0.8 kb in IL13 and the other spanning at least 20 kb in IL4, were identified in Caucasians and Japanese, but not in Africans. Within LD blocks at IL13 and IL4, very limited number of distinct haplotypes, which were shared between Caucasian and Japanese, were counted. Neutrality test was performed on the regions inside and outside the LD blocks suggesting that a selective sweep occurred at the region inside the LD blocks while the neutrality was maintained outside the LD blocks. The results allowed us to infer that a selective sweep could be one of the factors to generate and maintain LD block.

UABSNP58 on human chromosome 20 associated with insulin resistance. *S.M. Sell¹, T. Kekes-Szabo¹, D. Chen¹, C. Song¹, H. Chen¹, L. Baier², M. Traurig², R. Hanson².* 1) Dept Nutrition Sci, 346 Webb, Univ Alabama at Birmingham, Birmingham, AL; 2) NIDDK, Phoenix, AZ.

Several groups have reported linkage to type 2 diabetes on human chromosome 20q. This region has also been linked to other obesity-related traits, suggesting that a gene (or genes) on chromosome 20q may contribute to the obesity-related and pre-diabetic trait of insulin resistance. Molecular genetic and homozygosity mapping studies carried out in our laboratory have identified a single nucleotide polymorphism, UABSNP58, that is associated with increased risk for obesity-induced diabetes in subjects of English ancestry. The Pima Indians of Arizona have a high incidence of obesity and diabetes. Metabolic predictors of diabetes and obesity, such as insulin resistance, have been extensively characterized in subjects from this population. Therefore, UABSNP58 was genotyped in more than 1100 DNA samples from Pima Indians. This SNP was not associated with type 2 diabetes in these Pima subjects (N=739 diabetic and 433 non-diabetic). However, in 223 non-diabetic, full-heritage Pima Indians who had undergone a hyperinsulinemic, euglycemic clamp to assess insulin action, UABSNP58 was highly associated with insulin resistance at the high dose of insulin (8.06 ± 0.28 mg/min.kg. vs 9.32 ± 0.38 mg/min.kg; $p=0.0005$) after adjusting for age, sex, % fat and family membership). This association with insulin resistance supports a role for UABSNP58 (and/or an allele (s) in linkage disequilibrium with UABSNP58) in genetic susceptibility for insulin resistance, and consequently an increased risk for type 2 diabetes in some populations. The nearest known gene to UABSNP58 is the Kreisler mouse maf-related leucine zipper homolog (KRML1) a bZIP transcription factor. This gene is expressed in skeletal muscle and adipose tissue (Sell, unpublished) and other bZIP transcription factors have been implicated in diabetes-susceptibility; consequently, we consider KRML1 to be a good positional candidate gene. However, there may also be additional SNPs in linkage disequilibrium with UABSNP58 that contribute to insulin resistance. This work was supported by funds from NIH grants DK056336 and HD040788.

No association between the APOE gene and Autistic Disorder. *K.L. Raiford¹, Y. Shao¹, I.C. Allen¹, M.M. Menold¹, M.L. Cuccaro¹, J.R. Gilbert¹, H.H. Wright², R.A. Abramson², G. Worley¹, J.M. Vance¹, M.A. Pericak-Vance¹.* 1) Duke University Medical Center, Durham, NC; 2) University of South Carolina, Columbia, SC.

Autistic Disorder (AutD) is a neurodevelopmental disorder characterized by stereotypic and repetitive behavior and interests, together with social and communicative deficiencies. Peak linkage/association scores on several genomic screens indicate the presence of an autistic disorder susceptibility locus on chromosome 19p13.2 - q13.4. The apolipoprotein E (APOE) gene on chromosome 19 encodes for a protein, apoE, whose different isoforms (-E2, -E3, -E4) influence neuronal growth, participates in lipid transport and metabolism, repair, growth, and maintenance of axons and myelin during neuronal development. The APOE gene competes with the reelin gene for VLDL/APOER2 receptor binding. A previous report found evidence for an association between AutD and the reelin gene. In addition, it has been suggested that the APOE-2 allele has a protective effect against infertility and miscarriage in AutD families. Based on these data we examined APOE as a candidate gene in AutD. We tested for genetic association using family-based association methods in a data set of 163 multiplex Duke and AGRE AutD families (2 or more AutD affecteds per family) and 159 singleton Duke AutD families (1 AutD affected per family). We also tested APOE promoter SNPs 113cg, 219gt, 427ct, 491at, and 5361ct. We saw no significant evidence that AutD is associated with the APOE gene (PDT $p=0.93$; TRANSMIT $p=0.45$) or the APOE promoter SNPs.

Investigation of the association of candidate genes with Attention Deficit Hyperactivity Disorder. *J.L. Stone¹, V. Kustanovich¹, M. Ogdie¹, M. Yang², E. Paja³, J. McCracken³, S. Smalley^{2,3}, S. Nelson^{1,2}.* 1) Dept Human Gen, Gonda, #5554, Univ California, Los Angeles, Los Angeles, CA; 2) Center for Neurobehavioral Genetics, Univ California, Los Angeles, Los Angeles, CA; 3) Department of Psychiatry and Biobehavioral Sciences, Univ California, Los Angeles, Los Angeles, CA.

Attention Deficit Hyperactivity Disorder (ADHD) is the most common neuropsychiatric disorder among school-aged children. ADHD is a complex disorder with a considerable etiology attributed to genetics. A recently completed genome scan (Fischer, 2002) indicated several regions of suggestive linkage to the disease. Several reasonable candidate genes are located under the regions of suggestive linkage: DRD5 (4q16.1), CALCYON (10q26.3), HTR1A (5q12.3), HTR1B (6q14.1), HTR1E (6q15), HTR5A (7q36.3), SLC6A4 (17q11.2). CALCYON and DRD5 are involved in the dopamine pathway, while the other six genes are all involved in the serotonin pathway. A sample of 204 multiplex families containing over 270 affected sib pairs from the Los Angeles basin was genotyped for a series of microsatellite markers and single nucleotide polymorphisms (SNPs). Evidence of linkage was tested by applying the transmission disequilibrium test (TDT) to either genotypic or inferred haplotype data.

Genome Scan of Schizophrenia, Bipolar Disorder and Psychosis in Portuguese families. C.N. Pato^{1,2}, P. Sklar³, M. Daly³, A. Verner³, A. Kirby³, T. Hudson³, H. Medeiros¹, C.P. Morley¹, A. Macedo², A. Dourado², I. Coelho², J. Valente², M.J. Soares², C.P. Ferreira^{1,2}, C. Carvalho¹, J.L. Kennedy^{1,4}, M.H. Azevedo², E. Lander³, M.T. Pato^{1,2}. 1) Psychiatry and VA, SUNY-Upstate, Syracuse, NY; 2) Universidade de Coimbra, Coimbra, Portugal; 3) Whitehead Institute Center for Genome Research, Cambridge, Mass, USA; 4) Clarke Division, Centre for Addiction and Mental Health, Toronto, Canada.

Purpose: We have performed an initial genome-wide scan on 360 individuals from 67 multiplex Portuguese families primarily from island populations. The advantages of using Azorean and Madeiran families for mapping include their relatively recent settlement in the 1500s, geographic isolation and lack of significant inward migration. **Methods:** We genotyped 391 microsatellite markers for an approximately 10 cM resolution. Markers had an average heterozygosity of 75%. Families were analyzed in three diagnostic categories: schizophrenia (DSM-IV diagnoses of schizophrenia and schizoaffective disorder depressed), bipolar disorder (DSM-IV bipolar disorder or schizoaffective manic) or psychosis (lifetime history of psychotic episode). Multipoint nonparametric linkage analysis using GENEHUNTER software was performed. **Results:** In the schizophrenia families NPL scores of greater than 1.7 were obtained on chromosomes 1, 5, and 8. The regions on 1 and 5 also had NPL scores greater than 1.8 when all individuals with psychosis were considered regardless of disease phenotype. An additional chromosomal region was identified for psychosis on chromosome 11. In families with bipolar disorder, there were 6 chromosomal regions with NPL scores greater than 2.0 on chromosomes 2, 6, 9, 18, 19 and 20. We are currently fine mapping these regions in an additional 35 families to replicate the previous findings and to characterize candidate genes in the region. Our observation of evidence for linkage common to schizophrenia and psychosis may indicate that genes in these regions play a role in both phenotypes, while other evidence for linkage appears to be specific for bipolar disorder and schizophrenia and not the common phenotype psychosis.

Candidate gene analysis in autism. *K.S. Beyer*¹, *S.M. Klauck*¹, *F. Blasi*², *E. Bacchelli*², *A. Benner*³, *S. Epp*¹, *F. Poustka*⁴, *E. Maestrini*², *A. Poustka*¹, *The International Molecular Genetic Study of Autism Consortium (IMGSAC)*⁵. 1) Molecular Genome Analysis, Deutsches Krebsforschungszentrum, Heidelberg, Germany; 2) Department of Biology, University of Bologna, Italy; 3) Biostatistics, Deutsches Krebsforschungszentrum, Heidelberg, Germany; 4) Department of Child and Adolescent Psychiatry, J.W. Goethe University, Frankfurt, Germany; 5) <http://www.well.ox.ac.uk/~maestrin/iat.html>.

Autism is a severe developmental disorder with an onset in early childhood, characterized by marked social deficits, deviant language and a restricted range of stereotyped repetitive behaviors. A genetic etiology is strongly indicated by twin and family studies. The most recent genome screen completed by IMGSAC on a total data set of 152 sib-pairs revealed susceptibility loci on 12 chromosomes, with the highest results on chromosomes 2q (MLS 3.74 at D2S2188) and 7q (MLS 3.37 at D7S477). Using the carefully diagnosed sample of more than 140 trios recruited in Germany and Austria, analysis of positional and functional candidate genes especially from the region on chromosome 7q under the peak of linkage was performed. Coding regions of candidate genes (e.g. WNT2) were systematically screened for non-synonymous variants using SSCP or DHPLC (denaturing high performance liquid chromatography) followed by direct sequencing. Polymorphisms identified in these studies as well as known variants can be used in association studies. So far no strong contribution to the genetic etiology of autism of any of the genes under investigation was found in the whole patient sample. Due to the partial overlap of phenotypical symptoms between autism and Rett syndrome, the coding region of the methyl-CpG binding protein 2 (MECP2) gene on Xq28 has been systematically screened for mutations in 152 autistic patients from 134 German families and 50 unrelated patients from the IMGSAC affected relative-pair sample. Three novel non-synonymous variants cosegregating with autism in the available family members were identified. Taking into account the large size of our sample, we conclude that mutations in the coding region of MECP2 do not play a major role in autism susceptibility.

A third pass genome screen in panic disorder. *A.J. Fyer^{1,2}, S.P. Hamilton^{1,2}, M. Durner^{1,2}, G.A. Heiman¹, D.F. Klein^{1,2}, S.E. Hodge^{1,2,3}, J.A. Knowles^{1,2}, M.M. Weissman^{1,2}.* 1) Department of Psychiatry, Columbia University College of Physicians and Surgeons, New York, NY; 2) New York State Psychiatric Institute, New York, NY; 3) Department of Biostatistics, Columbia University, New York, NY.

Panic disorder (PD) is a common, disabling illness characterized by recurrent, unexpected episodes of intense anxiety, subsequent worry and phobic avoidance. Family, twin and segregation analytic data indicate that PD is moderately heritable (35-49%), but do not support a specific mode of transmission. We report a third stage genome screen from the Columbia Collaborative Panic Project. Two previous scans conducted in the first 23 and 34 families in this sample had their maximum lod scores (1.71 and 2.45 respectively) in the region of chromosome 7p15. In the current scan 391 microsatellite marker loci (average spacing 9cM) were genotyped in 1005 individuals from 120 multiplex panic disorder pedigrees. Data were analyzed under two modes of inheritance (dominant, recessive) using three pre-designated diagnostic thresholds for panic disorder (Broad, Intermediate, Narrow).

Results: Three loci (on chromosomes 2, 9, and 17) show maximal single locus lod scores >3.3 ; and one (chromosome 15) a score of 2.9. Convergent results from multipoint and NPL analyses were found for three (2,9,15) of these four regions. We also found continued evidence for linkage between a region on chromosome 13 and a previously hypothesized panic disorder "syndrome" related to bladder/ renal problems. Two markers in the identified area of chromosome 13 had single locus scores over 3 in the subset of syndrome families. There was decreased evidence for linkage in the previous region of interest on chromosome 7p (max lod <1).

These data indicate several chromosomal regions that may be important in the genetic contribution to panic disorder and are consistent with clinical data in suggesting a complex genetic architecture for this disorder.

The frequency of NOD2 risk alleles in the International IBD Genetic Consortium (IBDGC) Families. J.A. Cavanaugh and The Inflammatory Bowel Disease Genetics Consortium. The Canberra Hospital, Australia.

In 2001, three alleles in the NOD2 gene on chromosome 16 associated with susceptibility to Crohns disease (CD) were reported. Functional and positional evidence supports this association. The IBDGC now reports on an analysis of the NOD2 variants [Arg702Trp (C/T), Gly908Arg (G/C) and 980fs981(-/C)] in families previously used to validate linkage to the IBD1 locus with an NPL score of 5.79.

Table 1 shows details of allele frequencies in the probands (defined as the first affected sibling per family) for each disease grouping (CD, UC or mixed). As expected from the linkage evidence demonstrating that IBD1 locus is a CD locus, the highest allele frequencies are observed in CD probands. While individual centers have already produced some support for the identification of NOD2 risk alleles as the causative alleles in the IBD1 gene, this is the first comparison of the frequencies of these alleles on a population-by-population basis, and permits the accumulation of large numbers for disease group comparisons. Preliminary linkage analysis suggests that some evidence for linkage remains after the effect of NOD2 is removed.

Table 1

	ALL	CD	UC	Mixed
# probands	648	383	126	139
Arg702Trp	.07	.10	.02	.06
Gly908Arg	.04	.06	.02	.02
980fs981	.08	.10	.02	.06

Genetics of antinuclear antibody repertoires in Systemic Lupus Erythematosus. *M. Barreto¹, C. Fesel¹, F. Fontes¹, R. Andreia², J.F. Viana², F. Crespo², C. Vasconcelos², A.M. Vicente¹, C. Ferreira².* 1) Instituto Gulbenkian Ciencia, Oeiras, Portugal; 2) Associação dos Doentes com Lupus, Lisboa, Portugal.

SLE is a multifactorial disorder with heterogeneous presentation, in which genetic susceptibility plays a major role. The common denominator among SLE patients is IgG autoantibody production against a wide variety of nuclear antigens (antinuclear antibodies, ANA). The main objective of this study is the identification and characterization of genetic susceptibility factors for SLE. The strategy used is the identification of lupus-associated traits that are genetically less complex, and therefore more amenable to genetic mapping. For this purpose, and given the systematic presence of ANA in patients, we have analyzed serum IgG antibody repertoires against a HEp2 nuclear extract in a sample of 16 multiplex families, including 26 patients and 72 unaffected relatives, and 46 adult healthy controls. A quantitative immunoblotting procedure and multiparametric analysis show a distinct pattern of autoantibody reactivities in patients, compared with controls ($p=0.0092$ for principal component analysis (PCA) factor 1 and $p=0.042$ for PCA factor 2), with two major antigenic bands contributing for these PCA factors. Correlation coefficients for relative pairs were established for PCA factor 1 ($r_{M/F}=-0.419$, $r_{M/D}=0.348$, $r_{F/S}=0.428$, $r_{MA/N}=0.532$) and for PCA factor 2 ($r_{M/F}=0.127$, $r_{M/D}=0.128$, $r_{F/S}=0.653$, $r_{MA/N}=0.331$), indicating the presence of a genetic component for the autoantibody reactivity patterns in these SLE multiplex families. Heritability was estimated at 6% for PCA factor 1 and 21% for PCA factor 2. The present results confirm the specificity of ANA in SLE patients. Most important, the multiparametric analysis uncovered shared autoantibody reactivity patterns among relatives, indicating that this may constitute a genetic trait appropriate for mapping. Detailed segregation analysis of the patterns of autoantibody reactivities in a larger sample is required, paving the way for genetic mapping of this SLE associated phenotype.

Susceptibility loci for atopic dermatitis on chromosomes 3, 13, 15, 17, and 18 in a Swedish population. M.

Bradley^{1,2}, *C. Söderhäll*², *H. Luhtman*^{2,3}, *C-F. Wahlgren*², *I. Kockum*², *M. Nordenskjöld*². 1) Department of Dermatology and Venereology; 2) Department of Molecular Medicine, Karolinska Institutet, Stockholm, Sweden; 3) Present address: Department of Endocrinology, Wallenberg Laboratory, University Hospital MAS, Malmö, Sweden.

Atopic dermatitis is a hereditary, pruritic, inflammatory, and chronic skin disease that typically presents in the early childhood and may continue or recur later. The etiology of atopic dermatitis is unknown, but several lines of evidence indicate that it is a multifactorial disorder caused by the combined influence of genetic and environmental factors, even though the relative contributions of genes and environment are not known. To identify important loci that contribute to the development of atopic dermatitis, we conducted a genome-wide linkage analysis with 367 microsatellite markers, using a non-parametric affected relative pair method in 109 pedigrees. Three qualitative phenotypes and one semi-quantitative phenotype were studied. For the phenotype atopic dermatitis linkage to chromosome region 3p24-22 was found. For another phenotype, atopic dermatitis combined with raised allergen-specific IgE levels, suggestive linkage was found to chromosome region 18q21. For the semi-quantitative phenotype, severity score of atopic dermatitis, suggestive linkage was found to chromosome regions 3q14, 13q14, 15q14-15 and 17q21. Identifying chromosome regions linked to susceptibility genes for atopic dermatitis provides a platform from which the search for atopic dermatitis genes can proceed.

Candidate Gene Studies for Linkage and Genetic Association to Spina Bifida in Hispanic and non-Hispanic White Populations in North America. *T.J. Kirkpatrick¹, K.-S. Au¹, P.X. Tran¹, S. Bassett¹, S.H. Blanton², H. Northrup^{1,3}*. 1) Dept of Pediatrics, Univ Texas Medical School, Houston, TX; 2) Dept of Pediatrics, Univ of Virginia, Charlottesville, VA; 3) Shriners Hospital for Children, Houston, TX.

Spina bifida (SB) is one of the most common severe birth defects in North America with an incidence of 1/2,000. SB occurs secondary to a combination of genetic and environmental factors with heritability estimated at 60%. Due to the lack of clear-cut inheritance and paucity of families with multiple affected members, we have chosen to search for genetic linkage and/or association by candidate gene studies of simplex families (child-mother-father trios and child-parent pairs). Our sample set consists of 260 complete trios (130 Hispanic, 120 non-Hispanic White and 10 Other), 250 mother-child pairs (150 Hispanic, 80 non-Hispanic White and 20 Other), 25 father-child pairs (15 Hispanic, 8 non-Hispanic White and 2 Other). Our recent studies have focused on candidate genes in the following categories: growth factors and growth factor receptors (IGF1, IGF2, NGFb, FGF1, FGF3, TGFb and IGF2R), transcription factors (BRCA1, ZIC3 and CREBBP) and proto-oncogenes (WNT1 and BCL2). The candidate genes were selected based on function in development or animal models. Markers (di-, tri- and tetranucleotide repeats) from within or immediately adjacent to (within 5-10 kb) each gene were tested in the entire sample set. For some candidate genes, multiple markers were tested. Results are currently being analyzed by transmission disequilibrium testing (TDT) for linkage and association for the entire sample set, by ethnicity and by level of defect.

Program Nr: 1912 from 2002 ASHG Annual Meeting

Efficient fine-mapping of a type 2 diabetes locus on chromosome 20 through SNP typing on DNA pools. *P.E. Hollstein¹, K. Silander¹, L.J. Scott², T.E. Fingerlin², P.S. Chines¹, K.L. Mohlke¹, N. Narisu¹, M.R. Erdos¹, M. Li², T.T. Valle³, R.N. Bergman⁴, J. Tuomilehto³, M. Boehnke², F.S. Collins¹.* 1) National Human Genome Research Inst., NIH, Bethesda, MD; 2) Dept. of Biostatistics, U. of Michigan, Ann Arbor, MI; 3) Dept. of Epidemiology and Health Promotion, National Public Health Institute, Helsinki, Finland; 4) Dept. of Physiology and Biophysics, Keck School of Medicine, U. of Southern California, Los Angeles, CA.

The Finland-United States Investigation of NIDDM Genetics (FUSION) study aims to positionally clone variants that predispose to type 2 diabetes. A genome scan of 478 Finnish affected sibling pair families yielded the highest LOD score of 2.20 on chromosome 20 at 69.5 cM and a 1-LOD support interval of 11 cM (6.9 Mb). To fine-map this interval, we have used primer extension and matrix-assisted laser desorption/ionization time-of-flight mass spectrometry to genotype 220 SNPs on 3 DNA pools from diabetic cases (n=197, 250, and 499) and 2 DNA pools of control subjects (n=182 and 228). The average marker density was 30 kb and all SNPs had allele frequency >10%. For each pool and SNP, we calculated allele frequencies and standard deviation (SD) (average SD=1.93%) based on 4 PCR reactions spotted 4 times each (n=16). SNPs were prioritized based on frequency differences, SD, and sample size. We obtained allele frequency differences >5% between case and control pools in 23 SNPs, including a cluster of 6 SNPs spanning 102 kb. We typed individuals on these 6 SNPs and observed allele frequency differences consistent with those seen in pools. For one of the SNPs, we confirmed an allele frequency difference of 11% between cases with evidence of linkage to 20q13 and unaffected controls. For two other SNPs 500 kb apart we confirmed 10% allele frequency differences between 20q13-linked cases and unaffected controls, with p-values of 0.0001 and 0.0005. We are now typing additional SNPs on pools over the 6.9 Mb locus to reduce our current intermarker distances down to 15-20 kb and we will continue confirming significant results by typing individuals. This strategy should ultimately allow precise identification of the susceptibility variant(s) for type 2 diabetes on chromosome 20q.

Genetic linkage and association of haplotypes at the serotonin transporter locus in a rigid-compulsions subphenotype of autism. *J.L. McCauley¹, M. Dowd³, L.M. Olson¹, T. Amin¹, R.D. Blakely², S.E. Folstein³, J.L. Haines^{1,2}, J.S. Sutcliffe^{1,2}.* 1) Program in Human Genetics, Department Molecular Physiology & Biophysics; 2) Center for Molecular Neuroscience, Vanderbilt University, Nashville, TN; 3) Department of Psychiatry, Tufts Univ. and New England Medical Center.

Autism is a complex genetic neurodevelopmental disorder in which affected individuals display deficits in language and social relationships and patterns of compulsive and stereotyped behaviors and rigidity. While genome-wide linkage screens have identified a number of regions, locus heterogeneity complicates efforts to identify these genes for autism. To identify genetically more homogeneous family subsets, we performed a factor analysis of the Autism Diagnostic Interview to define subphenotypes in autism. Linkage analysis in a subset of families with compulsive behaviors and rigidity identified significantly increased evidence for linkage on chromosome 17q11.2, with a maximum HLOD score of 2.82 at D17S1294. The serotonin transporter locus (SLC6A4) maps nearby and is proposed as a candidate in autism, based upon the effect of selective serotonin reuptake inhibitors in treating compulsions and anxiety in autism and findings of hyperserotonemia in a subset of people with autism. We genotyped single nucleotide polymorphisms (SNPs) across the 25-kb transcriptional unit in 149 multiplex families. Three of these SNPs were recently proposed to associate with autism (Kim et al, *Mol Psychiatry* 7: 278, 2002). Analysis of individual markers for transmission disequilibrium (TD) revealed allelic effects for one SNP in intron 4 ($P < 0.02$), and analysis of multi-SNP haplotypes using TRANSMIT showed significant TD for two haplotypes defined by three other SNPs ($P < 0.02$ and $P < 0.04$). Examination of the rigid-compulsive subset revealed a similar result for the single SNP but substantially increased TD for the same haplotypes ($P < 0.002$ and $P < 0.005$). These data support a role for SLC6A4 in the etiology of autism and related traits, demonstrate the utility of subphenotypes for defining more homogeneous datasets for genetic studies and show that analysis of haplotypes is crucial for detection of risk alleles in complex genetic disease.

Dense linkage disequilibrium mapping in the 15q11-q13 maternal expression domain yields evidence for association in autism. *E.L. Nurmi¹, L.M. Olson², M.M. Jacobs¹, T. Amin², J.L. McCauley², A.Y. Lam², S.E. Folstein³, J.L. Haines^{1,2}, J.S. Sutcliffe^{1,2}.* 1) Center for Molecular Neuroscience; 2) Program in Human Genetics, Department of Molecular Physiology & Biophysics, Vanderbilt University, Nashville, TN; 3) Department of Psychiatry, Tufts University, New England Medical Center, Boston, MA.

Autism is a complex yet strongly genetic neurodevelopmental disorder. Chromosome 15q11-q13 has been proposed to harbor a gene contributing to autism susceptibility based on (i) maternal chromosomal duplications seen in autism and (ii) evidence for linkage and linkage disequilibrium (LD) at 15q markers in chromosomally normal autism families. In order to investigate and localize a potential susceptibility variant, we developed a dense single nucleotide polymorphism (SNP) map of the maternal expression domain in proximal 15q, consisting of 29 SNPs spanning the two known imprinted, maternally-expressed genes in the interval, UBE3A and ATP10C, and putative imprinting control regions. With a marker coverage of 1/10 kb in coding regions and 1/15 kb in large 5' introns, this map was employed to dissect LD in autism families. Four SNPs within ATP10C demonstrated evidence for preferential allelic transmission to affected offspring ($P < 0.05$). All four lie within islands of sequence homology between human and mouse genomes that may be directly functional or may instead belong to an ancestral haplotype containing a functional susceptibility allele. The region was further explored for recombination hot spots and haplotype blocks to evaluate haplotype transmission in our families. Interpretation of these data will require replication across data sets, evaluation of potential functional effects of associated alleles, and a thorough assessment of haplotype transmission within ATP10C and neighboring genes. Nevertheless, these findings are consistent with the presence of an autism susceptibility locus in 15q11-q13.

Analysis of nine candidate genes for autism on chromosome 2q. *E. Maestrini*¹, *E. Bacchelli*¹, *F. Blasi*¹, *M. Biondolillo*¹, *A.J. Bailey*², *A.P. Monaco*³, *International Molecular Genetic Study of Autism Consortium (IMGSAC)*⁴. 1) Dept. Biology, Univ of Bologna, Italy; 2) CSGDP, Inst. Psychiatry, London, UK; 3) WTCHG, University of Oxford, Oxford, UK; 4) <http://www.well.ox.ac.uk/~maestrin/iat.html>.

In order to identify susceptibility genes for autism, the IMGSAC performed a whole genome screen for linkage in affected sib-pair families and identified the strongest result on chromosome 2q31-q33. Supporting evidence for the presence of an autism susceptibility locus on 2q is provided by the convergence of linkage findings from independent genome scans. We are screening candidate genes mapping to this region, to identify variants that may contribute to the aetiology of autism. To date, we have analysed nine genes: DLX1, DLX2, TBR1, CHN1, GAD1, CREB2/ATF2, cAMP-GEFII, NEUROD1, and HOXD1. All coding regions and putative functional sequences have been screened by DHPLC and sequencing in a subset of 48 cases from IMGSAC families that are contributing to the linkage peak on 2q. Non-synonymous variants identified in each gene have been investigated in a control sample. In addition, the most frequent SNPs detected through the screening have been tested for association in the whole IMGSAC sample. The cAMP-GEFII gene provided the most interesting results. Four non-synonymous variants have been identified in this gene, each present in both affected sibs of a family and absent in 192 controls. The cAMP-GEFII gene was further investigated in a second set of 48 IMGSAC cases. One of the previously identified variants was found in an additional sib-pair, but no further non-synonymous variants were identified. Furthermore, analysis of 8 intragenic SNPs did not provide significant evidence for association with autism. The significance of these variants is unclear; their low frequency in IMGSAC families does not account for the relatively strong linkage at the 2q locus, and suggests that they are likely to represent very rare polymorphism rather than aetiological variants. In conclusion, no evidence was found that any of the above candidate genes strongly contributes to autism susceptibility. Further investigation is needed to clarify if variants in cAMP-GEFII may play a role in a small subset of cases.

Linkage Disequilibrium Mapping Provides Further Evidence for a Gene for Reading Disability on Chromosome

6P21.3-22. *M.C. O'Donovan¹, D. Turic¹, L. Robinson¹, M. Duke¹, D.W. Morris¹, V. Webb¹, M. Hamshere¹, A. Grierson¹, N. Williams¹, M. Van den Bree¹, R. Chowdhury², P. McGuffin³, J. Stevenson⁴, M. Krawczak^{1,5}, M.J. Owen¹, J. Williams¹.* 1) Psychological Medicine, UWCM, Cardiff, UK; 2) Dept of Neuroscience and Cognitive Dev, Babraham Institute, Cambridge, UK; 3) Social, Genetic and Developmental Psychiatry, IOP, Denmark Hill, London, UK; 4) Centre for Research into Psychological Development, Univ of Southampton, UK; 5) Department of Medical Genetics, UWCM, Cardiff, UK.

Linkage disequilibrium (LD) mapping was used to follow up reports of linkage between reading disability (RD) and a 18 cM region of chromosome 6p21.3-22. Using a two-stage approach, we tested for association between RD and 21 microsatellite markers in two independent samples of 101 (Stage 1) and 77 (Stage 2) parent/proband trios in which RD was rigorously defined. The most significant replicated associations were observed between combinations of markers D6S109/422/1665 (Stage 1 $p = 0.002$, (adjusted for multiple testing); Stage 2 $p = 0.0001$) and D6S506/1029/1660 (Stage 1 $p = 0.02$ (adjusted), Stage 2 $p = 0.0001$). The only two-marker association observed in both samples was with D6S422/1665 ($p = 0.01$; $p = 0.04$). No single marker showed replicated association but D6S506 produced values of $p = 0.01$ & 0.08 which were significant when combined ($p = 0.02$). We observed weaker and less consistent evidence of association in a region of confirmed linkage to RD in previous studies. The most consistently significant haplotypic association D6S109/422/1665, showed association with single-word reading, spelling, phonological awareness, phonological decoding, orthographic accuracy and random automatised naming, but not with vocabulary or Attention Deficit Hyperactivity Disorder. Our findings strongly support the presence of a gene contributing to RD in a region of chromosome 6 between markers D6S109 and D6S1260, but do not rule out the presence of a gene between D6S1556 and MOG.

Association analysis of ISL1 and PAX4 in Swedish Type 1 Diabetes families. *P. Holm¹, B. Rydlander¹, H. Luthman^{1,2}, I. Kockum¹.* 1) Dept Molec Med, Clin Genetics, Karolinska Hosp, Stockholm, Sweden; 2) Department of Endocrinology, Lund University, Malmö, Sweden.

Type 1 diabetes mellitus (T1DM) is an autoimmune disease caused by destruction of the pancreatic insulin-producing beta cells. ISL1 is a transcription factor, which together with other transcription factors regulates the development and function of the pancreatic islet cells. ISL1 have previously been studied for linkage and association to T2DM, in this study we are investigating the role of ISL1 in T1DM. Sequencing of the ISL1 gene was performed in 12 patients and 4 healthy controls to identify DNA variations, four of the SNPs found in the gene were then analysed in Swedish multiplex T1DM families. The variations found in the ISL1 gene were all in non-coding regions. A tendency to association with T1DM could be shown for the ISL1 SNP 47G allele. In order to investigate this association further, we investigated familial association by analysing transmission to affected individuals for haplotypes of SNP markers. The identification of this suggestive association to ISL1 markers will now make it possible to use case-control materials to confirm the involvement of ISL1 in T1DM susceptibility. Since interaction between several susceptibility genes are likely to occur in T1DM, we analysed interaction between the ISL1 locus and other chromosomal regions harbouring other genes involved in the development and maintenance of the endocrine pancreas. The closest microsatellite marker to each gene was selected for analysis of interaction with ISL1. We could demonstrate interaction between the ISL1 locus on chromosome 5 and chromosome 7q32, a region encoding the PAX4 gene. PAX4 is a transcription factor that plays an important role in the development and differentiation of the islet b- and d-cells. A binding site for ISL1 is present in the promoter region of the PAX4 gene, and it has also been shown that PAX4 has an inhibitory effect of insulin gene transcription by binding to its promoter. Three SNPs were chosen in the PAX4 gene for further studies and showed association to T1DM in the Swedish families when calculating PDT for haplotypes consisting of all three SNPs within the PAX4 gene.

Do circadian disturbances mediate the pathogenesis of Bipolar I Disorder? *H. Mansour¹, J.A. Wood¹, L. Brar¹, T. Monk¹, E. Frank¹, D. Kupfer¹, V.L. Nimgaonkar^{1,2}*. 1) Dept of Psychiatry, Western Psychiatric Institute and Clinic, Univ Pittsburgh, Pittsburgh, PA; 2) Dept of Human Genetics, Univ Pittsburgh, Pittsburgh, PA.

We are evaluating circadian function as well as variations in circadian genes in order to examine their relevance to bipolar disorder I (BPD1). We are using two relevant quantitative measures: the composite scale (CS), a measure of morningness-eveningness and the social rhythm metric (SRM), which estimates social cues that influence circadian function. We have recruited 100 BD1 cases (DSM IV criteria), their available parents and 349 community-based controls. For comparison, 70 patients with schizophrenia (SZ) and their parents are available. Analysis of variation suggested significant age by group interactions (sum of squares 1268.4; $F = 5.978$, 4 df, $p < 0.0001$). Trends for significant case-parent correlations were also observed (BD1: $r = 0.257$, 35 case-parent pairs, $p = 0.136$; SZ: $r = 0.177$, $p = 0.296$, 37 pairs). We are presently investigating SRM scores individually and in conjunction with CS. In parallel, we are also investigating polymorphisms in genes that critically influence circadian function. Haplotype-based Transmission Disequilibrium Tests (TDT), as well as case-control analyses did not reveal significant associations at the CLOCK locus using BD1 as the phenotype. We are currently investigating four other candidate genes: Timeless (Tim), Cryptochrome 1 (Cry1), Period 1 (Per1) and Bmal1 (ARNTL).

***RHD* maternal-fetal genotype incompatibility increases schizophrenia susceptibility.** C.G. Palmer¹, J.A. Turunen², J.S. Sinsheimer¹, S. Minassian¹, J. Lönnqvist², L. Peltonen¹, J.A. Woodward¹. 1) University of California, Los Angeles, CA, USA; 2) National Public Health Institute, Helsinki, Finland.

Fetal events and obstetric complications are associated with schizophrenia. We report the results of a family-based candidate gene study that assesses the role of maternal-fetal genotype incompatibility at the *RHD* locus in schizophrenia. We adapted the case-parent-trio log-linear modeling approach to develop a maternal-fetal genotype incompatibility test, performed using MISMATCH, that is sensitive to the effects of *RHD* maternal-fetal genotype incompatibility and distinguishes these effects from a high risk allele at or near the *RHD* locus. 88 case-parent trios, 72 case-mother pairs, and 21 case-father pairs were genotyped at the *RHD* locus. Of the 181 cases, 62% were male, 81% were second or later born, 80% were diagnosed with schizophrenia, 14% with schizoaffective psychosis disorder, and 6% with a schizophrenia spectrum diagnosis. Only 3 cases were born after prophylaxis against maternal isoimmunization had become common practice in Finland. Of the 160 cases for which maternal *RHD* genotypes were available, 7.5% had genotype D/d (Rh+) when the maternal genotype was d/d (Rh-). There was significant evidence for an *RHD* maternal-fetal genotype incompatibility ($c^2 = 3.52$, 1df, [1-sided] $p = .03$), and the value of the incompatibility parameter was estimated at 2.53. There was no evidence to support linkage/association at or near the *RHD* locus with schizophrenia ($c^2 = .90$, 2 df, [2-sided] $p = 0.64$). There also was no evidence to support the role of maternal genotype effect alone ($c^2 = .38$, 2 df [2-sided] $p = 0.83$). The *RHD* locus increases risk for schizophrenia through a maternal-fetal genotype incompatibility mechanism that enhances risk of an adverse prenatal environment, i.e., Rh incompatibility, rather than via linkage/association with a high-risk allele at or near the *RHD* locus. This biological mechanism is consistent with the teratogenic antibody hypothesis of interference with normal fetal neurodevelopment. This is the first candidate gene study to explicitly test for, and provide evidence in support of, a maternal-fetal genotype incompatibility mechanism in schizophrenia.

Identification of a High Risk Haplotype for the Dystrobrevin Binding Protein 1 (DTNBP1) Gene in the Irish Study of High Density Schizophrenia Families. *E. Van den Oord¹, P. Sullivan¹, D. Walsh², A. O'Neill³, K. Kendler¹, B. Riley¹.* 1) Psychiatry, Virginia Commonwealth Univ., Richmond, VA; 2) Psychiatry, The Queens University, Belfast, Northern Ireland; 3) The Health Research Board, Dublin, Ireland.

A recent report suggested significant associations between several SNPs in a previously unknown EST cluster with schizophrenia (Straub et al. 2002). The cluster was identified as the human dystrobrevin binding protein 1 gene (DTNBP1) by sequence database comparisons and homology with mouse DTNBP1 (Jiang et al. 2002). However, the linkage disequilibrium (LD) among the SNPs in DTNBP1 as well as the pattern of significant SNP-schizophrenia association was complex. This raised several questions such as the number of susceptibility alleles that may be involved and the size of the region where the actual disease mutation(s) could be located. To address the questions we performed different single marker tests on the 12 previously studied and 2 new SNPs in DTNBP1 that were re-scored using an improved procedure, and performed a variety of haplotype analyses. The sample consisted of 268 Irish multiplex families selected for high density of schizophrenia. Results suggested a simple structure where the LD in the target region could be explained by 6 haplotypes that together accounted for 96 percent of haplotype diversity in the whole sample. From these six, a single high risk haplotype was identified that showed a significant association with schizophrenia and explained the pattern of significant findings in the analyses with individual markers. This haplotype was 30 kb long, had a large effect, could be measured with two tag SNPs only, had a frequency of 6% in our sample, seemed to be of relatively recent origin in evolutionary terms, and was equally distributed over Ireland. Implications of these finding for follow up and replication studies are discussed.

A genome-wide search for celiac disease loci in Dutch affected siblings shows significant linkage to chromosome 19. *M.J. van Belzen¹, A.F.J. Bardoel¹, W. van der Hoeven², C.J.J. Mulder³, J. Meijer³, L.A. Sandkuij¹, P.L. Pearson¹, R.H.J. Houwen², C. Wijmenga¹.* 1) Medical Genetics, UMCU, Utrecht, The Netherlands; 2) Pediatrics, UMCU, Utrecht, The Netherlands; 3) Hepatogastroenterology, Rijnstate Hospital, Arnhem, The Netherlands.

Celiac disease (CD) is a common multifactorial disorder that affects the small intestine. Its estimated prevalence is 0.5% in Western populations. Ingestion of dietary gluten from wheat, barley and rye results in villous atrophy of the duodenum with hyperplastic crypts and infiltration of the gut epithelium with lymphocytes. So far, the only established locus for CD is the HLA region. Most CD patients express DQ2, almost all the others are DQ8. Concordance between HLA-DQ identical siblings is only 30%. Furthermore, the population frequency of DQ2 is 25%, which is much higher than the prevalence of CD. This indicates that non-HLA genes are also involved in the etiology of CD. Therefore, we conducted a genome-wide screen to identify new, non-HLA loci. Strict criteria were used for inclusion of affected sibpairs, since they were diagnosed in over 50 different hospitals. All initial biopsy specimens were recovered and evaluated by our own pathologist to insure homogeneity of the diagnosis. Over 300 microsatellite markers were typed in 67 families with a total of 74 Marsh III sibpairs. Multipoint linkage analysis was performed by the mapmaker/sibs program. We identified strong linkage to chromosome 19, with a LOD score of 3. Finemapping of this region and addition of 12 more sibpairs resulted in statistically significant linkage with a LOD score of 3.8. Six other loci with a LOD score >1 were found, including the HLA region with a LOD score of 6. Interestingly, the telomeric region on chromosome 5q, in which some evidence for linkage was found in three other CD genome screens, showed a LOD score of 1.2. More markers and families are currently typed for the candidate regions to evaluate the significance of our findings.

Fine mapping of Alzheimers disease linkage region on chromosome 10. *D. Turic¹, M. Dunstan¹, F. Rice¹, S. McIlroy², D. Craig², P. Passmore², A. Myers³, S. Lovestone⁴, J. Powell⁴, J. Hardy⁵, A. Goate⁶, M. Liddell¹, L. Jones¹, M. O'Donovan¹, M.J. Owen¹, J. Williams¹.* 1) Psychological Medicine, UWCM, Cardiff, United Kingdom; 2) Queens University Belfast, Belfast, United Kingdom; 3) Washington University, St Louis, United States; 4) Institute of Psychiatry, London, United Kingdom; 5) National Institute on Aging, Bethesda, United States; 6) Department of Psychiatry, St Louis, United States.

In a recent two-stage genome-wide screen for late onset AD we observed significant linkage to chromosome 10. The linked region is large spanning approximately 44cM from markers D10S1426 to D10S2327. We used linkage disequilibrium mapping with 44 microsatellite markers to further refine the MaxLOD-1 region (~22cM). A three stage design strategy was employed: (1) First, markers were tested for association in pooled DNA samples comprising of 128 AD cases, 57 affected sibling pairs (NINCDS-ARDB probable/definite, late onset AD) and 103 age matched controls sampled from the UK population; (2) In stage two markers reaching p-value of $p < 0.1$ using the DAIP pooled analysis method, were genotyped individually; (3) Finally, significant markers from the second stage ($p < 0.05$) were individually typed on an independent replication sample of 229 late onset AD cases and 230 controls sampled from Belfast, N.Ireland. Out of 44 markers four were positive at stage one: D10S567, D10S1790, D10S1762 and D10S1647, two of these, D10S1790 and D10S1647, remained significant after individual typing. Marker D10S1647 showed association with AD in the replication sample. However, this relationship did not show further evidence of replication in set of 92 AD cases and 94 controls sampled from the USA population (St Louis).

A Genome Search for Type 2 Diabetes Susceptibility Genes in West Africans. C. Rotimi¹, G. Chen¹, J. Zhou¹, D. Parish-Gause¹, H. Daniel¹, Y. Chen¹, A. Amoah², J. Acheampong³, K. Agyenim-Boateng³, B. Eghan Jr.³, J. Oli⁴, G. Okafor⁴, P. Furbert-harris¹, B. Osotimehin⁵, F. Abbiyesuku⁵, T. Johnson⁶, O. Fasimade⁶, R. Kittles¹, G. Dunston¹, F. Collins⁷ and Africa America Diabetes Mellitus (AADM) Study. 1) Natl Human Genome Ctr, Howard Univ, Washington, DC; 2) University of Ghana, Accra; 3) University of Science and Technology, Ghana; 4) University of Nigeria, Enugu; 5) UCH, Ibadan, Nigeria; 6) University of Lagos, Nigeria; 7) NHGRI, NIH, Bethesda.

A genomic scan was conducted to identify loci linked to type 2 diabetes in 691 individuals from 343 families from two West African ancestral populations of African-Americans (Ghana: Accra and Kumasi; Nigeria: Enugu, Ibadan and Lagos). A total of 390 STR markers were scored by the Center for Inherited Disease Research (CIDR) for an average spacing of 9 cM with no gaps greater than 20 cM. Multipoint linkage analysis was conducted using GENEHUNTER-Plus and ASM programs. Evidences of linkage were observed on chromosomes 1, 4, 10, 12, 17, 19 and 20 (p-value < 0.05). The highest LOD score of 2.63 was observed on chromosome 20 between markers D20S480 and D20S171 followed by chromosomes 12 (between markers D12S2070 and D12S395) and 19 (D19S714) both with a score of 1.92 and 1.81 respectively. Ordered subset analyses based on sibships with extreme mean values of diabetes related quantitative traits identified the sets of families which contributed disproportionately to the peaks in chromosomes 12, 19 and 20. We also conducted multipoint variance components linkage analyses on related diabetes traits with the GENEHUNTER2 program. The strong signal on chromosome 20, which lies in the region implicated as harboring diabetes and obesity susceptibility genes in previous studies reinforces and provides additional support that chromosome 20, may indeed contain susceptibility loci for diabetes. Linkage evidence provided in this study is particularly important given the evolutionary history of these West African populations and their well documented historic contribution to the forced migration of Africans to the Americans; African Americans have one of the highest rates of diabetes in the world.

Genome Search for Genes Underlying Susceptibility to Insulin Resistance Syndrome in Type 2 Diabetes Patients from West Africa. J. Zhou¹, G. Chen¹, A. Doumatey¹, P. Furbert-Harris¹, A. Amoah², J. Acheampong³, J. Oli⁴, B. Osotimehin⁵, T. Johnson⁶, K. Agyenim-Boateng³, G. Okafor⁴, F. Abbiyesuku⁵, O. Fasimade⁶, B. Eghan Jr.³, H. Daniel¹, Y. Chen¹, D. Parish-Gause¹, G. Dunston¹, F. Collins⁷, C. Rotimi¹ and Africa America Diabetes Mellitus (AADM) Study. 1) National Human Genome Center, Howard University, Washington, DC; 2) University of Ghana, Accra; 3) University of Science and Technology, Ghana; 4) University of Nigeria, Enugu; 5) UCH, Ibadan, Nigeria; 6) University of Lagos, Nigeria; 7) NHGRI, NIH, Bethesda.

Insulin Resistance Syndrome (IRS) represents a cluster of metabolic abnormalities including obesity, glucose intolerance, hypertension, and dyslipidemia. We use Principal Component factor analysis (PCFA) to evaluate linkage and association between genetic factors and IRS related phenotypes including BMI, Fat Mass, %Fat Mass, Blood Pressure, Insulin, Glucose, HDL, triglycerides and LEPTIN in our diabetes cohort from Nigeria and Ghana. A total of 856 individuals from 357 sib-pairs were included in these analyses. The PCFA yielded three principal factors: factor 1 (BMI [0.88], FM [0.93], PFM [0.91] and LOG LEP [0.76]) with eigenvalue of 3.4; factor 2 (LOG TG [0.89] and HDL [-0.90]) with eigenvalue of 1.8; factor 3 (SBP [0.86] and DBP [0.86]) with eigenvalue of 1.66. Factors 1, 2, and 3 respectively explained 34%, 17% and 16% for a total of 67% of observed total variance. Factors 2 and 3 were significantly higher in the cases than controls. Using GENEHUNTER, we performed multipoint variance component genome search for regions linked to the 3 complex phenotypes. All analyses were adjusted for gender, age and age. Strongest evidence of linkage was found for factor 2 (lipid traits; LOD =3.2, P = 0.00007; between D3S2427 and D3S1262); followed by factor 1 (adiposity traits; LOD =2.1, P = 0.0009; between D4S1644 and D4S1625) and factor 3 (BP traits; LOD = 2.1, p=0.001). Using QTDT, we demonstrated evidence of association in these linkage regions. In conclusion, we developed complex IRS traits, estimated heritability and found suggestive evidence of linkage and association on chromosome 3q27-28, 4q31 and 16p11.

Genome-wide Association of Diabetes Traits in the Old Order Amish. *P.L. St Jean¹, W.-C. Hsueh², H. Sakul³, M.W. Wagner¹, D.K. Burns¹, T.I. Pollin⁴, B.D. Mitchell⁴, A.R. Shuldiner⁴.* 1) GlaxoSmithKline, RTP, NC; 2) UCSF School of Medicine, San Francisco, CA; 3) Pfizer Global R&D, Groton, CT; 4) University of Maryland School of Medicine, Baltimore, MD.

We have performed genome-wide tests of association for diabetes traits in a genetically homogenous population, the Old Order Amish using 412 autosomal STR markers. The average intermarker density was 9.3 cM although chromosomes 1 & 14 were more densely typed due to prior evidence of linkage to diabetes. Our previous work showed that LD between STRs in the Amish averages between 5-10 cM making a genome-wide association with these markers a reasonable undertaking. Two traits were examined: Type 2 diabetes (DM) and a broader phenotype of DM or impaired glucose homeostasis (DM/IH). The DM data consisted of 201 subjects (59 with DM) in 25 pedigrees. The DM/IH data consisted of 374 subjects (125 with DM/IH) in 48 pedigrees. Association within families was assessed using Transmit 2.4 aggregating alleles occurring at a frequency $\geq 5\%$. Both global and allelic tests were examined. No tests were significant at a $P \leq 0.00012$ using a Bonferroni adjusted p-value. When a less stringent cut-off of $P \leq 0.005$ was employed the following associations were revealed. Chr 1: DM/IH and 3 STRs (D1S252, D1S534, D1S1187) between 154-172 cM. DM was also associated with D1S1187. Chr 5: DM/IH and D5S416 at 27.2 cM and D5S400 at 181.7 cM. Chr12: DM/IH and D12S352 at 0 cM. Chr 15: DM/IH and D15S117 at 48.7 cM. Chr18: DM/IH and 2 STRS - D18S464 at 31.6 cM and D18S478 at 50.2 cM. Two of these regions have provided evidence of linkage to diabetes traits in the Amish. The area on chromosome 1 shows evidence of linkage to both DM & DM/IH in the Amish. Other populations such as the Pima, Utah, UK and French Caucasians have reported linkage to diabetes traits in this region. D18S464 is within 3 cM of a peak linked to diabetes in obese Nordic families. In the Amish we have observed LOD scores between 1.4-3.0 for 2-hour glucose and HbA1C between 9-45 cM on chromosome 18. In summary, our association results in conjunction with linkage results provide supporting evidence for diabetes loci on chromosomes 1 and 18.

Use of pooled DNA in case-control studies: How precision of allele frequency estimation affects efficiency. *L.J. Scott¹, C. Li¹, T.E. Fingerlan¹, A.U. Jackson¹, K.L. Mohlke², K. Silander², F.S. Collins², M. Boehnke¹.* 1) Dept. Biostatistics, Univ Michigan, Ann Arbor, MI; 2) NHGRI, NIH, Bethesda, MD.

Fine-mapping of complex trait susceptibility regions requires genotyping of large numbers of SNPs. Constructing DNA pools from cases and controls can drastically reduce the required genotyping given that the method accurately and precisely estimates pooled allele frequencies. We examined the precision and number of replicates required to limit the number of false positives (FPs) due to the use of pools. For reference we typed 16 SNPs (previously typed on individuals) in 3 pools (n= 499, 228 and 182) using mass spectrometry (16 replicates per pool, SD = 2.1 + 1.0%). For our calculations we assumed pools sizes that would have 80% power, if typed in individuals, to detect 5 and 10% allele frequency differences in the population at a 5% significance level, i.e. 5% are FPs. Setting power at 80% in pools, we examined FPs for a variety of SDs and number of replicates. These results were virtually unaffected the control allele frequency (50% in Table). A FP of 10% in pools means that half of the significant pooling results would not be significant if individuals were genotyped (under the null). The number of replicates needed to maintain FP rates <=10% increased from 4 for 1% SD to 4-16 for 2% SD to 8- >16 for 3% SD. These calculations depend on the absence of systematic bias in the pooled measurements and thus it is important to assess both SD and potential bias in allele frequency estimates.

SD (%)	1	1	1	2	2	2	3	3	3
Replicates (n)	4	8	16	4	8	16	4	8	16
5% dif (%FP)	8	6	6	19	11	8	36	20	12
10% dif (%FP)	6	6	5	8	6	6	12	8	7

Screening for chromosomal aberrations in mentally retarded patients using MAPH. *J.T. Den Dunnen, M. Kriek, S. White, M. Kalf, S. Uitte De Willige, G.J.B. Van Ommen, M.H. Breuning.* Human and Clinical Genetics, Leiden Univ Medical Ctr, Leiden, Nederland.

Submicroscopic chromosomal rearrangements are believed to play an important role in the etiology of mental retardation. To facilitate the detection of these rearrangements we have implemented Multiplex Amplifiable Probe Hybridisation. MAPH is a PCR-based method to simultaneously determine the copy number of a large set, currently up to 80, of different chromosomal loci. The probes, usually exons from candidate genes, are individually cloned such that all can be amplified using one pair of primers. To detect copy number changes, the probes are hybridised to genomic DNA immobilized on nylon filters. After stringent washing, hybridised probes are recovered off the filters, quantitatively amplified and analysed using a 96 capillary sequencer. The yield, represented by peak height and area, is determined for each probe. Changes in probe yield correspond to changes in copy number of the sequence analysed, i.e. a deletion or duplication. The advantage of MAPH compared to other techniques, including SKY, FISH and array-CGH, is that the resolution of detection is limited only by the size of the probes used (100-500 bp). In addition, the technique facilitates the parallel screening of several tens of patients at many different loci in one experiment. We have generated a probe set covering 300 different genomic loci, including subtelomeric regions, regions involved in microdeletion syndromes and X-linked mental retardation and a set of genes evenly spread through out the rest of the genome. Using this probe set we have screened 200 mentally retarded patients. Preliminary results include rearrangements in both subtelomeric and pericentromeric regions, as well in several chromosomes. As reported before, we detected more aberrations in patients with mental retardation and dysmorphic features compared to patients with mental retardation only (for the subtelomeric probe set 13.3% and 7.3% respectively). Our long term goal is to develop a 3000-loci probe set covering the entire human genome with a one Mb spacing and to implement it for molecular karyotyping in a diagnostic setting.

Gene-gene Interaction in Drug-induced Weight Gain on Schizophrenic Patients. *T. Lan^{1,2}, Y. Wong¹, J. Chan¹, H. Hsieh¹, J. Sou^{1,3}, T. Hu¹, J. Chiu^{1,3,4}.* 1) Department of Psychiatry, Yu-Li Veterans Hospital, Hualien, Taiwan; 2) Institute of Genetics, School of Life Medicine, National Yang-Ming University, Taipei, Taiwan; 3) Institute of Public Health, Faculty of Medicine, National Yang-Ming University, Taipei, Taiwan; 4) Section of Psychiatry, Faculty of Medicine, National Yang-Ming University, Taipei, Taiwan.

Drug-induced weight gain has been considered as an emerging adverse side effect of atypical antipsychotics such as clozapine in treating schizophrenic patients. We recruited 93 schizophrenic patients treated with clozapine for 14 months after all consent form being completed. The body weight change between endpoint and baseline as the outcome, we genotyped several candidate genes related to obesity, including 5HT2A, ADRA1A, ADRA2A promotor, ADRB3, and TNF-alpha, for each participants. After adjusting for age, sex, baseline body weight, and TNF-alpha genotypes; a statistically significant interaction ($p = 0.030$) between ADRA1A genotypes and ADRA2A promotor genotypes was found on the weight gain in these schizophrenic patients. This suggests that schizophrenic patients with some specific combination of different genotypes of candidate genes for obesity have a higher tendency to gain weight compared to those without such characteristics.

Quantification of heteroplasmic A3243G mutation of mitochondrial DNA by real-time PCR. *R. Bai, L. Wong.* Inst for Mol & Hum Genetics, Georgetown Univ. Med. Ctr., Washington, DC.

It is well-known that the tRNA leu (UUR) point mutation at position 3243 in mitochondrial DNA (mtDNA) is associated with the syndrome of mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes (MELAS) and is also found in patients with maternally-inherited diabetes and deafness syndrome (MIDD) and progressive kidney disease. In order to correlate disease expression with mutation load, it is necessary to quantitate the percentage of the mutant mtDNA. The most commonly used method for quantification of A3243G mutant is PCR/RFLP that requires either radioactive material or DNA intercalating dye. This method usually can not provide accurate quantification if the mutant load is low. To overcome this difficulty, we established a real-time PCR assay to quantify the A3243G mutant mtDNA. The copy number of mtDNA was calculated from standard curve using TaqMan probes 6FAM-TTACCGGGCTCTGCCATCT-TAMRA and 6FAM-TTACCGGGCCCTGCCATCT-TAMRA for normal and mutant respectively. The percentage of mutant mtDNA copy was calculated from the normal and mutant mtDNA. Twenty A3243G positive samples detected by allele specific oligonucleotide (ASO) and quantified by PCR/RFLP method were studied. Experimental samples with different percentage of mutant A3243G mtDNA were generated by mixing the normal DNA sample with DNA containing 92% mutant DNA (detected by PCR/RFLP). Each measurement was performed in duplicate and each sample was repeated in at least two different runs. In addition, four control samples containing 75%, 25%, 10% and 1% of mutant were included in each run to ensure that the results from different test runs are comparable. Our results showed high reproducibility with a coefficient of variation (CV) of <5%. The results from the six experimental samples are very consistent with the percentages expected. The results from the 20 clinical samples are also consistent with the previous measurement, however, the real-time quantitative PCR method is much more sensitive in detecting low percentage (<1%) mutant. These results indicate that real-time PCR assay is a fast, sensitive, and reliable method for quantification of mutant mtDNA.

Methylation profiling of CpG islands spanning the MHC class II region and HLA-B in Ankylosing Spondylitis cases and controls. *D.T. Akey¹, J.M. Akey¹, J.D. Reveille², L. Jin¹.* 1) Department of Environmental Health, Center for Genome Information, University of Cincinnati, Cincinnati, OH; 2) Department of Rheumatology, University of Texas-Houston Health Science Center, Houston, TX.

Ankylosing spondylitis (AS) is an autoimmune disease with a complex pattern of inheritance. Although 90% of individuals with AS are HLA-B27 positive, the exact mechanisms contributing to disease susceptibility remain unknown. Recently, we have performed statistical analyses of markers in the HLA class II region in 180 AS sib-pairs that suggests the presence of a second AS susceptibility gene, which is subject to a parent-of-origin effect (GeneHunter Imprinting, maximum parent of origin LOD score = 1.62 for marker D6S1583). One potential mechanism that may result in a parent-of-origin effect is DNA methylation, which is the covalent modification of cytosine to 5-methylcytosine at CpG dinucleotides. To investigate the hypothesis that DNA methylation status may be a disease mechanism in the pathogenesis of AS, we have begun to systematically examine the methylation state of CpG islands in the HLA class II region as well as the class I gene, HLA-B. Specifically, melting curve based methylation specific PCR (McMSP), melting curve based COBRA (McCOBRA), and bisulfite sequencing are being used to determine the methylation status of 12 CpG islands spanning 722 Kb of the MHC class II region and a CpG island located within the promoter and first three exons of HLA-B in 21 AS pedigrees (96 individuals). Our study design allows for both family and population based analyses. These data will allow us to: 1) compare DNA methylation status of AS susceptibility genes in cases versus controls, 2) establish if methylation status of these loci are stably transmitted from parent to offspring, and 3) examine whether there are allelic differences in methylation status for HLA-B and class II genes in both normal and affected individuals. In summary, we will present the first large scale analysis of DNA methylation in the class II region and determine its role in AS susceptibility.

Normal Methylation Pattern At The 5' SNRPN Locus In Patients From The South Carolina Autism Project. S.A. Copeland-Yates^{1,2}, R.J. Schroer¹, C. Skinner¹, R.C. Michaelis¹. 1) Dept Biochemistry & Genetics, Clemson Univ, Greenwood, SC; 2) J.C. Self Research Institute, Greenwood Genetic Center, Greenwood, SC.

Several lines of evidence suggest that a disruption of activity in imprinted genes, especially those in 15q11-q13, may underlie some cases of autism. Duplications of 15q11-q13 are the chromosome abnormality most commonly seen in patients with autism. Until recently, all the 15q11-q13 duplications reported in patients with autism have involved the maternally derived chromosome 15, suggesting that an overdose of an imprinted gene(s) expressed solely from the maternally derived chromosome 15 may be the critical etiological factor in these cases. In addition, mutations in the gene encoding the methyl-DNA binding protein 2 (MECP2) have been shown to be responsible for Rett syndrome, one of the autism spectrum disorders. Differential methylation of CG cytosines is a hallmark of imprinted genes, and mutations in a methyl-DNA binding protein such as MECP2 may disrupt the regulation of activity in imprinted genes.

Southern blot analysis using methylation-sensitive restriction enzymes has been well established as a diagnostic method to determine the methylation status of a targeted CG cytosine in the 5' exon of the SNRPN gene in 15q11-q13. This test is routinely used to confirm or deny clinical diagnoses of Angelman syndrome (AS) or Prader-Willi syndrome (PWS). In addition, the more recently developed methylation-specific PCR assay has been shown to be a specific and highly sensitive technique to determine the methylation status of targeted cytosines, and is gaining popularity as a method for confirming diagnosis of AS and PWS.

Given the possibility that dysfunction of imprinted genes in 15q11-q13 may underlie some cases of autism, we used both these methods to assess methylation status in the 5' exon of the SNRPN gene in patients from the South Carolina Autism Project. The assessment has been completed for 150 patients at the present time, and no abnormalities in methylation status at this CG cytosine have been observed. Further experiments will focus on the two NotI sites in the 5' end of the UBE3A gene in 15q11-q13.

Association of Mitochondrial Deletions with Glasgow Coma Score in Traumatic Brain Injured Patients. *Y.P. Conley¹, D.W. Marion², M.E. Kerr³*. 1) Health Promotion & Development, Univ Pittsburgh, Pittsburgh, PA; 2) Neurological Surgery, Univ Pittsburgh Medical Center; 3) Acute & Tertiary Care, Univ Pittsburgh, Pittsburgh, PA.

The role of genetic factors in cellular repair following injury is increasingly recognized. Mitochondria are involved with cellular respiration, oxidative phosphorylation, apoptosis and energy production and are genetically programmed to perform these functions, which points to their potential importance in individual recovery following neurologic damage. Independent variables that have been implicated in functional recovery following neurotrauma include the age of the patient and the Glasgow Coma Score (GCS) upon hospital admittance, with increased age and lower GCS associated with poorer prognosis. We investigated a common mitochondrial deletion, del7436, in a cohort of 49 patients admitted with severe traumatic brain injury (GCS = 8) at the University of Pittsburgh Medical Center within the Brain Trauma Research Center. The mitochondrial DNA (mtDNA) was extracted from cerebrospinal fluid taken 12 hours post injury. Initially a pair of primers outside of the deletion region were utilized to make sure mtDNA was available in the sample and make sure it was amenable to PCR amplification. All 49 samples amplified using this primer set. A second set of primers was used to determine the presence or absence of the del7436 polymorphism. We found that the frequency of the del7436 deletion was much higher than expected (81.6%) and the presence of the deletion was associated with a lower GCS score ($p = .02$) after controlling for age. The presence of the deletion occurred significantly more often in those with a GCS of 3-6 versus 7-8. Also of interest is the fact that 5 of these 49 samples showed heteroplasmy for this region of the mitochondrial genome in addition to housing a deletion. This study demonstrates that mtDNA status following neurotrauma may play a role in the acute presentation and prognosis of brain injured patients and suggests that further investigations are warranted.

Mitochondrial DNA mutations in non-melanoma skin cancer: Possible genetic selection in tumorigenesis. *W. Giraldo-Rosa, A.C. Musiek, R.A. Vleugels, J.E. Sligh.* Division of Dermatology, Vanderbilt Univ Medical Center, Nashville, TN.

Recent publications have found a high frequency of mitochondrial DNA (mtDNA) mutations in a variety of malignancies. These mutations often were present in all of the mtDNA copies (homoplasmic) within the tumors. Proposed theories to explain the role of these mtDNA changes in tumorigenesis have included possible selective growth advantage or random stochastic segregation. We explored the role of mitochondrial DNA (mtDNA) changes in non-melanoma skin cancer (NMSC) using a genetic approach. Paired tissue specimens of NMSC tumors and adjacent tumor-free margin skin were obtained from surgical excisions in our Dermatology clinic. DNA was isolated from the specimens and long extension polymerase chain reaction (PCR) was used to amplify almost the entire mtDNA in a single reaction. The products were visualized using field inversion gel electrophoresis. mtDNA deletions were often the only forms detected in this assay from the margin skin from elderly patients. However, full length mtDNA was detected in the tumors in all cases despite a probable bias of this protocol to selectively amplify deleted mtDNA species. The increased detection of these full length products from tumors that develop within a background of skin harboring extensive mtDNA deletions suggests the possibility of a genetic selection for specific mtDNAs in the process of tumorigenesis. To investigate this possibility further, we analyzed the full length mtDNAs from the tumors at the single base level for point mutations by DNA sequencing of entire mitochondrial genomes. Homoplasmic point mutations in the mtDNA have been detected in our preliminary sequencing data including protein synthesis mutations affecting the mtDNA-encoded rRNA subunits and mutations affecting specific subunits of NADH dehydrogenase (complex I) and cytochrome c oxidase (complex IV). In addition, homoplasmic tRNA mutations have been detected in NMSC cell lines. We propose that a relative lack of mtDNA deletions within NMSC tumor specimens and the finding of a variety of point mutation types in NMSC tumors and cell lines argue against the random segregation theory of mtDNA mutation homoplasmy.

Identification of Novel Mitochondrial Mutations in Dupuytren's Disease Using Enhanced Multiplex DHPLC. A.

Bayat¹, J. Walter², P. McAndrew², H. Lamb², J.S. Watson¹, J.K. Stanley¹, M. Marino², M.W.J. Ferguson¹, W.E.R. Ollier¹. 1) CIGMR, Manchester,UK; 2) Transgenomic Ltd,UK.

Dupuytren's disease or contracture (DD) is a familial fibroproliferative disorder of late onset affecting the hands. It is extremely common in individuals of Northern European extraction. Genetic studies have yet to identify the genes involved in DD formation. Oxidative stress and production of free radicals maybe important factors in the pathogenesis of DD. Mitochondrial genes are also included in the regulation of apoptosis. DD tissue contains large numbers of myofibroblasts, which dropped by apoptosis during normal wound healing. High numbers of mitochondria have been observed in fibroblasts derived from DD tissue. we investigated the presence of mutations within the mitochondrial genome in twenty Caucasian Dupuytren's disease (DD) cases with maternally transmitted inheritance pattern and twenty controls matched for age, sex and race using an enhanced multiplex Denaturing High Performance Liquid Chromatography (DHPLC) approach. The modified DHPLC involved amplifying the mitochondrial genome in 18 fragments ranging in size from 300-2000bp using a novel proof reading polymerase (OptimaseTM Transgenomic Ltd, UK) with a low misincorporation rate. Fourteen of these fragments underwent subsequent restriction digestion using a combination of 5 restriction enzymes to enable multiplex DHPLC analysis; the remaining four underwent conventional DHPLC. As part of this whole mitochondrial genome-screening approach we confirmed a number of previously reported mutations and additionally identified a large number of novel mutations. Hitherto, unknown heteroplasmic mutation located within the mitochondrial 16s rRNA region was evident in 90 % of cases and absent from all controls. This mutation may be important in the pathogenesis of DD.

Enhanced detection of deleterious mutations by TTGE analysis of mother's and child's DNA side by side. *H. Kwon, D.J. Tan, R. Bai, L.J. Wong.* Molecular and human genetics, Georgetown University Medical Center, Washington, DC.

Mitochondrial DNA (mtDNA) disorders represent a group of heterogeneous diseases that are caused by mutations in mtDNA. A report demonstrated that analysis of 12 most common point mutations and deletions detected only about 6 % of disease causing mtDNA mutations in 2000 patients suspected of mitochondrial disorders, suggesting that a majority of mutations were not identified. Here, we have examined 45 pairs of mother and the affected child, by screening the entire mitochondrial genome with Temporal Temperature Gradient Gel (TTGE), using 32 pairs of overlapping primers. TTGE is an effective mutation detection method. It detects and distinguishes heteroplasmic mutations from homoplasmic mutations. By running mothers and child's DNA samples side by side and sequence only the DNA fragments showing different TTGE patterns, can avoid the excessive sequencing, particularly the benign polymorphisms. Mutations identified by sequencing were further confirmed by PCR/ASO (allele specific oligonucleotide) dot blot analysis or PCR/RFLP. A total 29 differences in sequence between the mother and child pair were identified. They are A189G, A235G, 249 delA, 303-309 insC, 311-315 insC, T414G, C497T, A1438G, C1428T, A3397G, T5561C, T5580C, G5821A, C5840T, A8326G, T10591G, G12207A, A12333G, C12239T, G12372A, G15995A, T16184-16192insCC, T16189C, C16223T, C16278T, C16294T, A16309G, G16390A and T16519C. Among these mutations, 11 of them are novel. The most significant are the A8326G and G15995A mutations, both were found in an affected female. A8326G is located at the anticodon region, right next to the first nucleotide of the triplet codon and it is invariable throughout evolution from yeast to human. G15995A mutation occurs at a stem region that results in the disruption of the first base pair of the stem region at the anticodon loop of tRNA pro and is highly conserved throughout evolution from sea urchins to mammals. Although many mutations were found in the non-coding regions, they may affect RNA transcription, RNA processing sites, and protein translation. Further functional studies will be necessary to determine the significance of these mutations.

Leigh syndrome associated with a homoplasmic A8344G MERRF mutation. *T.W. Prior¹, G.E. Herman², C.Y. Tsao³, D.R. Boué⁴, J.F. Atkin².* 1) Pathology, Ohio State Univ, Columbus, OH; 2) Pediatrics,; 3) Neurology,; 4) Pathology, Children's Hospital, Columbus, OH.

Leigh syndrome, subacute necrotizing encephalomyelopathy, is a progressive degenerative disorder of the central nervous system most often diagnosed in early infancy or childhood. Genetic heterogeneity is well recognized and the etiologies include both nuclear and mitochondrial gene mutations. We describe an infant with a clinical phenotype consistent with Leigh syndrome: hypotonic weakness, motor and mental regression, progressive respiratory insufficiency, abnormal neuroradiological features and death at the age of 23 months. Mitochondrial DNA studies revealed that the infant was homozygous for the common myoclonic epilepsy and ragged-red fibers (MERRF) A8344G point mutation, however ragged-red fibers, myoclonus, myoclonic epilepsy were all absent and respiratory chain enzyme activities were normal. Furthermore, although all maternal relatives tested were heteroplasmic for the A8344G mutation, migraine headaches were the only clinical feature observed consistent with MERRF. This case clearly demonstrates that the symptoms associated with the A8344G mutation are highly variable and the genetic background, secondary gene mutations, environmental factors and the degree of heteroplasmy may modify the phenotype. Lastly, patients with a clinical presentation and neuroradiological features consistent with Leigh syndrome should be screened for the MERRF A8344G mutation in order to provide an accurate diagnosis and genetic counseling.

Mitochondrial DNA mutations in type 2 diabetic patients from Qinghai, China. *Y.-G. Yao¹, Q.-P. Kong¹, P.-L. Geng², Y.-P. Zhang¹*. 1) Kunming Institute of Zoology, Chinese Academy of Sciences, Kunming, Yunnan, 650223 China; 2) Qinghai Medical College, Xining, Qinghai, 810001 China.

Type 2 diabetes mellitus is a heterogeneous disease that characterized by impaired glucose homeostasis. Several studies have suggested that mitochondrial DNA (mtDNA) mutations may play a role in the development of maternally inherited diabetes mellitus and deafness (MIDD). Among those mutations, the A3243G mutation in tRNA-Leu (UUR) was the most prevalent. In the present study, we screened for this mutation by using PCR-restriction fragment length polymorphism analysis (ApaI) in 78 type 2 diabetic patients and 49 normal controls from Qinghai Province, China. In addition, the hypervariable segment I sequences (HVSI) of mtDNA control region were sequenced in all the subjects and were assigned to mtDNA haplogroups according to the Chinese mtDNA phylogeny. Then, Fisher exact tests were performed to test whether the frequency of a specific haplogroup was different between the patients and controls. None was found to harbor the A3243G mutation in total 127 subjects. Nearly all haplogroups (A, N9a, Y, M7b, M7c, M8a, C, Z, M9a, B4, B5, D5, D, F) identified in type 2 diabetic patients were present in the normal controls. Haplogroups A, B, and D showed higher frequency in the normal controls (A: 10.2%; B: 20.4%; D: 34.7%) than in the patients (A: 5.1%; B: 12.8%; D: 23.1%), but the overall haplogroup distributions were not statistically significant different ($P > 0.05$) between the patients and the controls. Our results were in generally agreement with previous suggestion that mtDNA mutation was not a major cause for type 2 diabetes mellitus in Chinese, but still leaves room for further study with large sample size.

REAL TIME PCR TECHNIQUE ON MITOCHONDRIAL DNA STUDIES. *B. Rodríguez-Santiago¹, S. López², O. Miró², J. Casademont², V. Nunes¹.* 1) Centre de Genètica Mèdica i Molecular-IRO, Hospitalet de Llobregat, Barcelona, Spain; 2) Grup de Recerca Neuromuscular, Hospital Clínic, IDIBAPS, Barcelona, Spain.

A rapid and sensitive method has been developed in our laboratory to study **the relative abundance of mitochondrial DNA (mtDNA)** in different diseases with mitochondrial involvement. **Real time PCR** for mitochondrial **ND2 (mtND2)** and nuclear **r18S** sequences were performed in a fluorescence temperature cycler **Lightcycler** using the **SYBR Green I** dye. A known amount of DNA was serially diluted and amplified for the mtND2 and the r18S sequences to obtain two standard log-linear regression lines. The DNA samples with an unknown mtDNA amount are amplified following the same standard conditions by continuously monitored PCR to obtain the threshold cycle number (Ct). The Ct value of mtND2 and r18S amplification is interpolated in the standard log-linear regression lines to obtain the **mtND2/r18S ratio** used to compare patients and controls. Following this strategy our group has studied the abundance of mtDNA in **Alzheimers disease (AD)** and, recently, the effect on mtDNA caused by different treatments in **HIV** infected patients. In **AD**, DNA samples from three **brain** areas (cerebellum, hippocampus and frontal cortex) of 12 AD patients and 7 controls, and from blood of 17 patients and 27 controls were analysed. Frontal cortex from **AD** patients showed a 28% reduction in their mtDNA contents. In **HIV**, DNA samples of **lymphocytes** from five groups of infected patients were studied. One group included only patients who had not received treatment for the infection. The other groups were treated with different drug schedules for at least 6 months. All groups of treated patients were compared with the naive group. We found **significant mtDNA reduction** in the groups receiving **indinavir (d4T)** and **didanosine (ddI)**. The quantification by **SYBR Green I** with the **LightCycler** also offers interesting perspectives to analyse the **relative expression** of several mitochondrial mRNAs. (Supported by grants *Fundació La Marató TV3 2002/97* and *FIPSE 3102/00*).

Real time quantitative PCR analysis of mitochondrial DNA in patients with mitochondrial disease. *L.C. Wong, R.K. Bai.* Inst for Mol & Human Gen, Georgetown Univ Medical Ctr, Washington, DC.

Molecular diagnosis of mitochondrial DNA disorders is usually focused on point mutations and large deletions. In the absence of detectable mtDNA mutations, abnormal amount of mtDNA, either depletion or elevation, can be indicative of mitochondrial disorders. The amount of mitochondrial DNA (mtDNA), however, varies among individuals of different age and among different tissues within the same individual. In order to establish a range of mtDNA levels, we have analyzed 350 muscle and blood specimens from patients suspected of mitochondrial disorders using real time quantitative PCR method. The copy numbers of mtDNA and 18S rRNA gene were calculated from the standard curve using Taqman probes; 6FAM-5TTACCGGGCTCTGCCATCT3-TAMRA and VIC-5AGCAATAACAGGTCTGTGATG3-TAMRA for mtDNA and 18S rRNA gene (nuclear DNA, nDNA) respectively. The copy number ratio of mtDNA to nDNA was used as a measure of mtDNA content in each specimen. The mtDNA content in muscle increases steadily from birth to about 5 years of age, after that it stays at about the same level. On the contrary, the mtDNA content in blood decreases with age. The amount of mtDNA in skeletal muscle is about 5 to 20 times higher than that in blood. About 7% of patients had mtDNA levels in muscle below 20% of the mean of age-matched group and about 10% of patients had muscle mtDNA levels 2 to 16 fold higher than the mean of age-matched group. Both groups of patients with mtDNA depletion and proliferation had significant clinical manifestation of mitochondrial disease in addition to abnormal respiratory enzymes and mitochondrial cytopathies. Cardiomyopathy, lactic acidosis, abnormal brain MRI findings, hypotonia, developmental delay, seizure, and failure to thrive are general clinical pictures of the patients with mtDNA depletion. The average age of this group of patients is 4.2 years. Mutations in nuclear genes such as thymidine phosphorylase, DNA polymerase gamma, and thymidine kinase are probably the cause of mtDNA depletion. Our results demonstrate that real time quantitative PCR is a valuable tool for molecular screening of mitochondrial disease.

Mitochondrial effect on risk of developing late-onset Alzheimer disease (AD) is modified by gender. *M.A. Pericak-Vance¹, J.M. van der Walt¹, K.K. Nicodemus¹, E.R. Martin¹, C.C. Kroner¹, W.K. Scott¹, D.E. Schmechel¹, G.W. Small², P.M. Conneally³, A.M. Saunders¹, J.L. Haines⁴, J.R. Gilbert¹, J.M. Vance¹.* 1) Duke Univ; 2) Univ of California, LA; 3) Indiana Univ; 4) Vanderbilt Univ.

We examined the association of mitochondrial (mt) DNA sequence variation with AD in a Caucasian sample of 467 cases and 353 controls using logistic regression to test the effect of mt and SNPs. Gender and APOE were used as covariates. However, adjusting for APOE in our data did not significantly change results and thus was not included in subsequent analyses. Previous studies had suggested haplogroups (hpg) K and U were protective against AD but only when APOE was included. SNP combinations were used to assign individuals to a pre-defined European hpg (H, I, J, K, T, U, V, W, X). K hpg individuals showed a decrease in risk (OR=0.57; 95% CI, 0.34-0.97; p= 0.04) of AD versus those with the common H hpg confirming a previously reported association. The 10398G allele was significantly protective (OR=0.70; 95% CI=0.51-0.95; p=0.02). Stratification by gender was significant demonstrating striking differences in the levels of association when the sexes were considered separately. Males classified as hpg U showed an increase in risk (95% CI, 1.16-5.37; p=0.02) of AD versus the most common hpg H. This result is compelling as U is also a risk factor for Parkinson disease in males (JM van der Walt et al., ASHG 2002). Females did not show a significant effect with the U haplogroup (OR=0.65; 95% CI=0.37-1.15; p=0.14) and in fact the association trended in the opposite direction. The male specific results do not support previous reports that found U protective. The risk of AD was decreased in males who carried the 10398G allele (OR= 0.53; 95% CI, 0.32-0.89; p=0.02) versus males that carried the A allele. There was no significant effect in females for 10398G (OR=0.80, 95%CI, 0.53-1.22) although the OR was < 1.00. In summary we have extended our understanding of the effect of mt sequence variation on AD risk showing that mt is independent of APOE and that gender plays a role in the expression of this risk.

Program Nr: 1941 from 2002 ASHG Annual Meeting

Mitochondrial DNA deletions in skin from patients with non-melanoma skin cancer. *J.E. Sligh, A. Eshaghian, R.A. Vleugels, A. Slater, S. Stokes.* Division of Dermatology, Vanderbilt Univ Medical Ctr, Nashville, TN.

The potential role of mitochondrial DNA (mtDNA) changes in cutaneous photoaging was explored using a genetic approach. Photodamaged tumor-free margin skin was obtained from non-melanoma skin cancer (NMSC) patients undergoing skin cancer excision by Mohs micrographic surgery in our Dermatology clinic. DNA was isolated from the specimens and long extension polymerase chain reaction (PCR) was used to amplify 98 percent of the mitochondrial genome in a single reaction. The PCR products were visualized using field inversion gel electrophoresis. mtDNA deletions were abundant in margin tissue specimens from older patients and were often the only forms detected in this assay. These mtDNA deletions were characterized to investigate their utility as possible biomarkers of cutaneous photoaging. The observed mtDNA deletions were typically flanked by 3 bp to 15 bp direct or indirect repeats. The majority of deletions contained within this photodamaged skin did not match any previously reported mtDNA deletion contained within the Mitomap database of human mtDNA variations (<http://www.gen.emory.edu/mitomap.html>). A novel complex triple deletion was also found in the mtDNA from the skin of one patient. Some mtDNA deletions were detected from the skin of multiple individuals including a novel 6278 bp deletion whose frequency approached that of the previously well characterized 4977 bp common deletion. In conclusion, we have characterized many new mtDNA deletions from aging skin which support the use of mtDNA mutations as biomarkers of photoaging in the skin. Indeed, the mtDNA of the skin appears to be a prime target for deletion mutations associated with aging when compared to other tissues.

Identification of a novel candidate gene in the iron-sulfur pathway implicated in ataxia-susceptibility: human gene encoding Hsc20, a J-type co-chaperone. *G.F. Sun, L.E. Vickery, J.J. Gargus.* Dept Physiology & Biophysics, Univ California, Irvine, Irvine, CA.

Iron-sulfur proteins participate in a wide range of biochemical processes including many that are central to mitochondrial electron transfer and energy metabolism. Friedreich ataxia brought focus to the importance of this class of proteins in human neurological disease since loss-of-function alleles of frataxin produce functional mitochondrial defects in patients, and nulls of the yeast ortholog, *YFH1*, display a respiratory-deficient phenotype and a defect in Fe-S cluster formation. Other hereditary ataxia syndromes, including X-linked sideroblastic anemia with ataxia, seem to share these features. Recently, several genes encoding proteins involved in the biogenesis of Fe-S proteins have been identified in bacteria and yeast, and their human homologs are functional candidate genes in these syndromes. One of these genes, *hscB* in bacteria (*JAC1* in yeast) encodes a J-type co-chaperone designated Hsc20 that regulates interactions between the Fe-S cluster assembly protein IscU and the hsp-70-class molecular chaperone HscA/Hsc66. To set the stage for an analysis of the potential role of this gene in human disease, we defined the human *HscB* cDNA, its genomic locus and its pattern of expression in normal human tissues. A search of the human EST database with the *E. coli* HscB protein sequence revealed several human EST homologs, and the complete cDNA sequence of the human *HscB* was defined by sequencing an EST clone. The human *HscB* cDNA encodes 235 amino acids, including a putative mitochondrial import leader. Two BAC clones previously mapped to chromosome 22q11-12 contained most of the genomic sequence. The *HscB* gene is composed of six exons and five introns. Northern blot analyses of RNA from adult and fetal tissues defined a pattern of expression in mitochondria-rich tissues. A 1.4 kb transcript is expressed moderately in adult striate muscle, and weakly in adult kidney and liver. A 2.8 kb transcript is abundantly expressed in both adult and fetal liver. The expression pattern of *HscB* is compatible with its implied role in mitochondrial energetics and related disease phenotypes.

Program Nr: 1943 from 2002 ASHG Annual Meeting

Analysis of the neurotoxicity of the amyloid Ab peptides in *Drosophila melanogaster*. *O. Blard*¹, *A. Laquerriere*², *D. Champion*¹, *T. Frebourg*¹, *M. Lecourtois*¹. 1) INSERM EMI 9906, Faculty of Medicine, 76183 Rouen, France; 2) Department of Pathology, CHU de Rouen, 76031 Rouen, France.

Alzheimer's disease, the first cause of neurodegenerative dementia, is characterized by two cerebral lesions, senile plaques resulting from the deposition of Ab peptides and intracellularly neurofibrillary tangles which the main component is the microtubule-associated protein tau. If the abnormal production and/or aggregation of Ab peptides clearly represents the key event of the disease, the mechanisms underlying the neurotoxicity of Ab peptides remain controversial. We have used *Drosophila* as an experimental organism to analyze the mechanisms underlying the amyloid toxicity *in vivo* and to identify molecules able to interfere with this pathogenic process. First, we have generated DNA constructs allowing the expression of the Ab peptides in the cytoplasm, in the extracellular space or in the endoplasmic reticulum (ER). Transgenic flies have been then engineered using the Gal4-UAS system to express the human amyloid peptides both in the photoreceptor neurons and other cells. Analysis of the biological effects associated with the expression of these different Ab peptides will be presented.

Human genetic response to *Bacillus anthracis* spores. M.R. Altherr¹, S. Wachocki¹, T. Brettin¹, R. Gottardo¹, R. Iyer¹, R.A. Robison³, J.M. Ettinger². 1) B and; 2) NIS Divisions, Los Alamos National Laboratory, Los Alamos, NM; 3) Dept.Micro.,BYU, Provo, UT.

The bacterium *Bacillus anthracis* has been the focus of investigations for over one hundred years. Current events have renewed interest in this organism and its pathological consequences. Recent studies have demonstrated that spores germinate within the phagolysosome. However, the genetic response of the host immediately following the uptake of spores remains obscure. In this study, we have used established cell models exposed to spores from the attenuated *B. anthracis* Sterne strain. While the Sterne strain lacks the pXO2 plasmid and the genes encoding virulence factors associated with capsule formation, it has all the genetic information required for spore germination and release from the host cell. Therefore, the use of Sterne spores should not compromise these findings. We characterized the transcriptional response to *B. anthracis* spores using Affymetrix U133A Gene Chips at four time points using four completely independent replicates. Of the approximately 22,000 genes represented on the U133A array, 2,032 probes pairs exhibited a statistically significant response to the spore challenge in either or both cell lines at one or more time points when compared to an unchallenged control. Cells challenged with latex beads behaved like the unchallenged control and were quite distinct in their transcriptional response when compared to cells challenged with spores. Interestingly, there was significant heterogeneity in the response of two widely used model cell lines. Nevertheless, a total of 254 genes were common responders in both cell lines. Of these, 192 have been localized and all chromosomes are represented. 122 have some annotation in terms of ontology descriptions suggesting a role in a defined biological process, cellular component or molecular function. This means that 50 percent; of the responding genes have no suspected function. 75 percent; of those with suggested roles can be organized into one of seven functional groups. Of these, 33 contain putative polymorphisms in their coding sequence.

Program Nr: 1945 from 2002 ASHG Annual Meeting

Absence of MECP2 Mutations In Patients From The South Carolina Autism Project. *R.C. Michaelis¹, F. Lobo-Menendez¹, K. Sossey-Alaoui¹, S. Copeland-Yates¹, J.M. Bell², S.M. Plank², S.O. Sanford¹, C. Skinner¹, R.J. Simensen¹, R.J. Schroer¹.* 1) JC Self Research Inst, Greenwood Genetic Ctr, Greenwood, SC; 2) Presbyterian College, Clinton, SC.

The methyl-CpG binding protein 2 (MeCP2) gene has recently been identified as the gene responsible for Rett syndrome, one of the autism spectrum disorders. Most female patients with MeCP2 mutations exhibit the classical features of Rett syndrome (RS), including autistic behaviors. Most male patients with MeCP2 mutations exhibit moderate to severe developmental delay/mental retardation. Ninety nine patients from the South Carolina Autism Project (SCAP) were screened for MeCP2 mutations, including all 41 female patients from whom DNA samples were available plus the 58 male patients with the lowest scores on standard IQ tests and/or the Vineland Adaptive Behavior Scale. No pathogenic mutations were observed in these patients. One patient had the C582T variant, previously reported in the unaffected father of an RS patient. Two other patients had novel single nucleotide polymorphisms in the 3' UTR of the gene, G1470A and C1516G. These variants were seen in 12/82 and 1/178 phenotypically normal male controls, respectively. The findings from this and other studies suggest that mutations in the coding sequence of the MeCP2 gene are not a significant etiological factor in autism.

The myotonic dystrophy type 2 (DM2) CCTG expansion does not reduce *ZNF9* transcript levels or prevent splicing. *L.P.W. Ranum, M.L. Moseley, D.D. Jin, C.L. Liquori, J.W. Day.* Inst of Hum Genet, Univ of MN, Minneapolis.

We recently demonstrated that DM2 is caused by a CCTG expansion in intron 1 of the *zinc finger protein 9 (ZNF9)* gene, supporting a gain of function RNA model of DM pathogenesis. The DM2 expansion is huge, with CCTGs that can exceed 44 kb (mean ~20 kb). Similar to DM1, RNA containing the repeat accumulates as nuclear foci. Because repeat expansions decrease transcription in loss of function disorders (FA, FMR) and haploinsufficiency has been suggested to play a role in DM1, we performed a series of experiments to determine if the DM2 expansion interferes with normal *ZNF9* transcription and to define what portion of the *ZNF9* transcript is present in the nuclear foci. Consistent with normal splicing, RNA in situ hybridization in affected muscle and fibroblasts indicate that transcripts containing exon 1 (5' of the expansion) or exon 5 (3' of the expansion) localize to the cytoplasm but not to the CCUG-containing nuclear foci. Probes to sites distributed throughout intron 1 detect transcripts as small punctate signals that are evenly dispersed throughout the nucleus, but that do not co-localize to the much larger nuclear CCUG containing foci. The effects of the CCTG expansion on *ZNF9* expression were independently evaluated using monoallelic mouse-human cell lines containing either a normal or an expanded (~1000 repeats) human DM2 allele. RT-PCR between exons 2 and 1 amplified spliced human transcripts from cells containing either the normal or the expanded allele, and Northern analysis showed comparable levels of human *ZNF9* mRNA with no evidence of unprocessed transcripts. Similarly, equal transcript levels were detected by Northern analysis in diploid fibroblasts from either normal or affected individuals. Taken together, these results indicate that the DM2 expansion does not prevent transcription or splicing of *ZNF9*, the repeat-containing nuclear foci do not contain intron 1 or other portions of the transcript, and the DM2 expansion does not reduce allele specific or overall *ZNF9* mRNA levels. Our results are consistent with a gain rather than a loss of function model in which CCUG expansions themselves alter cellular function.

Genetic and molecular study of migraine. *M.J. Castro*¹, *I. Alonso*^{1,2}, *P. Maciel*¹, *A. Sousa*^{1,2}, *L. Guimarães*^{1,2}, *C. Fraga*³, *J. Barros*³, *J. Sequeiros*^{1,2}, *J. Pereira-Monteiro*³, *I. Silveira*¹. 1) UnIGENe, IBMC, Porto, Portugal; 2) ICBAS, Porto, Portugal; 3) Hospital de Santo António, Porto, Portugal.

Migraine is a highly prevalent primary headache disorder. The most common form of this disease is migraine without aura (MO), characterized by International Headache Society (IHS) guidelines as unilateral pulsating pain of moderate to severe intensity, aggravated by physical activity. Migraine with aura (MA) shares the same headache symptoms, but is preceded by aura, which are attacks of focal neurological symptoms. A rare autosomal dominant sub-type of MA is familial hemiplegic migraine (FHM) with severe symptoms during the attacks, such as hemiparesis and coma. A significant number of families with FHM have shown genetic linkage to chromosome 19p13; linkage to chromosome 1q has also been detected in some FHM families; however, several FHM families have not presented linkage to any of these *loci*. Mutations in a gene located on chromosome 19p13, the *CACNA1A* gene, that encodes for an α_{1A} -subunit of a brain P/Q-type calcium channel, have been described for different disorders: FHM, spinocerebellar ataxia type 6 (SCA6), and episodic ataxia type 2 (EA-2). To identify new genes and mutations involved in migraine, we ascertained 90 families with MO, MA or FHM and 1) performed linkage analysis in informative families, and 2) screened patients for mutations in the *CACNA1A* gene. Sixty-five families had migraine dominantly inherited, including four with FHM; 14 were isolated cases of migraine, whereas the remaining families had an unknown pattern of inheritance. Linkage analysis for chromosome 19p13 was performed with *CACNA1A* intragenic markers (CAG)_n and D19S1150. Mutation analysis was performed by SSCP and sequencing. Mutations already described in the *CACNA1A* gene were not found in our group of families. One family with FHM was excluded to the *CACNA1A* gene by linkage analysis. Three new polymorphisms in exons 13 (C2054G), 20 (T3755A) and 29 (T4898C) were detected. The study proceeds with the screening of the entire coding region of the *CACNA1A* gene and with linkage analysis for the additional *loci* implicated in migraine.

Association of Parkin with late-onset Parkinson disease. *S.A. Oliveira¹, W.K. Scott^{1,2}, E.R. Martin¹, J.M. Stajich¹, L.T. Middleton², J.L. Haines², M.P. Winn¹, M.A. Pericak-Vance^{1,2}, J.M. Vance^{1,2}, GSK Collaborative Parkinson Disease Group².* 1) Center for Human Genetics (CHG), PO Box 2903, Duke University, Durham, NC; 2) Duke CHG/ GlaxoSmithKline PD Genetics Collaboration.

Mutations in Parkin, an E2-dependent ubiquitin protein ligase, cause autosomal recessive juvenile parkinsonism, but its role in the late-onset form of PD is not firmly established. In a genomic screen of PD we detected linkage to D6S305, lying in the Parkin gene (LOD=5.47), in families with at least one member with an age at onset (AAO) < 40 years (early-onset PD families). Parkin mutations were identified using denaturing HPLC and sequencing. Genotyping was performed using the oligonucleotide ligation assay. Three intronic and three exonic single nucleotide polymorphisms (SNP) were used for association studies in families not known to carry Parkin mutations. 607 PD patients (average AAO \pm SD = 61.8 \pm 13.5 y), 872 unaffected controls (average age at examination \pm SD = 67.5 \pm 12.3 y), and 101 individuals with unclear diagnosis were included from a total of 397 families. Mutations were identified in 18% of early-onset families and 2% of late-onset families, which together comprise 4% of the total number of families. The AAO of patients with Parkin mutations ranges from 12 to 71 years. The most common change was a deletion of 40 bp in exon 3. Excluding exon 7, average AAO for patients with Parkin mutations was 31.5 years. Three mutations in exon 7 (Arg256Cys, Arg275Trp and Asp280Asn) were observed in individuals with late AAO (average AAO = 51 years), mostly in the heterozygous state. Combining our data set and that of the literature, these mutations were not found in over 900 unrelated control chromosomes. We detected no significant association ($p > 0.05$) of any of these SNPs with PD. These findings indicate that Parkin mutations do contribute to the common, late-onset form of PD. Importantly, it appears that Parkin mutations in the heterozygous state may act as susceptibility alleles for late-onset PD, especially those in the first ring finger (exon 7).

Novel point mutations in two compound heterozygous cases of Friedreich's Ataxia. *J.R. Leib¹, C. Stolle², J.P. Taylor¹, J.B. Caress³*. 1) Neurogenetics Branch, National Institute of Neurological Diseases and Stroke, National Institutes of Health, Bethesda, MD; 2) Genetic Diagnostic Laboratory, University of Pennsylvania School of Medicine, Philadelphia, PA; 3) Department of Neurology, Wake Forest University School of Medicine, Winston-Salem, NC.

Friedreich's ataxia (FRDA) is an autosomal recessive, multisystem degenerative disorder affecting approximately 1 in 40,000 individuals in the United States. FRDA results from loss-of-function mutations involving the X25 gene encoding the protein frataxin at chromosome 9q13. Approximately 96% of Friedreich's Ataxia (FRDA) patients harbor a homozygous expansion of a trinucleotide repeat (GAA) within intron 1 of the X25 gene. In the remaining FRDA cases, the patients are heterozygous at the X25 locus with one typical expanded allele and a point mutation. We report two such compound heterozygous patients with typical, severe FRDA phenotypes. Our first patient is a 25-year-old male with approximately 725 GAA and 7 GAA repeat sequences in intron 1 of the X25 gene. Sequencing revealed that his non-expanded allele also contains a novel point mutation (11-12 del TC) in exon 1 introducing a shift of the reading frame, creating 26 novel amino acids and a premature stop codon at amino acid position 91. Our second patient is a 31-year-old female with approximately 700 GAA repeat sequences in intron 1 and a non-expanded allele with a novel 2 base pair deletion in exon 2 (214-215 del AG). This frame shift mutation introduces 21 new amino acids and a premature stop codon at amino acid position 91. Similar to the expansion, these novel null mutations are predicted to preclude expression of frataxin mRNA.

DISCORDANT PHENOTYPES IN FIRST COUSINS WITH UBE3A MUTATION. *G.A. Molfetta^{1,2}, M.V.R. Munoz³, W.A. Silva-Jr⁴, J. Wagstaff², J.M. Pina-Neto¹.* 1) Dept Genetics, Ribeirao Preto - USP, Sao Paulo, Brazil; 2) Department of Pediatrics, University of Virginia School of Medicine, USA; 3) Clinica Materno Fetal, Florianopolis, SC, Brazil; 4) Center for Cell Therapy and Regional Blood Center, Ribeirao Preto, Brazil.

Angelman syndrome is a neurobehavioral disorder caused by defects of the imprinted UBE3A gene in chromosome 15q11-13. Different genetic mechanisms can result in loss of a functional maternal allele of UBE3A in AS: 70% are maternal 15q11-13 deletions; 7-9% from imprinting defects; 3-5% from UPD; and 4-8% from mutations in the UBE3A gene. The remaining 10-15% have no deletion, imprinting defect, UPD, or UBE3A mutation. UBE3A mutations are more frequent in familial than in sporadic patients and the mutations described so far seem to cause similar phenotypes in the familial affected cases. We describe two affected first cousins who have inherited the same UBE3A mutation from their asymptomatic mothers but presenting discordant phenotypes. The proband shows typical AS features. Her affected cousin shows a more severe phenotype, with asymmetric spasticity that led originally to a diagnosis of cerebral palsy; brain MRI shows schizencephaly associated with cortical dysplasia and subtle white matter atrophy in posterior cerebral areas. We have three hypotheses to this phenotypic discordance: the second cousin has an additional problem (genetic or environmental) besides the UBE3A mutation; the UBE3A mutation is interacting with a genetic variant in the second cousin to cause the severe phenotype; or this UBE3A mutation alone can cause either typical AS or the severe clinical picture seen in the second cousin. This family demonstrates that the presence of a brain malformation does not exclude the diagnosis of AS. Another unusual observation regarding this UBE3A mutation is the fact that it was transmitted from the cousins grandfather to only two sisters among eleven full siblings. As the expected rate of normal carriers within the sibship would be 50% if the maternal grandfather was a normal carrier, we hypothesize that the transmitting grandfather, now deceased, may have been mosaic for this mutation. Financial Support: FAEPA.

Comprehensive Mutation Scanning of RAR/RXR and Vitamin D Receptor genes in Patients with Schizophrenia and other Psychiatric Diseases: Three missense mutations at highly conserved residues. *J. Yan¹, J. Feng¹, J. Chen¹, N. Craddock², I. Jones², E.H. Cook Jr³, D. Goldman⁴, L.L. Heston⁵, S.S. Sommer¹.* 1) Dept of Molecular Genetics, City of Hope, Duarte, CA; 2) Div of Neuroscience, Univ of Birmingham, Birmingham, UK; 3) Dept of Psychiatry, Univ of Chicago, Chicago, IL; 4) Dept of Psychiatry, NIAA, NIH, Bethesda, MD; 5) Dept of Psychiatry, Univ of Washington, Seattle, WA.

Retinoic acid receptors (RAR), retinoid X receptors (RXR) and the Vitamin D receptor (VDR) are involved in the regulation of brain function. Defects in these receptors may contribute to schizophrenia or other psychiatric diseases. To test this hypothesis, the RAR and RXR genes (RAR α , β , γ & RXR α , β , γ) and the VDR gene were scanned by DOVAM-S (Detection of Virtually All Mutations-SSCP), a robotically enhanced multiplexed scanning method. In total, 196 subjects were scanned in each gene (including 100 patients with schizophrenia and a pilot experiment in patients with bipolar disorder (24), autism (24), ADHD (24), and alcoholism (24)). 3.2 megabases of genomic sequences were scanned in total. Seven VAPSEs (Variants Affecting Protein Structure or Expression) and 24 non-VAPSEs were identified. The data define structural variants that may be relevant to disease. Only the RAR β gene showed some potential relationship to schizophrenia. One VAPSE, N307T in the RAR β gene is at a residue that is highly conserved during evolution; e.g., N is conserved in the five available mammalian species, bird species and fish, hinting that these sequence changes will be of functional significance. A further case-control study showed a trend that the frequency of N307T is higher in schizophrenia than that in ethnically matched controls (4/498 vs 1/509). Three of the missense mutations identified at highly conserved residues are likely to be of functional significance. Ultimately some or all these VAPSEs may be associated with clinical phenotypes.

The dystrophin gene is associated with sporadic dilated cardiomyopathy: implications for clinical care. S.S.

Sommer¹, J. Feng¹, J. Yan¹, C.H. Buzin¹, J.A. Towbin². 1) Dept Molecular Genetics, City of Hope Natl Medical Ctr, Duarte, CA; 2) Dept of Pediatrics, Baylor College of Medicine, Houston, TX.

Dilated cardiomyopathy (DCM) is the major indication for heart transplantation. Approximately 30% of all DCM is thought to be inherited, while 70% is sporadic. Mutations in the dystrophin gene have been associated with the uncommon X-linked form of DCM. We hypothesized that missense mutations and other less severe mutations of the dystrophin gene might predispose to the common form of sporadic DCM. To test this hypothesis, 22 kb of genomic dystrophin DNA was scanned with DOVAM-S (Detection of Virtually All Mutations-SSCP) in each of 22 patients with sporadic DCM, including all 79 coding sequences and splice junctions, as well as six alternative exon 1 dystrophin isoforms (484 kb, total). Three putative new mutations (IVS5+1 G>T, K18N and F3228L) and seven polymorphisms were identified. The splice site mutation IVS5+1 is predicted to cause skipping of exon 5, which is within a region containing an actin binding site. The missense mutations occur at amino acids that display substantial evolutionary conservation. Screening of 236 control individuals failed to identify these 3 mutations. CK-MM (creatine kinase, skeletal muscle) was measured in 17 patients. The three patients with putative mutations had CK-MM level of 11,300, 430 and 270, respectively, while the 14 patients without mutations had values ranging from 20 to 200. The first comprehensive mutation scanning of the exons and splice junctions of the dystrophin gene in patients with sporadic DCM suggests that point mutations are associated with sporadic DCM without clinical evidence of skeletal myopathy. It may be prudent to add CK-MM to the clinical analysis of patients presenting with dilated cardiomyopathy in order to identify candidates at high risk for dystrophin mutations.

High throughput mutation detection in the mitochondrial genome using DHPLC. *J. Walter¹, H. Lamb¹, M.A. Marino²*. 1) Applied Genomics, Transgenomic Inc, Crewe, Cheshire, England; 2) Applied Genomics and Molecular Genetics, Transgenomic, Inc., Gaithersburg, MD.

Denaturing High Performance Liquid Chromatography (DHPLC) and the WAVE® System enables automated mutation detection via heteroduplex analysis. This technique is capable of providing high efficiencies when scanning for unknown mutations with very low false positive levels and no reported bias with regard to mutation type (single base changes or insertion deletion mutations). A further advantage is the ability to detect small proportions of a mutant allele in a wild type population. This high level of sensitivity, less than 1% of mutant in a wild type population, has been previously reported with reference to mutation detection in the mitochondrial genome (Smeets et al). Mutation detection in the mitochondrial genome is relatively easy due to its small size (approx. 16kb) however the heteroplasmic nature of the mitochondrial DNA population can result in the presence of mutations at very low levels which are difficult for most techniques to detect.

We report here significant improvements to the previously published technique to allow it to be used as a highly efficient scanning tool for the detection of unknown mutations. These improvements include redesign of the primer sets enabling streamlining of the procedure and the ability to minimise the number of different restriction enzymes used. Software analysis of the mitochondrial genome to reduce the number of DHPLC method conditions necessary whilst maintaining mutation detection efficiency. The use of a novel proof reading polymerase (Optimase™ polymerase) to reduce the number of misincorporations during the amplification procedure; maximising the sensitivity of the technique. Finally transferring the technique to the WAVE® System 3500HT platform enabling screening of the entire mitochondrial genome in less than 6 hours.

Investigating a possible relation between the amino acid variation N158S of the human heat shock protein Hsp60 and an increased susceptibility to Sudden Infant Death Syndrome (SIDS). *A. Teske¹, T. Rothämel¹, W.J. Kleemann², H.D. Tröger¹.* 1) Inst Legal Medicine, Medical Sch Hannover, Hannover, Germany; 2) Inst Legal Medicine, U Leipzig, Germany.

Hyperthermia (among other factors) combined with a dysfunctional heat stress reaction may potentially be life threatening and lead to SID. The gene of the human heat shock protein Chaperonin 60 (Hsp60) has been considered twice in relation to SIDS. Rahim et al. 1996 reported an RFLP in the hsp60 gene, which was characteristic for the 12 SID cases examined. Bross et al. 2001 found the amino acid variation N158S (asparagine to serine) in a single case of 65 SID cases analyzed. They postulate this occurrence as a possible rare disease allele of the hsp60 gene. Our work aims to examine this variation in relation to increased SIDS susceptibility.

The codon for the amino acid 158 (asparagine) is located in exon 5 of the hsp60 gene (position 8748-8843; GenBank Acc. No. AJ250915). The DNA of the SID cases was isolated from blood samples taken during autopsies at the Institute for Legal Medicine of the Medical School Hannover (Germany). The DNA of the controls was isolated from blood samples of children undergoing paternity testing at the same institute. For 31 SID cases and 20 controls, we sequenced a PCR fragment of the entire exon 5 in both directions (note for reviewers: in the final version we expect to show the results for 100 SID cases and 100 controls).

So far, no amino acid variation N158S was found in either of the SID cases or controls. Furthermore, no other mutations in the complete exon 5 of hsp60 could be discovered.

Based on our current results, a direct relation between the amino acid variation N158S in the gene of human heat shock protein Hsp60 and SIDS cannot be confirmed by our experiments.

Mutation of p53 gene in ocular pterygia. *D. Reisman¹, J. McFadden¹, N. Lin¹, R.G. Best¹, G. Lu^{1,2}*. 1) University of South Carolina, Columbia, SC; 2) Genzyme Genetics, Yonkers, NY.

Pterygium is a web-shaped growth of fibrovascular tissue onto the cornea that is continuous with the conjunctiva. It occurs at highest prevalence and most severely in tropical areas, and to a lesser and milder degree in cooler climates. UV-light exposure has been considered to be risk factor for pterygium. Furthermore, chromosome instability in pterygium suggests a DNA repair deficiency. UV-induced p53 mutations have been found to be associated with skin cancer, and sunlight exposure is the most important epidemiological risk in the development of pterygium, thus we hypothesize that interaction between UV-light exposure and somatic mutations in p53 may lead to uncontrolled cell growth in pterygium. Recently, we investigated genetic changes in a small-scale study including 9 pterygium samples and 10 controls. Chromosome instabilities were found in two out of the 9 cases of pterygium, and monoallelic deletion of p53 was detected in 5 cases by FISH analysis. Analysis of p53 protein and mRNA by RT-PCR in cells derived from pterygium patients revealed no detectable p53 expression while p53 protein was readily detectable in control samples. Analysis of the genomic DNA organization of the p53 gene indicates that the p53 gene from control and pterygium-derived cells has the same overall structure and no major rearrangements appear to be responsible for the loss of p53 expression. DNA sequence analysis in a selected sample was found to have the wild type p53 sequence. This is, to our knowledge, the first detection of p53 monoallelic deletion and chromosome instability in pterygium. We conclude from our findings that in a significant frequency of cases of pterygium, the p53 gene has undergone a monoallelic deletion. The remaining allele appears to remain wild type, and is transcriptionally silenced. The mechanism of silencing the p53 gene is currently under investigation and may include alternations in regulatory regions of the gene or methylation of important regions. (This study was supported by a Grant GA20037 (to G.L.) from Fight for Sight).

Dopamine Transporter Genotype (DAT1) Affects Stimulant Response in Children with ADHD. *M.A. Stein¹, I. Waldman², C. Sarampote¹, K. Seymour¹, A. Robb¹, C. Conlon¹, Z. Yang³, E.H. Cook³.* 1) Psychology, Psychiatry, and Pediatrics, Children's National Medical Ce, WASHINGTON, DC; 2) Psychology, Emory University, Atlanta, Ga; 3) Child and Adolescent Psychiatry, The University of Chicago, Chicago, Il.

Background: Stimulant medications, such as Methylphenidate (MPH), are the most common and effective treatments for ADHD. MPH acts primarily by inhibiting the dopamine transporter (DAT1). DAT1 codes for a protein responsible for the reuptake of dopamine from the synapse back into presynaptic terminals. The 480 bp allele of DAT1 has been associated with ADHD in several within family studies. Objective: We hypothesised that the presence of the 480 bp (i.e. high risk) allele would be associated with a positive response to stimulant medication in children with ADHD. Design/Methods: Children with ADHD (n = 42), ages 5-16 (mean = 8.8), underwent a 4 week, double blind, placebo controlled, crossover trial. Children were genotyped for DAT1 and evaluated on placebo and Concerta MPH at 3 dose levels: 18 mg, 36 mg and 54 mg qd. Parents and clinicians who were blind to genotype and medication status rated ADHD symptoms and stimulant side effects each week. Repeated measures analysis of variance was used to test differences in stimulant response by DAT1 genotype. Results: In contrast to those with no copies of the high risk allele, with increasing Concerta MPH dosage children with 1 or 2 copies were more likely to display a linear decrease in total ADHD symptoms ($R^2 = .19$, $p = .016$). Conclusions: In the presence of one or 2 copies of the DAT1 high risk allele, ADHD symptoms declined linearly with increased Concerta MPH dose. Replication with a larger sample and further study of reasons for lack of efficacy are ongoing.

Chromosome 15 and autism: Clinical characterization of phenotype. *M. Cuccaro¹, S. Donnelly¹, S.A. Ravan², R.K. Abramson², L. Elston¹, K. Decena², H.H. Wright², M.A. Pericak-Vance¹.* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) WS Hall Psychiatric Institute, Univ of South Carolina, Columbia, SC.

Autism (AutD) is a complex neurodevelopmental disorder. Epidemiologic and genetic analyses indicate that AutD is genetically heterogeneous and associated with a very wide range of clinical manifestations. Chromosomal region 15q11-q13 is one candidate region based on cytogenetic linkage and association findings. Ordered subset analysis (OSA) is an analytic method that identifies a homogenous subset of individuals that contributes to linkage in a particular chromosomal region. Using a factor derived from restricted and repetitive behaviors as the covariate in OSA, a subset of 23 AutD families were identified as contributors to linkage on Chr 15 (OSA N=46; 23 sibpairs). We compared these Chr 15 AutD sibpairs with the remaining AutD families that did not show evidence for linkage on composite indices from the Autism Diagnostic Interview-R (ADI-R) and Vineland Adaptive Behavior Scales (VABS). Between group comparisons revealed that the OSA defined subset was more impaired on a measure of social functioning (VABS Socialization $t=2.72$, $p=0.007$). In addition the OSA defined AutD group showed a trend toward significance reflective of lower overall adaptive functioning (Adaptive Behavior Composite $t=1.91$, $p=0.058$). The groups did not differ on either the ADI-R or VABS communication indices. These results are suggestive of a greater degree of social impairment in the OSA defined Chr15 AutD group. The VABS Socialization domain has been proposed as a quantitative index of social impairment in AutD. The results are consistent with the hypothesis that increased repetitive behavior exerts an effect on social and behavioral functioning. Additional efforts to investigate different phenotypic expression in AutD populations for application to genetic analysis will be extremely valuable in delineating the boundaries of AutD.

SELDI-TOF mass spectrometry as a tool for biomarker discovery in autism. *S.J. Walker¹, A.S.L. Xu², K.E. Vrana¹.*
1) Dept Physiology/Pharmacology, Wake Forest Univ Sch Medicine, Winston-Salem, NC; 2) CIPHERGEN Biosystems, Inc., Fremont, CA.

Autism is debilitating neuropsychiatric condition typically diagnosed between ages 3-6 years. While there is evidence of a genetic component associated with autism spectrum disorder (ASD), an "autism gene" has not yet been identified. Growing evidence suggests, however, that there are hallmark/physiologic abnormalities in autistic children that might be manifested in circulating proteins. Identifying these proteins will provide a way to study the important functional genomic changes associated with ASD. In this pilot study, serum from four autistic individuals and four non-autistic siblings (samples selected and purchased from the Autism Genetic Research Exchange [AGRE]) was assayed. The global differential expression of serum proteins in autistic samples compared to non-autistic controls was detected and analyzed using the surface enhance-enhanced laser desorption ionization time-of-flight (SELDI-TOF) mass spectrometry technology (CIPHERGEN Biosystems, Inc.; Fremont, CA) to profile patterns of lower molecular-weight serum proteins. The eight samples were assayed on a variety of chromatographic ProteinChip® array surfaces, under a variety of conditions designed to capture a subset of proteins, in an effort to identify protein profile differences between affected and non-affected samples. The pilot experiment (in which »750 mass spectra were generated) has so far revealed pattern differences that are apparent in serum fraction #4 (eluted at pH 5 column fractionation) assayed on the weak cationic exchange (WCX2) chip surface. From these data, it appears the autistic samples are lacking (or have a very reduced amount, compared to non-autistic samples) proteins at 6457, 6550, 17,440, and 28,100 daltons. These experiments demonstrate the potential for using the SELDI-TOF MS ProteinChip® technology to illuminate protein expression differences which, in turn, may lead to a better understanding of the functional genomic changes that underlie autism spectrum disorders. These studies were funded by the Wallace Foundation and the Autism Research Institute (ARI).

Application of IR-PCR for physical mapping of the autistic disorder candidate region on chromosome 15q12-q13. *S.-J. Kim, M.M. Menold, J.M. Vance, M.A. Pericak-Vance, J.R. Gilbert.* Department of Medicine and Center for Human Genetics, Duke University Medical Center, Durham, NC.

Chromosome 15q12-q13 has been implicated in the genetic etiology of autistic disorder (AutD). The physical mapping of this region is important to identify AutD candidate gene or genes on chromosome 15q12-q13. Previously, we generated a genomic contig map of the putative peak AutD candidate gene region. To identify 5' transcription sites and AutD candidate genes within the approximately 1.2-1.5 Mb contig, 28 BAC, PAC and P1 clones that span the region and contain Not I and numerous Eag I, BssHII and SacII sites were analyzed using Island Rescue PCR (IR-PCR). Eighty-three unique EagI, BssHII and SacII related sites were cloned and sequenced. We identified 45 unique CpG islands that met full CpG island criteria. The human draft sequence for 15q11-13 is unfinished. We performed a computation analysis of known sequence from the same region for CpG islands and identified 92 predicted CpG islands compared to our experimental IR-PCR results of 83 clones. The IR-PCR CpG islands were mapped onto the human chromosome 15 draft sequence assembly by BLAST analysis. Of the total 83 clones, 64 have been mapped onto the incomplete human genomic draft contig in this region. Of the 45 IR-PCR clones that met full CpG island criteria 31 were mapped to this region. We have used these CPG islands clones, derived from known genomic clones, to verify contig location and order in the assembly of the 15q12-q13 draft sequence. The assembly of 15q12-q13 draft contig was also compared with the comparative mouse map. Using a combination of northern blot analysis of CpG island clones and BLAST sequence analysis we have identified and mapped twenty clones that showed expression on northern hybridization to human fetal brain RNA, or a significant match to a known cDNA or EST.

Association studies of Renin-Angiotensin System (RAS) gene polymorphisms with clinical and histological features in primary IgA nephropathy (Berger's disease). *M. Brugnara¹, B. Brezzi², C. Patuzzo¹, M. Gomez-Lira¹, A. Lupo², G. Maschio², R. Magistroni³, A. Turco¹.* 1) Department of Mother & Child, Section of Genetics, University of Verona School of Medicine, Verona, Italy; 2) Division of Medical Nephrology, Unive of Verona, Italy; 3) Dept of Internal Medicine, Div of Nephrology, Univ of Modena, Italy.

With a population prevalence of up to 1.3%, IgAN represents the most common primary glomerular disease, and a leading cause of end-stage renal disease worldwide. The IgAN phenotype results from the complex interplay of genetic and non genetic factors. The RAS is well known to play a role in promoting kidney damage. In this study we tested whether RAS-gene polymorphisms (pol), already linked to several cardiovascular and kidney diseases, might be associated with clinical and/or histological features of IgAN. 95 unrelated Northern Italian biopsy-proven IgAN patients (pts) (aged 16 to 65y) were analysed for 1) the I/D pol of the angiotensin converting enzyme (ACE) gene, 2) two pol (T174M and M235T) in the angiotensinogen (AGT) gene, and 3) the A1166C pol of the angiotensin II receptor type 1 (ATR1) gene. At the time of biopsy all pts had measurements of their creatinine clearance (mean=98,8 ml/min), proteinuria (mean=1,25 g/die), and blood pressure, expressed as mean arterial pressure (MAP)(mean 100 mmHg). Using a multivariate analysis (ANOVA) we found significant association between the II ACE genotype and raised MAP at the time of biopsy (II pts=108+/-7 mmHg; ID and DD pts=99+/-11 mmHg; p=0,014), the percentage of the glomerular surface involved in sclerotic change (II pts= 28+/-10%-ID and DD pts= 11+/-5%; p=0,0006), and the chronicity index (II pts=5-ID and DD pts=3; p= 0,013). We also found that the AGT TT genotype 235T was associated with elevated proteinuria (TT pts= 1,8 +/-1 g/die-MT and MM pts= 1+/-0,8 g/die; p =0,009), high PAM (TT pts= 106+/-10 mmHg; MT and MM pts= 98+/-11 mmHg; p= 0,015), and the amount of mesangial proliferation (TT pts= 40%- MT and MM pts= 22%; p= 0,014). Thus, we present evidence that in our IgAN population some RAS gene variants appear associated with worsened clinical and histological outcomes.

Mutations in the SPINK 1 gene in idiopathic pancreatitis and neonatal hypertrypsinemia. *M. Gomez-Lira¹, D. Bonamini¹, C. Patuzzo¹, C. Castellani², L. Unis³, BM. Assael², PF. Pignatti¹.* 1) Mother & Child & Genetics, Univ Verona, Italy; 2) Cystic Fibrosis Center, Verona, Italy; 3) Transfusional Center, Hospital of Bussolengo, Italy.

Idiopathic chronic and acute recurrent pancreatitis (IP) and neonatal hypertrypsinemia, are genetically heterogeneous pancreatic alterations that have been associated with mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene. Mutations in the trypsinogen gene have been described in hereditary pancreatitis. Gain of function mutations of the trypsinogen gene lead to pancreatitis by enhancing activity or by preventing activated trypsin from being inactivated. Similar effects could be due to the loss of trypsin inhibitor function. Mutations in the serine protease inhibitor Kazal Type 1 (SPINK1) have been described in some IP patients. In this study we have analyzed the promoter region and the four exon and exon-intron boundaries of the SPINK1 gene in 32 IP patients, in 50 hypertrypsinemic neonates with normal sweat chloride level, and 50 controls. Mutation N34S (the most common mutation described in IP patients) was screened by genomic amplification followed by restriction analysis. Three IP patients (9.3%) and one control individual (2%) carried the N34S mutation of the SPINK1 gene. The 5'UTR and the four exons and exon-intron boundaries of the gene were screened for other mutations by DGGE analysis and sequencing. No other mutation was observed in IP patients that could be associated with an altered function of the SPINK1 protein. Interestingly, the N34S mutation was present in two patients who carried the 5T variant and one patient who carried the L997F mutation in the CFTR gene, suggesting a possible combined effect of the CFTR and the SPINK1 genes. We found no mutation in neonatal hypertrypsinemia indicating that the SPINK 1 gene is not likely to be associated with this phenotype.

Genetic susceptibility in cervical dystonia: confirmation of a role for the dopamine D5 receptor gene. F.

Brancati^{1,2}, EM. Valente¹, M. Castori^{1,2}, N. Vanacore³, S. Salvi¹, V. Caputo^{1,2}, B. Dallapiccola^{1,2}. 1) CSS Mendel Institute, Rome, Italy; 2) University of Rome La Sapienza Department of experimental medicine and pathology; 3) Istituto Superiore di Sanita, Rome.

Cervical dystonia (CD) is one of the most common form of primary dystonia. The pathogenesis of the disease is still unknown, although some evidence suggests a role for genetic factors. Recently, a polymorphism in the dopamine D5 receptor gene (DRD5) was associated to the disease in a British population, suggesting that DRD5 is a susceptibility gene for CD (Placzek et al.). To confirm these data, we performed a case-control study between the microsatellite (CT/GT/GA)_n at the DRD5 locus and two groups of 104 Italian dystonic patients and 104 healthy controls, matched for sex, age and ethnicity. The mean age of cases and controls was 49.6 14.9 years and 49.5 15.0 years respectively. Female to male ratio was 1.08. The frequency of allele 9 was higher in the group of CD patients compared to the control group (odds ratio = 2.44; 95% confidence intervals: 1.14-5.27; p=0.01), resulting in a double-fold increased risk of developing the disease. On the contrary, allele 3 was more common in control subjects compared with the patients group (odds ratio = 0.56; 95% confidence intervals: 0.30-1.06; p=0.06). Both susceptibility and protective DRD5 alleles in the present study were different to those reported in the British study. This is an interesting finding supporting the association between DRD5 and CD. In fact, the (CT/GT/GA)_n microsatellite is located at 5 outside the DRD5 coding region, making a functional role for this polymorphisms very unlikely. Therefore, we suggest that a functional, still unidentified, variant in DRD5 identical in the two populations, could be in linkage disequilibrium with two different (CT/GT/GA)_n alleles, depending on the different genetic background of the Italian and British populations. These results provide further evidence for an association between DRD5 and cervical dystonia, confirming the involvement of dopamine pathway in the pathogenesis of CD.

Drosophila as a model for discovering candidate genes in ADHD. *V. De Luca*¹, *P. Muglia*^{1,2}, *U. Jain*², *V.S. Basile*¹, *J.L. Kennedy*¹. 1) Neurogenetics, CAMH , Toronto, Ontario, Canada; 2) Adult ADHD Clinic, CAMH, Toronto, Ontario, Canada.

Attention deficit hyperactivity disorder (ADHD) is a prevalent psychiatric condition in children and follow up studies have indicated that 22-33% of patients continue to suffer from ADHD during late adolescence and adulthood. The risk factors for ADHD may be determined by additional mechanisms beyond the dopamine transporter and receptors. We are exploring new methodology for discovering these mechanisms. In drosophila, such an additional factor could be protein kinase G (PKG) that affects food-search behaviour. Here we initiated studies with the human homologue of PKG, the PRKG1 gene. The aim of this study was to investigate for the presence of linkage disequilibrium between the protein kinase G gene (PRKG1) and adult ADHD in a sample of 125 nuclear families. Genotyping data for the C2276T polymorphism were analyzed using the Transmission Disequilibrium Test (TDT). Sixty three nuclear families were informative for the TDT on C2276T polymorphism, which showed no preferential transmission of either allele (chi-square= 0.778, df=1, p= .316). These findings exclude a direct involvement of this genetic marker of the Protein kinase G gene in the pathogenesis of ADHD, but further studies of inattentive versus hyperactive subtypes and other SNPs at this locus, are warranted.

High Throughput Detection of Small Genomic Insertions and Deletions by Pyrosequencing technique. *D. Guo, Y. Qi, R. He, P. Gupta, D. Milewicz.* Dept Internal Medicine, Univ Texas/Houston Med Sch, Houston, TX.

The Human Genome Project has uncovered thousands of DNA sequence variants in the human genome including nucleotide tandem repeats, single nucleotide polymorphisms, and small insertions and deletions. These variants have been widely used as genetic markers for inherited disorder mapping, population genetics studies and forensic DNA analysis. Numerous techniques have been developed for high throughput detection of chromosomal variations such as (SNPs) and nucleotide tandem repeats. However, high throughput methods for detection of insertions and deletions of a small number of nucleotides are limited. In this report, we demonstrate that pyrosequencing technique can be used for a high throughput assay of these variations. Serial nucleotide deletions with 2bp, 5bp, 8bp, and 100bp respectively, were created in exon 8 of the versican gene, and then assayed by the pyrosequencing technique. The results showed that the pyrosequencing technique is able to detect up to 100bp nucleotide deletions and insertions. By modifying sequence program, this technique is able to detect a G deletion in FBLN5 and a complicated combination of an 11 bp nucleotide deletion and a 4 bp insertion in intron 33 of FBN2. Our results indicated that pyrosequencing technique is applicable for high throughput genotyping of nucleotide insertions and deletions in large populations for the study of genetic predisposition of disease.

A rare Eag I polymorphism that may confound fragile X diagnosis. *C.S. Dobkin¹, X.-H. Ding¹, G.E. Houck¹, E. Mitchell², W.T. Brown¹, S.L. Nolin¹.* 1) Dept Human Genetics, NYS Inst Basic Research, Staten Island, NY; 2) Las Vegas Perinatal Associates, Las Vegas, NV.

Fragile X diagnostic Southern analysis can detect deletions and restriction fragment length polymorphisms in addition to the triplet repeat expansion mutation. We have identified a rare Eag I polymorphism in the fragile X (FMR1) gene that reduces the normal EcoR I-Eag I restriction fragment from 2.8 kb to 1.9 kb. The polymorphism was identified in a boy (DOB 1/30/96) who was tested for the fragile X mutation because of delayed speech. This restriction polymorphism had originally been identified as a deletion by another laboratory. Southern analysis indicated that the mutation was located in intron 1 and that it was present on one of the mother's alleles. Sequence analysis showed that this polymorphism is a G-C transversion that results in a new Eag I site 651 nucleotides from the transcription start site. To determine whether the transversion was involved in the etiology of the delayed speech, we analyzed the FMR1 mRNA from a lymphoblastoid cell line established from the proband. Northern analysis indicated that the polymorphism had no effect on splicing or the abundance of the FMR1 transcript. The proband's younger brother who also has this polymorphism, shows no sign of developmental delay at 1 year of age. Review of Southern analyses of >200 normal X chromosomes did not reveal any additional occurrences of this new Eag I site. Thus, this is a rare intronic polymorphism that has no apparent effect on FMR1 expression but which can potentially lead to a mistaken diagnosis of the deletion form of the fragile X syndrome. Although point mutations and deletions affecting FMR1 function have been found, they are exceedingly rare. Polymorphisms that alter the fragile X diagnostic pattern but have no functional consequence are probably more common. As screening for fragile X is broadened to include individuals with only a slightly increased risk of carrying an FMR1 mutation, the detection of polymorphisms with no etiological significance is likely to increase.

Program Nr: 1966 from 2002 ASHG Annual Meeting

Mutation screen of the glutamate decarboxylase 67 (GAD67) gene and haplotype association study to unipolar depression. *J. Lappalainen*^{1,2}, *G. Sanacora*¹, *H.R. Kranzler*³, *R. Malison*¹, *L.H. Price*⁴, *J. Krystal*^{1,2}, *J. Gelernter*^{1,2}. 1) Yale University, School of Medicine, Department of Psychiatry, New Haven, CT; 2) VA Connecticut Healthcare System, West Haven, CT; 3) University of Connecticut, Department of Psychiatry, Farmington, CT; 4) Brown University, Butler Hospital and Department of Psychiatry and Human Behavior, Providence, RI.

Recent studies using ¹H-MRI to quantify gamma-aminobutyric acid (GABA) in human brain have demonstrated lower concentrations of this neurotransmitter in major depression (Sanacora et al., 1999). The majority of brain GABA is synthesized by glutamate decarboxylase-67 (locus, GAD67). This enzyme is therefore in a critical position for brain GABA homeostasis. We screened the translated regions of the GAD67 gene (16 exons) for mutations using SSCP and/or dHPLC in a sample of 43 individuals with major depression. We identified eight variants (5 base substitutions, 2 insertion/deletions and 1 tandem repeat). Three SNPs, located in the 5' non-coding, intron 8 and 3' non-coding regions of the gene, were genotyped in 103 European-American (EA) subjects with depression and 125 EA psychiatrically screened controls. The frequency of the rarer allele of the SNPs was > 20%. Linkage disequilibrium (LD) and haplotype frequencies were estimated using the 3LOCUS program (Long et al., 1995). Marker and haplotype frequencies were not significantly different between the cases and controls. Significant LD was observed between the 3' non-coding region and intron 8 SNP. These results start to establish a haplotype map for GAD67, and suggest that the GAD67 gene is not a major locus for predisposition to major depression.

Genotyping of the HTTLPR Ins/Del by dHPLC followed by Association/Linkage Disequilibrium to Behavior in a Southwest American Indian Isolate. X. HU, R. W. ROBIN, J. TAUBMAN, D. GOLDMAN. Lab of Neurogenetic, NIAAA/NIH, ROCKVILLE, MD.

BACKGROUND: Serotonin is pharmacobehaviorally implicated in anxiety/dysphoria and impulse control, both of which are genetically influenced. Serotonin's action as a neurotransmitter is terminated primarily by reuptake via the serotonin transporter (5-HTT). HTTLPR, a common 44bp ins/del polymorphism located in the 5' regulatory region of the gene, alters in vitro transcription and in vivo expression of the transporter. Linkage of this polymorphism to behaviors, particularly anxiety, has been reported. However, except for a previous sib-pair linkage in Finnish sibpairs, findings have been complicated by possibilities for ethnic stratification and genotyping errors inherent to gel-based genotyping. **METHODS:** We evaluated the relationship of HTTLPR to dimensionally measured anxiety and categorically assessed psychopathology in 582 Southwestern American Indians derived from inter-related pedigrees. dHPLC-based genotyping was performed by PCR of the GC rich region in the presence of 7-deaza-dGTP followed by automated analysis on a WAVE (Transgenomic, Inc., Omaha, NE) with a DNASep column and using 15 minute runs. Genotyping results were validated by comparison to genotypes from polyacrylamide gel. **RESULTS:** dHPLC is an efficient and highly accurate method for large-scale genotyping of this ins/del polymorphism. The transmission disequilibrium test (TDT) revealed the s allele was preferentially transmitted to affected individuals with alcoholism, posttraumatic stress disorder, anxiety, phobia, and major depression. **CONCLUSION:** These findings in an American Indian isolate support a role for HTTLPR in differential vulnerability to psychiatric disorders.

Program Nr: 1968 from 2002 ASHG Annual Meeting

Genetic risk detection using logistic regression analysis incorporating liability class applied in Alzheimer's disease. *K. Kamino¹, T. Kida¹, T. Miki², M. Takeda¹*. 1) Dept of Post-Genomics and Diseases, Osaka Univ. Grad. Sch. Med., Suita, Osaka, Japan; 2) Dept of Geriatric Medicine, Ehime Univ. Sch. Med., Ehime, Japan.

Genetic analysis of late-onset disease, especially Alzheimer's disease, is often difficult to replicate the positive association. This problem is partly due to disease penetrance. To solve this problem, we tested logistic regression with sex and apolipoprotein E allele with correction by liability class. We examined this statistics and found the risk for Alzheimer's disease in LDL receptor related protein (LRP), mitochondrial aldehyde dehydrogenase (ALDH2). Using this method, a polymorphism located at the short arm of chromosome 12 was also found to associate with Alzheimer's disease. This method will be useful to find the genetic risk sensitively .

The TGFb1 -509C/T promoter gene polymorphism as a risk factor for IgA nephropathy (IgAN)(Berger's disease). A. Turco¹, M. Gomez-Lira¹, M. Brugnara¹, B. Brezzi², A. Lupo², G. Gambaro³, F. Anglani³, D. Del Prete³, G. Maschio². 1) Dept of Mother & Child & Genetics, University of Verona School of Medicine, Verona, Italy; 2) Division of Medical Nephrology, Univ of Verona, Italy; 3) Dept of Medical & Surgical Sci, Nephrology Division, Univ of Padova, Padua, Italy.

TGFb1 is a cytokine that plays a critical role in the pathogenesis of glomerular damage by affecting cellular proliferation and matrix metabolism. In addition, it operates as an IgA-class switching factor, and its overproduction could also be etiologically involved in the individual susceptibility to IgAN, the commonest glomerulonephritis worldwide. Two TGFb1 gene polymorphisms, a C/T substitution at position -509 of the promoter region, and a T/C transition in exon 1 (cod10), are known to be associated with cardiovascular disease, nephritis, and with circulating protein levels. In this study we evaluated the possible association between these polymorphisms and the IgAN phenotype. 93 unrelated Italian patients and 100, sex matched healthy individuals from the same population were analyzed. Genotyping was performed by genomic DNA polymerase chain reaction (PCR), followed by restriction analysis. The results showed that the -509T variant was more frequent in IgAN patients than in controls, with allele frequencies of T=97/186 (53%) and T=75/200 (37%) respectively (p=0,0035). Genotype distributions were TT:CT:CC=22(24%); 53(57%); 18(19%) in IgA patients and TT:CT:CC= 14 (14%):47(47%):39(39%) in controls (p=0,003). The cod10 polymorphism showed no statistically significant differences between IgAN patients and controls. In summary, the presence of the -509T variant in the TGFb1 gene in our population appears to be a significant risk factor for the development of IgAN (OR=1,82-IC=98%-1,27 < OR <2,8).

Program Nr: 1970 from 2002 ASHG Annual Meeting

The *FMRI* Premutation Carrier And The Premature Ovarian Failure Phenotype. *A.K. Sullivan, L.J. Shubeck, E.G. Allen, W. He, J.J. Paquin, M.L. Leslie, L.H. Scott, S.L. Sherman.* Dept Human Genetics, Emory University, Atlanta, GA.

Premature ovarian failure (POF), defined as the cessation of menses before the age of 40, occurs in 1 in every 100 women in the general population. Approximately 20% of female *FMRI* premutation carriers experience POF. To date, the cause of POF in premutation carriers is unknown. In our study, we will evaluate whether *FMRI* CGG repeat size and/or parental origin is associated with increased risk for POF. Currently, we have obtained reproductive histories on 304 women ascertained through either families with the fragile X syndrome or the general population. We have confirmed *FMRI* CGG repeat size information on 214 of these women: 54 women have 61-199 repeats, 76 women have 41-60 repeats, and 84 women have <41 repeats. For those women with a *FMRI* CGG repeat size >40 repeats, parental origin information has been determined for 70 women. Follicle-stimulating hormone and luteinizing hormone levels have been measured on 89 women. Using linear and logistic regression analyses, we want to examine 1) if there is an association of age at menopause and/or POF with *FMRI* repeat size and 2) if parental origin of the large repeat size allele affects the risk for POF. If an association is found for repeat size and POF, we will determine the minimum number of repeats that increases the risk for POF. Preliminary data suggests that repeat size and parental origin may both play a role in the timing of menopause.

Mutation screening of candidate genes in congenital central hypoventilation syndrome. *I. Matera¹, T. Bachetti¹, R. Cinti¹, G. Santamaria¹, F. Mosca², F. Morandi³, M. Motta⁴, G. Ottonello⁵, R. Piumelli⁶, J.G. Schober⁷, C. Ghizzi⁸, M.P. Villa⁹, R. Ravazzolo¹, I. Ceccherini¹.* 1) Lab.Genetica Molecolare, G. Gaslini, Genova, Italy; 2) Dip. Neonatologia, Ist.Clin. di Perfezionamento, Milano, Italia; 3) U.O. Pediatria, Osp. Sacra Famiglia, Como, Italia; 4) U.O. Terapia Int. Neonatale, Spedali Civili, Brescia, Italia; 5) U.O. Anestesia e Rianimazione, Ist. G.Gaslini, Genova, Italia; 6) U.O. Terapia Int. Neonatale, Osp. Meyer, Firenze, Italia; 7) Kinderarzt-Kinderkardiologe-Neonatologe, Kinderklinik, Munchen, Germany; 8) U.O. Terapia Int. Pediatrica, Osp. Civile Maggiore, Verona, Italia; 9) Dip. Pediatria, Univ. La Sapienza, Roma, Italia.

Congenital central hypoventilation syndrome (CCHS, MIM 209880) is a rare neonatal disorder characterized by a failure of autonomic respiratory control. CCHS is frequently associated with Hirschsprung disease and tumors of neural crest origin. This has suggested a common molecular pathogenesis sustained by defect during the development of neural crest derived cells. We have already shown that the homeobox gene *RNX* is not mutated in our CCHS patients. The transcription factors *Mash1*, *Phox2a* and *Phox2b* are involved in the developing and specification of the autonomic nervous system. The *RET* proto-oncogene is normally expressed in cells of neural crest origin. On the basis of these observations, these genes were considered as candidate genes for CCHS. We have performed mutation screening by using denaturing high performance liquid chromatography and direct sequencing. No causative missense mutation of the entire coding region of the *ASH1* and *PHOX2B* genes was detected in any of the 19 CCHS index cases. *PHOX2A* and *RET* genes are under examination. We have also determined allele frequencies for five *RET* single-nucleotide polymorphisms in the CCHS patients. We found an association of some of these polymorphic *RET* variants with CCHS. This association suggests that this gene could contribute to the etiology of this disease, thus confirming a polygenic pattern of inheritance in CCHS. The search of additional candidate genes should be pointed toward genes involved in other neurocristopathies and/or in autonomic nervous system dysfunction.

SCA genotypes in Italian families with autosomal dominant cerebellar ataxia (ADCA). *C. Gellera*¹, *A. Brusco*², *A. Castucci*¹, *D. Vacca*¹, *C. Cagnoli*², *A. Saluto*², *C. Michelotto*², *C. Mariotti*¹, *S. DiDonato*¹, *F. Taroni*¹. 1) Div. Biochemistry & Genetics, Ist. Nazionale Neurologico C Besta, Milan, Italy; 2) Dept. Genetics, Biology & Biochemistry, University of Turin, Italy.

ADCA are a heterogeneous group of hereditary neurodegenerative disorders, primarily characterized by progressive cerebellar ataxia and clinically classified in different subgroups (ADCA I, IV). In the past few years, several genes (SCA genes) with different chromosomal localization were shown to be involved in the pathogenesis of these diseases, although the functions of most of the corresponding proteins are still unknown. The large majority of mutated genes harbor in the ORF an abnormal CAG expansion coding for a polyQ stretch; hence, a common pathogenic mechanism has been hypothesized in these disorders. Molecular investigations allowed genetic subgrouping of ADCA into spinocerebellar ataxias 1-17 (SCA1-17). SCA1, SCA2, SCA3, SCA6, SCA7, SCA12 and SCA17 are characterized by CAG repeat expansions while SCA8 is due to CTG enlarged repeats in the 3'UTR of a transcribed RNA and SCA10 is associated with the expansion of an intronic pentanucleotide (ATTCT) repeat. The other SCAs have been mapped by linkage analysis but the corresponding genes and molecular lesions have not been identified yet. We have clinically and genetically evaluated 172 Italian ADCA families. SCA1 and SCA2 were found to be the most common genotypes, accounting for 31% (54 families), and 36% (62 families) of cases, respectively. SCA3 (2 families), SCA6 (2 families), SCA7 (4 families), SCA8 (2 families), SCA17 (2 families) and DRPLA (3 families) were much less frequent. The remaining 41 families (24%) were found to be negative also for the recently identified mutations in SCA10, and SCA12 genes. The aim of this study is to report ADCA families presenting with rare genotypes in Italy and to select ADCA families negative for the known SCA genes in order to identify new SCA genes. Families with rare genotypes in Italy (i.e. SCA3, SCA6, SCA7, SCA8, SCA17 and DRPLA) have been closely examined either clinically and genetically.

Oxidative stress and apoptosis in the cellular model of Machado-Joseph Disease. *M. Hsieh¹, H.F. Tsai², S.Y. Li¹.* 1) Dept Life Sci, Chung Shan Med University, Taichung, Taiwan; 2) Institute of Medicine, Chung Shan Med University, Taichung, Taiwan, Republic of China.

Machado-Joseph disease (MJD) is an autosomal dominant spinocerebellar degeneration characterized by a wide range of clinical manifestations. Unstable CAG trinucleotide repeat expansion in MJD gene on long arm of chromosome 14 has been identified as the pathologic mutation of MJD. Because MJD is typically late-onset neurodegenerative disorder, we hypothesize that oxidative stress and apoptosis are contributory factors for the pathogenesis of this disease. In this study, we utilized neural SK-N-SH cells stably transfected with HA-tagged full-length MJD with 78 polyglutamine repeats to examine the effects of polyglutamine expansion on protein aggregation and cell survival under different stress. Our result showed that less than one percent of the mutant cells containing nuclear aggregates under basal condition. In addition, t-butyl hydroperoxide and various pro-apoptotic agents were used to assess the tolerance of the mutant cells. Cell Viability was determined by MTS assay. Mutant MJD cells were more sensitive to low concentration of t-butyl hydroperoxide (1 mM to 3 mM) than the normal cells without expanded MJD. We demonstrated that the ratio of GSH/GSSG increased about 4-fold in mutant MJD cells and the enzyme activities of Glutathione peroxidase and Glutathione reductase remained only 40% of those of the normal cells after 12-hour treatment of 1 mM t-BH. On the other hand, mutant MJD cells treated with 1 mM staurosporine showed significant decreased Bcl-2 level when compared to the normal cells. It is consistent to our observation that cells expressing mutant MJD were more sensitive to staurosporine-induced apoptosis. Taken together, MJD cells are more susceptible to the toxic insults than the normal cells without expanded MJD. We demonstrated that expression of full-length mutant MJD does not dramatically elevate protein aggregate formation under basal condition, but does significantly impair the ability of the cell viability to respond to stress and alter the redox status of the cellular proteins, which may lead to increase stress-induced cell death following stress.

Transglutaminase cross-linking of androgen receptor could inhibit the proteasome: possible pathogenic implications for spinobulbar muscular atrophy. *L.M. Mandrusiak^{1, 2}, L.K. Beitel¹, Y.A. El-haji^{1, 2}, T.C. Scanlon^{1,2}, C. Alvarado¹, B. Gottlieb^{1, 4}, M.A. Trifiro^{1, 2, 3}.* 1) Lady Davis Institute for Medical Research, Sir Mortimer B. Davis-Jewish General Hospital, Montreal, Canada; 2) Department of Human Genetics, McGill University, Montreal, Canada; 3) Department of Medicine, McGill University, Montreal, Canada; 4) Department of Biology, John Abbott College, Montreal, Canada.

Several different proteins bearing long polyglutamine (polyGln) tracts are known to cause neurodegenerative diseases by mechanisms that may involve a toxic gain of function. All these diseases are characterized by intracellular insoluble protein aggregates containing the Gln-expanded protein. The aggregates are ubiquitinated, but resistant to degradation by the proteasome. Expansions of the polyGln tract of the human androgen receptor (AR) cause spinobulbar muscular atrophy (SBMA). One established property of Gln residues is their ability to act as an amine acceptor in a transglutaminase-catalyzed reaction, resulting in a proteolytically resistant glutamyl-lysine cross-link. Transglutaminase (TG) is a calcium-dependent enzyme that naturally occurs *in vivo*. We have found that bacterially expressed AR is a substrate of guinea pig liver tissue TG *in vitro*. Both GST-AR fusion proteins and thrombin cleaved (to remove the GST) proteins were shown to react with TG. Western blots of the proteins following incubation with TG demonstrate that several different epitopes of the AR (1C2, polyGln tract, 441, amino acids 301-321, PG21, amino acids 1-20) appear to be lost. We propose that this is due to TG cross-linking of the AR, which interferes with antibody recognition. Interestingly, both intermolecular and intramolecular bonds appear to be formed. When AR with polyGln tracts of varying length were analyzed, it was found that expanded (50 Gln) AR has a greater propensity to form intermolecular bonds than the normal length protein. TG cross-linked intermolecularly bonded AR is hypothesized to decrease proteasome function by clogging the proteasome pore. The inhibited ubiquitin proteasome pathway could contribute to the selective cell death seen in the SBMA phenotype.

Histone Hyperacetylation and Reactivation of the Fragile X Syndrome Gene. *G. Neri*¹, *E. Tabolacci*¹, *R. Pietrobono*¹, *M.G. Pomponi*¹, *P. Chiurazzi*². 1) Institute of Medical Genetics, Catholic University, Rome, Italy; 2) Department of Pediatrics, University Hospital, Messina, Italy.

Fragile X syndrome is the most common inherited mental retardation condition and is almost always caused by the expansion of a CGG repeat in the promoter region of the *FMR1* gene, which is then abnormally methylated and becomes inactive. We demonstrated that treatment of fragile X lymphoblasts with the DNA demethylating drug 5-azadeoxycytidine (5-azadC) can reactivate the *FMR1* gene (Hum Mol Genet 7:109-113, 1998). Histone hyperacetylating drugs such as 4-phenylbutyrate and sodium butyrate alone induce only a modest reactivation, but strongly reinforce the effect of 5-azadC (Hum Mol Genet 8:2317-2323, 1999). We then investigated the methylation status of each CpG site in the *FMR1* promoter by bisulphite sequencing and proved that 5-azadC leads to a nearly complete demethylation of the promoter (Nucl Acids Res, in press). We went on to investigate the histone acetylation status using chromatin immunoprecipitation with polyclonal antiacetylated-H4 and antiacetylated-H3 antibodies (Upstate Biotechnology) and real-time fluorescent PCR with TaqMan probes specific for the *FMR1* and *HPRT* genes. We treated fragile X and normal lymphoblastoid cell lines with different concentrations of sodium butyrate and observed an increase of histone H4 acetylation and lesser increase (and sometimes a decrease) of histone H3 acetylation in treated cells. We found a similar increase in H4 acetylation after treatment of fragile X cells with 5-azadC alone, confirming that DNA demethylation eventually causes relaxation of chromatin conformation and histone reacetylation. We then explored the potential acetylating action of acetyl-L-carnitine (ALC), an FDA-approved drug which resembles butyrate. Preliminary results with ALC alone showed an increase of the immunoprecipitated DNA only from treated cells, although not clearly correlated with *FMR1* gene reactivation. Supported by grants from FRAXA Foundation, Sigma-Tau and MIUR, Italy.

Y Chromosome microdeletions in oligozoospermic and azoospermic idiopathic male patients. *F.E. Orkunoglu¹, H. Soydan², Y. Ozgok², Y. Saglam³, A. Sengul⁴, M. Dayanc², N. Imirzalioglu¹.* 1) Medical Genetics, Gulhane School of Medicine, Ankara, Turkey; 2) Urology, Gulhane School of Medicine, Ankara, Turkey; 3) University of Kadir Has, Dept Med Biology and Genetics, Istanbul, Turkey; 4) Immunology, Gulhane School of Medicine, Ankara, Turkey.

Y chromosome microdeletions have been reported as a possible genetic factor for male infertility. Molecular analyses of azoospermic and oligozoospermic males have suggested the existence of deletions in the four functional regions of intervals 5 and 6 on the Y chromosome associated with spermatogenic failure. The aim of this study was screening of microdeletions in the four-azoospermia factor (AZF) regions on the Y chromosome in Turkish infertile male patients with idiopathic azoospermia and oligozoospermia. 18 known sequence tagged sites (STS) primer pairs were tested in four multiplex PCR sets to detect Y microdeletions that associated with male infertility in patients and controls that are fathers. Microdeletions or gene-specific deletions were not detected in normospermic control subjects or in subfertile men with a sperm count of more than 1 10⁶/mL. Deletions of the AZFc region were detected in 3% of individuals with idiopathic azoospermia or oligozoospermia. AZFc may be the most important subregion to screen infertility. In addition, intact AZFa and AZFb subregions may be important for the presence of germ cells. As a result, the frequency of Y microdeletions in the Turkish population is similar to that from other countries.

Transmission of full mutation alleles from premutation males to daughters. *S.L. Nolin¹, C.S. Dobkin¹, L. Gane², X.H. Ding¹, G.E. Houck, Jr.¹, A.D. Gargano¹, A. Glicksman¹, S.Y. Li¹, W.T. Brown¹.* 1) NYS Institute for Basic Research in Developmental Disabilities, Staten Island, NY; 2) UC Davis M.I.N.D. Institute, Sacramento, CA.

In fragile X, the dramatic expansion in CGG repeat size to more than 200 in a full mutation is thought to occur exclusively on transmission from premutation females to their offspring. Males with premutation or full mutation alleles are observed to have premutation-size repeats in their sperm and transmit premutation alleles to their daughters. We report here two unrelated cases of transmission of full mutation-size repeats from premutation males to their daughters. In the first family, the FMR1 CGG repeat region was examined in DNA from the mother, father and three daughters. While the mother was found not to be a carrier for fragile X, the father carried a premutation allele of 105 repeats and two of the daughters carried alleles of 100 and 95 repeats. PCR analysis of a third daughter revealed a predominant band of 145 repeats and a series of bands extending into the full mutation range. Southern analysis revealed a series of unmethylated fragments that extended from premutation into the full mutation range, in addition to the bands representing the normal allele. In the second case, PCR and Southern analysis of one daughter of a premutation male revealed a series of repeats from 135 to >200. The unusual molecular patterns of the two females in these two families were notable for the unmethylated fragments observed in Southern analysis. This pattern is not associated with females carrying full mutation alleles that are maternally transmitted. Two similar cases have been reported elsewhere (Bridge et al., *Gen in Med* 1: 49, 23A, 1999; Ventura et al., *AJHG* 65:A471, 1999). We suggest a paternally transmitted allele may expand to a full mutation that has a distinctive molecular pattern. While this expansion leads to somatic instability typical of maternally transmitted full mutations, the size of the expansion is limited and does not appear to lead to aberrant methylation. This suggests that paternal transmission of the fragile X full mutation occurs by a unique mechanism.

A cerebellar FMR1 riboCGG binding protein. *T.C. Rosser, T.R. Johnson, S.T. Warren.* Howard Hughes Medical Institute and Department of Human Genetics, Emory University School of Medicine, Atlanta, GA.

Fragile X syndrome, a common form of mental retardation, results from an expanded CGG repeat in the 5' UTR of the FMR1 gene. Full mutations (>200 repeats) elicit silencing of the FMR1 locus and the absence of the FMR1 protein, FMRP. Premutation alleles (60-200 repeats) appear to be nonpenetrant for the full mutation phenotype, although such carriers have a higher incidence of other phenotypes. Premutation females have an increased incidence (24%) of premature ovarian failure when compared to the normal population (1%). Male premutation carriers may show an age-dependent progressive tremor and motor/gait problems. This is combined with cognitive decline associated with accumulations of inclusion bodies in cerebellar neurons and astrocytes. Since the premutation phenotypes are distinctive from those of fragile X syndrome, due to the absence of FMRP, it is possible that these phenotypes are RNA-mediated. We propose a mechanism similar to that described for another triplet repeat disorder, myotonic dystrophy (DM). In DM, a portion of the phenotype is thought to be due to the sequestering of a RNA-binding protein on the expanded rCUG-repeat. We hypothesize here that another RNA-binding protein, interacting with the rCGG-repeat of the FMR1 message, is similarly sequestered from its normal function(s) in premutation carriers. In order to identify such a rCGG-BP, we used in vitro transcription to fluorescently label RNA containing a CGG₍₁₀₅₎ repeat. We have shown by gel shift assays, the presence of a rCGG repeat binding protein in the cerebella of mice. Binding could be competed off with unlabelled rCGG but not with other RNA transcripts. Most interesting, this gel shift was not equivalent between male and female cerebellar lysates, suggesting this protein may be male-biased. Efforts currently are underway to purify the rCGG-BP and establish its identity by mass spectrometry.

CpG Methylation Modifies the Genetic Stability of Various Repeat Sequences. *C.E. Pearson^{1,2}, K. Nichol¹*. 1) Dept Genetics/Genomic Biol, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Dept Molecular & Medical Genetics, University of Toronto, Ontario, Canada.

Numerous disease states are associated with both repeat instability and aberrant CpG methylation, including fragile X mental retardation, myotonic dystrophy and specific cancers. The genetic stability of tandemly repeated DNAs is affected by repeat sequence, tract length, tract purity and replication direction. Alterations in DNA methylation status are thought to influence many processes of mutagenesis. Using bacterial and primate cell systems we have determined the effect of CpG methylation on the genetic stability of cloned di-, tri-, penta-nucleotide and minisatellite repeated DNA sequences. Depending upon the repeat sequence, methylation can significantly enhance or reduce its genetic stability. This effect was evident when repeat tracts were replicated from either direction. Unexpectedly, methylation of adjacent sequences altered the stability of contiguous repeat sequences void of methylatable sites. Of the seven repeat sequences investigated, methylation stabilized five, de-stabilized one and had no effect on another. Thus, while methylation generally stabilized repeat tracts, its influence depended upon the sequence of the repeat. The current results lend support to the notion that the biological consequences of CpG methylation may be effected through local alterations of DNA structure as well as through direct protein-DNA interactions. Since CpG methylation is highly regulated in a tissue- and development-specific manner its alteration may contribute to mutagenesis and disease etiology. Furthermore, methylation in bacteria may have technical applications to fill-in gaps or genomic "blind-spots" within genome draft sequences specifically enabling the analyses of DNA sequences that have been recalcitrant to isolation due to their extreme instability.

Bimodal, length-dependent, somatic instability of the GAA triplet-repeat sequence in Friedreich ataxia. R.

Sharma¹, S. Bhatti¹, M. Gomez¹, R. Clark¹, C. Murray³, T. Ashizawa⁴, S.I. Bidichandani^{1,2}. 1) Biochemistry & Molecular Biology, Oklahoma University Health Sci, Oklahoma City, OK; 2) Pediatrics, Oklahoma University Health Sci, Oklahoma City, OK; 3) Mathematics and Statistics, University of Central Oklahoma, Edmond, OK; 4) Neurology and VA Medical Ctr, Baylor College of Medicine, Houston, TX.

Friedreich ataxia is most commonly caused by large expansions of a GAA triplet-repeat sequence in the first intron of the *FRDA* gene. We have used small-pool PCR to investigate somatic instability of the GAA triplet-repeat sequence in peripheral leukocytes *in vivo*. We analyzed 15 normal alleles ranging from 8 - 25 triplets, one premutation allele with 44 triplets and 12 disease-causing expanded (E) alleles with 241 - 1105 triplets. Analysis of 7190 individual *FRDA* molecules derived from genomes containing E alleles showed a length-dependent increase in somatic variability with mutation loads ranging from 47 - 78%. E alleles with >500 triplets were four-fold more likely to undergo large contractions, 5% of which involved >50% of the initial allele length and 0.29% involved complete reversion to the normal / premutation size range. Conversely, E alleles containing <500 triplets showed an expansion bias. No somatic variability was detected in over 6000 *FRDA* molecules derived from carriers of normal alleles. The premutation allele with 44 uninterrupted GAA triplets was found to be unstable, ranging in size from 6 - 113 triplets. This establishes the threshold for somatic instability to between 26 and 44 uninterrupted GAA triplets in peripheral leukocytes *in vivo*, very similar to the observed threshold for expansions during germline transmission, and approximately the size of a eukaryotic Okazaki fragment. Consistent with the observed tendency for shorter E alleles (<500 triplets) to undergo expansion mutations, the premutation allele also showed a strong expansion bias. 6% of the 2304 *FRDA* molecules analyzed differed significantly from the initial allele length; 46% were expansions of 14 - 36%, but only 2% of the altered bands comprised similar sized contractions. We propose a replication-based model to explain the observed somatic instability.

Maternal uniparental isodisomy 20 in a fetus with trisomy 20 mosaicism: clinical, cytogenetic and molecular

analysis. *V. Velissariou¹, T. Antoniadi¹, J. Gyftodimou², K. Bakou¹, M. Grigoriadou², S. Christopoulou¹, A. Hatzipoulou¹, J. Donoghue¹, P. Karatzis³, E. Katsarou⁴, M.B. Petersen².* 1) Department of Genetics and Molecular Biology, Mitera Maternity and Surgical Center, Maroussi, Greece; 2) Department of Genetics, Institute of Child Health, Athens, Greece; 3) IVF Unit, Mitera Maternity and Surgical Center, Maroussi, Greece; 4) Department of Neurology, "P. & A. Kyriakou" Children's Hospital, Athens, Greece.

The clinical significance of trisomy 20 mosaicism detected prenatally remains uncertain, due to the rarity of liveborn cases with inconsistent clinical findings and lack of long-term follow-up and outcome. We describe a case of true trisomy 20 mosaicism in a liveborn girl with maternal uniparental isodisomy of chromosome 20 in the diploid blood cells. Trisomy 20 mosaicism was originally detected in amniotic fluid (98%) and was confirmed in the term placenta (100%), as well as in blood (10%) and urine sediment (100%) of the newborn. There was intrauterine and postnatal growth retardation but otherwise the newborn manifested no gross abnormalities. At 9 months of age moderate psychomotor retardation, central hypotonia with peripheral hypertonia, numerous minor morphogenetic variants, marked kyphosis, and extensive Mongolian spot were observed. To our knowledge this represents the first case of trisomy 20 mosaicism detected prenatally and confirmed in different tissues of the newborn, where uniparental disomy was demonstrated in the diploid cell line. It is discussed whether uniparental disomy for chromosome 20 in the diploid tissues of mosaic trisomy 20 fetuses can be of clinical significance.

Characterisation of a Microdeletion in Xp11.23 Cosegregating in a Small Family with X-Linked Retinitis Pigmentosa (RP2) and Psychosis. *D.L. Thiselton^{1,3}, O. Brandau², A. Meindl², B.P. Riley³, K.S. Kendler³, L. Van Maldergem⁴, A.J. Hardcastle¹.* 1) Dept. of Molecular Genetics, Institute of Ophthalmology, UCL, London, UK; 2) Abteilung fuer Padiatrische Genet der LMU, Munich, Germany; 3) Dept. of Psychiatry, VCU, Richmond, VA, USA; 4) Dept. of Medical Genetics, Institute of Pathology, Gerpennes, Belgium.

As part of a targeted STS-deletion screen of XLRP families to pinpoint the genomic critical region encompassing the RP2 gene, a family was identified in which 2 brothers, both affected with RP, shared a common deletion in Xp11.23. PCR analysis using a dense array of STS markers positioned onto a comprehensive physical map established that the deletion spanned ~700kb between markers DXS1408 and stsG9154, and includes the *RP2* gene. In addition to RP, the brothers share a history of psychosis, the more severely affected having a DSM-IV diagnosis of paranoid schizophrenia.

By analysis of genomic sequence data, we have generated novel STSs to more precisely delineate the deletion endpoints, and used both RT-PCR and bioinformatic tools to functionally annotate the deleted interval and identify genes and pseudogenes located within it. Long-range PCR, cloning and sequencing is now underway to determine the exact deletion breakpoint.

Several reports have provided evidence of a schizophrenia susceptibility locus on Xp11. The family described here may offer cytogenetic support for such a notion and assist in the search for associated genetic variants. Studies are in progress to more definitively ascertain the psychiatric phenotype in this family, to develop a characterized SNP map of the interval, and to examine the affected genes for mutations or sequence variants which may be associated with a similar disorder in relevant patient cohorts.

Genomic rearrangements resulting in *PLP1* deletion occur by non-homologous end-joining and cause different dysmyelinating phenotypes in males and females. *K. Inoue*¹, *H. Osaka*³, *V.C. Thurston*⁴, *J.T.R. Clarke*⁵, *A. Yoneyama*⁶, *L. Rosenbarker*¹, *T.D. Bird*⁷, *M.E. Hodes*⁴, *L.G. Shaffer*¹, *J.R. Lupski*^{1,2}. 1) Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Dept Pediatrics, Baylor Col Medicine, Houston, TX; 3) Dept Neurodegenerative Diseases, National Center for Neuroscience, NCNP, Tokyo; 4) Dept Med and Molec Genetics, Indiana Univ, Indianapolis, IN; 5) Dept Genetics, The Hospital for Sick Children, Toronto, Ontario; 6) Dept Pediatrics, National Rehabilitation Center for Disabled Children, Tokyo; 7) Dept Neurology, and Medicine, Univ of Washington, Seattle, WA.

Duplication of *PLP1* is responsible for the majority of patients with Pelizaeus-Merzbacher disease (PMD), while deletion of *PLP1* is infrequent. Genomic mechanisms for these submicroscopic chromosomal rearrangements remain unknown. We identified two families with *PLP1* deletion that arose from two different genomic recombination mechanisms. In one family, *PLP1* deletion resulted from a maternal balanced submicroscopic interstitial translocation of the entire *PLP1* gene to the telomere of the chromosome 19 (19qtel). *PLP1* on the 19qtel is probably inactive by virtue of a position effect, because a healthy male sibling carries the same 19qtel(*PLP1*) along with a normal X chromosome. In the other family, the deletion occurred during meiosis of a maternal grandfather via sister chromatid exchange. Genomic mapping of the deleted segments in three *PLP1* deletion families reveals that the deletions are smaller than most of the *PLP1* duplications and involve fewer genes. We hypothesize that the deletion is infrequent because larger deletions may be deleterious. Analyses of the DNA sequence at the recombination junction reveal *Alu-Alu* recombination in the translocation family. In the other two families, no homologous sequence was found flanking the breakpoints, but the distal breakpoints were embedded in low copy repeats (LCR-PMD), suggesting the potential involvement of LCR-PMD in these rearrangements. In one family, junction sequences revealed a complex recombination event. Our data suggest that *PLP1* deletions are not mediated by non-allelic homologous recombination at LCR, but rather non-homologous end-joining.

Several Novel Androgen Receptor Gene Mutations associated with Diverse Presentations of Androgen

Insensitivity Syndrome. *O.T. Mueller*^{1,3}, *H. Mason-Suares*^{1,2}, *A.W. Root*^{1,3}. 1) Molecular Genetics Laboratory, All Children's Hosp, St Petersburg, FL; 2) Eckerd College, St. Petersburg, FL; 3) University of South Florida College of Medicine, Tampa, FL.

Androgen Insensitivity Syndrome (AIS) presents in X,Y individuals as either complete (C), partial (P) or mild (M) forms and is associated with mutations in the androgen receptor (AR) gene. Individuals with CAIS have external female genitalia but have testes and are infertile. Partial AIS presents as individuals with ambiguous external genitalia or males with microphallus or hypospadias. Mild AIS presents as undervirilized males with gynecomastia. We determined the DNA sequence of the eight coding exons of the androgen receptor gene in 11 individuals referred for possible AIS. Five cases presented with ambiguous genital (possible PAIS) and six cases presented with female external genitalia (possible CAIS). Data on internal genitalia and steroid levels are available from some, but not all patients. All patients have an X,Y karyotype and a grossly normal SRY gene (not sequenced). Only one of the PAIS cases was found with a pathogenic mutation: a AGC->AGT synonymous change in codon 888 that introduces a cryptic splice donor sequence. This mutation was previously described and causes an alternate transcript skipping part of exon 8 and the 3'UTR. Normal length transcripts are also produced, explaining the partial phenotype. Three of the six cases of CAIS were found to have pathogenic mutations: one case with a previously described Asp to Ser change at codon 705 (N705S). Another CAIS case was discovered to have a C to A change at -59 bp from the start of the fourth exon. This intron change was not previously reported and it was not present in any of the other cases or 10 normal controls. The familial inheritance of this putative mutation will be presented to help establish its pathogenicity. A third case of CAIS was discovered to have a deletion of guanine in codon 870 that caused a frame shift revealing a premature stop triplet at codon 881. This is apparently one of the first descriptions of a frameshift deletion in the androgen-binding domain of this gene causing CAIS.

The Oral-facial-digital syndrome type 1 gene codes for human metanephric mesenchymal protein. *L. Romio¹, V. Wright¹, K. Price², P.J.D. Winyard², S. Malcolm¹, A.S. Woolf², S.A. Feather².* 1) Clinical & Molecular Genetics, Institute of Child Health UCL, London, UK; 2) Nephrourology Unit Institute of Child Health UCL, London, UK.

We recently identified OFD1, the gene responsible for the oral-facial-digital syndrome type 1, a cause of dominant polycystic kidney disease (PKD) and malformation of the face, oral cavity and digits. To date only a handful of mutations have been reported and nothing is known about the OFD1 protein. WAVE analysis and sequencing of the 23 OFD1 exons in further cases revealed several novel mutations, both in familial and sporadic cases, the majority leading to premature truncation of the protein. We analysed expression of OFD1 in first trimester normal human embryos: RT-PCR shows that OFD1 is widely expressed during development; with northern blot we could detect OFD1 mainly in brain, kidney, limb and tongue which are all organs affected by the disease. We raised a polyclonal antibody to a C-terminal epitope of the protein. In normal human embryos OFD1 immunolocalised to metanephric mesenchyme, oral mucosa, nasal and cranial cartilage and brain. We generated human renal mesenchymal cell lines and by western blot we detected a band of approximately 120kD, consistent with OFD1 size; a similar signal was also present in lysate of whole metanephroi. This is the first demonstration that OFD1 transcript and protein are expressed in early human development; based on the metanephric expression pattern OFD1 may play a role in differentiation of the renal mesenchymal lineage into nephrons.

A Novel Cell Model of the Polyglutamine Disease Spinal and Bulbar Muscular Atrophy. *J.L. Walcott^{1,2}, D.E. Merry²*. 1) Department of Pharmacology, University of Pennsylvania School of Medicine, Phila., PA; 2) Biochemistry and Molecular Pharmacology, Thomas Jefferson University, Phila., PA.

Spinal and bulbar muscular atrophy (SBMA) is one of a group of chronic progressive neurodegenerative diseases resulting from a polyglutamine repeat expansion. In SBMA patients, the polymorphic trinucleotide CAG repeat in exon 1 of the androgen receptor (AR) gene is increased, resulting in polyglutamine tract expansion. We have created a tetracycline inducible cell model of SBMA in PC12 cells expressing full-length androgen receptor with 112 repeats. Cells expressing highly expanded AR112 form ubiquitinated intranuclear inclusions containing the amino terminal portion of AR and heat shock proteins. The inclusions appear as distinct granular electron dense structures in the nucleus by electron microscopy. The formation of AR-containing inclusions is substantially increased with ligand treatment and correlates with decreased cell survival. This model mimics the formation of inclusions containing the amino terminal portion of AR and ubiquitin seen in patients and will serve as an excellent system for the study of SBMA pathogenesis and treatment.

Molecular modelling of CDH23 carrying missense mutations that cause DFNB12 strongly suggests impaired calcium-binding. A.P.M. de Brouwer^{1,2}, M. Roeters³, L.M. Astuto⁴, C.W.R.J. Cremers², F.P.M. Cremers¹, H. Kremer².
1) Department of Human Genetics, UMC St. Radboud, Nijmegen, The Netherlands; 2) Department of Otorhinolaryngology, UMC St. Radboud, Nijmegen, The Netherlands; 3) CMBI, University of Nijmegen, Nijmegen, The Netherlands; 4) Gene Marker Laboratory, Boystown National Research Hospital Omaha, NE, USA.

Mutations in the cadherin 23 gene (*CDH23*) cause recessive deafness DFNB12, Usher 1D and atypical Usher syndrome. DFNB12 is caused by missense mutations, whereas Usher 1D is caused by protein truncating mutations. Atypical Usher syndrome can be caused by both missense and truncating mutations. *CDH23* is part of the cadherin superfamily, of which the members are characterized by calcium-binding extracellular cadherin (EC) repeats that mediate cell-to-cell contact. *CDH23* is expressed in the inner and outer hair cells of the cochlea. The stereocilia organization of these hair cells is disrupted in *waltzer* (*v*) mice, the mouse model for Usher 1D. Primarily based upon these observations, *CDH23* is proposed to be part of the tip links or of the lateral links between the stereocilia. We identified two new missense mutations in *CDH23* in a family with sensorineural hearing loss. The EC repeats of *CDH23* containing these mutations as well as seven other EC repeats with mutations described elsewhere were aligned, which suggested that the substituted amino acid residues are part of the highly conserved calcium-binding sites. Molecular modelling of the mutated EC repeats based on the structure of E-cadherin, clearly showed that calcium-binding is impaired. Since calcium provides rigidity to the elongated structure of cadherin molecules enabling homophilic lateral interactions, these mutations are likely to impair interactions of *CDH23* molecules either with *CDH23* or with other proteins. By molecular modelling we computed the total length of the 27 EC domains from *CDH23* to be approximately 120 nm. This supports the suggestion that *CDH23* is a component of the lateral links, since the length is in the order of half the distance between neighbouring stereocilia in mouse.

Fine-mapping of the DFNA18 region and exclusion of ZNF9 as the disease gene. *D. Boensch^{1,3}, J. Schickel¹, R. Lang-Roth², C. Neumann¹, O. Witte³, A. Lamprecht-Dinnesen², T. Deufel¹.* 1) Institut fuer Klinische Chemie, Friedrich-Schiller Universitaet, Jena, Jena, Germany; 2) Poliklinik fr Phoniatrie und Paedaudiologie, Universitaet Muenster, Germany; 3) Klinik fuer Neurologie, Friedrich-Schiller Universitaet, Jena, Jena, Germany.

We have previously mapped a locus for non-syndromic autosomal dominant hearing loss, DFNA18, to a region on chromosome 3q22 overlapping the PROMM/DM2 locus. The majority of PROMM-pedigrees seem to map to the DM2 locus, and hearing loss has been described as one clinical feature in PROMM disease. This situation parallels that in myotonic dystrophy (DM1), localised on chromosome 19, where in some pedigrees hearing loss has even been reported as the only presenting symptom. Recently, a CCTG expansion (mean approximately 5000 repeats) within intron 1 of the zink finger protein 9 gene (ZNF9), segregating with the disease, has been identified in PROMM pedigrees mapped to the DM2 locus. The gene consists of five exons, four of which contain coding information for two alternatively spliced products. ZNF9, which is also known as cellular nucleic acid-binding protein (CNBP), contains 7 zinc-finger domains and has been implicated in the negative regulation of cholesterol biosynthesis as well as the modulation of the activity of human beta-myosin heavy chain gene (beta-MHC) by interaction with a repressor region; its developmental expression has been shown in *xenopus laevis*. We have excluded repeats and mutations within the ZNF9 gene in DFNA18 patients. After analysing further members of the pedigree, we were then able to fine-map the DFNA18 region which is now more telomeric, overlapping with DFNB15. Candidate genes, partially with cochlear expression, have been identified and sequencing is on the way.

Molecular analysis of the PDS gene in 16 families with Pendred syndrome. *D. Feldmann¹, F. Denoyelle², V. Duval¹, O. Messaz¹, R. Couderc¹, C. Petit³, E.N. Garabedian², S. Marlin⁴.* 1) Laboratoire de Biochimie, Hopital A. Trousseau, AP-HP, Paris, France; 2) Service d'ORL pediatrique, Hopital A. Trousseau, AP-HP, Paris, France; 3) Unite de genetique des deficits sensoriels, Institut Pasteur, Paris, France; 4) Unite de Genetique Clinique, Hopital A. Trousseau, AP-HP, Paris, France.

Pendred syndrome is an autosomal-recessive disorder characterized by congenital sensorineural hearing loss combined with goitre. It may account for as many as 10% of the cases of hereditary deafness. Mutations in PDS gene have been observed in patients with Pendred syndrome or with non syndromic deafness linked to 7q31 (DFNB4). We have studied the PDS gene in 16 unrelated families with Pendred syndrome. All the patients were prelingually deaf, with moderate or profound deafness. Cochlear malformations or a widened vestibular aqueduct was documented in 13/16. Goitre and or an abnormal perchlorate discharge test was present in all cases. We have developped a DGGE/sequencing method analysis of the entire coding part of the PDS gene. A large spectrum of mutations have been observed, but three mutations (Y530H, T416P, V138F) have been observed in respectively 12.5, 9.3 and 6.2% of all the mutated alleles. Three new mutations have been identified : S133X, IVS14+1G/A and S137P. The phenotype associated with these mutations will be described.

A deletion involving the GJB6 gene is not a frequent cause of nonsyndromic deafness in the Greek population. A.

Hatzaki¹, A. Pampanos², T. Antoniadis¹, T. Iliades³, N. Voyiatzis³, J. Economides⁴, P. Leotsakos⁴, P. Neou⁵, M. Tsakanikos⁵, I. Konstantopoulou⁶, D. Yannoukakos⁶, M. Grigoriadou², A. Skevas⁷, M.B. Kyriakou" Children's Hospital, Athens, Greece; 6) National Center for Scientific Research "Demokritos", Athens, Greece; 7) University of Ioannina, Greece.

Mutations in the gene encoding the gap junction protein connexin 26 (GJB2) at the DFNB1 locus are responsible for up to 40% of all cases of nonsyndromic prelingual deafness in different populations. However, a fraction of patients with GJB2 mutations have only one mutant allele, and some familial cases with linkage to the DFNB1 locus but with no mutation in GJB2 have also been reported. Recently, a deletion involving the GJB6 gene encoding connexin 30, which is also located at the DFNB1 locus, was reported in a proportion of prelingual deafness patients heterozygous for a GJB2 mutation. Homozygosity for the GJB6 deletion was also reported in a few deafness patients. We therefore thought to screen for the GJB6 deletion in a population-based material of prelingual deafness from Greece. The material consisted of 210 unrelated Greek patients (45 familial/165 sporadic cases) with nonsyndromic, prelingual, sensorineural deafness from various regions of the country. Biallelic GJB2 mutations were detected in 70 of the patients (33.3%), whereas 6 patients were heterozygous for the 35delG mutation with no second mutation detected by sequencing of the entire coding region of the GJB2 gene. Screening for the GJB6 deletion was carried out in the 6 35delG/- heterozygotes and in 25 familial cases without GJB2 mutations, using a specific PCR assay to amplify the breakpoint junction of the 342-kb deletion involving GJB6 (NEJM 2002;346:243-9). The GJB6 deletion was not detected in our material. We conclude that the GJB6 deletion is not a frequent deafness mutation in the Greek population as previously described in Spanish, French and Ashkenazi Jewish populations.

Prestin, a cochlear motor protein, is defective in non-syndromic recessive deafness. *X.Z. Liu¹, X.M. Ouyang¹, X.J. Xia², J. Zheng³, L. Fang¹, A. Pandya², L.L. Du¹, D. Corey⁴, K.O. Katherine⁵, C. Petit⁶, R.J.H. Smith⁷, K.S. Arnos⁵, P. Dallos³, T. Balkany¹, W.E. Nance², Z.Y. Prestin, a membrane protein that is predominantly expressed in the outer hair cells (OHCs) of the cochlea, is a member of a newly recognized class of molecular motors. This family of genes encodes anion-transporter-related proteins, specifically, solute carrier family (SLC) 26. Nine human genes have been cloned so far, including SLC26A2, SLC26A3, SLC26A4, and SLC26A6. Mutations in SLC26A4 can cause Pendred syndrome as well as autosomal recessive non-syndromic deafness. The discrete localization of prestin expression in the OHCs makes it a strong candidate gene for a human deafness. Here we report the cloning and characterization of the human prestin gene, SLC26A5. SLC26A5 is composed of 20 exons with a coding region of 2232 bp, spanning a genomic region of over 70 kb on chromosome 7. Histochemical studies of mouse cochlear preparations showed immunostaining for prestin only in the OHCs. The expression profile of prestin was also studied through RT-PCR and northern blot. Moreover, we have identified a 5-UTR splice acceptor mutation (IVS2-2A>G) in this gene which is responsible for recessive non-syndromic deafness in two unrelated families, thereby assigning an essential function to prestin in the hearing process. Supported by NIH R01 DC05575.

Frequency of the Connexin 30 deletion (Cx30del) in deaf probands from the U.S. and its occurrence of *cis* with Connexin 26 (Cx26) mutations. *W. Nance*¹, *X. Xia*¹, *V. Gupta*¹, *K. Arnos*², *K. Welch*², *B. Landa*¹, *S. Dobrowski*³, *S. Blanton*¹, *A. Pandya*¹. 1) Dept Human Genetics, Virginia Commonwealth Univ, Richmond, VA; 2) Dept Biology, Gallaudet Univ, Washington, DC; 3) NeoGen, Pittsburgh, PA.

Profound deafness affects 1 in 1000 newborns, with 50% or more having a genetic etiology. In the U.S., mutations in the Cx26 (GJ2) gene are the most common genetic cause. Del Castillo et al. (NEJM 346:243-249, 2002) recently described the digenic transmission of deafness resulting from mutations of the Cx26 and Cx30 (GJB6) genes, located within ~400 kb region on 13q12 and are both expressed in the cochlea. Deafness results when a recessive Cx26 mutation is paired in trans with a 342 kb deletion involving the Cx30 gene. Homozygotes for the deletion are also deaf. Although a digenic interaction between the products of the two genes is suspected, it has not been possible to exclude the possibility that the deletion simply influences the activity of a 5' regulator of Cx26. To determine the frequency of Cx26/Cx30 deafness in the U.S., we screened 626 deaf probands from a large national DNA repository. Among 430 deaf probands with normal Cx26 alleles, 1 was homozygous and 4 heterozygous for the Cx30del; among 62 heterozygotes for pathologic Cx26 alleles, 11 Cx30del carriers were found. Of particular interest, 1 of 134 Cx26 homozygotes was also a Cx30del carrier and must have carried the two mutations in *cis*. The frequency of Cx30del in our deaf probands is 0.014, and 17.7% of those who were heterozygous for recessive Cx26 alleles also carried Cx30del which thus accounted for their deafness. We have observed a second possible example of the *cis* configuration in a proband who appeared to have inherited a dominant form of deafness. If *cis* mutations do cause hearing loss, it would indicate true digenic inheritance rather than a regulatory interaction between the two genes. It could also provide a plausible explanation for Cx26 alleles that appear to be dominant in some families and recessive in others. Cx30 is an important feature of Connexin deafness, but the fact that Cx30del explains a fraction of deaf Cx26 heterozygotes clearly suggests the existence of other epistatic loci.

Suppression subtraction hybridization as a tool to identify cochlea-specific genes. *M.W.J. Luijendijk¹, H. Kremer², G. van Duijnhoven¹, T.R.J. van de Pol¹, H.G. Brunner¹, F.P.M. Cremers¹.* 1) Human Genetics, Univ Med Ctr Nijmegen, Nijmegen, The Netherlands; 2) Otorhinolaryngology, Univ Med Ctr Nijmegen, Nijmegen, The Netherlands.

To identify cochlea-specific genes, a cDNA library was constructed via suppression subtraction hybridization using human fetal cochlea RNA (16-22 weeks) as the starting material. The procedure was effective as could be shown by the enrichment of cDNAs representing cochlea-specific genes and the subtraction of cDNAs representing house keeping genes. After sequencing, 2616 clones could be analyzed further by BLAST analysis with EST-databases and databases with genomic sequences. Thereby, the majority of the clones could be accurately mapped on the human genome. Based on the BLAST analysis the clones can be grouped in five clusters. (1) Clones that represent a known gene (32 %) including several known deafness genes. (2) Clones that show homology with a known genomic sequence but not with known ESTs (32%). (3) Clones that show homology with known ESTs, but not with known genomic sequences (4%). (4) Clones that show homology with both known genomic and EST sequences. (5) Clones that show neither homology with known genomic sequences nor ESTs (4%). Clones in clusters 2, 4, and 5 represent, at least in part, new genes. To select clones representing genes that are specifically and/or preferentially expressed in the cochlea and thereby representing candidate genes for inherited hearing loss, we performed a semi-quantitative RT-PCR on twelve human fetal tissues. We first studied clones located in known deafness loci for which the causative gene has not yet been identified. Clones located in 9 DFNA loci and 12 DFNB loci were present in the analyzed clone set and a number of interesting clones emerged from this analysis. Now, clones from cluster 2 and 4 are under study. A selection of clones will be studied in more detail by isolating the full-length cDNA sequence and by determining the intron-exon structure. To address involvement of these genes in hearing loss, they will be tested for the presence of mutations in relevant families and/or a patient cohort.

Low frequency of the GJB6 342 Kb deletion in the belgian deaf population. *P. Hilbert¹, W. Wuyts², I. Del Castillo³, L. Mariage¹, N. Peeters², S. Ligny⁴, I. Courtmans⁴, A.F. Fourneau⁵, F. Moreno³, G. Van Camp², L. Van Maldergem¹.*

Congenital deafness is observed in 1 out of 1000 newborns. Approximately 50 % of these are thought to have a monogenic cause. The majority of individuals with non-syndromic genetic hearing loss show an autosomal recessive inheritance and mutations in GJB2 gene, encoding the gap-junction protein connexin 26, are responsible for about 50% of those cases. Interestingly, different studies have reported that 10 to 40 % of patients present only one mutant GJB2 allele. This proportion, unexpected since far higher than the population carrier frequency (varying from 2 % in the USA to 4 % in Italy), suggested the involvement of a mutation in a non-coding part of the gene or of a digenic effect. Recently, a 342 kb deletion upstream of GJB2, deleting another connexin gene (GJB6) located less than 50kb away, was shown to be associated to deafness both in the homozygous status and in heterozygosity with a GJB2 point mutation in trans. This deletion, called D(GJB6-D13S1830) was found in 22 out of 44 patients (50 %) heterozygous for a single GJB2 mutation from the Spanish population. This proportion raised to 22/33 (65%) if patients clearly not linked to DFNB1 were removed. The aim of our study was to evaluate the importance of the GJB6 in the belgian population. We analyzed 32 deaf individuals who were heterozygous for only one GJB2 mutation. Only 4 of these 32 heterozygous patients (13%) had the DGJB6 deletion. Our study shows that the DGJB6 deletion is significantly less frequent in Belgian GJB2 heterozygotes compared to Spain (2/32 versus 22/44 of the GJB2 heterozygotes, $p=0.001$). Our results indicate that DGJB6 is not sufficient to explain the excess of GJB2 heterozygotes in Belgium, and that additional mechanisms must exist.

A mutation of ESPN causes autosomal recessive nonsyndromic hearing loss, *DFNB36*. S. Naz¹, S. Riazuddin¹, S. Riazuddin³, A.J. Griffith², T.B. Friedman¹, E.R. Wilcox¹. 1) Section on Human Genetics, LMG, NIDCD, Rockville, MD; 2) Section on Gene Structure and Function, LMG, NIDCD, Rockville, MD; 3) National Centre of Excellence in Molecular Biology, Punjab University, Lahore, Pakistan.

In the inner ear, the stereocilia of hair cells contain parallel bundles of cross-linked actin filaments. Espin functions as an actin-bundling protein. A mutation in *Espn* encoding espin causes deafness and vestibular dysfunction in the *jerker* mouse (Zheng et al. 2000, Cell 102:377). We have ascertained a family segregating hereditary hearing loss due to a mutation of *ESPN*. Hearing loss is one of the most prevalent sensory defects in humans. Since 1994, 35 nonsyndromic autosomal recessive deafness loci have been mapped, designated as *DFNB1* to *DFNB35*, and 15 of these genes have been identified. We performed a genome-wide search to identify the gene responsible for hearing loss in a consanguineous family from Pakistan with four affected individuals exhibiting prelingual, sensorineural, profound deafness. A 6 cM region was identical by descent in the affected individuals on chromosome 1p36 between markers *DIS2845-DIS2694*. A two-point lod score of about 4.0 was obtained with the linked markers defining a new recessive deafness location, *DFNB36*. *ESPN* is one of the genes in the 1p36 critical interval and was a candidate for *DFNB36* due to the association of a mutation in the mouse ortholog *Espn* with hearing loss in *jerker* mice. *ESPN* exons were PCR amplified and sequenced. We found a mutation in *ESPN* co-segregating with hearing loss. All affected individuals were homozygous for a four base pair deletion resulting in a frameshift predicted to affect the last thirty amino acids of *ESPN*. The obligate carriers in the family were heterozygous and this mutation was not detected among 150 unaffected control DNA samples from Pakistani individuals. Deletion mutagenesis experiments have suggested that *Espn* contains two actin-binding sites at its carboxy terminus (Bartles et al. 1998, J Cell Biol 143:107). The mutation identified in the affected individuals of the *DFNB36* family affects the second of the two actin binding domains. Our results establish *ESPN* as an essential protein for hearing in humans.

Mapping of a new autosomal recessive nonsyndromic hearing loss locus (DFNB32) to chromosome 1p13.3-22.1. S.

Bourguiba Sfax, Tunisie; 3) Unite de Genetique des Deficits Sensoriels, Institut Pasteur Paris, France; 4) Centre National de Genotypage, Evry, France; 5) Collagen Research Unit, Biocenter and Department of Medical Biochemistry and Molecular Biology, University of Oulu, Finland; 6) Service d'Ophtalmologie, C.H.U. H. Bourguiba Sfax, Tunisie.

Approximately 80% of the hereditary hearing loss is nonsyndromic. Isolated deafness forms transmitted in the recessive mode are the most frequent (85%) and the most severe. Thirty-one different DFNB loci have been mapped and 13 of the corresponding genes have been identified. We have ascertained a large consanguineous Tunisian family with congenital profound autosomal recessive deafness. All affected individuals are otherwise healthy, with normal life spans and without dysmorphic or other abnormal findings. Genotype analysis excluded linkage to known recessive deafness loci in this family. Following a genome wide, a linkage was detected only with locus D1S206 on chromosome 1, thereby defining a novel deafness locus, DFNB32. In order to confirm linkage and for fine mapping the genetic interval, 12 individuals belonging to this family were added and 19 microsatellite markers were tested. A maximum two-point lodscore of 4.1 was obtained at marker D1S2896. The interval of DFNB32 locus overlap with DFNA37 locus. In an effort to identify the DFNB32 gene, we have tested the Coll11A1 gene that have been mapped to the DFNB32 interval. This gene is an excellent candidate because : (i) is responsible of two syndromic deafness, Marshall and stickler syndromes (ii) mutations in the homologue mouse mutant produce hearing impairment. The entire coding region of Coll11A1 was screened and no mutation was observed. Towards the identification of the gene, a search of the Human Cochlear cDNA Library and EST Database was done. A gene corresponding to one of the EST found is being screened.

Five novel mutations in the SLC26A4 gene, associated with Pendred Syndrome. *L.H. Hoefsloot, A. Claassen, M. Leferink, I. de Wijs, H. Scheffer.* Dept Human Genetics, University Medical Center, Nijmegen, Netherlands.

Pendred Syndrome is characterized as an autosomal recessive congenital neurosensory deafness, often accompanied by a vestibular function defect, cochlear malformation, and goiter. Mostly patients are euthyroid, with compensated hypothyroidism. Pendred Syndrome is caused by mutations in the SLC26A4 gene.

The most common form of inner ear abnormality, enlarged vestibular aqueduct (EVA), is associated with characteristic clinical findings, including fluctuating and sometimes progressive sensorineural hearing loss and disequilibrium symptoms. Patients with EVA do not fulfill the criteria for Pendred syndrome, but in many cases also mutations in the SLC26A4 gene are found.

Despite its apparent homology to sulphate transporters, the SLC26A4 gene encodes a chloride-iodide transport protein. Iodide is an important anion in the thyroid, and this might explain the thyroid involvement. Its precise function in the mid-ear is uncertain, but given the enlargement of the aqueduct in most cases, a function in the chloride transport has been inferred.

Twenty two patients diagnosed or suspected with Pendred Syndrome or EVS were sent for mutation analysis in the SLC26A4 gene. All 21 exons including the intron-exon boundaries were examined using sequence analysis. In 10 patients two mutations were identified. Of these 20 alleles, 7 alleles (35%) had the L236P mutation and 2 (10%) had the T416P mutation. However, 6 alleles carried novel mutations, including one novel mutation that was encountered twice (M1T), both times in combination with the L236P mutation. The other changes were two missense mutations (S392N, G102R) and two splice site mutations. In one patient only one previously described mutation (V138F) was detected. Clinical data will be matched with the mutations found to search for genotype-phenotype relations.

The vestibular Headbanger mouse mutant with long and circular stereocilia: myosin VIIa as a candidate gene. *R.*

*Hertzano*¹, *C. Rhodes*², *H. Fuchs*³, *M. Hrabé de Angelis*³, *K.P. Steel*², *K.B. Avraham*¹. 1) Dept. of Human Genetics and Molecular Medicine, Sackler School of Medicine, Tel Aviv University, Tel Aviv, Israel; 2) MRC Institute of Hearing Research, University Park, Nottingham, UK; 3) GSF Research Center for Environment and Health, Institute of Experimental Genetics, Neuherberg, Germany.

The ethylnitrosourea (ENU) mutagenesis program is a systematic approach for the identification and characterization of genes involved in hearing loss. The Headbanger *Hdb* mouse mutant is a dominant mutation generated by the ENU mutagenesis program. The behavior of the mouse is suggestive of a vestibular dysfunction. The Headbanger phenotype consists of a circular arrangement of the outer and inner hair cells stereocilia in the cochlea, mainly in the apex, with progressive splaying and fusion of the inner hair cells stereocilia. The hair cells in the utricle are very long, thin and wispy. Seventy-one N2(C3HxC57BL/6) mutant mice were generated using a backcross mapping protocol. Genomic DNA extracted from the tails of these mice was used to construct a low resolution map using microsatellite repeat markers and SNPs in 3 and 5' UTRs, polymorphic between C3H and C57BL/6. A computer software named Pattern was developed to summarize and analyze genotyping results in the format of haplotypes. The chromosomal localization of the mutation was traced to a 1.5cM interval on chromosome 7 that spans over 8 million base pairs. By intercrossing F2(C3HxC57BL/6) mutants, mice homozygous for the mutation were generated. Using a positional-candidate gene approach, an A/T transversion was found in codon 531 of mouse myosin VIIa mRNA causing an Isoleucine to Phenylalanine amino acid substitution. Myosin VIIa protein levels in the cochlea of the mutant mice were assayed by western blot analysis, and showed a down-regulation of protein levels when compared to controls. Immunohistochemical analysis of postnatal day 1 organ of Corti explants did not reveal mislocalization of the protein. It is possible that another ENU induced mutation within the above mentioned linkage interval is responsible for the Headbanger mouse phenotype.

The D(GJB6-D13S1830) deletion with GJB2 mutations in Brazilian families. *E. Sartorato*¹, *C.A. Oliveira*¹, *F. Alexandrino*¹, *A.T. Maciel-Guerra*². 1) Lab de Genetica Humana/CBMEG, Univ Estadual de Campinas, Campinas, SP., Brazil; 2) FCM - Depto Genetica Medica, Univ Estadual de Campinas, Campinas, SP., Brazil.

Mutations in the connexin 26 gene (Cx-26; GJB2) are the most common cause of nonsyndromic hearing loss in many world populations. However, approximately thirty percent of the patients with a Cx26-mutation show only a monoallelic mutation whose pathogenicity has not been proved. We studied 12 patients with Cx-26 mutation in only one allele. In the first family an apparent "normal" allele was segregating with hearing loss. Our index case, a 13-month-old girl, was referred due to bilateral profound sensorineural deafness. She was the first child of a 29-year old woman and her unrelated 29-year-old husband, both of them deaf. Her father, as well as a paternal aunt, had congenital profound sensorineural deafness. In turn, her mother and a maternal aunt had normal speech development in infancy, and hearing difficulties were noted after the age of six years; both of them have now profound sensorineural hearing loss. The paternal and maternal grandparents had normal hearing and were not consanguineous. Both the paternal and the maternal aunts had deaf husbands, and both gave birth to normal hearing boys. We found the deletion D(GJB6-D13S1830) cooperating with the 35delG and V95M mutations in different members of the family. The contribution of the deletion to the phenotype of deafness remains to be explained. We also found this deletion in other family, together with a heterozygous GJB2 mutation. We must be aware to the need of studying D(GJB6-D13S1830), which is now described also in Brazilian families.

High prevalence of W24X mutation in Indian families with Non-Syndromic Deafness. *R. Vijaya, M. Ghosh, M. Kabra, P.S.N. Menon, R.C. Deka**. Genetics Unit, Department of Pediatrics & Department of Otorhinolaryngology*, All India Institute of Medical Sciences, New Delhi, India.

Mutations in the gene GJB2, coding for the gap-junction protein Connexin 26 are responsible for more than 50% cases of prelingual non-syndromic deafness in many Caucasian populations. Among these, the 35delG mutation accounts for up to 85% in Mediterranean population, 70% in United States, and 58% in Israel. The 167delT mutation accounts for 42% of the connexin 26 mutations in Israel and frequent in Ashkenazi Jews while the R134W mutation is common in Africans. Among the Asian countries, 235delC is common in the Japanese population with a frequency of 1-2%. In order to evaluate the extent to which 35delG and three other mutant alleles W24X, W77X and Q124X, contribute to the non-syndromic deafness in Indian population, we screened 329 affected individuals belonging to 110 families from various States of India which included 16 families with sporadic cases. All the families had three or more individuals affected who also had affected relatives. The degree of hearing loss in the affected individuals was either severe and/or profound but intrafamilial variability was notable. Genomic DNA was extracted and the four mutations were detected by allele-specific PCR. Out of 110 families, 36 families (32.7%) were positive for these mutations and a total of 175 mutant alleles were identified. Amongst the 36 families, 26 families (72.2%) were homozygous and 5 families were heterozygous for W24X mutation. Three families were biallelic, W24X/W77X in two families and W77X/35delG in one family. Two sporadic cases were homozygous for Q124X. Therefore mutations in GJB2 gene represent a major cause of recessively inherited non-syndromic deafness in Indian population. It appears that 35delG may not be a common mutant allele as observed in other populations but W24X was identified frequently. This demands a need to evolve a strategy for screening for the mutations in the GJB2 gene in the Indian subcontinent. Availability of a simple DNA based diagnosis for the detection of W24X is indispensable and molecular diagnosis becomes an integral part of genetic counselling for non-syndromic deafness.

Genotype-phenotype correlation and expression analysis of the WFS1-gene responsible for nonsyndromic hearing impairment and Wolfram syndrome. *G. Van Camp¹, K. Cryns¹, S. Thys¹, L. Van Laer¹, M. Pfister², K. Flothman¹, H. Kremer³, W. Reardon⁴, R.J.H Smith⁵.* 1) Department of Medical Genetics, University of Antwerp, Belgium; 2) Department of Otolaryngology, University of Tübingen, Germany; 3) Departement of Otorhinolaryngology, University Medical Centre St Radboud, Nijmegen, The Netherlands; 4) National Centre for Medical Genetics, Our Lady's Hospital for Sick Children, Crumlin, Dublin, Ireland; 5) Molecular Otolaryngology Research Laboratories, Department of Otolaryngology, University of Iowa, Iowa City.

The WFS1 gene is responsible for Wolfram syndrome, also called DIDMOAD (Diabetes Insipidus, Diabetes Mellitus, Optic Atrophy and Deafness), which is an autosomal recessive disease. In addition, heterozygous mutations have been found in families with fully penetrant autosomal dominant low frequency sensorineural hearing impairment (ADLFHI). This is remarkable, as the hearing impairment in DIDMOAD shows reduced penetrance and mainly affects the high frequencies. We have completed mutation screening of WFS1 in 8 autosomal dominant families and 10 sporadic cases in which affected persons had LFHI. We identified 7 missense mutations and a single amino acid deletion affecting conserved amino acids in 6 families and one sporadic case. The success rate in ADLFHI is high, but the low success rate in simplex cases suggests that there are environmental causes of LFHI or unknown autosomal recessive genes. Among the 10 WFS1-mutations reported in LFHI, none is expected to lead to premature protein truncation and 9 cluster in the C-terminal protein domain. We compared these characteristics to those of the mutations causing Wolfram syndrome, and found some remarkable differences. In Wolfram syndrome, 64% of the mutations are inactivating, and the mutations are evenly spread over the complete protein. We have performed expression analysis of the WFS1 gene in the inner ear in mice and rats at different stages of development using immunohistochemistry and in situ hybridization. Both techniques showed compatible results, and indicated clear expression in different cells of the inner ear at different stages of development.

Secretion and subcellular localization of wild-type cochlin, and of mutants causing the sensorineural deafness and vestibular disorder, DFNA9. *N.G. Robertson¹, V. Patriub¹, S.A. Hamaker¹, J.C. Aster^{1,3}, C.C. Morton^{1,2,3}.* 1) Depts. Pathology; 2) Ob/Gyn, Brigham & Women's Hosp; 3) Harvard Medical School, Boston, MA.

Five missense mutations in the *COCH* gene have been identified in the FCH/LCCL domain of its encoded protein, cochlin, and are pathogenic for the autosomal dominant hearing loss and vestibular dysfunction, DFNA9. This domain was shown to have a novel fold; *in vitro* expression of this domain with 3 of 4 DFNA9 mutations results in its misfolding. Misfolded proteins are known to accumulate and become prone to degradation, or to aggregate and cause toxicity. The observation of eosinophilic deposits in DFNA9-affected inner ear structures may also indicate aberrant folding, secretion, or solubility of the mutated protein. To study the biological consequences of misfolding in cochlin, we performed transient transfections of wild-type and mutant cochlin constructs into mammalian cells in culture. The entire coding region of *COCH* (~1.65 kb, 550 aa) was cloned into a eukaryotic expression vector with C-terminal HA tags. Three missense mutations were introduced separately into the construct and transfected into 293T- HEK, COS-7, and 3T3 cell lines. Immunocytochemistry revealed concentrated localization of cochlin in perinuclear structures consistent with the Golgi apparatus and endoplasmic reticulum for both wild-type and mutant cochlin. Western blots of total protein lysates from transfected cells and of the secreted media immunoprecipitated with anti-HA showed equal amounts of normal and mutant cochlin in the cellular fraction and in the media from transfected cells. These results indicate that wild-type and mutant cochlin expressed in mammalian cells are secreted in a similar fashion via the Golgi/ER secretory pathway and that the presence of these mutations does not appear to interfere with secretion or lead to intracellular retention and/or degradation of the protein. Alternative mechanisms of pathology caused by these missense mutations may be the loss of function of the FCH/LCCL domain or lack of proper folding and binding of this domain to other components in the extracellular matrix of the inner ear.

Mutations in myosin IIIA cause nonsyndromic progressive hearing loss DFNB30. *V. Walsh¹, T. Walsh¹, S. Vreugde², R. Hertzano², H. Shahin^{2,3}, S. Haika², M.K. Lee¹, M. Kanaan³, M.C. King¹, K.B. Avraham².* 1) Medicine and Genome Sciences, Univ. of Washington, Seattle, WA; 2) Department of Human Genetics and Molecular Medicine, Sackler School of Medicine, Tel Aviv Univ., Israel; 3) Department of Life Sciences, Bethlehem Univ., Bethlehem, Palestinian Authority.

The DFNB30 locus is represented by an extended Israeli family originating in Mosul, Iraq. The hearing loss in this family is progressive, beginning in the second or third decade of life. Until now, all families reported with progressive hearing loss showed a dominant pattern of inheritance. A genome scan revealed age-dependent recessive inheritance, although homozygosity was restricted to only a part of the critical region. Therefore it was not surprising to discover several mutations in the MYO3A gene, corresponding to the haplotypes segregating in the family. The hearing loss is caused by three different loss-of-function mutations in myosin IIIA: a nonsense mutation and two splice site mutations. Most interesting, individuals who were homozygous for the nonsense mutation had an earlier onset of hearing loss and their hearing loss is more severe than that of individuals that are heterozygous for the nonsense and either of the splice mutations. Class III myosins are hybrid motor-signaling molecules, with an N-terminal kinase domain, highly conserved head and neck domains, and a class III-specific tail domain. Expression of mammalian myosin IIIA is highly restricted, with the strongest expression in retina and cochlea. Furthermore, recessive null mutations in the *Drosophila* homolog of MYO3A (NINAC) delay termination of the photoreceptor response and lead to progressive retinal degeneration. Although hearing impaired individuals have never complained of visual problems, detailed ophthalmological tests will determine whether the retina is affected, as another myosin is involved in both deafness and retinitis pigmentosa. In *Drosophila* rhabdomeres, NINAC interacts with actin filaments and with a PDZ scaffolding protein to organize the phototransduction machinery into a signaling complex. We will present data from our yeast 2-hybrid screen in our attempts to identify the mammalian myosin III interactors.

The spectrum of GJB2 and mtDNA mutations in prelingual nonsyndromic deafness in Greece. A. Pampanos¹, M. Grigoriadou¹, T. Iliades², N. Voyiatzis², J. Economides³, P. Leotsakos³, P. Neou⁴, M. Tsakanikos⁴, T. Antoniadi⁵, A. Hatzaki⁵, I. Konstantopoulou⁶, D. Yannoukakos⁶, J. Gyftodimou¹, A. Skevas⁷, M.B. Petersen¹. 1) Inst. of Child Health, Athens, Greece; 2) Aristotle Univ. of Thessaloniki, Greece; 3) "Aghia Sophia" Children's Hosp., Athens, Greece; 4) "P. & A. Kyriakou" Children's Hosp., Athens, Greece; 5) "MITERA" Maternity Center, Maroussi, Greece; 6) N.C.S.R. "Demokritos", Athens, Greece; 7) Univ. of Ioannina, Greece.

Mutations in the GJB2 gene encoding connexin 26 have been shown as a major contributor to prelingual nonsyndromic deafness, with one specific mutation (35delG) accounting for the majority of mutations detected in the GJB2 gene in Caucasian populations. Several mtDNA mutations have also been reported as causes of nonsyndromic childhood hearing impairment, but a more precise estimate of the prevalence of these mutations has only been analyzed in a few population-based studies. In a collaboration with the major referral centers for childhood deafness in Greece, patients were examined by ARMS-PCR for the detection of the 35delG mutation, direct genomic sequencing of the GJB2 gene, and PCR-RFLP for the detection of mtDNA mutations A1555G, A7445G, and 7472insC. A total of 232 patients with prelingual sensorineural deafness were studied, where syndromic forms and environmental causes of deafness had been excluded. Biallelic GJB2 mutations were found in 78 patients (33.6%): 68 35delG/35delG homozygotes and 10 compound heterozygotes with the 35delG mutation and another mutation (L90P 3 alleles, W24X 2 alleles, R184P 2 alleles, delE120 1 allele, 291insA 1 allele, and 88delA 1 allele). The homoplasmic A1555G mutation was detected in two cases (one sporadic and one familial) and the A7445G mutation was found in one sporadic case of mild hearing impairment. We conclude that GJB2 mutations are responsible for a large proportion of prelingual nonsyndromic deafness in the Greek population. Mutations in the mtDNA are responsible for only a small fraction of prelingual deafness, but the identification of an mtDNA mutation is vital for genetic counseling.

Program Nr: 2005 from 2002 ASHG Annual Meeting

Analysis of Connexin 26 mutations in a population of deaf patients. *V.A. Stevenson¹, M. Ito¹, J.M. Milunsky^{1,2}*. 1) Center for Human Genetics, Boston University School of Medicine, Boston, MA; 2) Department of Pediatrics, Boston University School of Medicine, Boston, MA.

The most common genetic cause of non-syndromic hearing loss are mutations in the Connexin 26 gene. At the Center for Human Genetics, samples sent for Connexin 26 mutation analysis are usually first screened for the common mutations 35delG and 167delT [Ashkenazi Jewish population] and then sequenced if requested. Between January 2001 and May 2002, we identified 14 35delG homozygotes, 3 167delT homozygotes, and 1 35delG/167delT compound heterozygote. In addition, sequence analysis identified 34 other affected alleles. Fifteen individuals were compound heterozygous for 35delG and another mutation. Two individuals were compound heterozygous for 167delT and another mutation. Eleven individuals were either heterozygous (5), homozygous (2), or compound heterozygous (4) for various other Connexin 26 mutations. In addition, we report 5 new mutations in the Connexin 26 gene: F191S, E129X, W3C, L6W, and del151TTinsC. These mutations were all identified in patients with at least one other mutation in the Connexin 26 gene, and thus likely represent novel disease-causing mutations. In conclusion, screening only for the common mutations 35delG and 167delT could fail to diagnose up to one quarter of affected individuals. A large portion of individuals in whom Connexin 26 mutations other than the common mutations were found were of non-Caucasian ancestry. Therefore, we recommend full Connexin 26 sequencing in those affected individuals of non-Caucasian ancestry.

Auditory Neuropathy in a family with Mohr-Tranebjaerg Syndrome due to a nonsense mutation in TIMM8a.

R.J. Varga¹, R. Lewis², W.J. Kimberling¹. 1) Center for Hereditary Communication Disorders, Boys Town National Research Hospital, Omaha, NE 68131; 2) Cullen Eye Institute, Dept of Ophthalmology, Baylor University, Houston TX 77030.

Mohr-Tranebjaerg Syndrome (MTS) is characterized by early-onset post-lingual deafness and late-onset dystonia or ataxia, progressive visual deterioration, paranoid psychotic features and mental deterioration. Mutations in TIMM8a have been shown to cause MTS by not allowing the import of the hTim23 protein into the mitochondria. TIMM8a is a nuclear-coded gene located on Xq22. A family with three affected males in two generations have been found to have a nonsense mutation, 135 C>T (Q34X), in exon 1 of the TIMM8a gene. These males have many of the classical features associated with MTS, but in addition the hearing loss has been determined in the youngest affected family member to be an auditory neuropathy. Auditory neuropathy is a type of hearing loss characterized by absent or abnormal auditory brainstem response with normal outer hair cell function. It was predicted that an auditory neuropathy phenotype would be associated with MTS by Merchant et al. (*Otol Neurotol.* 2001 Jul;22(4):506-11) who found near complete loss of spiral ganglion cells and preserved organ of Corti in the temporal bone of an MTS patient with the 151delT mutation in TIMM8a. The case presented here is the first where outer hair cell function was determined clinically in an MTS patient. This patient had an unsuccessful trial with hearing aids and has since stopped wearing them. While cochlear implants have been shown to be beneficial in some cases of auditory neuropathy, the family has been informed of the studies by Merchant, et al. and been advised that a cochlear implant might not work due to the progressive loss of the spiral ganglion. This family verifies the prediction that MTS is associated with an auditory neuropathy and demonstrates the importance of a genetic diagnosis in deciding the type of therapy for hearing disorders.

Total absence of the alpha2(I)Collagen chain due to a homozygous COL1A2 mutation in a patient with an EDS-like phenotype. A. De Paepe¹, S. Symoens¹, L. Nunes², S. De Almeida², K. Wettinck¹, R. Dekens¹, F. Malfait¹, P.J. Coucke¹. 1) Medical Genetics, 0K5, Univ Hosp Gent, Ghent, Belgium; 2) Medical genetic service, Hospital Dona Estefania, Lisboa, Portugal.

We report a homozygous mutation in Type I Collagen (COL1A2) in a 6 year old Portuguese boy from a consanguineous marriage presenting an Ehlers-Danlos (EDS) phenotype with generalized joint hyperlaxity, hypotonia, skin hyperextensibility, external rotation of the hands and long, thin fingers. Biochemical analysis on skinfibroblasts showed the presence of proalpha1(I) and alpha1(I) chains but no evidence of proalpha2(I) or alpha2(I) chains neither in the medium nor in the cell layer. Mutation analysis of the genomic DNA revealed a homozygous one basepair insertion in exon 7 of the COL1A2 gene (COL1A2-292insC). The resulting frameshift introduces a premature termination codon in the next aminoacid position. This mutation was also identified in the heterozygous form in both parents who are apparently healthy. Until now, only 4 patients with a total alpha2(I) collagen chain deficiency have been described. They show however markedly different phenotypes: one presented severe Osteogenesis Imperfecta (OI) type III, whereas the 3 other patients presented a mild, EDS-like or EDS/OI phenotype. Although the clinical study of our family is still in progress, the phenotype is mild and resembles that of the 3 EDS patients. It is unclear how an apparent total lack of the alpha2(I) chains can produce such differences in phenotypic severity. In the patient with OI Type III and the one with OI/EDS phenotype the causal COL1A2 mutation was identified as a 4 bp deletion and a splice site mutation, respectively. In the latter patient, it was assumed that minute amounts of normal alpha2(I) chains are still produced, which ameliorate the clinical phenotype from a severe OI to a much milder EDS/OI phenotype. Here, the presence of a homozygous stopcodon in exon 7 (resulting from a frameshift), renders this mechanism unlikely. Other genetic factors must be responsible to explain the predominant phenotypic expression in the soft tissues and the minimal degree of bone fragility in the present case.

Development of a human muscle expression data warehouse. *M.A. Bakay, J. Chen, E.P. Hoffman.* Research Center for Genetic Medicine, Childrens National Medical Center, Washington DC.

Data generated on DNA sequence, mRNA ESTs, and emerging SNPs is now integrated into genome browsers on the relatively static DNA code. Transcription and proteome profiles have many more variables that make integrated databases more challenging, and we have shown that the associated noise from experimental variability, tissue heterogeneity, and inter-patient SNP noise are considerable factors to consider (Bakay et al. 2002). To begin to develop publicly accessible data warehouses on human tissues, we have focused on muscle in both health and disease, using whole genome-anchored Affymetrix U133 arrays, and Oracle web interfaces with queries enabled across all profiles, and across species. Here we an initial installment of 25 patient muscle biopsies, including Duchenne muscular dystrophy, Becker muscular dystrophy, dysferlin deficiency (LGMD2B), and normal controls. For the sake of this presentation, we focus on changes of the dystrophin mRNA as a function of diagnosis. We found that dystrophin mRNA was statistically significantly reduced relative to controls, consistent with nonsense-mediated RNA decay and frame shift mutations. However, Becker dystrophy patients show an increase in dystrophin mRNA relative to controls, consistent with compensatory up-regulation due to the semi-functional protein. Dysferlin deficient patients, while showing secondary reductions of dystrophin by immunocytochemistry, showed normal levels of dystrophin mRNA. We then tested whether the large-scale profiling of biopsies would permit the delineation of expression fingerprints that are diagnostic of different underlying defects. We compared DMD-vs-Dysferlin and BMD-vs-Dysferlin deficient samples. We have found 149 and 82 genes survived cut-off $p < 0.05$ and Fold Change > 2 for Dysferlin-vs-DMD and Dysferlin-vs-BMD, respectively. Dysferlin gene had higher expression in both DMD and BMD groups with FC = 2.1 and $p = 0.01$ (DMD) and 0.004 (BMD). Dystrophin genes was significantly down regulated in DMD-vs-Dysferlin groups with $p = 0.004$ and FC = 5. Our data suggests that diagnostic profiles can be developed, and signature genes reflective of each disease can be identified.

The human cyclic nucleotides phosphodiesterase (PDE) Prune protein: a dual cellular compartment localization and functional properties. A. Dangelo¹, A. D'Andre¹, P. Carotenuto¹, V. Aglio¹, L. Garzia¹, G. Arrigoni², A. Ballabio¹, M. Zollo¹. 1) TIGEM, TIGEM, Naples, ITALY; 2) HSR San Raffaele, Laboratorio di Anatomia Patologica, Milan, ITALY.

The human prune homologue gene is located on 1q21.3 epidermal cluster region. The gene is frequently amplified in sarcoma and breast cancer. A model of negative regulation of prune versus nm23-H1 anti-metastasis protein has been postulated. On the basis of sequence alignment we found a newly identified phosphodiesterase (PDE) PDE11A containing a catalytic site motif equally present in the human prune protein. To investigate prune activity a scintillation proximity assay was performed on the purified histidine-tagged prune protein produced by the Baculovirus expression system. Prune is functioning as a cyclic nucleotides phosphodiesterase preferentially on cAMP substrate. In progress are the analysis with different inhibitors of prune PDE activity since phosphodiesterase inhibitors are considered as potential anti-inflammatory and anti-proliferative agents in human skin. The human PRUNE gene is expressed in the basal and granular layers of human skin and map in the epidermis cluster locus where two skin multigenic disorders have been identified so far (Atopic Dermatitis OMIM # 603165 and Psoriasis OMIM# 177900). We have cloned the human PRUNE cDNA under the control of the loricrin promoter, to drive the expression in both the undifferentiated and differentiated skin layers. Four founders lines have been produced. Prune protein is predominantly a cytoplasmic protein. By direct immunofluorescence experiments we have investigating prune and nm23 protein localization in SK-N-SH, SK-N-BE, SH-5YSY and IMR-32 Neuroblastoma-derived cell-lines. A predominant prune nuclear localization was observed for the first time. Functional studies of the role of prune in the nucleus compartment will be presented.

Program Nr: 2010 from 2002 ASHG Annual Meeting

Enzyme activity of GTP cyclohydrolase I mutations and their relevance to dopamine insufficiency. *S.M. Hague, C. Evey, M. Baptista, M. Cookson, J. Hardy, A. Singleton.* Neurogenetics, NIA, Bethesda, MD.

Mutations in GTP cyclohydrolase I (GCH-1) the rate limiting enzyme in tetrahydrobiopterin biosynthesis are associated with a number of diseases of dopamine insufficiency, including Dopa-responsive dystonia and hyperphenylalanemia (HPA). Currently, there are 60 reported mutations in GCH-1. Mutations have been shown to decrease the level of enzyme activity with a concomitant reduction in dopamine synthesis. Previously, we have also demonstrated GTP cyclohydrolase mutations in 3 of 180 cases of parkinsonism. In the three families studied a Pro23Leu transition was identified and in one of these an additional Pro69Leu was observed in cis with the Pro23Leu mutation. We postulate in the families examined these observed mutations may reduce the level of tetrahydrobiopterin synthesis and ultimately the level of dopamine, contributing to the observed parkinsons disease. To test this hypothesis we have assayed the level of GCH-1 using a formate release assay in a number of cell lines from PD patients and from additional controls. We report the results of this assay herein and discuss the implications of this finding in parkinsons disease.

Accumulation of deoxyuridine due to primary thymidine phosphorylase deficiency. *R. Marti, Y. Nishigaki, M. Hirano.* Neurology, Columbia University, New York, NY.

Background: Mitochondrial NeuroGastroIntestinal Encephalomyopathy (MNGIE) is an autosomal recessive disorder caused by loss-of-function mutations in the gene encoding thymidine phosphorylase (TP). In MNGIE patients, depletion, multiple deletions and point mutations of mitochondrial DNA (mtDNA) have been identified. We have previously described alteration of thymidine metabolism in these patients, with high circulating concentrations of thymidine. In the present work, we screened for alterations in the levels of other circulating nucleosides in the plasma of MNGIE patients, that could contribute to the pathomechanism of this disease.

Material and Methods: Reversed phase HPLC, with elution in gradient and with UV detection was used to quantify the circulating concentration of nucleosides. Plasma samples from 22 patients and 20 healthy controls were analyzed.

Results: Similar to previous results, we identified increased levels of thymidine in MNGIE patients (8.1 ± 3.2 mM; range 3.9 - 17.5) compared to controls (<0.05 mM). In addition, deoxyuridine (dUrd) was present in the plasma of all analyzed MNGIE patients (13.2 ± 3.6 mM; range 5.5 - 21.8). No detectable dUrd was found in any of the analyzed controls (<0.05 mM). Concentrations of dUrd in the patients were slightly higher than the corresponding levels of thymidine.

Conclusion and Hypotheses: Loss of function of TP in MNGIE patients leads to extracellular accumulation of dUrd, in addition to the previously described increases of thymidine. Extracellular accumulation of dUrd in MNGIE patients could result in increases of the normally low intracellular levels of deoxyUTP, leading to incorporation of uracil into mtDNA. Uracil misincorporation may contribute to the mtDNA alterations observed in this disease.

Affymetix Genechip expression profiling of CLN6-deficient late infantile NCL. *R.N. Boustany¹, C.A.F. Teixeira^{1,2}, S. Lin³, M.C.S Miranda^{2,4}, M.G.R. Ribeiro^{2,4}.* 1) Div Pediatric Neurology, Duke Univ Medical Ctr, Durham, NC; 2) Unidade de Neurobiologia Genetica do Instituto de Biologia Molecular e Celular da Universidade do Porto, Portugal; 3) Duke Bioinformatics Shared Resource, Duke Univ Medical Ctr, Durham, NC; 4) Unidade de Enzimologia do Instituto de Genetica Medica do Porto, Portugal.

The neuronal ceroid lipofuscinoses (NCLs) are a group of autosomal recessive neurodegenerative diseases characterized by cognitive and motor decline, blindness and seizures and by progressive neuronal loss in the brain and retina. Six NCL genes have been identified, the most recent of which is CLN6, a novel transmembrane protein of unknown function. In this study Affymetrix Genechip analyses were performed in cultured fibroblasts from normal controls and a number of NCL types. The CLN6-deficient cases included 3 Portuguese patients homozygous for the I154del common Portuguese mutation and 1 Costa Rican patient homozygous for the common Costa Rican c.214GT mutation. The CLN6-deficient profiles were distinct from all other NCL variants analyzed suggesting a unique pathobiology for this variant, and a possible role for the use of genechip technology in the identification of new disease variants. We applied a threshold that identified genes with 2-fold change or more in either direction in comparison with the control. This analysis generated a group of 16 up and down-regulated genes that provide clues as to the function of this novel gene as well as some insight into the cell biology of this NCL variant. The function and interrelationship of these sixteen genes will be discussed.

***MutationView* : A Graphical On-line Database System for Mutations and Polymorphisms in Human Disease**

Genes. *S. Minoshima*¹, *M. Ohtsubo*¹, *S. Mitsuyama*¹, *S. Ohno*¹, *T. Kawamura*¹, *S. Ito*², *F. Ito*³, *N. Shimizu*¹. 1) Dept Molec Biol, Keio Univ Sch Med, Tokyo, Japan; 2) Dept Environ Health Sci, Setsunan Univ, Hirakata, Japan; 3) Dept Biochem, Setsunan Univ, Hirakata, Japan.

More than 1100 disease-causing genes have been reported. Databases for mutations in these disease-causing genes are indispensable for the diagnostics, therapeutics and basic research of the diseases. At present, mutation data are maintained as individual Locus-specific Databases (LSDBs) only for selected numbers of diseases and therefore more comprehensive database system with common graphical user-interface is required. We have established the *MutationView* as an integrated graphical mutation database. Currently, the *MutationView* has collected 8176 entries of mutations/polymorphisms from 1497 literatures, dealing with 200 genes involved in 190 distinct diseases. The characteristic features of the *MutationView* are as follows:

(1) Several ways are available to have an access to the gene of interest through the chromosomal map of the gene or disease, anatomical charts of disease-associated organ or tissue, and schematic figures of causative gene products and related proteins.

(2) Various data display and analysis functions are available: Genomic/cDNA structure of normal gene, functional domain structure of protein, zooming-in and -out of the nucleotide and amino acid sequences, plotting mutations with the histogram of case number, changes in the nucleotide sequence and restriction sites, classification based on mutation type, dominant/recessive and symptom, experimental information such as PCR primers and reaction conditions.

(3) Mutation data can be placed in any web server and therefore *MutationView* system is ideal to link global mutation databases managed by LSDB curators.

The user ID and password are issued upon formal applications through the URL <http://mutview.dmb.med.keio.ac.jp>. Computer demonstration will be performed at the meeting.

Sequencing of Candidate Genes for Non-Syndromic Cleft Lip and Palate Finds Rare Etiologic Variants. *C.J. Nishimura, J. Harrington, B. Ludwig, J. Allaman, A. Vieira, P. Jezewski, R. Schultz, S. Kondo, J. Avila, A. Warrington, Y. Watanabe, J.C. Murray.* Pediatrics, The University of Iowa, Iowa City, IA.

Non-syndromic cleft lip and palate occurs in about 1 in 1000 live births. We are performing a comprehensive sequencing project to identify etiologic mutations and SNPs in candidate genes for cleft lip and palate. Genes included in this screening project: LHX8, MSX1, P63, PVRL1, PVRL2, SKI1, TGFA, TGFB1, TGFB3, and IRF6. The samples screened are from 100 each of non-syndromic cleft lip and palate cases from Iowa and the Philippines. Primers were developed flanking the coding regions and splice sites for each gene. Sequencing was performed bidirectionally and variants were detected using Polyphred analysis. Variants are confirmed by re-sequencing of the affected proband and by sequencing other family members and controls. Polymorphic variants are being used for transmission disequilibrium studies. Variants in LHX8, MSX1, and SKI1 are being examined for a possible etiologic cause for non-syndromic cleft lip and palate. A variant in exon 7 of SKI1 creates a Proline to Leucine change in a proband with unilateral cleft lip and palate born to unaffected parents, neither of which has the variant. In exon 5 of LHX8, an affected proband, an affected sibling and their unaffected mother have a variant, which changes a Glutamic acid to Alanine. Several variants in MSX1 affect highly conserved amino acid residues. In aggregate these results support a role for rare variants in some cases of non-syndromic clefting and support the polygenic model of etiology.

Skeletal defects and male infertility locus on mouse chromosome 9. K.B. Cha¹, I.J. Karolyi¹, A. Hunt¹, A.M. Wenglikowski¹, J.E. Wilkinson¹, D. Dolan², G. Dootz², A.A. Finnegan³, L.D. Siracusa³, S.A. Camper¹. 1) Human Genetics, Univ. of Michigan Medical School, Ann Arbor, MI; 2) Otolaryngology, Univ. of Michigan Medical School, Ann Arbor, MI; 3) Microbiology and Immunology, Kimmel Cancer Center, Jefferson Medical College, Philadelphia, PA.

Skeletal disorders constitute a diverse group of genetic diseases. Over 200 forms of osteochondrodysplasias have been described. Some have been mapped genetically and are understood at the molecular level, but many forms have unknown etiology. Mouse mutants have contributed significantly to our understanding of skeletal development and homeostasis, and they play an important role in discovering critical genes that would not be predicted based on our current knowledge of skeletal development.

We discovered a spontaneous mutation resulting in growth insufficiency and named it chagun (*cha*), a Korean word for small. Mutant males are sterile. The growth impairment, which follows an autosomal recessive inheritance pattern, is detectable by weaning, and adult mutants weigh approximately 75% of their normal littermates. Skeletal abnormalities include shortened skull, shortened limbs, and enlarged joints. The number of vertebrae and ribs is normal. These results suggest that the growth insufficiency is due to a developmental defect of bone or cartilage. Histological analysis of the femur demonstrates loss of structural integrity of the growth plate and a reduction in trabecular bone in dwarf mice.

The mutant karyotype is normal. To map the mutant locus, mutant females were crossed to *Mus castaneus* males. Intercross progeny demonstrate fully penetrant growth insufficiency and male infertility. A genome scan with polymorphic markers revealed association of the phenotype with distal chromosome 9, which exhibits synteny homology with segments of human chromosomes 3 and 15. Although the parathyroid hormone receptor maps within this region, *Pthr* has been excluded genetically as the cause of growth insufficiency in chagun mice. Thus, identification of the mutant gene in this new mutant mouse may reveal a novel cause of skeletal dysplasia.

Exclusion of the candidate gene matrilin-1 in a cohort of 22 multiple epiphyseal dysplasia (MED) patients. *S.M. Huguenin*^{1,2}, *D.H. Cohn*^{2,3}. 1) UCLA Intercampus Medical Genetics Training Program; 2) Medical Genetics, Department of Pediatrics, Cedars-Sinai Medical Center, Los Angeles, CA; 3) Departments of Human Genetics and Pediatrics, UCLA School of Medicine, Los Angeles, CA.

Multiple epiphyseal dysplasia (MED) is a phenotypically and genetically heterogenous osteochondrodysplasia. Clinically, MED varies from the mild Ribbing type to the severe Fairbank type, with common features including delayed epiphyseal ossification, mild short stature, and joint pain. Six different MED loci have been identified; the genes encoding cartilage oligomeric matrix protein (*COMP*), the three chains of type IX collagen (*COL9A1*, *COL9A2*, *COL9A3*), and matrilin-3 (*MATN3*) in the autosomal dominant forms of MED, and the diastrophic dysplasia sulfate transporter (*DTDST*) gene in an autosomal recessive MED phenotype. However, the known loci only account for approximately 50% of MED patients. The matrilins are a four-member family of non-collagenous oligomeric extracellular matrix proteins, each containing von Willebrand factor A domain(s), EGF-like repeat(s), and a carboxyl terminus coiled-coil oligomerization motif. The tissue expression patterns of *MATN1* and *MATN3* are specific to cartilaginous tissue of the growing skeleton, whereas *MATN2* and *MATN4* have a broader tissue distribution and are mainly expressed in non-skeletal tissues. Furthermore, the *MATN1* and *MATN3* proteins often co-localize and are known to co-assemble into either homo- or hetero-oligomers. The identification of mutations in *MATN3* in two MED families suggested the possibility that mutations in *MATN1* could produce MED. To test this hypothesis, the sequences of the eight exons, including exon/intron boundaries, of *MATN1* were determined in genomic DNA from 22 MED patients in which *COMP*, *COL9A1*, *COL9A2*, *COL9A3*, and *DTDST* loci were excluded. No mutations were identified, excluding structural mutations in *MATN1* as the cause of MED in this cohort. While regulatory mutations cannot be excluded, lack of an overt skeletal phenotype in the *Matn1* knockout mouse suggests that such mutations might not be expected. Our data suggest that if mutations in *MATN1* can cause MED, such defects are rare.

Screening of patients with trigonocephaly with markers from the 9p and 11q regions. *F.S. Jehee¹, D. Johnson⁴, L. Alonso³, K. Abe¹, N. Alonso², H. Matushita², C. Kim², S. Cavaleiro³, S.A. Wall⁴, A.O.M. Wilkie⁴, M.R. Passos-Bueno¹.*
1) CEGH, IBUSP, Brazil; 2) FMUSP, Brazil; 3) UNIFESP, Brazil; 4) Craniofacial Unit, Oxford, UK.

Trigonocephaly is caused by metopic craniosynostosis and can occur as an isolated clinical feature or as part of a syndrome. Deletions in two chromosomal regions, del(9p22-24) and del(11q23-24), are associated with syndromic phenotypes which include almost invariably trigonocephaly. Therefore, there might be genes at 9p and 11q that cause the premature fusion of the metopic suture when in hemizygoty. We are screening patients for hemizygoty in the regions above mentioned to: i) verify if isolated trigonocephaly is caused by microdeletions, ii) reduce the candidate regions for these genes, which currently encompass approximately 10 cM. A cohort of 46 patients with either isolated or syndromic trigonocephaly was studied. Large deletions were found in 6 syndromic cases: one del11q and five del9p. These findings did not reduce the critical regions. The origin of the deletion could be determined in 5 cases, 4 being paternal: three del9p and the del11q and one maternal: del9p. Karyotype analysis was performed in the parents of 5 cases and revealed that two del9p originated by balanced translocations while the other two del9p and the del11q are de novo deletions. No evidence of microdeletions was found in the other 40 patients. This could suggest that a) microdeletions in these regions are quite rare, b) there are false negative results because of non-informative markers and c) the metopic synostosis is caused by mutations within a gene in the region rather than by a microdeletion. We are also screening our patients for mutations in candidate genes within the critical regions. SSCP analysis was carried out for the coding region of the CER1 gene, an antagonist of BMP4, located at 9p23. We identified a novel SNP (CG at position c195), which does not seem to be associated with the trigonocephaly in our patients since its frequency (40%) is the same as in a control sample. No other mutation was detected indicating that CER1 may not be involved in the etiology of this malformation. FAPESP, PRONEX, HHMI.

Osteoporosis Pseudoglioma Syndrome Caused By A Novel, Homozygous, 2-Base Pair Deletion In The LRP5

Gene. *S. Mumm*^{1,2}, *D. Wenkert*², *J. Hagen*¹, *M.P. Whyte*^{1,2}. 1) Div Bone & Mineral Diseases, Washington Univ Sch Medicine, St. Louis, MO; 2) Center for Metabolic Bone Dis and Mol Res, Shriners Hospital for Children, St. Louis, MO.

Osteoporosis pseudoglioma syndrome (OPPG) is an autosomal recessive disorder caused by inactivating mutations in the gene which encodes the low density, lipoprotein receptor-related protein 5 (LRP5). Clinical features include early-onset blindness (described as retinal dysplasia within the first few months of life, or phthisis bulbi with calcifications and cataract formation diagnosed after 1 year of age), micro-ophthalmia, osteoporosis leading to fractures, wormian bones, hypotonia, and developmental delay. A 1-year-old Caucasian girl of aunt/nephew parentage was found by routine eye exam at 4 days-of-age to have no red reflex. Bilateral retina detachment with persistent fetal retinal vasculature were unexplained. Ophthalmologic surgery preserved light/dark perception. At age 11 months, bilateral distal femur fractures occurred during a fall. She was osteopenic. Our assessment showed microcephaly, micro-ophthalmia, hypotonia, and hyperextensibility of all joints. At age 12 months, after she came out of a spica cast, compression fractures of T8 were noted. At 13 months compression fractures of T10-T12, L1, L2, and L4 were also noted. Mutation analysis of LRP5, including sequencing of exons and intron/exon boundaries, revealed a homozygous 2-base pair deletion (3194-3195delAC) in exon 14. This causes a frame shift at amino acid 1065 (D1065fs) and addition of 71 missense amino acids. OPPG reveals that LRP5 acts significantly in bone accrual. In 2002, a single base pair change in exon 3 of LRP5 was shown to cause a benign phenotype, autosomal dominant high-bone mass trait. Deactivating mutations in LRP5 cause OPPG syndrome with 6 homozygous disease-causing frame shift and nonsense mutations in LRP5, as well as 6 heterozygous putative disease causing missense mutations. These mutations were found in a variety of exons but not exon 14. Our patient has a novel, homozygous, 2-base pair deletion in yet another region of LRP5 which is, therefore, important for the normal functioning of the gene product.

Characterization of Peripheral Leukocytes in PAPA Syndrome, an Autoinflammatory Disease. *C.A. Wise¹, D. Zhang¹, H. Liu¹, E.A. Arce², V.M. Pascual².* 1) Seay Research Ctr, Texas Scottish Rite Hosp, Dallas, TX; 2) UT Southwestern Medical School and Baylor Institute for Immunology Research, Dallas, TX.

PAPA (pyogenic arthritis, pyoderma gangrenosum, and acne) syndrome, is an inherited disorder marked by recurring, destructive, early-onset, arthritis. Inflammatory flares lead to massive accumulation of sterile neutrophils within joints and muscle, variously accompanied by skin ulcerations and cystic acne. These clinical features resemble other more common disorders including inflammatory bowel disease and rheumatoid arthritis, suggesting etiological overlap. To reconstruct the pathogenesis of PAPA syndrome we recently identified the responsible gene, PSTPIP1, and demonstrated that disease-causing missense mutations compromise binding to PEST-type protein tyrosine phosphatases (PTPs). PSTPIP1 is an adaptor protein that interacts with various other proteins including CD2, c-Abl, and Wiskott-Aldrich syndrome protein. We originally hypothesized that inflammation might be mediated by T cells as in classic autoimmune disease; however, we have found no changes in T cell function in patients compared to controls. Alternatively, cells of myeloid lineage may mediate PAPA syndrome. Supporting this is the report that PSTPIP1 protein interacts with pyrin, a protein expressed exclusively in myeloid cells and responsible for Familial Mediterranean Fever (FMF), an autoinflammatory disorder with clinical features similar to PAPA syndrome. We have now investigated the expression of PSTPIP1 in neutrophils and monocytes. PSTPIP1 is detected in highly purified fractions of both cell types by RT PCR and Western blotting. Interestingly a population of oversized neutrophils that appear apoptotic is detected in patients but not control samples. Using FACS analysis we have also detected a population of enlarged, HLA DRII-positive monocytes in these patients. These results are consistent with a role for myeloid cells in PAPA syndrome in which apoptotic pathways are activated, possibly mediated through pyrin. Further characterizations of these cells are in progress. Biochemical pathways identified in these experiments will reveal insights into PAPA syndrome and related inflammatory diseases.

Program Nr: 2020 from 2002 ASHG Annual Meeting

Identification of novel cartilage-expressed genes. *R. Pogue*¹, *E. Sebald*¹, *D. Cohn*^{1,2}, *D. Krakow*^{1,2}. 1) Pediatrics, Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) Departments of Human Genetics and Pediatrics, UCLA School of Medicine, Los Angeles, CA.

To identify novel candidate genes for the osteochondrodysplasias, we performed a microarray experiment using a custom array to identify cDNA clones with particularly high levels of expression in human fetal articular chondrocytes relative to dedifferentiated chondrocytes in culture. Differential expression was then independently tested using real-time PCR. We present here eight genes with a high differential expression. Of these, two have been previously characterized (IL6R & RTP-801), two contain identifiable protein motifs (ZIP domain, SNF2 & DEXDc domains), and four are novel genes with homology to existing ESTs but no similarity to any gene of known function. One of the novel genes (designated CCL-138) has a particularly limited range of tissue expression (cartilage, hypothalamus, uterus, cochlea), making it a candidate target for experiments investigating skeletal development. Not only are these genes candidates for osteochondrodysplasia disease genes, but they also represent markers whose expression characterizes the differentiated state of chondrocytes.

Huntingtin's misfolding may hinder its export from the nucleus. *J.C. Cornett^{1,2}, H. Zhou¹, S.H. Li¹, X.J. Li¹.* 1) Dept Human Gen, Whitehead Bldg, Emory Univ, Atlanta, GA; 2) Graduate Program in Genetics and Molecular Biology.

Nuclear accumulation and aggregation of polyglutamine proteins is a common feature of polyglutamine diseases. In Huntington disease (HD), N-terminal huntingtin fragments, even without conserved nuclear localization sequences (NLS), are able to accumulate in the nucleus and form nuclear inclusions, whereas full-length mutant huntingtin is predominantly present in the cytoplasm. These facts suggest that small N-terminal huntingtin fragments may be passively translocated in the nucleus. The nuclear environment is likely to favor protein misfolding and thus retains mutant huntingtin in the nucleus. To test this hypothesis, we transfected HEK293 cells with NLS-linked huntingtin exon 1. Consequently, its concentration in the nucleus is largely determined by its export from the nucleus. NLS-huntingtin with a normal repeat (NLS-20Q) was less concentrated in the nucleus than that with an expanded repeat (NLS-150Q), suggesting that normal huntingtin is readily exported from the nucleus. Co-expression of chaperones (HSP40 and MRJ) that reduce huntingtin misfolding and aggregation significantly decreased the nuclear concentration of NLS-150Q, leading to an increase of its cytoplasmic concentration. Another chaperone (HSP70) that does not affect huntingtin aggregation showed no or much less effect on the nuclear accumulation of NLS-huntingtin. Treatments that decrease the activity of HSPs also increase huntingtin's aggregation and its nuclear accumulation. We propose that the nuclear accumulation of huntingtin is largely due to huntingtin misfolding that could affect the export of huntingtin from the nucleus.

New mutations of NaV1.1 gene encoding a neuronal sodium channel in families with GEFS+. *G. Annesi¹, A.A. Pasqua¹, S. Carrideo¹, D. Civitelli¹, P. Spadafora¹, F. Annesi¹, G. Incorpora³, A. Polizzi³, I.C. Cirò Candiano¹, P. Tarantino¹, A. Gambardella².* 1) Inst of Neurological Sciences, National Research Council, Cosenza, Italy; 2) Institute of Neurology, University of Magna Graecia, Catanzaro, Italy; 3) Institute of Pediatrics, University of Catania, Italy.

Generalized epilepsy with febrile seizures plus (GEFS+) is a familial epilepsy syndrome characterized by the presence of febrile and afebrile seizures. One of the loci for GEFS+ has been reported on chromosomal band 19q13.1, and subsequently a mutation of the voltage-gated sodium channel beta1-subunit gene has been identified in a family with GEFS+. Recently, mutations of the alpha subunit of the sodium channel, NaV1.1 on chromosome 2q24 have been reported in individuals with the GEFS+ phenotype. In this paper we studied 8 Italian families with GEFS+, by mutation analyses of genes NaV1.1 and beta1. Genomic DNA was extracted by standard methods. The 26 exons of NaV1.1 and 5 exons of SCN1B were individually amplified using primers based on intronic sequence, and PCR products were analyzed by single strand conformation polymorphism (SSCP) and sequence. In two GEFS+ families, we identified two novel mutations of the gene NaV1.1, that co-segregate with the disorder. In the remaining 6 families, screening of NaV1.1 gene revealed several single nucleotide polymorphisms (SNPs). The SNPs were found at low frequency in both GEFS+ and control populations. In the SCN1B gene we found no variants that co-segregate with GEFS+ phenotype, only one variant was identified in intron 5 (IVS5-10 C>G) which did not segregate with GEFS+ and was observed in control populations. The results of our study further support the role of Nav 1.1 gene in the etiology of this peculiar epileptic disorder. It also provides evidence of a genetic heterogeneity because several GEFS+ families did not carry any mutations in either gene. Obvious candidates include other neuronal sodium channels and proteins that interact with sodium channels.

MAP Kinase pathway in the Ts65Dn mouse model of Down syndrome. *K. Gardiner*¹, *K. O'Brien*¹, *L. Crnic*², *M. Davis*³. 1) Eleanor Roosevelt Inst, Denver, CO; 2) University of Colorado Health Sciences Center, Denver, CO; 3) The Jackson Laboratory, Bar Harbor, ME.

The Ts65Dn mouse model of Down syndrome is trisomic for ~100 genes with homologues on human chromosome 21. The phenotype of the Ts65Dn mouse includes age-related deficits in hippocampal-based learning, degeneration of basal forebrain cholinergic neurons and abnormalities of concentrations and distributions of nerve growth factor (NGF). Three observations suggest the involvement of the MAP kinase signaling pathway in the Ts65Dn and Down syndrome phenotypes: NGF signals through the MAPK pathway, hippocampal-based learning can be inhibited by inhibiting MAPK and the chromosome 21 genes - ITSN, APP, TIAM1, and SYNJ1 - influence or are predicted to influence the MAPK pathway. To test this hypothesis we have measured protein levels of the four chromosome 21 genes and several MAPK components in the brains of Ts65Dn and normal mice of ages 4-6 months. As expected the levels of chromosome 21 proteins were increased ~50% in the Ts65Dn vs normal mice. Levels of MAPK proteins, however, were variable: levels of phosphorylated ERK1/2 decreased (~25%) while levels of total ERK2 were unchanged; levels of phosphorylated Akt1 and ChAT also were decreased; levels of total ERK5 were unchanged. These data show that the MAPK pathway is perturbed in the trisomic mice and suggest a link between increased expression of chromosome 21 genes and a cellular and cognitive phenotype. These observations are being extended to mice of younger and older ages, to specific brain regions and to targets of the MAPK pathway.

Identification of Novel Genes involved in Spinal Muscular Atrophy using High Density Microarrays. *K.N. Anderson, A. Potter, C. Ponting, K.E. Davies.* Human Anatomy and Genetics, University of Oxford, Oxford, Oxon, UK.

Spinal Muscular Atrophy (SMA) is a common motor neuron disease of childhood that is usually fatal in infancy and is characterised by profound weakness and wasting. The disease is caused by mutations or deletions within the Survival Motor Neuron (SMN) gene in over 97% of cases. Although the SMN protein is known to have an essential housekeeping role in RNA metabolism, the reason for the specific motor neuron loss in the disease remains unclear.

Microarrays are a powerful tool for examining differences in gene expression profile between cDNA populations. In this study, nylon cDNA arrays spotted with 75,000 clones representing approximately 90% of the human genome were used. Primary muscle cultures were established from an SMA patient and from two age and sex matched normal controls. RNA was harvested from confluent, differentiated myotubes. ³³P dATP labelled cDNA was then hybridised onto nylon filters, the resulting signal was detected on a phosphoimager and analysed using ImageneTM and GenespringTM software. All experiments were carried out in triplicate to minimise background noise. Genes which were greater than 2 fold up or down regulated in the SMA patient sample compared to both normal controls were analysed further. Two normal control samples were used to further decrease the chance of false positive results. Cluster analysis was also carried out on the data to look for patterns of change within known gene pathways.

The SMN gene was down regulated in the SMA patient sample as expected but a number of genes involved in RNA metabolism and also synaptic transport were up regulated in the patient sample. A number of these expression differences have been confirmed using real time PCR and these results will be discussed further.

Western blot analysis is ongoing but the initial results of these microarrays suggest that this technique can be used to provide unique and exciting insights into the cellular pathology of Spinal Muscular Atrophy.

A single-base insertion in SPG3A is associated with autosomal dominant hereditary spastic paraplegia. D.

Fortini¹, C. Casali¹, A. Tessa², M. Damiano¹, C. Patrono², F. Cricchi¹, L. Bernedetti¹, G.A. Amabile¹, E. Bertini², F.M. Santorelli^{1,2}. 1) Dept. Neurology, ORL & Rehab, "La Sapienza" University, Rome, Italy; 2) Molecular Medicine and Neurology, IRCCS - Bambino Ges, Rome.

Hereditary spastic paraplegia (HSP) comprises a clinically heterogeneous group of neurodegenerative disorders of the motor neuron system that cause progressive spasticity and weakness of the lower limbs. To date, eight autosomal dominant HSP loci have been identified, but only one gene cloned, namely SPAST on chromosome 2p22, encoding the protein spastin. Recently, mutations in a second gene, SPG3A, have been claimed to be causative in pure autosomal dominant HSP pedigrees linked to chromosome 14q11q21. We now report on a novel frameshift mutation (c.1688insA) resulting in premature translation termination of the SPG3A product atlastin, providing definitive evidence that SPG3A is truly the second disease gene in ADHSP.

Mutations of SPG4 are responsible for a loss of function of spastin, an abundant neuronal protein localized to the nucleus. *D. Charvin*¹, *N. Fonknechten*², *C. Cifuentes-Diaz*¹, *V. Joshi*¹, *J. Hazan*², *J. Melki*¹, *S. Betuing*¹. 1) Molecular Neurogenetics Laboratory, INSERM, University of Evry, E9913, Genopole, 2 rue Gaston Cremieux, CP5724, 91057, Evry, France; 2) Genoscope, Centre National de Sequenage, Evry, France.

Mutations of spastin are responsible for the most common autosomal dominant form of hereditary spastic paraplegia (HSP), a disease characterized by axonal degeneration of corticospinal tracts and posterior columns. Generation of polyclonal antibodies specific to spastin has revealed two isoforms of 75 and 80 kDa in both human and mouse tissues, with a marked tissue-specific variability of the isoform ratio. Immunoblot and immunolabelling experiments showed a nuclear localization of spastin with a high expression in neural tissues. In addition, these experiments have revealed that spastin expression is restricted to neurons and not glial cells. These data indicate that axonal degeneration linked to spastin mutations is caused by a primary defect of neurons. Protein analysis of HSP patients carrying either nonsense or frameshift spastin mutations did not reveal truncated protein. Moreover, semi-quantitative RT-PCR amplification analysis of spastin RNA revealed a reduced amount of spastin transcripts caused by instability of mutated RNA in HSP patients. Taken together, these data suggest that a dosage effect of spastin in neurons is the molecular mechanism underlying this form of HSP. Identifying agents able to induce the expression of the non-mutated spastin allele should represent an attractive therapeutic strategy in this disease.

Program Nr: 2027 from 2002 ASHG Annual Meeting

Roles of p53 in Huntington's Disease: possible involvement for mitochondrial function and cytotoxicity. *B. Bae, S. Igarashi, M. Fujimuro, Y. Ozeki, C.A. Ross, S.H. Snyder, A. Sawa.* Depts. of Psychiatry, Neuroscience, and Oncology Center, Johns Hopkins Univ. Sch. of Med. Baltimore, MD.

We reported that p53 was highly upregulated by mutant Huntingtin (Htt) with the expanded polyglutamine repeats both in a HD cell model (PC12 cells with Htt) and Htt transgenic animals, which conferred increased p53-mediated gene expression. We also reported that deletion of p53 increased cellular viability in HD cell model as well as normalized impaired behavior under rotarod tasks and reduced hyperactivity in rotational movements which were found in HD animal models. Here we present an additional data to support roles of p53 in HD animal models; a reduced mortality and restoration of impaired pre-pulse inhibition in mutant Htt transgenic mice when p53 was partially deleted. HD patient lymphoblasts display vulnerability in mitochondrial depolarization, which can be influenced by p53. Therefore, we have analyzed mitochondrial membrane potential as a possible downstream mechanism of Htt/p53. We observed mitochondrial depolarization in PC12 cells expressing mutant Htt, but not normal Htt, which is prior to cell death. The mitochondrial depolarization was normalized by the addition of a p53 inhibitor. Since mitochondria play a role in calcium homeostasis as well as cell death initiation, we are now studying intracellular calcium level of mutant Htt cells and response to glutamate, with or without inhibition of p53.

Autosomal Recessive forms of Axonal Charcot Marie Tooth (CMT)disease: Founder effect in LMNA and mutation spectrum in GDAP1 genes. *H. Azzedine¹, M. Tazir², N. Birouk³, G. Durosier¹, D. Ente¹, M. Salih⁴, O. Dubourg¹, A. Vandenberghe⁵, G. Stevanin¹, D. Grid⁶, A. Brice¹, E. Le Guern¹.* 1) INSERM U289, Hopital Salpetriere, 75013 Paris, France; 2) Hopital Mustapha, Sevice de Neurologie, Algiers, Algeria; 3) Hopital des specialites, Service de Neurogenetique, Rabat, Morocco; 4) Department of Paediatrics, College of Medecine, Riyadh, Saudi Arabia; 5) Hopital de l'antiquaille, Lyon, France; 6) AFM-Genethon, Paris, France.

CMT is a pathological and genetically heterogeneous group of hereditary motor and sensory neuropathies characterized by slowly progressive weakness and atrophy, primarily in peroneal and distal leg muscles. Two major types have been distinguished: demyelinating and axonal. Thirty loci and various modes of inheritance were described: autosomal dominant, X linked and autosomal recessive (ARCMT). 3 loci were reported on the axonal form of ARCMT: 1q21, 8q13 and 19q13. We selected 43 consanguineous families with axonal ARCMT including 72 patients among 193 sampled subjects. Linkage analysis and homozygosity mapping were performed using microsatellite markers spanning the 3 ARCMT regions. 15 families (35%) were linked to the 1q21 locus (LMNA gene), 12 (28%) to the 8q13 locus (GDPAD1 gene) and only one family was linked to 19q13 (2%). In conclusion, ARCMT families were rarely linked to the 19q13 locus in contrast to two other loci, which are frequent in our series. Direct sequencing of the corresponding genes was performed on linked families. In families with putative linkage to 1q21, the R298X mutation in the LMNA/C gene was predominant (73%), highly suggesting a founder effect in North Africa. In families with putative linkage to 8q13, the S194X mutation was predominant in Morocco (4/5), but rare in other regions of North Africa, also highly suggesting a founder effect. Haplotype reconstruction with markers flanking LMNA and GDAP1 are in progress to test these hypotheses. Furthermore, we identified a new mutation (R318G) in a compound heterozygote of Moroccan origin, also carrying the S194X mutation. Finally, about 32% of families were not associated with the known loci, demonstrating further genetic heterogeneity.

Holoprosencephaly : mutational screening and functional analysis of human SHH missense variants. C.

Dubourg^{1,2}, L. Pasquier³, M. Blayau², L. Lazaro³, M.R. Durou², C. Aguilera³, S. Odent³, V. David^{1,2}. 1) UMR 6061, Faculty of Medicine, Rennes, France; 2) Laboratory of Molecular Genetics, CHU Pontchaillou, Rennes, France; 3) Service of Clinical Genetics, CHU Pontchaillou, Rennes, France.

Holoprosencephaly (HPE ; 1,2/10.000 live births ; 1/250 conceptuses) is a common development defect affecting both the forebrain and the face. Clinical expressivity is variable, ranging from a single cerebral ventricle and cyclopia to clinically unaffected obligated carriers in familial HPE. The disease is genetically heterogeneous but additional environmental agents also contribute to the aetiology of HPE. This study includes 150 unrelated nonchromosomal HPE cases (100 typical HPE, 25 atypical cases, 25 polymalformative cases). We provide clinical data regarding the subgroup of typical HPE and report 25 novel heterozygous mutations (17% for all the cases, 25% for typical HPE), 13 in Sonic hedgehog gene (SHH), 6 in ZIC2, 5 in SIX3, and 1 in TGIF. Fourteen mutations were found in familial cases whereas 11 mutations were identified in apparently sporadic cases. In addition to clear loss-of-function mutations conferred by nonsense or frameshift alteration in the coding sequence, genetic screening has revealed missense codons with less obvious functional consequences. The ability to discriminate between a loss-of-function mutation and a silent polymorphism is important for genetic testing for inherited diseases like HPE where the opportunity for prenatal diagnosis may be considered. We report here a functional test where the significance of SHH aminoacids replacements observed in the human population is tested by the C3H10T1/2 osteoblast transformation and phosphatase alkaline production under the Sonic Hedgehog action.

Spartin, the Troyer syndrome gene, suggests defective endosomal trafficking underlies some forms of hereditary spastic paraplegia. *A.H. Crosby, H. Patel, M.A. Patton, C. Proukakis, H. Cross.* Dept Medical Genetics, St George Hosp Med Sch, London, England.

Troyer syndrome (TRS) is an autosomal recessive complicated form of hereditary spastic paraplegia present at high frequency amongst the Old Order Amish (for a detailed clinical description see accompanying abstract). We have identified a single extensive Amish pedigree comprising 21 affected individuals. Having excluded known HSP loci, we used homozygosity mapping assuming a founder effect to position the TRS locus (SPG21) within a 731kb interval of chromosome 13q12.3. This region comprises eight PACs encompassing 15 complete transcripts and the first three exons of a 16th transcript. Sequence analysis of all coding exons in the interval revealed the homozygous deletion in affected individuals of a single base pair in exon four (1110delA) of a novel, highly conserved gene designated spartin. This frameshift mutation is predicted to result in the substitution of the 29 amino acid residues following the mutation, and to truncate the protein by 268 residues (fs369-398X399). Single strand conformation polymorphism (SSCP) and sequence analysis of spartin exon four reveals that this mutation cosegregates perfectly with the disease in this population. The 1110delA mutation was also confirmed in the RNA extracted from the lymphocytes of affected individuals. In order to determine if this change represents a polymorphism, SSCP was used to screen 760 normal control chromosomes of mixed Caucasian (80%), Asian (10%) and African (10%) descent, as well as 44 chromosomes originating from the same Amish community but not closely related to the TRS cases. No 1110delA mutations were detected. By comparative sequence analysis, we have identified three novel functional domains in spartin. Importantly one of these (MIT) is also present in spastin, mutated in more common forms of HSP, as well as in molecules that may function in endosomal trafficking. This finding reveals a functional link between two molecules mutated to result in HSP and highlights a putative mechanism responsible for some forms of neurodegeneration.

Genetic heterogeneity in Silver syndrome. *C.D. Fenske¹, T.T. Warner², H. Patel¹, M.A. Patton¹, C. Proukakis¹, A.H. Crosby¹.* 1) Medical Genetics Unit, St George's Hosp Medical, London, England; 2) Department of Clinical Neurosciences, Royal Free and University College Medical School, London, UK.

The hereditary spastic paraplegias (HSPs) are a group of clinically and genetically heterogeneous neurodegenerative disorders of the motor system. Silver syndrome (SS) is an autosomal dominant form of HSP in which the spasticity is associated with marked amyotrophy and weakness of the small muscles of the hands. We previously reported the localisation of the SS locus (SPG17) to a 13cM interval on chromosome 11q12-q14 and exclusion of two candidate genes (CNTF and CCS) as being causative of the disease. Here we report the identification of a second pedigree mapping to the SPG17 locus, and the exclusion of three additional families. This demonstrates further locus heterogeneity in HSP, even in this rare complicated form of the disease.

Single Cell Genomic DNA Analysis via Laser Capture Microscopy: Evaluation of LOH in the Development of Cerebral Cavernous Malformations. *K.A. Gee¹, L. Nowak¹, J. Zabramski², S. Coons³, E.W. Johnson¹.* 1) Neurogenetics/Neuropharm; 2) Neurosurgery; 3) Neuropathology, Barrow Neurological Inst, Phoenix, AZ.

The principle gene thought to be responsible for familial cerebral cavernous malformations (CCMs), CCM1, was identified as KRIT1. KRIT1 is a member of the Krev-1/rap1A/Ras family of proteins that play a role in tumor suppression/cell division suppression. CCM1/KRIT1 is believed to be causative in approximately 50-70% of familial CCM cases. To date no one has identified any individual homozygous for the mutated KRIT1 gene, allowing the possibility that homozygosity might be a lethal condition. The loss of KRIT1 function in vascular cells due to a mutation would in effect remove this suppression allowing for a tumor-like proliferation of endothelial cells. A reasonable hypothesis that could explain the focal nature of CCMs suggests that these "vascular tumors" may develop due to loss of the wild-type KRIT1 allele in the developing cerebral vasculature. Laser Capture Microscopy (LCM) will be used to address the idea that this loss of heterozygosity (LOH) in KRIT1 in cerebrovascular endothelial cells is a trigger for the development of CCMs. LCM allows the harvesting of definitively tagged cells with a resolution as small as individual nuclei. We will selectively harvest endothelial cells from CCM tissue removed during surgery and compare the KRIT1 alleles found there with the patients genomic haplotype derived from circulating lymphocytes and/or from non CCM derived endothelial cells where available. LCM brings to gene expression studies what quantitative autoradiography brought to pharmacological studies in the 1980's: substantially increased anatomical resolution. Regionally discrete changes are often missed when large areas of tissue are examined since the robust "normal" signal present in most of the tissue masks any neuroanatomically discrete variations that might be of interest. Whatever the mechanism, these data point to a key role for the KRIT1 and the Krev-1/rap1a pathway in the complex process of angiogenesis, and potentially, in other forms of cerebrovascular disease.

Chudley-Lowry syndrome results from absence of the XNP protein. *F.E. Abidi¹, A.E. Chudley², S. Daniels¹, T. Moss¹, H.A. Lubs³, R.E. Stevenson¹, C.E. Schwartz¹.* 1) J.C. Self Research Institute, Greenwood Genetics Center, Greenwood, SC; 2) Genetics Health Sciences Center, FE229-820, Winnipeg, MB R3A IR9, Canada; 3) University of Miami School of Medicine, Genetics Division/Department of Pediatrics, PO Box 016820/D-820, Miami, FL.

Chudley-Lowry syndrome (MIM # 309490) is an X-linked recessive condition characterized by moderate to severe mental retardation, short stature, mild obesity, hypogonadism, a depressed nasal bridge and anteverted nares (Chudley et al., 1988). The family consists of 3 affected males in two generations. Marker analysis had localized the gene between Xp21-Xq26. An obligate carrier was tested for X-inactivation (XI) and showed a highly skewed (95:5) pattern. The combination of the clinical phenotype, consistent with XLMR-hypotonic facies, the skewed XI and the localization covering Xq13, suggested the existence of an XNP mutation might be the cause of the syndrome. Eighty percent of all the mutations reported in the XNP gene are found in the zinc finger and the helicase domains of this gene. Unfortunately analysis of these domains in the proband of Chudley-Lowry family did not detect any mutation. Therefore, we designed a RT-PCR based strategy to expand the study to the rest of the gene. The RT-PCR analysis revealed a nonsense mutation (C109T) in exon 2 of the XNP gene, giving rise to a stop codon at position 37 (R37X). As a result, the affected males completely lack the XNP protein, although the presence of a premature stop codon does not affect the stability of the altered XNP transcript. Our findings suggest that Chudley-Lowry syndrome is yet another syndrome that is allelic to the XLMR-hypotonic facies syndrome. Interestingly, the lack of the XNP protein has not resulted in as a severe phenotype in the family as missense mutations. This would indicate that the absence of XNP protein appears cause less disruption of development and brain function than some altered forms of the XNP protein. One explanation is that some XNP mutations may be exerting a dominant-negative effect.

Familial epilepsy incorporating "benign" infantile convulsions: phenotypic overview, linkage to chromosome 19q and analysis of candidate genes. *S.A. McKee, A.E. Hughes.* Dept of Medical Genetics, Queen's University Belfast, Northern Ireland.

PURPOSE: Epilepsy affects 2-4% of people at some point in their lives. Genetic factors are important in idiopathic epilepsy, but kindreds displaying mendelian inheritance are rare. Several genes (notably ion channels) have been implicated in some such families, offering insights into more common forms of epilepsy. We studied a large Irish family with a history of seizures, consistent with autosomal dominant inheritance.

METHODS: 32 consenting family members were interviewed and examined, DNA was obtained, and medical records were consulted. Genome-wide linkage analysis was undertaken, adopting a stringent affected-only data model. Candidate genes were sequenced.

RESULTS: The most consistent phenotype was of generalised seizures beginning ~3mo, lessening by ~2yr. Many subjects had seizures persisting into childhood or adulthood. The severity of seizures appeared to be greater in males in the most recent generation, suggesting anticipation and sex-bias. 18 subjects were classed as affected, and there were 4 obligate gene carriers. A LOD score of 3.62 was found at D19S220 on chromosome 19q. No other regions of significant linkage were detected in the genome. Nearby candidate genes included the ion channels SCN1B and KCNK6; no mutations were found in these genes. A polyglutamine tract in the neuronally-expressed NUMBL gene did not show evidence of expansion.

CONCLUSIONS: The phenotype in this family is different from recognised genetic epilepsy syndromes. It bears similarities to benign familial infantile convulsions (BFIC), but there are important differences, particularly in the persistence of seizures into later life, possible anticipation, and the high degree of variability. One form of BFIC has previously been mapped more proximally on 19q; further work is required to determine whether these seizure disorders are allelic, or due to different genes.

Program Nr: 2035 from 2002 ASHG Annual Meeting

Presentation of one family Affected with HIBM,a report from Iran. *S. Joughehdoust, Y. Shafeghati, M. Ataii, M. Houshmand.* NRCGEB, Tehran, tehran, Iran.

Hereditary Inclusion Body Myositis is a chronic progressive muscle disorder .Inheritance is autosomal recessive. It is started with insidious onset in second or third decades of life and associated with distal muscle weakness in the upper extremities and proximal muscle weakness in the lower extremities. Our patient is 24 years old girl that suffers from muscular weakness. Positive findings in her physical exam are mild weakness of neck flexors,deltoid and scapular muscles and in lower extremity , severe iliopsoas , gluteal ,plantar and dorsiflexor weakness. The quadriceps however is normal.EMG shows myopathic feature and muscle biopsy is compatible with muscular atrophy,neurogenic .All of the above findings are typical for HIBM. HIBM is prevalent in Iranian Jews.The patient is from an unconsanguineous marriage and her grand parents were from Iranian Jewish ancestors. In our lab we are analyzing a mutation in the 3UTR region of CNTFR mRNA gene,this gene is a 305 bp long .The method is PCR/RFLP. To detect homozygote or carrier state all members of her family will be examined for this mutation. In spite of its autosomal recessive pattern of inheritance we are planning to find a relation between mitochondrial myopathies mutations and HIBM, because the basis of both disorders is lack of ATP synthesis.

Molecular characterization of *ZFHX1B* in patients with SIP1 deficiency. *N. Ishihara*^{1,7}, *K. Yamada*¹, *Y. Yamada*¹, *K. Miura*², *K. Ohya*⁴, *A. Nakayama*⁵, *M. Yoneda*⁶, *M. Nagaya*³, *N. The Hirschsprung disease-mental retardation syndrome (MIM 235730) is genetically and clinically quite heterogeneous. Recently, we identified mutations in *ZFHX1B*, encoding Smad-interacting protein 1 (SIP1), associated with the autosomal dominant form of this disease. Patients who have nonsense or frameshift mutations of *ZFHX1B* in one of alleles typically show profound mental retardation, delayed motor development, microcephaly and facial dysmorphism, with various combinations of Hirschsprung disease, epilepsy, congenital heart diseases and abnormal brain findings. We have been continuing molecular analysis of *ZFHX1B* and identified an insertion of 382-bp of AluYa5 in exon 8 (390fs430X) as well as a novel insertion of 19 nucleotides, instead of the 14-bp deletion (465fs467X) found in typical cases. Moreover, a 3-bp deletion mutation (N99del) was also identified in one allele from a patient suffering moderate mental retardation and megacolon. To investigate whether the mild clinical features observed in the patient with the 3-bp deletion in *ZFHX1B* might have been caused by dysfunction of transcriptional repression of SIP1, we constructed expression vectors containing full length *ZFHX1B* cDNAs with and without mutations identified in patients with SIP1 deficiency. The aim is to demonstrate molecular mechanisms of mental retardation caused by SIP1 deficiency by co-transfection of *ZFHX1B* cDNAs and chimeric constructs of the E-cadherin promoter region driving luciferase into HEK293 cells.

g-synuclein gene alternation in a case of dementia with Lewy bodies (DLB). *H. Ohtake*¹, *O. Onodera*^{1,2}, *S. Igarashi*^{1,2}, *M. Saito*¹, *H. Takahashi*³, *A. Ishikawa*⁴, *J. Idezuka*⁵, *M. Wakabayashi*⁵, *B. Giasson*⁶, *V.M.-Y. Lee*⁶, *J.Q. Trojanowski*⁶, *S. Tsuji*¹. 1) Dept of Neurol; 2) Molecul Neurosci; 3) Neuropathology, Brain Res Inst, Univ Niigata, Niigata, Japan; 4) Niigata Nat Hosp, Niigata, Japan; 5) Ojiya Sakura Hosp, Niigata, Japan; 6) Center for Neurodegenerative Dis Res and Dept of Patho and Lab Med, Univ Pennsylvania, Philadelphia, PA.

DLB and Parkinson's disease (PD) are characterized by intracellular inclusions, Lewy bodies. α -Synuclein (SNCA) has been shown to be a major component of Lewy bodies and to have a property of forming fibrils. Despite the amino-acid sequence similarities among the synuclein family genes, b- and g-synucleins (SNCB, SNCG) tend to be more soluble compared to SNCA. It has been suggested that SNCB and SNCG inhibit fibrillation of SNCA. Two missense mutations of SNCA have been reported in AD-PD. In 2001 Limprasert *et al.* reported a DLB case with a missense mutation in SNCB. We hypothesized that loss of the physiological function of SNCB or SNCG to protect fibril formation of SNCA can also cause DLB or PD. We analyzed the coding sequences of synuclein family genes in 3 pedigrees (2 with AD inheritance and one with consanguineous marriage) and 2 sporadic cases. Among them, we identified an A257G missense mutation of SNCG in an 81-year-old woman without family history, but no mutations in others. This mutation results in substitution of glycine for glutamic acid and expected to be more insoluble. Interestingly, the amino acid of SNCA corresponding to the mutated codon in SNCG is glycine, identical to the glycine in the mutant SNCG at the same codon, and furthermore, this substitution is located at the position corresponding to the region near the 11 hydrophobic residues of SNCA, which plays important roles in fibrillation of SNCA. These data raise the possibility that the mutant SNCG promote fibrillation of not only SNCA but also SNCG. Since detailed information on the family members are unavailable, and her offsprings were too young to be evaluated for disease presentations, further follow-up studies will be required. We propose that this mutation in SNCG is potentially responsible for pathogenesis of DLB.

A simple method to confirm clinical diagnosis of autosomal recessive Spinal Muscular Atrophy by Denaturing High Performance Liquid Chromatography (DHPLC). *R. Mazzei¹, F.L. Conforti¹, M. Muglia¹, T. Sprovieri¹, A. Magariello¹, A. Patitucci¹, A.L. Gabriele¹, A. Quattrone^{1, 2}.* 1) Institutes of Neurological Sciences, National Research Council, Mangone , CS, Italy; 2) Institute of Neurology, School of Medicine of Catanzaro, Italy.

Spinal Muscular Atrophy (SMA) is characterized by degeneration of motor neurons in the spinal cord, causing progressive weakness of the limbs and trunk, followed by muscle atrophy. SMA is one of the most frequent autosomal recessive diseases, with a carrier frequency of one in 50 and the most common genetic cause of childhood mortality. Recessive SMAs are caused by mutations in the Survival Motor Neuron gene (SMN). There are two nearly identical copies of this gene, the telomeric SMN (SMNt) and its centromeric counterpart (SMNc), present on chromosome 5q13; however, only the SMNt gene is affected in SMA. Furthermore, small deletions or point mutations have been found in patients in whom SMNt is present. In this study, we describe a new method to detect SMA gene deletion by Denaturing High Performance Liquid Chromatography (DHPLC), which is also simple to perform, but is faster and more specific. As telomeric and centromeric copies of exon 7 of the SMN gene differ only by a single base pair, denaturation and slow renaturation of PCR products of this exon leads to formation of heteroduplexes and homoduplexes. The same also occurs in exon 8. Therefore, by using DHPLC we should obtain a different resolution in normal controls from that in patients carrying the deletion. The main advantages of our approach are that it is simple to perform, and is faster and less expensive than previously described methods. Furthermore, it leads to clear and unambiguous results.

Deficiency of α -dystroglycan in muscle-eye-brain disease. *H. Kano*¹, *K. Kobayashi*¹, *R. Herrmann*², *T. Voit*², *H. Topaloglu*³, *T. Endo*⁴, *T. Toda*¹. 1) Div Functional Genomics, Dept Post-Genomics and Diseases, Osaka Univ Grad Sch Med, Osaka, Japan; 2) Dept Pediatrics and Pediatric Neurology, Univ Essen, Essen, Germany; 3) Dept Pediatric Neurology, Hacettepe Children's Hospital, Ankara, Turkey; 4) Glycobiology Research Group, Tokyo Metropolitan Institute of Gerontology, Foundation for Research on Aging and Promotion of Human Welfare, Tokyo, Japan.

α -Dystroglycan is a component of the dystrophin-glycoprotein-complex (DGC), which is the major mechanism of attachment between the cytoskeleton and the extracellular matrix. Muscle-eye-brain disease (MEB) is an autosomal recessive disorder characterized by congenital muscular dystrophy, ocular abnormalities and lissencephaly. We recently found that MEB is caused by mutations in the protein *O*-linked mannosyl transferase (POMGnT1) gene. POMGnT1 is a glycosylation enzyme that participates in the synthesis of *O*-mannosyl glycan, a modification that is rare in mammals but is known to be a laminin-binding ligand of α -dystroglycan. We examined skeletal muscle tissue samples from MEB patients to evaluate the state of the DGC and to search for proteins that are modified by POMGnT1. Immunohistochemistry and immunoblotting were performed using anti-laminin α 2 chain, anti- α -dystroglycan, anti- β -dystroglycan, and anti-dystrophin antibodies. Immunoreaction to the anti- α -dystroglycan antibody was barely detectable on the surface membranes of skeletal muscle fibers in MEB patients relative to the control. On the other hand, immunoreactivity of laminin α 2 chain, β -dystroglycan and dystrophin proteins were similar between MEB patients and the control. Immunoblot analysis of protein extracts from muscle tissue gave consistent results in which the muscle specimen from the MEB patient showed a lack of α -dystroglycan expression, although normal levels of β -dystroglycan were observed. This finding suggests that α -dystroglycan is a potential target of POMGnT1 and that altered glycosylation of α -dystroglycan may play a critical role in the pathomechanism of MEB and some other forms of muscular dystrophy.

Mutations in the TGIF gene and SIX3 gene in patients with holoprosencephaly. *J. Herbergs¹, H.W. Moerland¹, J.J. Van der Smagt³, G.M.S. Mancini², M. Van Haelst², H.J.M. Smeets¹.* 1) Department of Clinical Genetics, Academic Hospital Maastricht, Maastricht, The Netherlands; 2) Department of Clinical Genetics, Erasmus University, Rotterdam, The Netherlands; 3) Leiden University Medical Hospital, Leiden, The Netherlands.

Holoprosencephaly (HPE) is a common, severe malformation of the brain that involves abnormal formation and septation of the developing central nervous system. In mild HPE microcephaly, a single central incisor, hypotelorism or other craniofacial findings can be present with or without associated malformations. Mutations in several genes are known to cause HPE. In our lab four genes known to be involved in the pathogenesis of HPE are initially analysed for pathogenic mutations, namely SHH, ZIC2, SIX3 and TGIF. In a small series of patients a new truncating mutation was detected in the SIX3 gene and a missense mutation in the TGIF gene. The patient with a SIX3 mutation has semilobar HPE with cleft palate, while the patient with a TGIF mutation presented with more severe HPE. The mutation in the TGIF gene could affect a region of the protein constituting a repression domain, which is dependent on HDAC and contains a SMAD-interacting region. The mutation, however, was also detected in one of the parents, presenting hypotelorism and microcephaly.

Gene expression profiling of SMA mouse models using cDNA microarray. *R. OLASO¹, V. JOSHI¹, N. PAULINE¹, N. ROBLOT¹, G.M. LATHROP², J. MELKI¹.* 1) Molecular Neurogenetics Laboratory, INSERM E.9913, Université d'Evry, GENOPOLE, 91057, Evry, France; 2) Centre National de Genotypage, Evry, France.

Spinal Muscular Atrophy (SMA) is a common autosomal recessive neuromuscular disorder characterized by degeneration of motor neurons leading to progressive paralysis with muscular atrophy. Mutations of the Survival of Motor Neuron gene (SMN1) are responsible for SMA. Previous studies have suggested that SMN protein is implicated in several processes. However, the molecular pathway linking SMN defect to SMA phenotype remains to be elucidated. The Cre-loxP recombination system has been used to direct deletion of the murine *Smn* exon 7 to either neuronal or skeletal muscle cells. Both neuronal and muscular mutant mice display severe muscle paralysis leading to early death through motor neuron or skeletal muscle degeneration respectively. These data indicate that both neurons and skeletal muscle are involved in SMA pathogenesis. To refine the degenerative process in SMA and identify the targets of SMN1 gene defect, we have undertaken a comparative gene expression study using cDNA microarray. We compared targeted tissues from control and mutant mice (either neuronal or muscular) at different stages of the disease. Skeletal muscle or spinal cord mRNA extracted from control and SMN mutant mice were reverse-transcribed, labelled with Cy5 or Cy3 dyes and hybridized to the array. For each age (10, 20 and 30 day-old), 3 couples of mutant/control animals were used. We have selected genes over or under-expressed at least 1.9 fold in 3 experiments. Preliminary results showed that less than 200 out of 8000 genes examined were differentially expressed in skeletal muscle of 20 day old muscular mutant mice. We are currently ordering all these genes by functional families. As expected, several muscle specific genes were underexpressed in the mutant mice. Comparing gene expression profiling in neuronal and muscular SMN mutant mice at different ages should allow to reduce the number of candidate genes. This study should contribute to clarify the physiopathology of SMA, the function of SMN and should help to design potential targeted therapeutic molecules.

P172H MUTATION IN THE TM4SF2 GENE ACCOUNTS FOR 1% OF NON-FRAGILE X MENTAL RETARDATION IN BRAZILIAN PATIENTS. *C.M.C. Maranduba^{1,2}, A.M. Vianna-Morgante¹, M.R. Passos-Bueno¹.* 1) Centro de Estudos do Genoma Humano, Departamento de Biologia, Universidade de São Paulo, São Paulo, Brasil; 2) Centro em Interunidades em Biotecnologia, Instituto de Ciências Biomédicas, Universidade de São Paulo, São Paulo, Brasil.

X-linked mental retardation (XLMR) affects approximately 1 in 600 males, comprising (1) syndromic forms (MRXS), among which the fragile X syndrome is the most prevalent of the 68 syndromes so far described, and (2) nonsyndromic forms (MRX). To date, eight genes have been found to be associated with MRX: FMR2, OPHN 1, GDI1, PAK3, TM4SF2, ARHGEF6, VCX-A and IL1RAPL. IL1RAPL and TM4SF2 mutations appear to account for 5-10% of MRX, while the other mutations are associated with less than 1% of the cases. We are presently screening the coding region and the exon-intron boundaries of IL1RAPL and TM4SF2 genes, through SSCP analysis and sequencing, in 105 mentally retarded male patients (25 familial and 80 isolated cases) who were shown not to carry the fragile X mutation. Four of the eight known exons of the IL1RAPL gene were analyzed in 50 patients, and two altered migration patterns were detected after SSCP, sequencing being under way. All the seven exons of the TM4SF2 gene were analyzed in 96 patients. A CA transversion at the nucleotide c.515 (P172H) was detected, which was confirmed by the SNUPE test (Amersham Biotech). This change was maternally inherited and was not carried by the healthy brother of the patient. Our survey of 100 control chromosomes did not reveal this mutation, that was first described in a familial MRX case by Zemni et al. (Nat. Genet. 24, 167 2000). Our results adds to the indication that the P172H mutation is pathogenic, with a prevalence of about 1% among non-fragile X mental retardation cases in our sample. Therefore, testing for the P172H mutation in the TM4SF2 gene should be considered in the routine diagnosis of mentally retarded individuals. Supported by FAPESP, PRONEX and CNPq.

A worldwide distribution and a broader clinical spectrum of muscle-eye-brain disease: a genotype-phenotype

correlation. *K. Kobayashi¹, K. Taniguchi¹, K. Saito², H. Yamauchi³, D.K. Jin⁴, E. Parano⁵, R.V. Coster⁶, H.*

Toda¹. 1) Div Functional Genomics, Dept Post-Genomics and diseases, Osaka Univ Grad Sch Med, Osaka, Japan; 2) Dept Pediatr, Tokyo Womens Med Univ, Tokyo, Japan; 3) Dept Pediatr, Dokkyo Univ Sch Med, Tochigi, Japan; 4) Dept Pediatr, Sungkyunkwan Univ, Seoul, South Korea; 5) Dept Pediatr, Univ Catania, Catania, Italy; 6) Div Neurometabol disord, Ghent Univ Hosp, Ghent, Belgium; 7) Dept Pediatr Neurol, Hacettepe Childrens Hosp, Ankara, Turkey; 8) Dept Pediatr and Pediatr Neurol, Univ Essen, Essen, Germany; 9) Glycobiol Res Gr, Tokyo Metropolitan Inst Gerontol, Tokyo, Japan.

Muscle-eye-brain disease (MEB) is an autosomal recessive disorder prevalent in Finland, which is characterized by congenital muscular dystrophy, brain malformation (type II lissencephaly), and ocular abnormalities. Since the phenotype has a substantial overlap with those of Fukuyama-type congenital muscular dystrophy (FCMD) and Walker-Warburg syndrome (WWS), these three diseases are considered to be caused by a similar pathomechanism. Recently, we found that MEB is caused by mutations in the protein *O*-linked mannose b1,2-*N*-acetylglucosaminyltransferase 1 (POMGnT1) gene. We describe here the identification of seven novel mutations in six of not only non-Finnish Caucasian but also Japanese and Korean patients with suspected severe FCMD, MEB, or WWS. Including the seven mutations reported previously, all 13 mutations are dispersed along the whole POMGnT1 gene. A weak correlation between the location of mutation and clinical severity was observed; patients with mutations in the vicinity of the 5 terminus of the POMGnT1 coding region show relatively severe symptoms such as hydrocephalus, while patients with mutations in the vicinity of the 3 terminus have milder phenotypes. Our results suggest that MEB patients may exist in many population groups outside of Finland with a worldwide distribution beyond our expectations, and that the clinical spectrum of MEB is broader than recognized previously. These emphasize the importance of considering MEB and searching the POMGnT1 mutations, in WWS and in the worldwide outside of Finland.

Mutational Analysis and Identification of Differential Methylation Patterns in the SGCE Gene in Patients with Myoclonus Dystonia. L. Liu¹, P. de Carvalho Aguiar¹, R. Saunders-Pullman², C. Klein³, S. Bressman², L. Ozelius¹ and The Myoclonus-Dystonia Study Group. 1) Molecular Genetics, Albert Einstein College of Med, Bronx, NY; 2) Department of Neurology, Beth Israel Medical Center, New York; 3) Departments of Neurology and Human Genetics, Medical University of Lbeck, Lbeck, Germany.

Myoclonus-dystonia (M-D) is an autosomal dominant disorder characterized by myoclonic jerks and dystonia that are often responsive to alcohol. In the majority of families, the disease has been linked to chromosome 7q21 while loss of function mutations in the gene for epsilon-sarcoglycan (SGCE) have been reported. Mutation analysis was performed on the SGCE gene in families with M-D using denaturing high performance liquid chromatography (DHPLC). In total, we identified 20 mutations including: 6 frameshift mutations predicted to generate truncated proteins; 3 nonsense mutations resulting in the insertion of immediate stop codons; 5 splicing mutations expected to delete specific exon from the protein and 6 missense mutations. All six missense mutations were not seen in 500 control chromosomes and each is predicted to change a conserved amino acid in the protein. The SGCE gene is imprinted in mice. Pedigree analysis in M-D families showed a significant difference in penetrance according to the parental origin of the disease allele, suggesting that SGCE may be imprinted in humans as well. Differences in methylation were observed in the 5' UTR CpG rich region of the SGCE gene by Southern blot analysis using methylation sensitive enzymes demonstrating differential expression of the two parental alleles. In addition to lymphoblastoid lines, brain tissue was also used on the Southern blots and revealed the same imprinting pattern. This indicates that methylation of the promoter region of the SGCE gene may result in imprinting and that this mechanism operates in at least two different tissue types.

Deletion breakpoint analysis in a patient with Pelizaeus-Merzbacher disease (PMD) and comparison with duplications. *G.M. Hobson¹, C.M. Ritterson¹, T.D. Bird², W.H. Raskind², J.Y. Garbern³, K. Sperle¹.* 1) A I duPont Hosp Children, Wilmington, DE; 2) University of Washington, Seattle, WA; 3) Wayne State University, Detroit, MI.

Pelizaeus-Merzbacher disease (PMD) is an X-linked recessive dysmyelinating disorder of the central nervous system. Approximately 60% of cases are due to duplication of a genomic region that includes the PLP1 gene. While PLP1 gene duplications vary in size and breakpoint, most are tandem and intrachromosomal in origin. Another 15% to 25% are due to point mutations. Only two complete deletions of the PLP1 gene have been reported, one of >73 kbp determined by FISH analysis using BACs, and the other of >29 kbp determined by Southern blot analysis. A probable grandpaternal origin has been reported for duplications and for the deletion of >73 kbp. The disease phenotype of the patient with a deletion of >73 kbp was described as similar to that of duplication patients. The phenotype of patients with the deletion of >29 kbp is less severe than that of duplication patients, and is characterized by a longer time interval before requiring a wheelchair. In addition to the central nervous system findings, patients with deletions have peripheral neuropathy. Using sequence information available from the Human Genome Project, we have designed primer pairs in the genomic region around the PLP1 gene and performed breakpoint analysis of the deletion of >29 kbp by quantitative comparative multiplex PCR. We determined that the deleted region is >180 kbp and it includes at least one gene in addition to PLP1, RAB9-like, a member of the Ras superfamily. The deletion data will be refined and compared with duplication data of patients who have duplication endpoints nearby. Deletion and duplication breakpoint analyses and eventual determination of the genomic sequence at the breakpoints will provide insight into the molecular mechanisms involved.

Glycine receptor mRNA level correlates with phenotype severity and downstream gene changes in spastic and spasmodic murine models: an expression profiling study. *A. Molon, S. Di Giovanni, F. Murillo, E.P. Hoffman.*
Center for Genetic Medicine, Children`s Hospital, Washington , DC.

Glycine is the major inhibitory neurotransmitter in the spinal cord and brainstem. The glycine receptor (GlyR) is composed by two types of subunits: a and b. In humans, mutations in the GlyR subunit genes cause hereditary hyperekplexia, an autosomal dominant disorder. Two murine homozygote mutants are models for GlyR mutations: the spasmodic (Spd) mouse carries a mutation in the a subunit (Ala52Ser), while the spastic (Spa) mouse harbors an insertion (LINE 1) in the b subunit. Affected littermates show a variable phenotype, ranging from limb paralysis (severe), to mild startle response (mild). In order to define the relationship between mutation type, glycine mRNA levels, downstream pathogenic events, and the variable clinical phenotype, we expression profiled spinal cords of both mutants, showing different levels of phenotype severity, using Affymetrix MU74A v2 array including 12478 probe sets. Specific RNAs were verified by QMF-RT-PCR using infrared primers. The severe spastic animals showed widespread expression changes in the spinal cord, while the mild animals were similar to normal profiles. We found that GlyR mRNA levels correlated with severity of phenotype. In particular, GABA and glutamate receptors and genes involved in their transport were significantly decreased together with profiles associated with neuritogenesis and lipid biosynthesis; these functional groups were shared with experimentally-induced mild spinal cord damage. Cell cycle progression genes (G2/M phase) in inherited spinal cord damage (Spa) were differentially induced relative to spinal cord trauma (G1/S stage). The induction of cell cycle checkpoints is likely detrimental to neuronal viability. Our results suggest that variations in the level of GlyR transcription may determine the severity of phenotype. Further, we identify gene transcriptional pathways shared between a genetic defect and environmental injury, while other pathways are specific to one type of injury and are associated with a downstream transcriptional cascade that may reflect and mediate a generalized metabolic neuronal depression.

Tau pathology and motor disturbances in the human tau P301S transgenic mouse model. *J.R. Murrell, M. Takao, B. Ghetti.* Dept of Pathology, Indiana Univ Sch Med, Indianapolis, IN.

Neurofibrillary pathology with abnormal microtubule-associated protein tau (gene = MAPT; protein = tau) is one of the main pathological lesions of several types of dementia including Alzheimer disease, Pick disease and progressive supranuclear palsy. Studies of families with frontotemporal dementia with parkinsonism linked to chromosome 17 (FTDP-17) have shown that mutations in MAPT cause diverse but mutation-specific lesions in the adult brain. Mutations in MAPT impair tau function, promote tau fibril formation, disrupt normal MAPT gene splicing and affect the normal ratio of 3:4 repeat-containing tau. Though some information is known about the effects of tau mutations, the actual mechanisms leading to neurodegeneration still need to be elucidated so that therapeutic measures can be developed. In order to study these tau-induced mechanisms of neurodegeneration, a transgenic mouse model with the human P301S tau mutation was created. This mutation was chosen because of the early onset (late 20s), unique pathology and variable clinical phenotype seen in humans. The human tau transgene is under the control of the mouse prion promoter. Two founder lines show above normal expression of the human tau gene. Hemizygous and homozygous animals from these founders show both motor and behavioral deficits at ages 11 months and 6 months, respectively. Tau positive inclusions were observed in the cingulate, somatosensory, motor, and entorhinal cortices as well as the hippocampus, caudate nucleus, putamen, cerebellum, midbrain, pons, medulla, and the anterior and posterior gray horns of the spinal cord. Thioflavin S staining suggests the presence of insoluble tau deposits. This animal represents a good model of tauopathy and should prove to be a valuable tool for studying the stages of neurodegeneration and testing potential therapeutic interventions.

Transgenic mouse model of spinal and bulbar muscular atrophy. *M. KATSUNO, H. ADACHI, A. KUME, G. SOBUE.* NEUROLOGY, NAGOYA UNIVERSITY GRADUATE SCHOOL OF MEDICINE, NAGOYA, AICHI, JAPAN.

Spinal and bulbar muscular atrophy (SBMA) is an X-linked late-onset motor neuron disease characterized by proximal muscle atrophy, weakness, contraction fasciculation, and bulbar involvement. Heterozygous female carriers are usually asymptomatic, although some express subclinical phenotypes. The molecular basis of SBMA is the expansion of a trinucleotide CAG repeat in the first exon of the androgen receptor (AR) gene, which encodes the polyglutamine (polyQ) tract. The presence of nuclear inclusions (NIs) is a pathologic hallmark of SBMA as well as most other polyQ diseases. Previously reported transgenic (Tg) mouse models of SBMA showed progressive motor deficits and NIs, although no sexual difference of phenotypes was demonstrated. In the present study, we generated Tg mice carrying a full-length AR containing 97 CAGs under the control of a cytomegalovirus enhancer and a chicken - actin promoter. Three of 5 lines exhibited small body size, short life-span, progressive muscle atrophy and weakness as well as reduced cage activity; all of which were markedly pronounced and accelerated in the male Tg mice, but not observed or far less severe in the female Tg mice regardless of the line. Western blot analysis revealed nuclear accumulation of mutant AR, and NIs were demonstrated in the neurons of the spinal cord, cerebrum, cerebellum, brain stem, and dorsal root ganglia as well as non-neuronal tissue such as the heart and muscle; these findings were also significant in male Tg mice, whereas female showed subtle abnormalities. Our findings reiterate the importance of nuclear localization of the mutant protein in the disease mechanism, and provide profound insight to the pathophysiology of SBMA.

An *in silico*-based approach for identification of a novel gene for Charcot-Marie-Tooth disorder. *G.M. Saiji*¹, *H. Takashima*¹, *J.R. Lupski*^{1,2}. 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Pediatrics, Baylor College of Medicine, Houston, TX.

Thirteen genes and sixteen genetic loci have been associated with Charcot-Marie-Tooth (CMT) and related disorders. In order to identify candidate genes in these sixteen regions, we designed an *in silico*-based approach. Using the tools of bioinformatics, we identified and mapped putative paralogs of the thirteen known CMT genes. Our hypothesis was that paralogs, which fall, in these sixteen critical regions should have a good potential as candidate genes for CMT. Using this *in silico* strategy, we identified six such positional candidates. One of these, *EMP3*, has already been ruled out (*Am J Hum Genet* **68**, 269-274). To validate these results, the most promising candidate, based on similarity score, was analyzed by DHPLC and sequencing for DNA sequence variation in our panels of CMT patients. So far, two mutations have been identified in this gene. This has thus validated our *in silico*-based approach for the identification of novel CMT genes. This strategy could thus likely be extended for the identification of disease-causing genes associated with other genetic disorders.

A mouse model of cerebral cavernous malformations generated by targeted mutation of the mouse *Ccm1* (Krit1) gene. *N.W. Plummer*¹, *M.W. Becher*², *D.A. Marchuk*¹. 1) Department of Molecular Genetics and Microbiology, Duke University Medical Center, Durham, NC; 2) Department of Pathology, University of New Mexico Health Sciences Center, Albuquerque, NM.

Cerebral cavernous malformations (CCM) are lesions in the central nervous system consisting of aggregates of enlarged capillary-like vascular channels without intervening brain parenchyma. Hemorrhage of CCMs can result in migraines, seizures, or lethal stroke. Three inherited forms of CCM have been mapped, and the mutated gene has been identified for *CCM1*. In order to develop an animal model of CCM, we have mutated the mouse *Ccm1* (Krit1) gene by homologous recombination in embryonic stem cells. The fifth and sixth coding exons were replaced by an IRES-LacZ cassette to facilitate analysis of *Ccm1* expression patterns. RT-PCR analysis of heterozygous and homozygous embryos confirmed that no wild-type transcripts are produced by the mutant allele. Heterozygous mutant mice are viable and fertile, but homozygotes die by embryonic day 11.0. Brain sections from heterozygous animals were stained with X-Gal to test the hypothesis that *Ccm1* is expressed in the vasculature of the brain. Surprisingly, the most intense staining was in the epithelial cells of the ependyma, with weaker staining in the choroid plexus. The ependymal staining is interesting, in light of recent observations that tight junctions of the blood-brain barrier are absent in CCMs. Ependymal tight junctions contribute to the barrier between brain parenchyma and cerebrospinal fluid. Subtle morphological abnormalities were observed in the choroid plexus of heterozygous mice, and scattered, abnormally dilated blood vessels were present in year-old heterozygotes, suggesting that these mutants will be a useful animal model of CCM.

A Novel Mouse Model of Infantile Neuroaxonal Dystrophy. *S.M. Parker¹, D.M. Bouley², J. Jones McIntire², E. Hadar², R.J. Coryell¹, K.H.L. Ching¹, S.J. Hayflick¹.* 1) Departments of Molecular and Medical Genetics, Pediatrics and Neurology, Oregon Health & Science University, Portland; 2) Department of Comparative Medicine, Stanford University School of Medicine, CA.

Infantile neuroaxonal dystrophy (INAD; OMIM 256600) is a rare autosomal recessive neurodegenerative disorder characterized by psychomotor regression, visual impairment and dementia. Swollen axons (spheroids) are seen throughout the central and peripheral nervous systems. Neither the basic molecular defect nor the gene for this disorder has been identified.

A mutant mouse demonstrating early onset progressive neurologic impairment arose spontaneously in a congenic strain. In this colony, the incidence of affected offspring to known carrier parents is 25% with no gender bias, supporting an autosomal recessive pattern of inheritance. Although the pups appear normal at birth, affected mice are smaller than littermates, unthrifty and poorly groomed by 3-4 weeks of age. Beginning around 4 weeks, muscle wasting and weakness of the hind limbs becomes evident. In later stages of disease, the mice display blepharitis and paralysis of the hind limbs, generally requiring euthanasia by 6-8 months of age. Neuropathological studies reveal numerous axonal spheroids in both gray and white matter of the brain and through all levels of the spinal cord. The spheroids stain positively for PAS, with aggregates of mitochondria, increased neurofilaments, layered stacks of membranous loops and evidence for astrocytosis seen by light microscopy. Electron microscopy of degenerating axons demonstrates axoplasmic masses, degenerate organelles and membrane-bound dense bodies.

These mice may represent a model for INAD based on the pattern of disease inheritance and their early clinical and pathologic phenotype. Mammalian models for later onset or localized neuroaxonal dystrophies have been reported; however, none demonstrates the early and generalized phenotype seen in these mice. This novel mouse mutant may be valuable in identifying the human INAD gene and understanding the pathophysiology of neuroaxonal dystrophies.

Analysis of Spinocerebellar Ataxia Type 12 and DRPLA Genes In Colombian Individuals. *L. Perez¹, O.L Pedraza³, C. Duran¹, M.L Gomez¹, J.C. Prieto^{1,2}.* 1) Instituto de Genetica Humana, Universidad Javeriana, Bogota, Colombia; 2) Hospital la Victoria, Departamento de Genetica, Bogota, Colombia; 3) Departamento de Neurologia, Hospital San Ignacio, Universidad Javeriana, Bogota, Colombia.

Autosomal dominant cerebellar ataxias (ADCA) constitute a group of neurodegenerative disorders characterized by ataxia, dysphagia and dysarthria with onset of symptoms usually in the third or fourth decade of life that can be classified clinically into three major categories: ADCA type I is characterized by ataxia associated with other neurological features, ADCA type II is distinguished clinically by the presence of a pigmentary macular dystrophy and ADCA type III, which is characterized by a relatively pure cerebellar syndrome. Nine spinocerebellar ataxia genes (SCA1,2,3,6,7,8,10,12,17) and two other related ataxia genes (DRPLA, FRDA) have been cloned allowing the genetic classification of these disorders. Previously, we have reported that, among our ataxia patients, SCA8 occurs in 1.2%, FRDA in 28.9%, and Vitamin E deficiency in 3.6%. The symptoms and clinical signs observed in the patients were: gait and limb ataxia (100%), nystagmus (17%), pyramidal tract signs (21%), intellectual impairment (21%), epilepsy (7%), retinal degeneration (3%), and deafness (3%). We have now extended our testing to include DRPLA and SCA12. We investigated the normal size range of DRPLA and SCA12 alleles by genotyping normal Colombian individuals. CAG repeat ranges were 10-24 for DRPLA and 6-16 for SCA12. Frequencies of all alleles and heterozygosity were estimated and compared to several ethnic groups. We analyzed the CAG expansion of SCA12 and DRPLA in affected patients and did not find mutations in 108 patients studied. Variable percentages of known CAG repeat expansion have been reported in other ADCA studies. The ranges obtained for DRPLA and SCA12 in the Colombian population are below those reported for other ethnic groups. Thus, DRPLA and SCA12 do not appear to be an important etiological factor among our population. 70% of the patients studied did not have mutations in SCA1,2,3,6,7,8, DRPLA, or FRDA genes. Therefore, SCA10, SCA17, or other ataxia genes yet to be identified, might explain some of these cases.

Two novel mutations in the CACNA1A gene leading to identical functional consequences but with different phenotypic expression. *A.M.J.M. van den Maagdenberg¹, G.M. Terwindt², E.E. Kors², P. Imbrici³, N.J. Giffin⁴, C.R. Sherrington⁵, R.C.G. van de Ven¹, M.G. Hanna³, D.M. Kullmann³, P.J. Goadsby⁴, M.D. Ferrari², R.R. Frants¹.* 1) Department of Human Genetics, LUMC, Leiden, The Netherlands; 2) Department of Neurology, LUMC, Leiden, The Netherlands; 3) Department of Clinical Neurology, Institute of Neurology, University College London, Queen Square, London, United Kingdom; 4) National Hospital for Neurology and Neurosurgery, Queen Square, London, United Kingdom; 5) Department of Neurology, St. James University Hospital, Leeds, United Kingdom.

Mutations in the CACNA1A gene which encodes the pore-forming Cav2.1 subunit of neuronal P/Q type Ca²⁺⁺ channels have been shown to cause a spectrum of diseases, including familial hemiplegic migraine (FHM), episodic ataxia type 2 (EA-2), spinocerebellar ataxia type 6 (SCA6) and recently epilepsy. We screened all 47 coding exons of the CACNA1A/Cav2.1 gene by single-strand conformation polymorphism (SSCP) analysis and direct sequencing in DNA of the probands of two families. In one family a highly variable phenotype was observed, including migraine, fluctuating weakness, and ataxia, the second family showed typical EA-2 features. DNA analysis revealed two novel mutations in codon 1854 resulting in the same premature stop (Y1854X) in the predicted protein sequence. The truncation mutations are present in alternatively spliced exon 37A that is used mutually exclusively with exon 37B. Expression studies were performed in *Xenopus* oocytes using a CACNA1A construct harboring the Y1854X mutation and demonstrated no current, indicating a clear loss-of-function effect for this mutation. When co-expressed with the mutant, no effect was observed on wildtype Cav2.1 for several electrophysiological parameters. In contrast, previously described observations with nearby located truncation mutation R1820X, that is associated with epilepsy, showed a dominant-negative effect on wildtype. Apparently, multiple pathogenic mechanisms are associated with CACNA1A causing EA-2 and related phenotypes and mutations in the CACNA1A gene, even if they lead to the same functional defect, can cause a wide spectrum of clinical features.

A novel sequence motif highlights a functional link between spartin and spastin, mutated in hereditary spastic paraplegia. *H. Patel*¹, *F. Ciccarelli*², *C. Proukakis*¹, *M.A. Patton*¹, *P. Bork*², *A.H. Crosby*¹. 1) Dept Medical Genetics, St George's Hosp Medical Sch, London, England; 2) European Molecular Biology Laboratory, Meyerhofstr. 1, 69012 Heidelberg, Germany.

The hereditary spastic paraplegias (HSPs) are a clinically diverse group of disorders that share the primary feature of progressive lower limb spasticity and weakness. Despite the large and ever increasing number of loci mapped for the various forms of HSP, the genes for only a few forms of the disease have thus far been identified, each essentially with an unclear mechanism of action. We have recently shown that mutations in spartin underlie an autosomal recessive variant of HSP (Troyer syndrome) present at high frequency amongst the Amish. Comparative sequence alignment reveals that spartin contains three novel protein domains, one of which is also present in spastin, commonly mutated in autosomal dominant forms of HSP. This ~80 amino acid domain is located in the N-terminal region of spastin, which has recently been implicated in microtubule interaction. Multiple alignment confirms that this domain is also present in VPS4, SKD1 and SNX15, all of which are involved in endosomal trafficking. Consequently we have named this novel domain MIT (microtubule-associated domain involved in intracellular transport). The identification of the MIT domain in both spartin and spastin implicates a functional link and hints at a molecular mechanism responsible for these forms of HSP.

A large six generations Indian pedigree with congenital nystagmus: clinical and genetic data. *U. Radhakrishna¹, U.C Rao¹, U. Ratnamala¹, M. Raveendrababu¹, R. Singh², J.V. Solanki³ and Genetics Study group.* 1) GeneHealth, Green Cross Voluntary blood bank & Genetic Centre, 201, Anilkunj, Paldi, Ahmedabad; 2) Nayanjyot, Dr. P.L. Desai Eye Centre, Navrangpura, Ahmedabad; 3) Department of Animal Genetics & Breeding, Veterinary college, Gujarat Agriculture University, Anand, India.

Congenital nystagmus (CN) is characterised by bilateral uncontrollable ocular oscillations and it occurs at a frequency of 1/1,500 live births. Families with X-linked, autosomal dominant and autosomal recessive modes of inheritance have been reported. The genes responsible for X-linked (NYS1) and autosomal dominant (NYS2) CN have been mapped to chromosomes Xp11.4-p11.3 (*Am J Hum Genet* 64: 1141-46, 1999), Xq26-q27 (*Am J Hum Genet* 64: 600-7, 1999) and 6p12 (*Genomics* 33: 523-6, 1996), respectively, but no mutation causing gene is yet identified. We report a large six-generation Indian pedigree with isolated non-syndromic nystagmus (NYS2) (OMIM 164100), in which the anomaly segregates as an autosomal dominant trait. The pedigree consists of 87 individuals including 23 affecteds (15 males/8 females). Clinical examinations were carried out on nine selected affected individuals including colour vision examinations and eye movement recordings. All the examined individuals showed asymmetric pendular eye movements with unidirectional jerky nystagmus. The clinical status of the remaining family members were collected by history. No other associated anomalies such as decreased vision, strabismus, colour blindness, ocular albinism or congenital stationary night blindness were present in this family. Karyotype analysis of five affecteds showed no chromosomal anomaly. Linkage studies with markers closely linked to NYS2 will either confirm allelism to this locus or support evidence for genetic heterogeneity and may reduce the genetic interval encompassing the NYS2 gene.

Recurrent mutations in PTCH1 gene observed in French patients with Gorlin syndrome. *P.P.E. Gorry^{1,3}, N. Boutet¹, D. Lafon¹, M.F. Avril², M. Longy¹, D. Lacombe³*. 1) Laboratoire d'Oncogenetique Institut Bergonie, Bordeaux, France; 2) Service de Dermatologie, Institut Gustave Roussy, Villejuif, France; 3) Service de Genetique Medicale, CHU Pellegrin-Enfants, Bordeaux, France.

We report novel, de novo and recurrent mutations in PTCH1 gene. Our results highlight the spectrum of mutations in Gorlin syndrome. While no phenotype-genotype correlation could be found, we discuss the criteria for clinical diagnosis in front of molecular studies. In conclusion, we have screened for PTCH mutations in French Gorlin patients for the first time. Half of our patient population was composed of sporadic cases. Novel mutations and polymorphisms were identified in this group of patients. While no mutations hot spot was previously described in the literature, we identified recurrent mutations. Beyond the high sensibility of dHPLC PTCH mutations screening, we could suspect that mutations of the promoter and intronic sequences, or small rearrangements of the gene, are probably under estimated. This should conduct us to develop complementary methods for PTCH molecular diagnosis. Finally based on this molecular study, we could propose that the hereditary character is not dispensable for the diagnosis of the Gorlin syndrome if dysmorphic symptoms are present.

Sex chromosomes escape non-homologous associations of interstrand cross-link-induced radial formation. *A.E.*

Hanlon Newell¹, Y.M.N. Akkari¹, A. Rosenthal¹, C.A. Reifsteck¹, M. Grompe^{1,2}, S.B. Olson¹. 1) Dept. of Molec. & Med. Genetics, OHSU, Portland, OR; 2) Dept. of Pediatrics, OHSU, Portland, OR.

Following exposure to high concentrations of DNA crosslinking agents such as mitomycin C (MMC) and diepoxybutane (DEB), mammalian cells display characteristic chromosomal abnormalities known as radials. Radials appear as exchanges between the chromatids in fixed mitotic cells that have been treated with DNA crosslinking agents. These figures presumably form due to a failed attempt to repair the resulting DNA interstrand crosslinks (ICLs) and had been thought to occur randomly between both homologous and non-homologous chromosomes. Cells from patients with Fanconi anemia (FA) display these same characteristic formations but with much lower concentrations of ICL-inducing agents. Although radial formation has been used to diagnose FA for more than three decades, there has been relatively little analysis and description of these chromosomal structures. Understanding the mechanism of formation of radials should help in elucidating the mechanism of ICL repair and the function of the FA pathway.

For this purpose, we analyzed G-banded radials from normal and FA primary human fibroblasts treated with appropriate concentrations of MMC. Among 382 radials analyzed, only three involved homologous chromosomes and these interactions were between different arms and/or regions of the chromosomes. In addition, the X and Y chromosomes were noticeably not involved in radial formation. Analysis of band location and association points revealed a random distribution of radials throughout the length of the autosomes, at both light and dark bands, with longer chromosomes being involved at an increased frequency, especially in FA cells. In addition, we found that radials can form between human and mouse chromosomes in hybrid cells. Together, these observations suggest that radials represent either failed recombination between short stretches of homologous sequences or simply random exchanges, primarily on autosomes. A model for ICL repair and escape of the sex chromosomes from radial formation will be discussed.

Identification of novel glomulin gene mutations responsible for inherited glomuvenous malformations

(glomangiomas). *P. Brouillard*¹, *M. Ghassibé*¹, *L.M. Boon*^{1,2}, *A. Penington*³, *O. Enjolras*⁴, *J.B. Mulliken*⁵, *M. Vikkula*¹.

1) Laboratory of Human Molecular Genetics, Christian de Duve Institute of Cellular Pathology and Université catholique de Louvain, Brussels, Belgium; 2) Center for Vascular Anomalies, Division of Plastic Surgery, Université catholique de Louvain, Brussels, Belgium; 3) Department of Plastics and Maxillofacial Surgery, Royal Children's Hospital, Victoria, Australia; 4) Consultation des Angiomes, Hôpital Lariboisière, Paris, France; 5) Vascular Anomalies Center, Children's Hospital, Harvard Medical School, Boston, MA, USA.

Glomuvenous malformations (GVMs, glomangiomas), localized defects of vascular morphogenesis, are single or multiple bluish-purple lesions that occur mainly in skin. Histologically, the distended veins present smooth muscle-like "glomus cells" in the media. GVMs are usually dominantly inherited and, with the more common mucocutaneous venous malformations, they are among the most frequent lesions in centers that specialize in treatment of vascular anomalies (Vikkula et al., 1998). Using positional cloning, we recently identified the causative gene that we named glomulin (Brouillard et al., *Am J Hum Genet* 2002). 13 of the 14 mutations identified in 20 families cause premature stop codons. Thus, GVMs are likely to be caused by loss-of-function of glomulin. In addition, as these inherited vascular lesions are localized, we hypothesized that a somatic second hit, leading to complete localized lack of glomulin, may be needed. In fact, we identified a truncating somatic mutation that was different from the patients inherited genetic alteration in a resected tissue sample. We report on the identification of a series of additional mutations, confirming the loss-of-function mechanism to be responsible for GVMs. (vikkula@bchm.ucl.ac.be) (<http://www.icp.ucl.ac.be/vikkula>).

Mutations in the genes *KCND2* and *KCND3* encoding the ion-channels conducting the cardiac transient outward current (I_{TO}) is not a frequent cause of Long QT syndrome. R. Frank-Hansen¹, L.A. Larsen², P.S. Andersen¹, C.

Jespersgaard¹, M. Christiansen¹. 1) Department of Clinical Biochemistry, Statens Serum Institut, Copenhagen, Denmark; 2) The Wilhelm Johannsen Centre for Functional Genome Research, Department of Medical Genetics, IMBG, University of Copenhagen, Copenhagen, Denmark.

Mutations in genes encoding cardiac potassium and sodium channel subunits are found in approximately 50% of patients diagnosed with long QT syndrome (LQTS), a potentially lethal cardiac arrhythmogenic disorder characterized by prolongation of the QT interval in electrocardiograms. The absence of mutations in the five known LQTS genes in the remaining half of the patients indicate the existence of additional genes associated with the disease.

The genes *KCND2* and *KCND3* encoding the potassium channels conducting the transient outward current (I_{TO}) in the cardiac action potential (AP) have been associated with prolongation of AP duration and QT prolongation in murine models. The role of *KCND2* and *KCND3* as candidates for LQTS association was investigated by mutation screening in DNA samples obtained from 43 unrelated LQTS patients, all without mutations in the five known LQTS genes. The mutation screening was performed by single strand conformation polymorphism, either gel-based or by automated capillary electrophoresis (CE-SSCP). The analysis revealed the existence of several single nucleotide polymorphisms (SNPs), both in *KCND2* and in *KCND3*. Based on mutation screening of 48 normal controls (danish blood donors), all SNPs are considered normal variants. The data suggests that mutations in *KCND2* and *KCND3* are not a frequent cause of long QT syndrome.

Screening of the *FBLN5* Gene to Identify Genetic Alterations in Patients with Aortic Tortuosity. *P.A. Gupta*¹, *R.M. He*¹, *D.G. Guo*¹, *S.N. Hasham*¹, *C.C. Miller*², *A.L. Estrera*², *H.J. Safi*², *D.M. Milewicz*¹. 1) Internal Medicine, UT Houston Medical School, Houston, TX; 2) Cardiothoracic Surgery, UT Houston Medical School, Houston, TX.

Fibulin 5, encoded by *FBLN5*, is a calcium-dependant, elastin-binding, extracellular matrix protein that is expressed in the cardiovascular system during embryogenesis and adulthood. The phenotype of the *FBLN5*-knockout mouse included severe tortuosity of the aorta, emphysema, and loose skin. Based on the murine phenotype, we screened the DNA of 22 unrelated patients with severe tortuosity of the aorta, termed megaaorta syndrome. We screened the 11 exons of *FBLN5* using genomic DNA from the patients, intron-based, exon-specific primers, and direct sequencing. Two polymorphisms were identified: C1407T in exon 9 and an A to G transversion 25 bp 5' to the start of exon 2. Two unique alterations were identified: an A to G transversion 29 bp 3' to exon 5 and a 1 bp deletion 238 bp 5' to the start codon in exon 1. The 1 bp deletion was not present in 120 ethnically matched chromosomes. The family members of both individuals with unique changes are currently being investigated. Further analysis of the two unreported alterations will provide information on the role that *FBLN5* plays in aortic disease.

Familial deafness, congenital heart defects, and posterior embryotoxon caused by cysteine substitution in the first EGF-like domain of JAG1. *C. Le Caignec¹, M. Lefevre², J.J. Schott³, A. Chaventre¹, M. Gayet⁴, C. Calais⁵, J.P.*

Moisan¹. 1) LEPA, Faculte de medecine, Nantes, France; 2) Service de cardiologie, CHU, Nantes, France; 3) INSERM U533, Faculte de medecine, Nantes, France; 4) Service de radiologie, CHU, Nantes, France; 5) Service d'ORL, CHU, Nantes, France.

Congenital heart disease is the most common birth defect, occurring in approximately 1% of live births. Although multifactorial inheritance has been postulated for the majority of cases, single gene transmission is demonstrated by the observation of mutations in NKX2.5 or JAG1 within families segregating congenital heart defects. We report a kindred with hearing loss, congenital heart defects, and posterior embryotoxon segregating as an autosomal dominant trait. Six of seven available affected patients manifested mild-to-severe combined hearing loss predominantly affecting middle frequencies. Two patients were diagnosed with vestibular pathology. All patients had congenital heart defects, including Tetralogy of Fallot (ToF), ventricular septal defect or isolated peripheral pulmonic stenosis (PPS). No individual in this family met diagnostic criteria for any previously described clinical syndrome. A candidate gene approach was undertaken and culminated in the identification of a novel Jagged1 (JAG1) missense mutation (C234Y) in the first cysteine of the first EGF-like repeat domain of the protein. JAG1 is a cell surface ligand in the Notch signaling pathway. Mutations in JAG1 have been identified in Alagille syndrome (AGS) patients. Our findings revealed a unique phenotype with highly penetrant deafness, posterior embryotoxon, and congenital heart defects but variable expressivity in a large kindred which demonstrate that mutation in JAG1 can cause hearing loss.

Hereditary Haemorrhagic Telangiectasia: ENG and ALK1 mutations in Dutch patients. *T.G.W. Letteboer¹, R.A. Zewald¹, J.J. Mager², C.J.J. Westermann², J.K. Ploos van Amstel¹.* 1) Medical Genetics, University Medical Center, Utrecht, The Netherlands; 2) St. Antonius Hospital, Nieuwegein, The Netherlands.

Hereditary Haemorrhagic Telangiectasia (HHT or Rendu-Osler-Weber disease (MIM 187300)) is an autosomal dominant disorder characterized by localized angiodysplasia. The resulting vascular lesions are direct arteriovenous connections without an intervening capillary bed. This can result in a range of malformations from smaller mucocutaneous telangiectases to large visceral arteriovenous malformations. The clinical presentation can be quite heterogeneous. Specific organs tend to be more affected such as the skin, lung, gastrointestinal tract and the brain. The estimated prevalence in the Netherlands is 1:30,000, but this is very likely to be an underestimation. Mutations in at least two genes have been shown to be associated with the disease, endoglin (ENG on chromosome 9q34) and ALK1 (ACVRL1 on chromosome 12q13). We have studied 68 probands of Dutch origin with the Rendu-Osler-Weber disease performing sequence analysis on genomic DNA, for both the ENG gene (exon 1-14) and ALK1 gene (exon 2-10). To date, approximately 90% of the coding sequence has been analysed. Mutations were found in both genes: 43% of the probands had a mutation in the ENG gene, whereas 30% had a mutation in the ALK1 gene. No proband has been identified with mutations in both genes. The mutations detected were deletions, insertions, nonsense, missense and splice site mutations. Currently, we are organizing the clinical data to get insight in 1. the inter- and intra-familial variation of the phenotypes and 2. the genotype-phenotype relationship of the two patient groups with an endoglin respectively an ALK1 mutation. Appropriate medical attention can be given to those having a mutation, complications can be prevented and clinical screening of non-carrier children in the family becomes unnecessary.

Program Nr: 2063 from 2002 ASHG Annual Meeting

TBX5 is a transcription activator with a functional domain in its C-terminus. *T. Huang, L. Scott, L. Li, L. Feutch.*
Div Human Genetics, Univ California, Irvine, Irvine, CA.

TBX5 is a member of the T-box gene family and encodes a transcription factor involved in cardiac and limb development. Mutations of TBX5 cause Holt-Oram syndrome (HOS), an autosomal dominant condition with congenital cardiac defects and forelimb anomalies. Here, we report that TBX5 is a transcription activator and that the functional domain is located in its C-terminus. Using a series of deletion mutations of TBX5, we narrowed down its functional domain to a cluster of amino acids. Point mutagenesis further elucidates the crucial amino acids. This result would enhance our understanding of the function of TBX5 and its structure-function relationship.

Identification of the gene responsible for familial capillary malformation. *M.S. Vikkula¹, I. Eerola¹, L.M. Boon^{1,2}, S. Watanabe³, J.B. Mulliken⁴.* 1) Laboratory of Human Molecular Genetics, Christian de Duve Institute of Cellular Pathology and Université catholique de Louvain, Brussels, Belgium; 2) Center for Vascular Anomalies, Clin univ St-Luc, Brussels, Belgium; 3) Division of Plastic Surgery, Showa University School of Medicine, Tokyo, Japan; 4) Vascular Anomalies Center, Children's Hospital, Harvard Medical School, Boston, MA, USA.

Vascular anomalies comprise a heterogeneous group of disorders the severity of which varies from life-threatening lesions to cosmetic harm (Vikkula et al., Trends in Cardiovascular Medicine, 1998 and Matrix Biology, 2001). They are localized defects of vasculogenesis/angiogenesis and thereby provide a tool to study the mechanisms involved in these processes. Capillary malformation (CM, or port-wine stain) is the most common vascular malformation occurring in 0,3% of newborns. CMs are small flat cutaneous lesions that consist of an increased number of ectatic capillary-like channels within papillary dermis. Vascular birthmarks, such as salmon patch, are milder variants of CM that occur in up to 40% of newborns. Unlike common macular stains, the reddish coloration of CMs does not disappear, but becomes darker with advancing age. Increased incidence of lesions in first-degree relatives of CM patients and several reported familial cases suggest that genetic factors may play a role in the pathogenesis of CM. Here we report on our genomewide linkage analysis performed on 13 families with inherited CM. In non-parametric linkage analysis, statistically significant evidence of linkage (peak Z-score 6.72, p-value 0.000136) was obtained in an interval of 69 cM on 5q11-5q23. Parametric linkage analysis gave a maximum combined HLOD score of 4.84 (a-value 0.67) from the same region and the analysis using only the linked families, defined a smaller, statistically significant locus of 23 cM (LOD score 7.22). Positional candidate gene analysis in this large region recently led to the identification of the mutated gene that seems to cause pathological angiogenesis by haploinsufficiency. Thus, a novel target for anti-angiogenic therapy has been unravelled.(vikkula@bchm.ucl.ac.be)(<http://www.icp.ucl.ac.be/vikkula>).

PTPN11 gene mutations in syndromic and non-syndromic pulmonary valve stenosis. A. Sarkozy^{1,2}, E. Conti¹, M.C. Digilio³, D. Seripa¹, B. Marino⁴, M.G. Matera¹, G. Esposito^{1,2}, V.M. Fazio¹, A. Pizzuti^{1,2}, B. Dallapiccola^{1,2}. 1) Dept. Exp. Med. and Pathol., Univ. "La Sapienza", Rome, Italy; 2) IRCCS-CSS, S. G. Rotondo and CSS-Mendel, Rome, Italy; 3) Division of Med. Genet., Bambino Gesù Hosp., IRCCS, Rome, Italy; 4) Sect. of Pediatric Cardiol., Inst. of Pediatrics, Univ. "La Sapienza", Rome, Italy.

Pulmonary valve stenosis (PVS), occurs in 4/10000 births. PVS can be isolated, or part of different syndromes. PVS is a common feature of Noonan (NS) and Multiple Lentiginos/LEOPARD (ML/LEOPARDS) syndromes. Both isolated and syndromic PVS are inherited as an autosomal dominant mutation. In syndromic PVS, the valvular stenosis is due to a valvular leaflet dysplasia, rather than to intrauterine hemodynamic factors, as probably in non-syndromic cases. However, syndromic PVS with normal leaflets has been also reported. Ptpn11 mutant mice show PVS with dysplastic leaflets, while PTPN11 mutations have been reported in NS and ML/LEOPARDS patients. In our cohort of 27 NS and ML/LEOPARDS patients with PVS, 41% had PTPN11 mutations. To investigate the role of PTPN11 mutations in the pathogenesis of different PVS, we screened PTPN11 gene mutations in 23 patients with non-syndromic PVS. PTPN11 coding region was screened by SSCP, and fragments with an aberrant migration were sequenced. The prevalence of PTPN11 mutations in syndromic patients with PVS was assessed both in those with normal or with dysplastic leaflets (20 vs. 7 patients). No patient with non-syndromic PVS presented PTPN11 mutations. Conversely, 73% of the 11 mutated syndromic patients with PVS, had leaflet dysplasia. PTPN11 mutations were detected in 40% of the PVS cases with dysplastic leaflets, and in 43% of those with normal leaflets. These results suggest a major relationship of PTPN11 mutations only with syndromic PVS, and not with non-syndromic cases. This conclusion is also supported by the higher incidence of PTPN11 mutations in syndromic PVS with valvular dysplasia. However, since three cases of syndromic PVS had normal leaflets, in association with PTPN11 mutations, occurrence of PTPN11 mutations in syndromic PVS should not be restricted to the presence of valvular dysplasia.

Carney Complex: Genetic analysis of the R1a Regulatory Subunit of Protein Kinase A (*PRKAR1a*). *M. Veugelers*¹, *Y. Song*¹, *J. He*¹, *B. Meyer*², *E. Legius*³, *D. Eccles*⁴, *A. Irvine*⁵, *C.T. Basson*¹. 1) Department of Medicine, Weill Weill Medical College of Cornell University, New York, NY; 2) Swiss Cardiovascular Center Bern, University Hospital Bern, Switzerland; 3) Center for Human Genetics, K.U.Leuven, Leuven, Belgium; 4) Wessex Clinical Genetics Service, Princess Ann Hospital, Southampton, UK; 5) Division of Dermatology, The Children's Memorial Hospital, Chicago, IL.

Carney complex is a familial multiple neoplasia syndrome characterized by cardiac myxomas in the setting of spotty skin pigmentation and endocrinopathy. Using positional cloning, we have previously identified the *PRKAR1a* gene (regulatory subunit R1a of protein kinase A) as a causative gene at chromosome 17q24. Analysis of the complete *PRKAR1a* coding region, by DNA-sequencing and dHPLC, was performed in 45 Carney complex probands, together representing 26 families and 19 apparently sporadic cases. We identified *PRKAR1a* mutations in 18 familial cases and 9 sporadic patients. Linkage to 17q24 and a potential locus at 2p16 could be excluded in 5 families. With the exception of two mutation hotspots in exon-5 and exon-7, all identified mutations were unique and randomly distributed across the coding region. There were no obvious genotype-phenotype correlations, but we observed the occasional presence of congenital heart disease, all in Carney complex patients with *PRKAR1a* mutations. RT-PCR analysis indicated that mutant mRNAs were degraded by nonsense mediated mRNA decay, causing *PRKAR1a* haploinsufficiency. However, three mutations escaped nonsense mediated mRNA decay. Western blotting analysis indicated that at least one of these mutations is expressed at the protein level. We observed increased cAMP-induced PKA activity in EBV-transformed lymphocytes of patients with *PRKAR1a* mutations. Our analyses indicate that most *PRKAR1a* mutations result in *PRKAR1a* haploinsufficiency and that in lymphocytes heterozygous for these mutations, there is an increased cAMP responsiveness causing dysregulated PKA activity. Furthermore, we have found evidence for genetic heterogeneity in Carney complex, and ongoing studies will identify novel genes that cause Carney complex.

Molecular analysis suggests the first sporadic case of FSHD in the South African population. *M. Alessandrini¹, A. van der Merwe¹, F.F. Maree^{1,2}, C-M. Schutte³, E. Honey⁴, R.R. Frants⁵, S.M. van der Maarel⁵, A. Olckers^{1,2}.* 1) Centre for Genome Research, Potchefstroom University, Pretoria, South Africa; 2) DNAbiotec, South Africa; 3) Dept of Neurology, University of Pretoria, South Africa; 4) Dept of Genetics, University of Pretoria, South Africa; 5) Dept of Human Genetics, Leiden University Medical Centre, The Netherlands.

Facioscapulohumeral muscular dystrophy (FSHD) is a progressive myopathy preferentially affecting the facial, shoulder girdle and upper arm muscles. It is one of the most common muscular dystrophies after Duchene and Myotonic dystrophy. Symptomatic presentation is generally observed in the second decade of life with a penetrance of approximately 95% by the age of 20 years. A high degree of variability is observed when comparing affected patients with signs of asymptomatic shoulder girdle or facial weakness in the 7th decade, to cases with severe proximal and distal upper and lower limb involvement in early childhood. FSHD follows an autosomal dominant mode of inheritance with a unique DNA rearrangement linked to the distal region of chromosome 4q35. However, no transcribed sequences in this region have been directly linked to the disorder. A deletion of an integral number of 3.3 kb repeat sequences at the 4q35 chromosomal region results in the clinical phenotype. Effective molecular diagnosis is, however, compromised due to several factors. The most striking of these being the simultaneous detection of a non-pathogenic region on chromosome 10q26, that not only displays a high degree of homology, but is also rearranged in a similar fashion to the 4q35 repeats. The frequency of sporadic FSHD cases has been reported to be 0.33 in the Brazilian population. Here we report the identification of the first sporadic case in the South African FSHD population. The patient was clinically diagnosed as severely affected at the age of 16 years. The presence of a 14kb deletion fragment was observed in this individual via Southern blot analysis using probe p13E-11. The parental status of the individual was confirmed via chromosome 4 haplotype analysis. The absence of deletion fragments in both of her parents confirms the sporadic nature of this case.

Genetic evidence for a possible novel SMA gene in a family with spinal muscular atrophy. *H.H. Lemmink, A.H. van der Hout, C. Lummen, J. Dijkhuis, H. Scheffer, C.H.C.M Buys.* Clinical Genetics, Academic Hospital Groningen, Groningen, Netherlands.

In around 95 percent of patients with spinal muscular atrophy (SMA) mutations have been identified in the SMN1 gene localized at chromosome 5q12-13. Recently, a second gene for SMA has been identified. Mutations were described in the immunoglobulin m binding protein 2 (IGHMBP2) gene localized on chromosome 11q13 in patients suffering from spinal muscular atrophy with respiratory distress (SMARD) resulting from paralysis of the diaphragm. This group of patients is clinically and genetically distinct from classical SMA patients (type I, II, and III) and probably represents around 1 percent of the total population of SMA patients.

We have studied two affected brothers who were clinically defined as classical SMA type I in accordance with examination of muscle biopsy specimen and EMG analysis. In this family we have excluded exon 7 deletions of the SMN1 gene and pathogenic mutations in IGHMBP2. Also linkage analysis was performed for both chromosomal regions (5q12 and 11q13) and both regions could be excluded. From our study we conclude that there is a possible third gene involved in the pathogenesis of SMA.

Generating mouse models for autosomal dominant hereditary Spastic Paraplegia Type 4 (SPG4). *J. Schickel¹, D. Boensch¹, R. Sudbrak², G.E. Homanics³, J. Neesen⁴, T. Deufel¹.* 1) Institut fuer Klinische Chemie und Laboratoriumsdiagnostik, Universitaetsklinikum Jena, Bachstr. 18, 07740 Jena, Germany; 2) Max-Planck-Institut fuer Molekulare Genetik, Ihnestr.73, 14195 Berlin, Germany; 3) Department of Anesthesiology and Critical Care Medicine, University of Pittsburgh, Pittsburgh, PA 15261, USA; 4) Institut fuer Humangenetik, Universitaet Goettingen, Heinrich-Dueker Weg 12, 37073 Goettingen, Germany.

Autosomal dominant hereditary spastic paraplegia (AD-HSP) is a genetically heterogeneous neurodegenerative disorder characterised by progressive weakness and spasticity of the lower limbs caused by the specific degeneration of the corticospinal tracts, the longest axons in humans. SPG4 is the most common form and is caused by mutations in the spastin gene, an ATPase belonging to the AAA family. The gene, located on chromosome 2p21-p22 is ubiquitously expressed in adult and fetal tissues. We have identified two SPG4 mutations in German AD-HSP families that result in measurably different phenotypes: A deletion of the first nucleotide of exon 9 leading to a premature stop codon is predicted to generate a truncated protein of 393 amino acids, and a large genomic deletion resulting in the loss of exons 13-16. Patients carrying those mutations differ clinically in transcranial magnetic stimulation studies providing a phenotypic correlate of a given genetic change in the SPG4 gene. With the aim to elucidate the function of the spastin gene and its role in the pathogenesis of spastic disorder, we have set out to generate genetically engineered mouse models carrying these two mutations defining distinct human disease phenotypes. We analysed the genomic organization of the mouse orthologue of SPG4 using screened PAC-clones. Subclones from the corresponding PACs were generated and further characterized by extensive restriction mapping and Southern blot analysis. On the basis of this work targeting vectors were designed and constructed. Electroporation of ES cells was performed and the identification for gene targeting is under way.

The first compound heterozygote individual identified in the South African FSHD population. *A. van der Merwe*¹, *M. Alessandrini*¹, *F.F. Maree*^{1,2}, *C.M. Shutte*³, *E. Honey*⁴, *R.R. Frants*⁵, *S.M. van der Maarel*⁵, *A. Olckers*^{1,2}. 1) Centre for Genome Research, Potchefstroom University for CHE, Pretoria, South Africa; 2) DNAbiotec, South Africa; 3) Dept of Neurology, University of Pretoria, South Africa; 4) Dept of Genetics, University of Pretoria, South Africa; 5) Dept of Human Genetics, Leiden University Medical Centre, The Netherlands.

Facioscapulohumeral muscular dystrophy (FSHD) is characterised by weakness and atrophy of the facial and shoulder girdle muscles. The phenotypical expression varies in severity, rate of progression and age of onset. The FSHD phenotype segregates as an autosomal dominant trait and is caused by a deletion of an integral number of 3.3kb repeat units on chromosome 4q35. However, the underlying genetic mechanism still remains elusive. Probe p13E-11 is utilised to detect the DNA rearrangements, but cross-hybridises to chromosome 10q26. Comparison between 4q35 and 10q26 indicated that both regions contain similar 3.3kb repeat units. The presence of a 24kb deletion fragment was observed in a South African FSHD family consisting of 8 generations and 480 individuals. Two deletion fragments of 24kb and 34kb, both in the pathogenic range, were detected in a single individual of this family. One of his three children inherited a 24kb fragment, while the other two inherited 34kb fragments. As it is known that translocation events may occur between chromosomes 4 and 10, the chromosomal origin of the 34kb fragment could not initially be determined with any certainty. Verification of the chromosomal origin of the 34kb fragment was, however, crucial for accurate molecular diagnosis of these two children. Haplotype analyses of chromosomes 4 and 10, utilising nine and six STRP markers respectively, were undertaken to confirm the chromosomal origin of this fragment. These analyses verified that the 34kb fragment is of chromosome 4 origin and therefore conclusively identified the first compound heterozygote case in the South African FSHD population. Correlation between severity of the disorder and the size of the deletion fragment within this family may be useful in the elucidation of the phenotype-genotype relationship in FSHD.

A dominant loss-of-phosphorylation IKBA mutation is associated with anhidrotic ectodermal dysplasia and severe T cell immunodeficiency. A.. Smahi¹, G. Courtois⁷, J. Reichenbach³, F. Le Deist², C. Cancrini⁶, R. Doffinger³, A. Durandy², M. Bonnet³, S. Dupuis-Girod⁵, M. Caniglia⁶, P. Rossi⁶, A. Fischer^{2, 4}, A.. Israel⁷, A. Munnich¹, J.L. Casanova^{3, 4}. 1) Genetique INSERM U393, Hopital Necker, Paris, France; 2) INSERM U429 Hopital Necker, Paris, France; 3) INSERM U550 Hopital Necker, Paris, France; 4) Unit d'Immuno-Hematologie, Pediatrique, Hopital Necker, Paris, France; 5) Hematologie Pediatrique, Hopital Debrousse, Lyon, France; 6) Division of Immunology and Infections Diseases, Bambino Gesù, Rome Italy; 7) URA CNRS 1773 Institut Pasteur, Paris, France.

An X-linked recessive form of Anhidrotic Ectodermal Dysplasia with Immuno-Deficiency (EDA-ID) has been ascribed to mutations in the NEMO gene, which encodes a regulatory subunit of the IKK complex, resulting in an impaired NF- κ B activation. We identified a boy with EDA-ID with no detectable NEMO mutation. In order to study the NF- κ B signalling pathway, we stimulated the patient's fibroblasts with TNF α and IL1 β . Electrophoretic mobility shift assay revealed that both stimuli failed to trigger NF- κ B DNA-binding into the nucleus. As the key step in NF- κ B activation is the phosphorylation of NF- κ B inhibitors, an IKK kinase assay was performed on patient's fibroblasts after TNF and IL1 stimulation. This test showed no defect in the IKK activation, but a strong and specific defect in I κ B α degradation. I κ B β and I κ B ϵ were degraded normally. It has been previously shown that the phosphorylation of two important residues of the I κ B α protein (S32 and S36) is crucial for its ubiquitination and degradation and the subsequent translocation of NF- κ B into the nucleus. For this reason, I κ B α cDNA and genomic DNA were completely sequenced and a *de novo* heterozygous G to T substitution was found (S32I). Remarkably, the immunological abnormalities of the EDA-ID syndrome caused by IKBA deficiency differ from those of the EDA-ID caused by NEMO mutations. Indeed, our IKBA-deficient patient had profound abnormalities of T lymphocyte development and proliferation. This is the first report of a mutation in the IKBA gene, the first evidence of its involvement in autosomal EDA-ID and its crucial role in T cell biology.

Program Nr: 2072 from 2002 ASHG Annual Meeting

PCR Technique and significance in Fragile X Syndrome. *L.A. Bastaki, SA. AL -AWADI, FA. HEGAZI, NA. TURKY, MA. MUSTAFA, KA. NAGUIB.* Maternity Hosp, Kuwait Medical Genetic Ctr, Khaldiya, Khaldia, Kuwait.

Objectives: To explore the potential application of PCR molecular methodology in detection of fragile X syndrome among suspected groups of mentally retarded male patients. Settings: Kuwait Medical Genetics Centre, Kuwait. Design prospective study included 182 mentally retarded males. Methods: 182 mentally retarded male patients who fulfill 5 or more criteria of fragile X syndrome were screened clinically and molecularly using the amplification of the triplet repeat sequences at FRAXA and FRAXE loci by PCR technique and southern blot in some positive cases. Results: 20 patients (10.9%) proved to be highly suspected of having fragile X syndrome due to mutation at FRAXA locus. None has mutation at FRAXE locus. Out of those 20 patients, 11 (55%) were confirmed to be positive by applying cytogenetic techniques while 7 cases (35%) were +ve by applying southern blotting techniques. Both prepubertal and post pubertal criteria of fragile X syndrome were discussed. Conclusion: The usage of PCR technique in diagnosis of fragile X syndrome is the most suitable technique in case of screening mentally retarded patients. Southern blotting technique is needed for confirmation of PCR positive results as well as detection of size repeat.

LMNA founder mutation in autosomal recessive axonal Charcot-Marie-Tooth disease reveals a novel

laminopathy. A. DeSandre-Giovannoli¹, M. Chaouch², S. Kozlov³, N. Kassouri², M. Tazir⁴, A. Vandenberghe⁵, T. Hammadouche⁶, C.L Stewart³, J.M. Vallat⁷, D. Grid⁸, N. Levy¹. 1) INSERM U491, Marseille, France; 2) service de neurologie, CHU Ben Aknoun, Algiers, Algrie; 3) Cancer and Developmental Biology Laboratory, NCI/Frederick, Frederick, MD; 4) service de neurologie, CHU Mustapha, Algiers, Algrie; 5) Laboratoire de Neurogenetique, Lyon, France; 6) Institut Pasteur, algiers, algrie; 7) Service de Neuropathologie, CHU Dupuytren, Limoges, France; 8) Genethon III, Evry, France.

Charcot-Marie-Tooth disease (CMT) is the most common motor and sensory inherited neuropathy, and, on the basis of electrophysiologic criteria, it has been divided into demyelinating (CMT1), and the axonal types (CMT2). Homozygosity mapping was performed on consanguineous algerian families affected with autosomal recessive (AR)-CMT2 and candidate genes from the critical interval were sequenced. In parallel, ultrastructural analysis from affected patients and Knock out mice were performed. Linkage to the 1q21..3 region was evidenced in 3 families. All affected individuals shared an ancestral homozygous haplotype. An homozygous LMNA (lamin A/C) mutation (C892T), causing an Arg to Cys substitution at the highly conserved residue 298 (R298C), was identified in all affected patients. A further analysis of CMT2 families from algeria identified the same homozygous mutation in patients from 5 more unrelated families. A sural biopsy from patient and nerves from Lmna ^{-/-} mice were examined. In human, a marked loss of myelinated and unmyelinated fibers was observed, with absence of large myelinated fibers. No onion bulbs or regenerating clusters were seen. Lesions of axons and myelin were also observed in nerves from Lmna ^{-/-} mice. Mutations in LMNA, encoding Lamin A/C, have been involved in Emery-Dreifuss myopathy, Dilated Cardiomyopathy, Lipodystrophy and, now, in a neuropathic phenotype (AR-CMT2). Deeper morphological and functional explorations on patients and Lmna KO and KI mice will give us new hints towards a better understanding of nerve-muscle interactions, and to the question as to whether mutations in the Lamin A/C proteins have tissue-specific or, viceversa, pleiotropic effects.

Multiple Mutations in PKHD1 in a Small Newfoundland Community. *L.C. Wilkins¹, E. Dicks², J. Green², P. Parfrey², W.S. Davidson¹.* 1) Molec Biol & Biochem, Simon Fraser Univ, Burnaby, BC, Canada; 2) Division of Medical Genetics, Memorial University of Newfoundland, St.John's, NF, Canada.

Newfoundland's geography, settlement, and socioeconomic development have produced a population useful for the study of genetic diseases. The presence of multiple genetic isolates and high coefficient of kinship have predisposed such isolates to autosomal recessive kidney diseases such as autosomal recessive polycystic kidney disease (ARPKD). ARPKD is a rare genetic disease with an estimated incidence of 1/20000 live births. It is characterized by enlarged and echogenic kidneys, as well as oligohydramnios secondary to a poor urine output. We have been examining a large extended kindred from a small Newfoundland community with six ARPKD affected individuals; three of which are of known consanguinity (Sibship A) and three of suspected consanguinity (Sibship B, C). Recently, the gene responsible for ARPKD has been identified. Mutational analysis was performed on the affected individuals of Sibship A and a homozygous mutation was identified (GLY-TRP, 11374 GGG-TGG). This same mutation was found in affected individuals of sibship B and C. Interestingly, the mutation in sibship B and C was heterozygous, indicating at least two mutations responsible for ARPKD in this small genetic isolate in Newfoundland. This observation agrees with haplotype analysis which predict two or more mutation carrying chromosomes associated with this disease. Other autosomal recessive diseases such as Bardet-Biedl Syndrome and Retinal dystrophy have also revealed multiple mutations in what was suspected to be a genetic isolate of a homogeneous origin in the Newfoundland population.

A t(4;6)(q12;p23) disrupts a novel gene, ADYC2, in a patient with acrodysostosis and short stature. *J.G. Dauwese¹, B.B.A. de Vries², C.H. Wouters², E. Bakker¹, G. Rappold³, M.H. Breuning¹, D.J.M. Peters¹.* 1) Center for Human and Clinical Genetics, Leiden University Medical Center, The Netherlands; 2) Clinical Genetics Center Rotterdam, The Netherlands; 3) Institute of Human Genetics, University of Heidelberg, Germany.

The index patient is a 34 year-old male, height 1.40m, arm span 1.26m, with normal intelligence and normal head circumference. He had extreme brachydactyly of both hands, more pronounced in the right hand, and to a lesser degree, brachydactyly of the feet. The right hand also shows partial syndactyly between digII and III. X-ray investigation showed acrodysostosis with relatively short ulna. In addition, the aorta was sclerotic with insufficiency of the aortic valves. Both parents had normal postures. A de novo 46,XY,t(4;6)(q12;p23) was found. BAC clones spanning the chromosome 4 and 6 breakpoints were identified by FISH. In close proximity of the chromosome 4 breakpoint the PDGFRA gene is located distally and the GSH2 homeodomain gene proximally. Both genes were not disrupted by the translocation. The GSH2 gene and functional parts of PDGFRA were screened for mutations in 150 individuals with idiopathic short stature. We only detected a stop mutation in the GSH2 homeodomain in two control individuals with normal postures, indicating that loss of one functional copy of GSH2 does not result in a disease-phenotype. The sequence of a chromosome 6 BAC clone revealed an EST close to the breakpoint. We sequenced the corresponding cDNA and identified a gene, named ADYC2 (acrodysostosis candidate 2), which is disrupted by the translocation in intron 1. ADYC2 is a novel gene with unknown function that spans 112Kb of genomic DNA. The gene consists of 13 exons, encodes a cDNA of 2783 bp with an ORF of 1487 bp and is ubiquitously expressed. The protein contains a MBOAT domain, which is found in proteins belonging to a superfamily of membrane-bound O-acyltransferases. In 150 persons with idiopathic short stature we did not find a mutation. In conclusion: We identified a novel gene, ADYC2, which is disrupted in a patient with acrodysostosis, but which is not commonly mutated individuals with short stature.

Myoclonus in a patient with a deletion of paternal e-sarcoglycan locus on chromosome 7p21. *R. Deberardinis¹, D. Conforto¹, K. Russell¹, J. Kaplan², B.S. Emanuel¹, E.H. Zackai¹.* 1) Division of Human Genetics and Molecular Biology, and; 2) Division of Neonatology, The Children's Hospital of Philadelphia, University of Pennsylvania School of Medicine, Philadelphia, PA.

Autosomal dominant myoclonus dystonia syndrome (MDS) is characterized by myoclonic and/or dystonic movements in absence of dysmorphia, mental retardation, or growth abnormalities. In most families, MDS is caused by mutations in the gene SGCE, which encodes e-sarcoglycan and is located on chromosome 7q21. Data from several sources, including multi-generation pedigrees revealing parent-of-origin effects on MDS penetrance, suggest that SGCE is maternally imprinted. We present a 32-month-old patient with a complex phenotype including myoclonus, microcephaly, short stature, mildly dysmorphic facies and language delay. Chromosome analysis revealed an interstitial deletion affecting chromosome 7q21. We used fluorescence in situ hybridization to estimate the size of our patients deletion (9.0-15 Mbp) and to confirm absence of SGCE on the affected chromosome. Polymerase chain reaction analysis of polymorphic markers in the region revealed that the paternally inherited chromosome contained the deletion, consistent with a model of maternal SGCE imprinting. Our patient is the first case of MDS caused by a de novo interstitial deletion of the SGCE gene, and represents a new contiguous gene disorder. The case underscores the need to consider chromosomal deletions in patients whose phenotypes are more complex than the classic presentation of a known disease. Furthermore, the apparent maternal imprinting of SGCE and other genes on 7q21 raises the possibility that our patient, with a deletion on his paternally inherited chromosome, has a null phenotype for those genes. This mechanism, similar to that of Prader-Willi syndrome, should provide important information about the function of genes in the region.

Agenesis of the corpus callosum, severe mental retardation and intractible epilepsy in a female with a *de novo* paracentric inversion X(p11.2p22.1) that disrupts *ARX*. *Y. Peng, M. Kato, D.H. Ledbetter, W.B. Dobyns.* Dept of Human Genetics, University of Chicago, Chicago, IL.

Mutations of the X-linked gene *ARX* have recently been associated with a wide range of phenotypes in males including X-linked lissencephaly with abnormal genitalia (XLAG), X-linked infantile spasms (ISSX) or West syndrome, mental retardation with myoclonic epilepsy and spasticity, Partington syndrome (X-linked mental retardation and dystonia), and X-linked non-syndromic mental retardation. XLAG is associated with null mutations and missense mutations in the homeodomain (Kitamura et al., 2002; Kato et al., this conference), while the other phenotypes have been associated with missense mutations including a polyalanine expansion and a separate polyalanine duplication (Bienvenu et al., 2002; Stromme et al., 2002). Several mothers and sisters of genotypic males with XLAG have agenesis of the corpus callosum (ACC), associated with either a normal phenotype or mild mental retardation and rare seizures. No symptoms were mentioned in female relatives of boys with less severe *ARX* mutations. Thus, the spectrum of phenotypes in heterozygous females is not yet known. We report a girl evaluated at 10 months because of severe mental retardation and intractible epilepsy, including infantile spasms. Her brain MRI showed complete ACC with no other abnormalities. Chromosome analysis showed a small paracentric inversion: 46, X, inv(X)(p11.22p22.12) *de novo*. FISH on metaphase cells showed that PAC clone 258N20, which contains *ARX*, was split with part of the signal seen at each end of the inversion. Southern blots using *ARX* exon 5 as a probe showed abnormal bands with multiple enzymes. Analysis of the restriction map and results from Southern blot placed the telomeric breakpoint in a small 20 bp region in intron 4. X-inactivation studies using the androgen receptor assay showed a normal pattern (60:40 ratio). We conclude that *ARX* is disrupted in this patient, with truncation after exon 4. Her phenotype matches that of males with ISSX due to missense mutations of *ARX*. Thus mutations of *ARX* in females are associated with variable ACC, mental retardation and epilepsy.

A novel mutation in the protein C gene causing neonatal purpura fulminans. *K.K. Abu-Amero¹, M.H. Al-Hamed¹, F.S. Al-Batniji²*. 1) Dept. of Genetics, King Faisal Spcilaist Hospital, Riyadh, Saudi Arabia; 2) Pediatric Dept., Riyadh Armed Forces Hospital, Riyadh, Saudi Arabia.

Case report: A 9 months old Saudi boy was admitted to the NICU from the labor ward due to multiple bullae on the left lobar region of the abdomen, right cheek, right elbow and occipital region filled with fluid. The diagnosis of the epidermolysis bullosa was made and after the appearance of the scrotal haematoma, a haematology consultation raised the diagnosis of thrombosis due to protein C deficiency. He was treated with fresh frozen plasma (FFP), as PC-concentrate was not available. His parents are young, the father is 28 years old, while the mother is 25 yeras old and are first-degree relatives. Neither had personal or family history of thrombosis. The cousin of the index case had protein C deficiency diagnosed at another hospital, treated with fresh frozen plasma, but died at the age of one year. Methods: Genomic DNA was prepared from the patient and parents blood samples using standard methods. The 9 exons of the protein C gene were amplified by PCR using oligonucleotide primers described previously. Sequencing was carried out on the amplified PCR products using the same Primers used for amplification. Results: The index have severe protein C deficiency with PC activity level of < 0.01 U/ml (normal level 0.70-1.40 U/ml) and antigenic levels of 0.02 U/ml (normal level 0.70-1.40 U/ml). The father and the mother have PC activity levels of 0.69 and 0.66 U/ml respectively and Protein C antigenic levels of 0.67 and 0.63 U/ml respectively. Both parents and the index case were normal for Factor V Leiden mutation and Prothrombin G20210A variant. A previously undescribed mutation due to CCTG insertion after nucleotide 8826, in codon Thr-371 of exon 9 of the PC gene was found in the patient, in the homozygous state, and in both parents, in the heterozygous state. This insertion was not detected in a normal control. The mutation (8826, ins CCTG) resulted in a frame-shift with a stop at codon 381 resulting in premature protein termination. Conclusion: This frame-shift mutation agrees with the presence of quantitative PC deficiency in the affected member of the family.

Molecular mechanisms of Smith-Magenis syndrome - breakpoint analysis and gene identification. *W. Bi¹, J. Yan¹, P. Stankiewicz¹, S.-S. Park¹, K. Walz¹, L. Potocki^{1, 2, 3}, J.R. Lupski^{1, 2, 3}.* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Pediatrics, Baylor College of Medicine, Houston, TX; 3) Texas Children Hospital, Houston, TX.

Smith-Magenis syndrome (SMS) is a multiple congenital anomaly/mental retardation syndrome characterized by behavior problems, minor craniofacial and skeletal abnormalities, and sleep disturbance. More than 90% of SMS patients have an ~4 Mb heterozygous deletion of a genomic segment on chromosome 17p11.2 flanked by large and highly homologous low-copy repeats (SMS-REPs). Nonallelic homologous recombination between the SMS-REPs results in both the SMS deletion, and the reciprocal duplication of 17p11.2, a subtle clinical syndrome.

To determine the molecular aetiology of the apparent homology mediated recombination between misaligned SMS-REPs, we screened for the unequal crossing-over points in 14 patient somatic cell hybrids that retain only one allele of chromosome 17 with SMS common deletion. Our breakpoint analysis indicated that half of the patients have undergone a crossing-over event in an ~12 Kb region within the KER gene cluster. Thus, a recombination hotspot is located in the KER gene cluster within the ~170 Kb homologous regions between the SMS-REPs. Interestingly, there is an ~2.2 Kb AT-rich palindrome flanking the proximal KER gene cluster, which may potentially facilitate the unequal crossing-over.

To determine which genes are responsible for SMS through haploinsufficiency effects, we refined the critical region (SMCR) to an ~1.1 Mb genomic interval by breakpoint analysis of SMS patients with unusual deletions. Furthermore, preliminary studies suggest that the genes for SMS features may be located in an ~210 Kb interval within the SMCR on the basis of one individual with an unusual deletion who does have typical SMS feature. Eight genes are located within this region, including candidate genes *LLGL1*, *FLJ20308*, *SMCR7*, and *SMCR8*. The corresponding mouse genes *Flj20308*, *Smcr7*, and *Smcr8* have been assembled. To determine their roles in SMS, construction of mutated mice by gene targeting is in progress.

A novel mutation in PITX3 associated with an autosomal dominant form of congenital cataract. Z. Yang¹, W. Lin², G. Pellerano³, M.E. Valdez-Guerrero³, G. Pellerano-Nobo³, D. Taveras³, R. Caraballo³, L. Jiang¹, S. Thirumalaichary¹, J. Pan¹, K. Zhang¹. 1) Moran Eye Center and Program in Human Molecular Biology & Genetics, University of Utah, Salt lake city, UT; 2) Division of Health Sciences and Technology, Harvard Medical School, Boston, MA; 3) Complejo Hospitalario Dr.Luis E. Aybar,Santo Domingo, Dominican Republic.

Purpose: To report clinical phenotype and genetic study in one large family with congenital cataract. **Methods:** Ophthalmic examination and genetic study were conducted in one large kindred with an autosomal dominant form of congenital cataract. Genomic DNA was extracted from blood samples of members of this kindred. Genotyping analysis was performed using polymorphic DNA markers encompassing Paired-like Homeodomain Transcription (PITX3) gene. Each of the 4 exons of PITX3 gene was amplified by PCR and sequenced using Beckman CEQ2000 sequencer. **Results:** Of 25 individuals who were at risk of inheriting the disease gene in one family with an autosomal dominant form of congenital cataract, 15 were diagnosed with congenital cataract based on decreased visual acuity and ophthalmic examination. The onset of disease phenotype is at birth. The disease phenotype progresses from nuclear sclerosis to total cataract. Linkage analysis with short tandem repeat polymorphic markers revealed positive linkage to 10q24-25 with a lod score of 4.4 at theta=0 with D10S1239. DNA sequence analysis identified a 1-bp deletion (550delG), leading to a frame-shift, losing 86 amino acid fragment at the C-terminus, and synthesis of an aberrant peptide from amino acid position 217 to 307. This sequence change segregated with the disease phenotype and was not observed in 200 normal controls. **Conclusions:** Congenital cataract in this family is caused by a novel PITX3 gene mutation. Mutations in PITX3 have been reported in anterior segment mesenchymal dysgenesis and cataract. This study confirms that the PITX3 gene play an important role in normal eye develop and lens formation.

The MFS2 gene, the second gene implicated in Marfan syndrome, is now located in a region of 500KB. *G. Collod-Beroud¹, K. Dahan¹, M-C. Bouterin¹, M. Mouiseddine¹, G. Jondeau², G. Delorme², O. Dubourg², J-P. Bourdarias², C. Junien^{1,3}, C. Boileau^{1,3}.* 1) INSERM U383, Hopital Necker-Enfants Malades, AP-HP, Paris, France; 2) Service de Cardiologie, Hopital Ambroise Pare, AP-HP, Boulogne, France; 3) Laboratoire Central de Biochimie, d'Hormonologie et de Genetique Moleculaire, Hopital Ambroise Pare, AP-HP, Boulogne, France.

MFS was the founding member of the "heritable disorders of connective tissue". Cardinal manifestations of this autosomal dominant syndrome involves the eye, skeleton, and cardiovascular systems. It is now well established that defects in the fibrillin gene located on chromosome 15 (FBN1) cause not only classic Marfan Syndrome (MFS), but also a large range of milder, overlapping phenotypes. By excluding the FBN1 locus in a large French family we raised the issue of genetic heterogeneity in MFS and the implication of a second locus (MFS2). Linkage analyses, performed in this family with dispersed anonymous DNA markers, localized MFS2 initially to a region of 9 cM between D3S1293 and D3S1283 which map at 3p24.2-p25. The analysis was subsequently enlarged to new family members and new dinucleotide and tetranucleotide DNA markers. These data compiled with our data of positionnal cloning allowed us to order markers and to refine the genetic localization of MFS2 between markers D3S2336 and D3S2466. This region has an estimated physical distance of nearly 0.5 Mb. The transcriptionnal map of the critical region contains only 2 known genes that are poor candidates (RAR beta, and TOP2B) and 2 mRNAs coding for human homologs of genes known in other species. We are currently studying these two candidate genes. The expression of these candidates observed in a range of 13 different tissus is consistent with the features observed in MFS. Large and small rearrangements, point mutations as well as qualitative or quantitative transcript abnormalities are under investigation to determine which of these two genes is the MFS2 gene.

Program Nr: 2082 from 2002 ASHG Annual Meeting

De novo mutation of the connexin 26 gene associated with recessive non syndromic deafness. *Y. Hujeirat, S. Shalev.* Genetic Institute, HaEmek medical center, Afula, Israel.

Mutations of the connexin 26 (GJB2) gene account for about 50% of all genetic sensorineural hearing loss. We report a 18 months old Arab moslem boy who has congenital hearing loss. He is the first child of healthy young parents, who are not related. Molecular tests for 35delG, W77R, R184P, 101delAG and V37I mutations which have been reported among Arabs in the region revealed that the proband has 35delG and R184P mutations. The father is a carrier of 35delG, and the mother was negative for both mutations. Segregation analysis of polymorphic markers (from chromosome 7,9,11,13,17)confirmed the presence of biparental contribution. This is the first de novo mutation of connexin 26 associated with recessive hearing loss.

IS THERE AN ASSOCIATION BETWEEN DELETIONS/POINT MUTATIONS IN THE DYSTROPHIN GENE AND MENTAL IMPAIRMENT IN DUCHENNE/BECKER PATIENTS ? *D.N.F. Vagenas^{1,2}, A.M.P*

Cerqueira¹, A. Torres¹, R.C. Pavanello¹, M.R. Passos-Bueno¹, M. Zatz¹. 1) Centro de Estudo Genome Hum, Univ de São Paulo, Sao Paulo, Brasil; 2) Centro em interunidades em biotecnologia, USP, São Paulo, Brasil.

Duchenne (DMD) and Becker (BMD) muscular dystrophies are allelic X-linked recessive disorders caused by mutations in a gigantic gene, with 79 exons, which encodes dystrophin. The phenotype is caused in about 60% of the cases by deletions, 5-6% by duplications, while the remaining cases are caused by point mutations. About 30-50% of the DMD patients have mental impairment (MI) but its cause is still unknown. An association between MI and deletions/mutations in the region encompassing exons 45-79 exons, involved in brain dystrophin isoforms has been suggested. In an attempt to confirm this observation we are assessing the mental ability (based on the intelligence Scale for Children/WISC) in a very large group of DMD/BMD patients. Among 1092 patients who were ascertained in our center, 692 (analyzed through multiplex PCR, SSCP, PTT and sequencing) had the diagnosis of dystrophinopathy confirmed: 654 have deletions and 38 point mutations. Mental capacity evaluated in 519 patients showed that 239 (46%) have MI while the remaining 54% have an apparently normal IQ. When the analysis was repeated for different regions of the gene, we observed that the proportion of patients with MI was 39% (50/127) for the proximal region (exons 1-20), 47% (178/377) for the central region (exons 41-54) and 46,9 % (164/349) for the region encompassing exons 45 to 79. Understanding the cause of MI in Duchenne dystrophy remains a great challenge. Supported by CEPID-FAPESP, PRONEX, CNPq.

More than 500 FBN1 mutations associated with Marfan syndrome and overlapping disorders in the extensive update of the FBN1 mutation database. *S. Le Bourdelles¹, I. Dehaupas¹, S. Grey¹, C. Junien^{1,2}, C. Beroud^{1,3}, C. Boileau^{1,2}, G. Collod-Beroud².* 1) Laboratoire Central de Biochimie, d'Hormonologie et de Genetique Moleculaire, Hopital Ambroise Pare, AP-HP, Boulogne, France; 2) INSERM U383, Hopital Necker-Enfants Malades, AP-HP, Paris, France; 3) Laboratoire de Biochimie et Biologie Moleculaire, Hopital Cochin, AP-HP, Paris, France.

Marfan syndrome (MFS) is a dominantly inherited disease of connective tissue involving the eye, skeleton and cardiovascular systems. Mutations in the FBN1 gene (encoding fibrillin-1, the major structural component of 10-12 nm microfibrils of the extracellular matrix) were first associated with MFS and subsequently with a large spectrum of conditions phenotypically related to this disorder like ectopia lentis, neonatal MFS, isolated skeletal features (or Marfanoid skeletal syndrome), atypical MFS without cardiac implication, some cases of thoracic aortic aneurysms... All the mutations described in FBN1 are widely distributed throughout the gene with no apparent disease specific or structural/function relationship. To date, the only genotype/phenotype relationship is still limited to exons 24 to 32 in which most mutations causing neonatal MFS are clustered. To facilitate the mutational analysis of FBN1 mutations and the identification of structure/function and phenotype/genotype relationships, we created, in 1995, a human FBN1 mutation database which gives access to a software package that provides specific routines that are optimized multicriteria research and sorting tools. The database has been modified to follow the guidelines on mutation databases of the Hugo Mutation Database Initiative. The current update shows more than 500 FBN1 mutations. The global molecular analysis of the mutations file reveals that percentage of recurrence is more important (25%) than initially suspected; number of de novo mutations compared to transmitted mutations is surprising (48.5%); One third of the mutations are predicted to result in truncated proteins; Two third of the mutations are missense mutations affecting primarily the numerous calcium binding EGF-like modules. The database is available at <http://www.umd.necker.fr/>.

Molecular analysis of 840 mutations in the human LDL receptor gene database (UMD-LDLR). *J. Rabes^{1, 2}, L. Villéger¹, M. Abifadel^{1, 3}, D. Allard¹, C. Béroud¹, C. Junien^{1, 2}, C. Boileau^{1, 2}, M. Varret¹.* 1) INSERM U383, Paris, France; 2) Service de Biochimie, CHU Ambroise Paré, Boulogne, France; 3) Faculté de Pharmacie, Université Saint-Joseph, Beirut, Lebanon.

To date, more than 900 mutations have been identified in the LDLR gene, encoding the low-density lipoprotein receptor, in subjects with Familial Hypercholesterolemia. We have compiled a database containing standardized data for each LDLR mutation, and developed the software that provides sorting tools and allows optimized multicriteria research [<http://www.umd.necker.fr:2004>]. The analysis of the 840 point mutations in the UMD-LDLR database gives the following information: [1] 60% of the mutations are missense, and 21% occur in CpG dinucleotides known to be mutational hot spots; [2] although widely distributed throughout the gene, there is an excess of mutations in exons 4 ($P<0.001$) and 6 ($P<0.05$)(ligand-binding repeats), 7 ($P<0.05$) and 9 ($P<0.001$)(EGF-like repeats); [3] there is a deficit of mutations in exons 10 ($P<0.02$) and 13 ($P<0.001$)(EGF-precursor-like), 15 ($P<0.001$) (O-linked-sugar), 16 ($P<0.001$) (transmembrane), 17 ($P<0.02$) and 18 ($P<0.01$)(cytoplasmic); [4] 41% of the small deletions occur between repeated sequences and can be explained by the slipped-mispairing model described by Krawczak and Cooper; [5] 66% of the mutations in the ligand-binding domain affect conserved amino-acids involved in LDL binding; [6] the functional data available for 183 (29%) mutations indicate 38% of class 2B (transport defective) and 33% of class 1 mutations (null alleles); [7] finally, the investigation of genotype/phenotype correlations is difficult since the clinical data is usually incomplete in mutation reports.

Clinical and molecular variants of ceroid lipofuscinoses among French patients. *C. Caillaud, J.P. Puech, J. Dussau, L. Poenaru.* Dept Genetique, Cochin Institute, Paris, France.

Neuronal ceroid lipofuscinoses (NCL) are inherited neurodegenerative disorders characterized by the accumulation of autofluorescent lipopigments in various tissues. Their clinical signs are psychomotor retardation, impaired vision, seizures and premature death. Four main NCL forms are distinguished according to clinical and morphological features : infantile (INCL), late-infantile (LINCL), juvenile (JNCL) and adult (ANCL), but numerous atypical forms have also been described. Eight loci have been delineated as responsible for these different forms (from CLN1 to CLN8), some of them encoding soluble enzymes : palmitoyl protein thioesterase for CLN1, tripeptidyl-peptidase I (TPP-I) for CLN2.

LINCL is the most common clinical form in France. The CLN2 locus was frequently involved, as demonstrated by the presence of a tripeptidyl-peptidase I deficiency in a majority of patients. Complete sequencing of the CLN2 exons showed the predominance of two previously reported mutations (Arg208Stop and 3556 G>C), accounting each for around 30 % of the alleles. Novel private mutations were also characterized, such as deletions, splice, nonsense or missense mutations. A TPP-I deficiency was also found in one patient with JNCL carrying the 3556 G>C mutation in association with a novel point mutation. Some LINCL patients had no TPP-I deficiency and are likely candidate for the other NCL loci. Further studies will be focused first on the recently cloned CLN6 gene and later on the CLN7 locus, when characterized.

Classical INCL patients exhibited palmitoyl-protein thioesterase (PPT) deficiency and common or rare mutations in the CLN1 gene. Involvement of this gene was also demonstrated in one patient with an early juvenile form. Classical JNCL forms were associated either with the common 1.0 kb deletion or with private mutations of the CLN3 gene. Our results will allow to delineate the NCL loci involved in variant forms of NCL and to offer a reliable genetic counselling and prenatal diagnosis to couples at-risk for these diseases.

Enigmatic complexity in neurofibromatosis type 1 (NF1): three independent pathological mutations in the *NF1* Gene in an NF1 family. *M. Upadhyaya*¹, *E. Majounie*¹, *P. Thompson*¹, *S. Han*¹, *C. Consoli*¹, *I. Cordeiro*², *D. Cooper*¹.
1) Dept Medical Genetics, Univ Wales Col Medicine, Cardiff, Wales; 2) Uniclade de Genetica, Pediatria-P1808, Lisbon, Portugal.

Neurofibromatosis type 1 (NF1) is one of the most common autosomal dominant disorders with a prevalence of ~1 in 3500. The mutation rate calculated for the *NF1* gene ($3.1-10.4 \times 10^{-5}$) is one of the highest reported in humans. About half of all NF1 cases represent new mutations. The identification of inherited lesions in the *NF1* gene has proven difficult owing to the size and complexity of the gene, the existence of numerous processed pseudogenes and the considerable allelic heterogeneity manifested by NF1 patients. We report the identification of 3 independent pathological mutations of the *NF1* gene in a Portuguese NF1 family. Of two affected sibs, one had a 1.5 Mb maternally derived deletion whilst the other possessed a paternally derived nonsense mutation in exon 22 (R1241X). Both parents were clinically normal. A paternal cousin, was subsequently also diagnosed and was found to harbor a novel disease causing frameshift mutation in exon 29 (5406insT). This change was not present in either of his parents. Haplotyping analysis excluded both non-paternity and genetic recombination in all three patients. The disease allele-bearing chromosomes from the two sibs were different from the disease allele-bearing chromosome of their cousin. No obvious microsatellite alterations were detected in any member of the family suggesting that genome-wide instability was not an explanation for these findings. All three lesions occurred *de novo* on different chromosomal backgrounds and are likely to have been generated by radically different mechanisms viz. recombination, methylation-mediated deamination and slipped mispairing respectively. No evidence for mosaicism was identified in the parents. The probability of finding an NF1 family with two additional independent non-identical, pathological *NF1* gene lesions occurring *de novo* must be of the order of $(10^{-4})^2 = 10^{-8}$.

Using *Drosophila melanogaster* to identify Angelman syndrome therapeutic targets. *L.T. Reiter, M. Bowers, E. Bier.* Dept. of Biology, UCSD, La Jolla, CA.

The human *UBE3A* gene encodes an E3 type ubiquitin ligase, E6-AP, that marks specific protein targets for ubiquitin-mediated degradation. *UBE3A* is expressed biallelically in most human tissues, but is genetically imprinted in the brains of mammals. An overabundance of the proteins targeted by functional E6-AP in hippocampal and cerebellar neurons is potentially the cause of the neurological defects observed in AS patients. Identifying these target proteins could lead to new therapeutic strategies. Using the [Homophila](#) database, we identified a *Drosophila* homologue of *UBE3A*, which we named the *Drosophila* Angelman syndrome gene (*d-as*). Two different transcripts of *d-as* were cloned from whole flies by RT-PCR. The shorter transcript uses a cryptic splice site in exon V fused to exon I resulting in a protein product that is 71% similar to human E6-AP. The larger transcript is expressed in a developmentally regulated fashion and in the adult head. Using antibodies against human E6-AP distinct protein isoforms were identified in embryos and adult heads. Antibody staining indicates expression of D-as protein in the early CNS and endocrine secreting cells of the embryonic proventriculus. Using an existing strain containing a p-element inserted into the 5-UTR of *d-as*, we generated both lethal and semi-lethal alleles of *d-as*. Heterozygotes carrying a putatively downregulated allele over a lethal overexpressing allele exhibit a progressive degenerative phenotype in the eye. Ubiquitous temperature induced misexpression of human E6-AP or D-as results in neurologically compromised flies and death after two hours. With these reagents in hand we have initiated a genetic screen for second site modifiers of *d-as* mutant phenotypes to identify potential protein targets of D-as. We are also performing 2-D gel electrophoretic analysis on protein extracts from D-as misexpressing flies to identify proteins which have been downregulated by excess E6-AP or D-as. Once the D-as protein targets have been isolated, we will search for the corresponding proteins in humans and assay their abundance in the brains of AS patients as well as the corresponding mouse model for AS.

***RMRP* Gene Mutations and Clinical Presentation of Cartilage-Hair Hypoplasia: Extensive Allelic Heterogeneity and Lack of Genotype-Phenotype Correlations Indicate Modifier Genes.** A. Superti-Furga^{1,7,8}, A. Atkinson², E. Kirk³, S. Unger², M. DiRocco⁴, R. Savarirayan³, G. Mortier^{5,8}, B. Zabel^{6,8}, J. Ziegler³, C. Roifman², L. Bonafé^{1,7,8}. 1) Univ Childr Hosp, Zurich, Switzerland; 2) Hosp Sick Children, Toronto, Canada; 3) Sydney Childr Hosp, Sydney, Australia; 4) Ist Gaslini, Genova, Italy; 5) Med Genet Centre, Gent, Belgium; 6) Univ Childr Hosp, Mainz, Germany; 7) Univ Childr Hosp, Lausanne, Switzerland; 8) European Skeletal Dysplasia Network.

To characterize the clinical spectrum associated with mutations in the *RMRP* gene responsible for Cartilage-Hair Hypoplasia (CHH; MIM 250250), we have performed mutation analysis in patients with classical presentation (skeletal dysplasia and immune deficiency) as well as with partial phenotypes such as isolated metaphyseal dysplasia (MIM 250460), or immune deficiency and/or anemia in infants and young children without recognizable metaphyseal changes. We have identified four reported and thirteen unreported mutations in ten unrelated non-Finnish families. All probands are compound heterozygous, with no instance of homozygosity. Mutation types include insertions between TATA box and transcription start as well as single nucleotide substitutions at base-pairing and non-pairing residues. No relationship emerges between type of clinical presentation and type of mutation. - **Conclusions:** (1) extensive mutation heterogeneity and abundance of polymorphism suggest high mutability of the *RMRP* gene; (2) broad phenotypic spectrum and lack of strong genotype-phenotype correlations point to the existence of disease-modifying genes; (3) clinical presentations may include immuno-hematologic disease before metaphyseal dysplasia can be recognized; as such children may profit from timely therapeutic interventions, early molecular diagnostics can be important.

Analysis of *SFTPB* in 40 Sporadic or Familial Neonatal and Pediatric Cases with Severe Unexplained

Respiratory Distress. *M. Tredano*¹, *M. Griese*², *J. de Blic*¹, *T. Lorant*¹, *C. Houdayer*¹, *F. Cartault*³, *J. Elion*¹, *R.*

*Couderc*¹, *M. Bahuaud*¹. 1) Biochimie Biologie Moléculaire (MT, TL, CH, RC, MB), Hôpital Trousseau; Pneumologie Pédiatrique (JB), Hôpital des Enfants-Malades; Biochimie Génétique (JE), Hôpital Robert-Debré, AP-HP, Paris, France; 2) Ludwig-Maximilians Universität, München, FRG; 3) Service de Pneumologie et Génétique, CHD, Saint-Denis, Île de La Réunion.

We have analyzed the surfactant SP-B protein and its encoding gene (*SFTPB*, MIM 178640) in 40 unrelated pediatric patients with unexplained respiratory distress (URD). There was high consanguinity (8 kindreds) and an underlying autosomal recessive trait could be inferred in most cases, with overall high sex ratio (32/17) suggesting proband's gender to impact on penetrance. The clinical/biological presentations fitted into three major nosologic frames. I, SP-B deficiency (9 probands, scarcer than previously suggested), complete or incomplete, with homozygous/compoundly heterozygous mutations identified (6 probands), including one from the population isolate of Réunion Island (496delG). In addition, there was a consanguineous kindred in which incomplete deficiency was unambiguously unlinked to *SFTPB*. II, Pulmonary alveolar proteinosis (PAP, 19 probands), with typical storage of PAS-positive material within the alveoli with foamy macrophages and variable interstitial reaction, which was diagnosed in most patients from Réunion Island. Mutation and/or segregation analyses excluded *SFTPB* as a disease locus, although slight metabolic derangement related to SP-B and/or mild *SFTPB* changes could somehow contribute to disease. III, URD without evidence for SP-B deficiency or PAP (12 probands), equally unlinked to *SFTPB*, although a singular patient had a unique, possibly causal, maternally-derived heterozygous genetic change (G4521A). The population frequency of five known and four novel SNPs was studied, providing as many potential markers for pulmonary disease related to *SFTPB*. Overall, URD was found to be heterogeneous, both phenotypically and genetically, even in population isolates where founder effect might have been expected.

A homozygous cathepsin C gene mutation is responsible for Haim-Munk syndrome. *L.A. De Marco¹, R.S. Gomez², J.E. Costa², V.F. Cury¹.* 1) Dept Pharmacology, Univ Federal de Minas Gerais, Belo Horizonte MG, Brazil; 2) Department of Oral Surgery and Pathology, Univ Federal de Minas Gerais, Belo Horizonte MG, Brazil.

Palmoplantar keratoderma is a heterogeneous condition characterized by hyperkeratosis and erythema of the soles of the feet and palms of the hands. Haim-Munk syndrome (HMS) (MIM # 245010) and Papillon-Lefevre syndrome (PALS) (MIM # 245000) are rare autosomal recessive type IV palmoplantar ectodermal dysplasia and differs from other palmoplantar keratosis by their association with severe early onset periodontitis. Haim-Munk syndrome is a disorder that involves hyperkeratosis, arachnodactyly and nail deformities (onychogryphosis). The skin manifestations and nail deformities in HMS are more extensive and severe and the periodontium is less severely affected, in contrast to PALS. Several mutations of the lysosomal protease cathepsin C gene have been described in Papillon-Lefevre syndrome and only two mutations have been associated with Haim Munk syndrome. However, genotypic and phenotypic correlation has not been completely established. In the present study we describe a subject affected with Haim-Munk syndrome. DNA sequence analysis of CTSC gene from the affected patient identified one mutation (587TC) in exon 4, that altered the original CTT to a CCT codon. This mutation results in the substitution of a conserved leucine residue at position 196 by a proline (Leu196Pro). Of the 40 controls tested, none was found to have this missense mutation. This same mutation has been previously found to cause Papillon-Lefevre syndrome in one unrelated Brazilian kindred. Our findings suggest that the 587TC mutation may have either been inherited from common ancestors or other genetic or environmental factors could be important determinants of the clinical phenotype of both conditions. However, given their ethnicity, it is highly unlikely that there is a common ancestor. In summary, we here show a novel mutation in the cathepsin C gene responsible for Haim-Munk syndrome, suggesting that both Haim-Munk and Papillon-Lefevre syndromes are allelic variants of cathepsin C gene mutations, and other factors may be important determinants of the clinical phenotype.

Keratin-9 gene mutation in a family with EPPK. *L. Peleg*¹, *M. Karpati*¹, *B. Goldman*¹, *B. Amichai*². 1) The Ganek Gertner Institution of Human Genetic' Sheba Medical Ctr, Ramat Gan, Israel; 2) Department of Dermatology, Huzot Clinic of Kupat Holim, Ashkelon Iarael.

Epidermolytic palmoplantar keratoderma (EPPK), Voerners type is an autosomal dominant disorder, which belongs to a heterogeneous group of genodermatoses. The gene associated with EPPK was mapped to 17q11-q23, to the type 1 (acidic) keratin gene cluster. In 1993 the cDNA of Keratin 9 (KRT9) was cloned and sequenced. The gene product is expressed in the epidermis of the palms and soles. Most of the mutations associated to EPPK have been located within the highly conserved domain of the first α -helix motif of the KRT9 polypeptide (residues 156-171). A mutation in a different region was reported in one family only. The known mutations have been identified in varying ethnic background. We studied four affected and two non-affected individuals of three generations of an Ashkenazi Jewish family from Russia. In addition DNA samples of two non-related healthy controls were also analyzed. An A to G substitution at position 545 was identified by sequencing a 200 bp fragment (bp 497-697). The mutation generate a substitution of asparagine to serine at position 160. Since this mutation does not alter a recognition site of any known restriction enzyme, its presence was confirmed by sequencing all the studied DNA samples. The mutation was restricted to the affected individuals' DNA and was not found in the four healthy individuals. As this mutation was already reported in an Austrian-Alpine family with EPPK, an analysis of the polymorphic CA repeat region in intron 4 of the gene was undertaken. In the Austrian family the disease was associated with an allele containing 21 repeats. In the present family (six members) four alleles were revealed: 17, 20, 22 and 23 CA repeats. The mutation 545A to G was associated with the allele containing 20 repeats. These results suggested that different ancestors introduced the mutation in the two families.

Facioscapulohumeral dystrophy: Premature activation of the myogenic program? *D.A. Figlewicz, J.E. Sowden, A. Haefele, J.R. Forrester, K. Barrett, V. Kavcic, R. Tawil.* Dept Neurology, Univ Rochester Medical Ctr, Rochester, NY.

Facioscapulohumeral dystrophy (FSHD) is an autosomal dominant disorder resulting from deletion of 3.3kb repeats on chr 4q35. Part of the phenotype of the FSHD deletion(s) is observed in myoblasts prepared from FSHD patient muscle biopsy. Our previous studies suggest that FSHD myoblasts may be dividing less robustly either because they are leaving the cell cycle early, or because they are displaying replicative senescence. The cyclin dependent kinase inhibitor, p21, is upregulated in FSHD myoblasts; it is important to know whether this occurs in conjunction with the transcription factor MyoD (as observed in normal muscle differentiation), or whether it occurs independently of MyoD. Our recent data support the former option. FSHD myocytes fuse at a faster rate than controls, suggesting that the muscle differentiation program has been turned on. Quantitation of actual mRNA levels of MyoD and 4q35 genes which are expressed in muscle (ANT,ALP/SMT7,hFAT) confirms their highly significant upregulation. Moreover, Pearson Correlation analysis reveals that SMT7 and ALP expression are significantly correlated with MyoD expression ($p = 0.017$ and 0.035 , respectively). All of these data suggest that: MyoD is upregulated earlier, and to a greater extent, in FSHD myoblasts, and that its upregulation is correlated with turning on the myogenic program. Therefore the upregulation of p21 is likely to represent the logical continuation of the normal myogenic program in FSHD myoblasts. Because the behavior of FSHD myoblasts resembles that of control myoblasts undergoing replicative senescence, we wish to establish whether FSHD myoblasts have experienced true replicative senescence, or whether their loss of replicative capacity is based on other mechanisms disrupting the normal cell cycle. We have quantitated centromeric and telomeric DNA of myoblast samples from FSHD patients, muscle disease controls, and normal controls. The T/C ratio would be expected to be significantly less in FSHD myoblasts if muscle satellite cells had undergone a greater number of divisions prior to muscle biopsy. Thus far, our data do not support this. Funded by NIAMS 08R1AR48340A-01.

The Thoracoabdominal Syndrome (TAS): Narrowing the critical interval region and searching for the TAS gene.

*L. Finkel*¹, *R. Carmi*², *R. Parvari*³. 1) Department of Immunology and Microbiology, Faculty of Health Sciences, Ben Gurion University, Beer Sheva, Israel; 2) Dean, Faculty of Health Sciences; 3) Department of Immunology and Microbiology, Faculty of Health Sciences, Ben Gurion University, Beer Sheva 84105, Israel.

TAS presents a closure defect confined to the ventral midline. The main clinical manifestations of this syndrome are closure defect of the midline abdominal wall (ventral hernia) seen in all affected individuals, as well as a defect in the antero-lateral diaphragm manifested almost exclusively in affected males. TAS has been described in only one Jewish-Lybian family by our group and the mode of inheritance suggested from the familial segregation of anomalies is X-linked dominant. Linkage analysis study of 27 individuals of the Jewish-Lybian TAS kindred finely localized the TAS genes to Xq27, with no crossing over events with DXS1232 and DXS984, which are located approximately 350Kb apart. Lod scores of 5.49 and 6.36 were obtained for DXS1232 and DXS984, respectively. The TAS interval was thus defined between markers F9 on the centromeric side and DXS1205 at the telomeric side (about 1.6Mb), each showing a crossing over event in a different individual. The sequencing of the interval is almost completed with only two possible gaps. In order to narrow down the critical interval we have developed 15 additional polymorphic markers. On the centromeric side a new polymorphic marker narrowed the interval by 355Kb. Another polymorphic marker 328Kb telomeric to DXS984 showed no crossing over events. Further telomeric to this site there is a segmental duplication that prevents from developing additional polymorphic markers. Thus the telomeric border remains DXS1205. Two candidate genes in the critical interval: CDR1 and SPANXB1 were screened for mutations in an affected male by PCR amplification of the coding exons and their borders. No mutations were identified. Half of the coding region from the N-terminal side, including the HMG box of the SOX3 gene showed no mutations. 24 additional ESTs were identified in the critical interval that are now under study.

Development of a high-sensitive and low-background human muscle cDNA microarray to study muscular dystrophy. *T. Tsukahara*¹, *S. Noguchi*^{1,2}, *M. Fujita*^{1,2}, *R. Kurokawa*^{1,2}, *A. Tsujimoto*³, *I. Nishino*^{1,2}. 1) Dept Neuromuscular Research, Natl Inst Neuroscience, NCNP, Tokyo, Japan; 2) CREST, JST, Japan; 3) DNA Chip Research Inc., Yokohama, Japan.

The comprehensive gene expression analysis in disease muscles should be a powerful tool to understand the molecular pathomechanism of the muscle disease. However, there are two major problems in hybridization-based gene expression analysis: 1) Possibility of cross-hybridization of probes with homologous genes may not be negligible. 2) Huge amount of samples are necessary and thus a single muscle biopsy specimen is not enough for the analysis. To overcome these difficulties, we newly developed a human muscle cDNA microarray with high sensitivity and reliability. To make probes, we collected all sequence data annotated to be expressed in skeletal muscle from public databases. Sequences homologous with rRNA, mtDNA, and repetitive sequences were excluded from candidates. PCR primers were designed so as to specifically amplify the fragments of 450-550bp in length in the vicinity of 3 ends of each singleton. Each fragment in the database was amplified from muscle cDNA pools and confirmed by sequencing. We obtained 5,310 muscle-expressed genes including all known causative gene for muscular dystrophies and their associated genes. Amplified clones were purified and spotted onto a PLL-coated slide glass. We used a tyramide signal amplification system to enhance the signal. In triplicate experiments using human skeletal muscle total RNA as a target, our microarray demonstrated good reproducibility ($R=0.94-0.98$) in the range of the 100-100,000 relative fluorescence intensity. The fluorescence intensity of each target spot was linearly increased in the range of 1-4 microgram of total RNA, indicating that one microgram of total RNA was enough for the analysis. With our new cDNA microarray, we successfully obtained gene expression profile from less than mg of a single frozen muscle biopsy specimen. Our data were basically compatible with the previously published data, indicating that our cDNA microarray is a powerful tool to analyze molecular pathology of the disease in each patient.

Molecular analysis of *PTPN11* gene encoding protein tyrosine phosphatase SHP-2 and phenotype-genotype correlation in Japanese patients with Noonan syndrome. *Y. Aoki*¹, *T. Niihori*¹, *X. Yang*¹, *K. Kurosawa*², *H. Ohashi*³, *T. Kondo*⁴, *E. Ishii*⁵, *Y. Suzuki*¹, *S. Kure*¹, *Y. Matsubara*¹. 1) Department of Medical Genetics, Tohoku University School of Medicine, Sendai, Japan; 2) Division of Medical Genetics, Kanagawa Children's Medical Center, Yokohama, Japan; 3) Division of Medical Genetics, Saitama Children's Medical Center, Saitama, Japan; 4) Department of Pediatrics, Nagasaki University of Medicine, Nagasaki, Japan; 5) Department of Pediatrics, Saga Medical School, Saga, Japan.

Noonan syndrome (NS) is characterized by short stature, characteristic facial appearance including hyperterolism and ptosis, various congenital heart defects, broad or webbed neck, and mild mental retardation. Recently, missense mutations in *PTPN11*, the gene encoding protein tyrosine phosphatase SHP-2 (src homology region-2 domain phosphatase-2), were detected in approximately 50% of familial or sporadic patients with NS. Mutations detected in these patients were clustered in amino-terminal src-homology 2 (N-SH2) and protein tyrosine phosphatase (PTP) domains, implying that they were gain-of-function mutations. To identify mutations in NS patients from different ethnic background, we analyzed 20 Japanese patients with familial or sporadic NS. Fifteen coding exons with adjoining intronic sequences were amplified by PCR and sequenced. One novel mutation (Ser502Thr) and 7 previously reported mutations were found in 9 of 20 unrelated patients analyzed. Phenotype-genotype analysis showed that pulmonary stenosis was more prevalent among the patients with *PTPN11* mutations than those without mutations (7/9 vs. 4/11). The patient with the Ser502Thr mutation had an episode of transient abnormal myelopoiesis at 3 months of age and was associated with neuroblastoma at 6 months, suggesting the extending characteristics of the mutation. These results confirm the previous reports that missense mutations in *PTPN11* gene are responsible for NS in the different ethnic background.

Growth hormone gene deletions resulting from unequal homologous recombination enhanced by the presence of chi-like sequences. *C.T. Moseley¹, M.D. Orenstein², J.A. Phillips III¹*. 1) Department Pediatrics, Vanderbilt University School of Medicine, Nashville, TN; 2) Martin Luther King Magnet High School for Engineering and Health Sciences on the Pearl Campus, Nashville, TN.

Familial growth hormone deficiency type 1A is an autosomal recessive disease caused by deletion of both growth hormone-1 (GH1) alleles. To determine the location of crossover sites that resulted from unequal homologous recombination within the human GH gene cluster causing GH1 gene deletions, we mapped the breakpoints in six unrelated subjects who were homozygous for 6.7-kilobase (kb) deletions that encompassed GH1 but had different RFLP haplotypes. To do this, we designed primers to amplify a 1.2-kb deletion junction fragment for each subject. Restriction map and sequence analyses localized the breakpoints for all six subjects within two blocks of highly homologous DNA sequences that lie 5' and 3' to the GH1 gene. In five of these six cases, the unequal homologous recombination event occurred between two 79-bp perfect repeats that were 3329-bp 5' and 3284-bp 3' to the GH1 capsite. In the sixth subject, the recombination occurred between two 64-bp perfect repeats that were 4113-bp 5' and 2498-bp 3' to the GH1 capsite. Interestingly, none of the repeats contained Alu sequences. Further, the 79-bp and 64-bp repeats were extremely short compared to other repeat sequences also found within these two blocks of homologous DNA. A search for recombination-prone motifs revealed chi-like sequences in the 64-bp (5' - TCTGGTAA - 3') and the 79-bp (5' - CATGGTGG - 3') breakpoint regions. Our findings suggest that the chi-like sequences may be important in defining sites for homologous recombination that cause GH1 gene deletions.

CAG/CTG repeat expansions at the HDL2 locus are a common cause of Huntington disease in black South

Africans. A. Krause¹, J. Temlett², K. van der Meyden³, C.A. Ross⁴, C. Callahan⁴, R.L. Margolis⁴. 1) Human Genetics, NHLS, Johannesburg, Gauteng, South Africa; 2) Department of Neurology, University of the Witwatersrand, South Africa; 3) Department of Neurology, Pretoria Academic Hospital, South Africa; 4) Department of Psychiatry, Johns Hopkins University School of Medicine, Baltimore, USA.

Huntington disease (HD) is an autosomal dominant neurodegenerative disorder, typically presenting with choreiform movements and subcortical dementia. A CAG repeat expansion in the IT15 gene on chromosome 4p is responsible for most cases of HD. Recently a CAG/CTG repeat expansion in the junctophilin-3 (JPH3) gene on chromosome 16q23 has been implicated in a subset of clinically diagnosed HD cases that did not have an expansion in the HD gene. The disorder caused by this mutation has been designated Huntington disease type 2 (HDL2). All HDL2 positive patients to date have been of African or African-American ancestry, with the exception of one Moroccan and one Mexican patient. In a sample of white South African individuals tested for HD, 75% (57/76) of individuals had expansions. Only 41% (14/34) of black South African patients, ascertained through the same referral system, were positive for HD expansions. Individuals who tested negative for the HD repeat expansion were tested for the HDL2 expansion. In the white South African group, to date 0% (0/6) of individuals tested positive. However, 35% (7/20) of black South African individuals tested positive, with repeat lengths between 40 and 49 (unaffected 8-28), confirming a diagnosis of HDL2. Clinical features in the 7 positive HDL2 cases are indistinguishable from HD. Age at presentation ranged from 47 to 62 years. At least 3 of these individuals have a positive family history of a Huntington-like disease. HDL2 mutations account for 21% of Huntington disease in the black South African individuals tested, suggesting that this locus contributes significantly to the HD phenotype in this population. It should thus be incorporated into routine HD diagnostic testing. Further, these findings suggest that one of the origins of the HDL2 mutation may have been in Africa.

Genetic heterogeneity of Huntington's Disease: screening of mutations in the DRPLA and TBP genes, HDL-1 and

-2 loci. *G. Stevanin¹, H. Fujigasaki¹, A.S. Lebre¹, C. Jeannequin¹, A. Camuzat¹, R.L. Margolis², C. Dode³, A. Brice^{1,4}, A. Durr^{1,4}.* 1) INSERM U289 and Institut Federatif des Neurosciences, Groupe Hospitalier Pitie-Salpetriere, Paris, France; 2) John Hopkins University School of Medicine, Baltimore, MD, USA; 3) Laboratoire de Biochimie et Genetique Moleculaire, Groupe Hospitalier Cochin-Port Royal, Paris, France; 4) Federation de Neurologie et Departement de Genetique, Cytogenetique et Embryologie, Groupe Hospitalier Pitie-Salpetriere, Paris, France.

Huntington's disease (HD) is an autosomal dominant neurodegenerative disorder resulting mainly from the loss of neurons in the striatum. Patients suffer from progressive and unremitting chorea, rigidity and cognitive impairment. A CAG repeat expansion in the IT15 gene on chromosome 4 is responsible for the vast majority of cases with HD phenotypes. This mutation accounts for 88% of HD cases in our series. We identified 88 HD patients without expansions in the IT15 gene and analyzed them for mutations previously reported in Huntingtons disease-like patients : i) a 192 nucleotide insertion in the PRPN gene encoding the prion protein (HDL1 locus) ii) a CTG/CAG repeat expansion in the gene encoding Junctophilin-3 (HDL2 locus) iii) CAG expansions in the DRPLA and TBP genes, reported in patients presenting with cerebellar ataxia and chorea and/or dementia and behavioral disturbances. CAG expansions in the DRPLA gene and insertions in the PRPN gene were not found in our series. On the contrary, expanded repeats at the HDL2 locus and in the TBP gene accounted for 2 and 4 patients with typical HD, respectively. HDL2 patients came from Morocco and French West Indies and carried 49 and 43 repeats. Both presented with chorea and dementia associated with cerebellar symptoms in one. Expansions of 43 to 49 repeats in the TBP gene were detected in 4 European HD-like patients. Dementia was the common feature of these patients and was associated with: ataxia and myoclonia (n=1), chorea (n=1), or with ataxia and chorea (n=2). In conclusion, repeat expansions at the HDL2 and TBP loci account for less than 1% each, in our series of HD-like patients. Further genetic heterogeneity is then expected.

Repeat analysis of the ZNF9 gene in DMPK expansion negative DM patients. *H. Scheffer¹, A. Tieleman², G. Padberg², M. de Visser³, M. Leferink¹, F. Hol¹.* 1) Human Genetics, Univ Medical Ctr Nijmegen, Nijmegen, Netherlands; 2) Neurology, Univ Medical Ctr Nijmegen, Nijmegen, Netherlands; 3) Neurology, Academic medical Ctr, Amsterdam, Netherlands.

Myotonic dystrophy (DM) is a multisystem disorder and the most common form of muscular dystrophy in adults. Patients exhibit myotonia, proximal and distal limb weakness, frontal balding, cataracts, and cardiac arrhythmias. One form of the disorder (DM1) is caused by an expanded CTG repeat in the 3 untranslated region of the DMPK gene. Recently, a second gene causing similar clinical symptoms was identified. DM2 is caused by a CCTG expansion located in intron 1 of the ZNF9 gene. Expanded allele sizes range from 75 to approximately 11,000 CCTG repeats, with a mean of approximately 5,000 repeats. We have analyzed the ZNF9 CCTG repeat in 12 unrelated DM patients presenting with the classical DM symptoms in whom a CTG DMPK expansion had been excluded. In 4 cases no expansion was identified, whereas in 8 cases a CCTG expansion was present. These results show that a substantial proportion of DM patients without DMPK CTG expansion is due to a ZNF9 CCTG expansion. Patients without DMPK or ZNF9 expansions may be caused by pathogenic alleles of a third locus. Alternatively, a different disease clinically resembling DM may in fact affect the patients in whom negative test results were obtained. The technical approach included fragment length analysis of amplified CCTG ZNF9 repeats in order to exclude DM2 by the presence of two normal length alleles. Subsequently, Southern analysis using part of the ZNF9 intron 1 as a probe was used. Since expanded alleles can be extremely large, and could be easily missed, it is recommended to compare the hybridization intensity of the normal allele with a reference probe. It can be noted that no somatic mosaics having two normal length as well as expanded repeat size ZNF9 fragments have been observed.

A new recessive syndrome of Cerebellar Ataxia with Saccadic Intrusions maps to 1p36. *M. Burmeister¹, S. Li¹, R.J. Leigh², I.N. Beshpalova¹, J. Weber³, B. Swartz².* 1) Mental Hlth Res Inst, Dept. of Psychiatry and Human Genetics, Univ Michigan, Ann Arbor; 2) Dept. of Neurology, Case Western Reserve University, Cleveland, OH; 3) Marshfield Medical Research Foundation, Marshfield, WI.

A family of Slovenian descent presented with at least 5 of 14 sibs affected by progressive ataxia, saccadic intrusions on fixation, axonal sensory neuropathy, and myoclonic jerks without EEG abnormalities. Although difficulties in reading and concentrating were reported, cognition appears unaffected. Disease onset was insidious, but early signs are remembered in their 20s. SCA1-3, 6-8, Friedreichs ataxia, EPM1 and MJD have been excluded by commercial mutation tests. Linkage to known recessive ataxias on 19p13.3 (Cayman Ataxia) and 21q (UL-PME) was excluded. A Genome Scan with 374 short tandem repeat polymorphisms was performed at Marshfield on the mother, 5 affected, and 4 unaffected offspring. For several markers linkage could not be excluded. On 1p36, additional markers (ABIs 5 cM genome scan panel, performed at U of M Sequencing Core) were tested on these plus one additional unaffected individual. Several markers were completely informative and nonrecombinant and showed linkage with a maximal LOD score of 3.03 at 0 cM. The nonrecombinant region is flanked by recombinant markers D1S468 and D1S507 and spans about 30 cM or about 13 Megabases. Candidate genes within the nonrecombinant interval are KCNAB2, a K-Channel which when knocked out in mice leads to decreased life expectancy, occasional seizures and myoclonic jerks after cold water stress, and Kinesin KIF1B, dominant mutations of which have been shown to cause the sensory neuropathy syndrome Charcot Marie-Tooth Disease type 2A. Since all 4 grandparents came from the same valley in a remote area of Slovenia, homozygosity mapping is likely to allow further fine mapping, to be followed by candidate gene testing.

Genetic mapping and identification of a new autosomal nonsyndromic recessive deafness locus *DFNB37*. Z.M. Ahmed^{1,2}, R.J. Morell¹, S. Riazuddin¹, M.M. Ahmad¹, S.A. Mohiddin³, R.C. Caruso⁴, S.N. Khan², L. Fananapazir³, T. Husnain², A.J. Griffith^{1,5}, S. Riazuddin², T.B. Friedman¹, E.R. Wilcox¹. 1) Section on Human Genetics, LMG, NIDCD,NIH, Rockville, MD; 2) National Center of Excellence in Molecular Biology, Punjab University, Lahore, Pakistan; 3) Clinical Cardiology Section, NHLBI, NIH, Bethesda, MD; 4) Section on Ophthalmic Molecular Genetics, NEI, NIH, Bethesda, MD; 5) Section on Gene Structure and Function, LMG, NIDCD, NIH, Rockville, MD.

Autosomal recessive profound nonsyndromic deafness in a large family from Pakistan (PKDF10) was found during a genome-wide scan to co-segregate with markers on chromosome 6q, defining *DFNB37*. A fully linked marker supported a lod score of 6.53 at $q=0$. Subsequently, linkage to *DFNB37* was found in two additional families segregating recessive nonsyndromic deafness from Pakistan (PKDF71,PKSR14). All three families are unrelated and carry different haplotypes for the markers in the linkage region. In addition to pure-tone audiometry, participating family members underwent medical history interviews, balance tests, and, in a subset of hearing impaired subjects, funduscopy, ENG and ERG exams were performed. Affected individuals from PKDF10 had a delay in developmental milestones and an abnormal ENG, confirming a malfunctioning vestibular organ. Upon sequencing a candidate gene from the *DFNB37* linkage region, a single base pair insertion in the open reading frame, predicted to cause a frameshift and premature termination, was homozygous in affected individuals of family PKDF10. Affected individuals of family PKDF71 have a homozygous nonsense mutation in the second to the last exon of the same gene. The deaf individual of family PKSR14 has a homozygous missense mutation. This mutation was not found among 351 normal representative DNA samples from Pakistan or from the Human Diversity panel (C.C.R.). The two other mutations were not found by sequence analysis among DNA from 100 normal control samples. More than 200 families segregating recessive deafness from Pakistan and India are currently being screened for *DFNB37* to find the relative contribution of this gene to deafness in Southeast Asia.

Linkage and mutation analysis of a family with autosomal dominant late onset macular degeneration. R.

Ayyagari¹, A.J. Karoukis¹, T. Sturm¹, J.E. Young², E. Reichel³, R. Ambasudhan¹, S.C. Khani¹. 1) Department of Ophthalmology, University of Michigan, Ann Arbor, MI; 2) Department of Ophthalmology, State University of New York at Buffalo, Buffalo, NY; 3) Ophthalmology, Tufts University, Boston, MA.

PURPOSE: To map and clone the gene causing a unique late onset autosomal dominant macular degeneration in a large five-generation family with prominent atrophic and exudative features closely resembling those found in age-related macular degeneration (AMD) and Sorsby fundus dystrophy (SFD). **METHODS:** Phenotype was characterized by fundus photography, fluorescein angiography, visual field testing, ERG and visual function tests on selected individuals and by reviewing ophthalmologic data on others. Microsatellite markers were analysed using standard protocols. Linkage analysis was carried out using MLINK program. Mutation analysis of candidate genes was carried out by PCR amplification of exons followed by direct sequencing. **RESULTS:** All the affected individuals displayed characteristic late onset atrophic macular changes with or without superimposed choroidal neovascularization. Disease symptoms are first manifested in later half of 5th decade. We obtained blood samples from 17 affected members, 17 unaffected and 5 spouses. Linkage, haplotype and mutation analysis have excluded the *TIMP3*, *Bestrophin*, *ELOVL4*, *EFEMP1* genes associated with macular degenerations. Significant negative LOD scores were obtained with markers linked to Stargardt's macular degeneration, Age related macular degeneration, North Carolina macular degeneration loci. Analysis with additional markers has given significantly high positive LOD scores suggesting linkage. Additional markers linked to this region are being tested to confirm linkage. **CONCLUSIONS:** We identified a family with late onset macular degeneration phenotype that mimics AMD and SFD. We have excluded most of the previously known candidate gene loci by linkage and mutation analysis.

A 288 bp exonic insertion and novel missense mutations in PAX9 in families with autosomal dominant

hypodontia. *P. Das*¹, *M. Hai*², *C. Elcock*³, *S.M. Leal*³, *D.T. Brown*⁴, *A.H. Brook*³, *P.I. Patel*^{1,2}. 1) Dept Neurology, Baylor Col Medicine, Houston, TX; 2) Dept of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Dept of Oral Health and Development, School of Clinical Dentistry, Clarendon Crescent, Sheffield S10 2TA, UK; 4) 5001 Highway 190, Suite A6, Covington, LA 70433.

We previously reported a frameshift mutation in PAX9 as an underlying cause for familial autosomal dominant oligodontia involving posterior teeth (Nature Genet 24: 18-19, 2000). More recently, we reported a submicroscopic deletion (~56 Kb) encompassing PAX9 and SLC25A21 in a small nuclear family where a father and his daughter were affected with severe hypodontia involving both primary and permanent molars (Hum Genet, 110: 371-376, 2002). Since PAX9 was the only odontogenic gene within this deletion, we concluded that haploinsufficiency for PAX9 is the underlying cause for hypodontia. Here we report the molecular analysis of three additional families with hypodontia. In two of these families (DEN 3 and DEN9), PAX9 was associated with the disease phenotype by linkage analysis. DHPLC analysis followed by DNA sequencing in affected members of these two families revealed missense mutations, namely, a leucine substituted by proline in family DEN3 and a lysine substituted by glutamic acid in DEN9, within the paired domain of PAX9. A 288 bp insertion within exon 2 of PAX9 was detected in two identical twins affected with hypodontia in the third family, resulting in a putative frameshift mutation and a premature stop codon. These studies extend the spectrum of mutations in PAX9 associated with hypodontia, and include the categories of heretofore-undescribed missense mutations and a large exonic insertion.

EVIDENCE FOR A GENETIC HETEROGENEITY OF MEGALOBLASTIC ANAEMIA 1 IN TUNISIAN PATIENTS. *C. Bouchlaka*¹, *C. Maktouf*¹, *T. Sfar*², *A. Ayadi*², *A. M'kaour*³, *M. Sioud*³, *N. Gueddich*⁵, *Z. Belhadjali*⁴, *K. Dellagi*¹, *S. Abdelhak*¹. 1) Immunology, Inst Pasteur, Tunis, Tunisia; 2) C.H.U, Tahar Sfar, Mahdia, Tunisia; 3) hôpital d'enfants, Tunis, Tunisia; 4) C.H.U, Aziza othmana, Tunis, Tunisia; 5) C.H.U, Monastir, Tunisia.

Imerslund-Grasbeck syndrome or megaloblastic anaemia 1 (MGA1) is a rare autosomal recessive disorder characterised by a selective intestinal cobalamine malabsorption. MGA1 occurs worldwide, but its prevalence is high in Norway, Finland and several Middle Eastern countries. In Tunisia, more than 20 patients have been diagnosed. The locus MGA1, has been previously mapped by linkage analysis in Finish and Norwegian families to a 6 cM region on chromosome 10p12.1. The gene "CUBN" encoding the Intrinsic factor (IF)-vit B12 receptor, also called cubiline, was recently identified by positional cloning. Two specific mutations have been described in 17 finish MGA1 patients. P1297L was the most prevalent mutation. Involvement of "CUBN" gene in MGA1 was investigated by linkage analysis in Tunisian families. Eight patients belonging to six consanguineous families have been included in this study. Segregation analysis was performed using four microsatellite markers (D10S1476- D10S504- CUBN - D10S1714) overlapping the "CUBN" region. Haplotype analysis and homozygosity mapping have shown that in four families, the patients were homozygous by descent for all the markers, suggesting a likely linkage to MGA1 locus. These patients have been screened for the P1297L mutation by direct sequencing. No one of our patients bared this prevalent finish mutation. One patient belonging to a consanguineous family was heterozygous for all the markers including the intragenic marker (CUBN) but his haplotype differed from his unaffected brother. This patient may be a compound heterozygote or probably did not cosegregate with MGA1 locus. Another patient born to a consanguineous family was also heterozygous for all the markers and share the same haplotype as his unaffected brother, excluding linkage to MGA1 locus. These results suggest a genetic heterogeneity in MGA1, this has been already suggested by genetic studies of a canine model.

What Defines a Critical Region for Gene Finding? *W.S. Davidson, L.C. Wilkins.* Molecular Biology & Biochemistry, 8888 University Drive, Simon Fraser University, Burnaby, BC, V5A 1S6 Canada.

Linkage analysis has traditionally been the method used to define a locus associated with a genetic disease. The location of the gene is refined on the basis of advantageous recombination events that permit the identification of regions that are shared by affected individuals and excluded from unaffected individuals in the same kindred. Even within a large extended family, recombination events are infrequent and thus the critical region is usually too large for immediate positional cloning of the gene. In order to reduce the critical region to a size that is amenable for gene identification and the search for the mutation(s) causing the disease, one normally has to rely on a combination of cross-overs in different families. We encountered problems with this standard approach during the search for the gene associated with autosomal recessive kidney disease (ARPKD). Our approach involved analysing a known consanguineous Newfoundland family in which a recombination event reduced the previously described critical region from one end. Using a combination of microsatellite markers and single nucleotide polymorphisms, it was possible to reduce the region of homozygosity in affected individuals within the previously defined critical region to 230 kbp. Several gene prediction approaches identified 13 potential exons. Although sequence variants were observed in these regions of the DNA from family members, no mutation associated with the disease was found. The gene for ARPKD (PKHD1) has recently been described and 10 of our predicted exons corresponded to exons 52-61 of PKHD1. We have subsequently identified the homozygous mutation in this kindred. The mutation resides in exon 62 of PKHD1 which is outside the critical region defined using the standard methodology described above. Our experience with this problem should alert the gene finding community that, when using multiple families to define critical regions, one must consider the possibility that the mutation in a particular family can reside outside what may be considered the standard critical region. (Funding for this work was provided by the Canadian Institutes for Health Research).

A New Gene for Autosomal Dominant Cerulean Cataract Type-3. *V. Kumar¹, D. Singh², K. Sperling³, J.R. Singh¹.*
1) Ctr Gen Disorders, Human Gen, Guru Nanak Dev Univ, Punjab, India; 2) Dr Daljit Singh Eye Hospital, Amritsar, India; 3) Institute of Human Genetics, Charite Humboldt-University, Berlin, Germany.

Purpose: Gene mapping by linkage analysis in an autosomal dominant congenital cataract (ADCC) family. **Methods:** Gene mapping studies were carried out in an autosomal dominant congenital cataract family of Indian origin, having 12 members in 3-generations, as affected with cerulean cataract. More than 100 fluorescently labelled microsatellite markers, selected from known candidate gene regions, were used for the analysis. Genotyping was done with GENOTYPER 2.5.1 software on ABI-377 sequencer. 2-Point and multipoint linkage analysis were carried out using the MLINK and LINKMAP components of the linkage program package ver. 5.1 respectively. **Results:** On the basis of obtained 2-point and multipoint lod score values, we initially excluded the known loci for cerulean cataract type-1 and type-2 at 17q24 and 22q11.2-12.1 respectively. Further the other known candidate gene regions on chromosomes 1, 2, 3, 9, 10, 11, 12, 13, 14, 15, 17, 19, and 21 were also excluded, as the obtained 2-point lod score values were less than 2 at $\alpha=0.001$, except for the markers on chromosome 16. A maximum positive LOD score of 3.9 at $\alpha=0.000$ indicative of linkage, was obtained with 3 markers on chromosome 16. Multipoint analysis carried out with these analysed markers also supported the linkage, with a maximum LOD score of 3.612 between markers D16S518 and D16S511. Multipoint and haplotype analysis narrowed the cataract locus to a 16.6 cM region between markers D16S3097 and D16S511 that corresponds to the 16q22 region on chromosome 16. **Conclusion:** This is the first report of mapping a gene for cerulean type cataract, at 16q22. Since the gene for cerulean cataract type-1 and type-2 have already been mapped at 17q24 and at 22q11.2-12.1 respectively, the present study further supports the genetic heterogeneity for this type of cataract. On the basis of localization of Marner type and posterior polar cataract to the same region i.e. 16q22, the possibility of allelic heterogeneity in congenital cataract cannot be excluded.

Evidence for further genetic heterogeneity in posterior polymorphous dystrophy. *E. Heon*¹, *C.E. Willoughby*^{1, 2}, *G.D. Billingsley*¹, *H. Herbert*², *S.B. Kaye*². 1) Ophthalmology, Vision Science Research Program, Toronto Western Hospital Research Institute, Univ Toronto, Toronto, ON, Canada; 2) Royal Liverpool University Hospital, Liverpool, UK.

Posterior polymorphous dystrophy (PPD; OMIM#122000) is a progressive disorder of the corneal endothelium which is normally dominantly inherited. The corneal endothelial cells develop epithelial characteristics in PPD and provide hallmark pathological findings. We identified mutations in the VSX1 homeobox gene have been identified in PPD and keratoconus, and mutations COL82A have been described in PPD and Fuchs endothelial dystrophy. The aim of this study is to document the spectrum of the ocular phenotype and genetically characterize a three generation pedigree with PPD. Eleven family members (5 affected and 6 unaffected) had a full ocular assessment including corneal topography and pachymetry. The proband underwent penetrating keratoplasty (corneal transplantation) allowing histological confirmation of the diagnosis. The corneal material was examined by light microscopy and demonstrated positive immunohistochemical staining for cytokeratins. Microsatellite markers for the VSX1 and COL82A loci were selected and genotyping performed on a Pharmacia automated sequencer. Two-point linkage analysis used the MLINK program of the LINKAGE package v5.2. Linkage to VSX1 and COL82A was excluded in this family with histologically confirmed PPD. The clinical and genetic analysis of this family further outlines the genetic heterogeneity of PPD.

Evidence consistent with linkage to 15q of a non-chromosome 4 linked FSHD family. *B.L. Randolph-Anderson, J.M. Stajich, F.L. Graham, M.A. Pericak-Vance, M.C. Speer, J.R. Gilbert.* Ctr Human Genetics, Box 3445, Duke Univ Med Ctr, Durham, NC.

Facioscapulohumeral muscular dystrophy (FSHD; MIM 158900) is a primary disease of muscle with early symptoms including facial or shoulder girdle weakness and subsequent involvement of pelvic girdle and extremity muscles as the disease progresses. The majority of FSHD families are linked to the 4q35-qter region (FSHD1A), although genetic heterogeneity (FSHD1B) has been established within this diagnostic classification. We have identified two FSHD families in which non-linkage to chromosome 4 has been confirmed (DUK1361 and DUK2531). Genomic screening has identified a region on chromosome 15 consistent with linkage. Several markers in an 18cM region on chromosome 15 provided positive lod score values. Multipoint analysis gave supporting evidence for the results revealed in the two point data analysis, with a peak lod score of 3.20 in these families. While haplotype analysis suggests that the most likely interval spans D15S1004 and D15S536, one individual in family 1361 tentatively classified as affected (individual 9019) in this pedigree excludes the region in its entirety. Initial analysis of the D4Z4 repeat indicates that this affected individual has a repeat length of 30 kb; however, haplotype analysis of the pedigree conclusively eliminates the 4q region in this family. These data raise the possibility that this affected individual may be a phenocopy. A search for candidate genes in the region identified POLG, which encodes the gamma subunit of mitochondrial DNA polymerase. Mutations in this gene are responsible for the myopathic disease progressive external ophthalmoplegia. We have investigated POLG for evidence of mutation by PCR sequence analysis of the 22 coding exons and the promoter region in two affected individuals. To date, these investigations suggest that POLG is not the gene responsible for FSHD1B in this family. Further investigations of genes in this region are underway.

A Novel Homozygous Fusion Allele in a Patient with Type 2 Gaucher Disease. *N. Tayebi, B. Stubblefield, E. Sidransky.* Section on Molecular Neurogenetics, NIMH, NIH.

The deficiency of the lysosomal enzyme glucocerebrosidase results in Gaucher disease, an autosomal recessive inherited disorder. Based upon the presence and the progression of neurological symptoms, Gaucher disease is divided into type 1, non-neurologic, type 2, acute neurologic and type 3, subacute neurologic forms. The human glucocerebrosidase gene (GBA) on 1q21 has a pseudogene sharing 96% sequence homology located 16 kb downstream of the functional gene. We have studied patients with type 2 Gaucher disease in detail, utilizing molecular techniques including PCR, long-template PCR, direct sequencing, southern blot and polymorphic site analyses. Among 37 patients with type 2 Gaucher disease, 18 recombinant alleles (24%) were identified in 14 patients. These alleles arise from a recombination between GBA and its pseudogene after unequal pairing between the 2 chromosomes. Among 4 patients homozygous for recombinant alleles, 3 patients carried a short stretch of pseudogene sequence, ranging from 824-1193 bp, resulting from a gene conversion event. Based on sequencing and southern blot analyses, the fourth, a 19 week fetus, showed homozygosity for a fusion allele. The site of crossover in the sequence for both alleles occurred within the last 186 bp of exon 9 or at the beginning of intron 9. A true homozygous fusion allele has not previously been demonstrated. However, since parental DNA samples were not available for this case, the possibility of a deletion of one allele remains. DNA rearrangement events between the gene and pseudogene in the GBA locus appear to be lethal events when they occur on both alleles. Genetic studies of neuronopathic patients with Gaucher disease should be performed in great detail, to more accurately describe the recombinant alleles and to better resolve the relationship between genotype and phenotype in this disorder.

The mitochondrial leader sequence is present in all OPA1 mRNAs expressed in human brain. *M. Fiket, C. Alexander.* Neuroscience, Max-Delbrueck-Center, Berlin, Germany.

Autosomal dominant optic atrophy (ADOA) is the most prevalent hereditary optic neuropathy resulting in progressive loss of visual acuity, centrocoecal scotoma, and bilateral temporal atrophy of the optic nerve with an onset within the first two decades of life. This disease is caused by mutations in the OPA1 gene, which was identified by a positional cloning approach. The gene is located on chromosome 3q28 and is split into 31 exons. Examination of the N-terminal leader sequence of the deduced protein sequence revealed the typical features of a protein imported into the matrix space of mitochondria, which has been experimentally proven by reporter gene assays. Purpose: Preliminary northern blot analysis revealed the presence of OPA1 transcripts in all tissues examined but at varying abundances and sizes (Alexander et al. 2000). Minor differences in length (3-270 bp) can be accounted for by a splicing hot spot involving exons 4, 4b, 5, 5b (Delettre et al., 2001), but an explanation for the major size differences observed in the range of kilo bases was lacking. We sought to examine the sequence content of all OPA1-mRNA species observed by northern blotting in the brain. Especially, we were aiming at elucidating whether all OPA1 mRNAs expressed in the human CNS contained the sequence part coding for the mitochondrial import motif. Methods: PolyA+mRNA samples of more than 10 different human brain areas were examined by northern blot hybridisation. Radioactively labelled probes corresponding to different protein domains of the human OPA1-cDNA (AB011139) were used in the hybridisations. Results: Our experiments revealed the same multiple-band pattern in all tissue samples examined. Four different mRNA species of a length of 4, 5, 6, and 7 kb were identified. The sequence encoding the mitochondrial import motif was present in all of these transcript variants. Conclusion: We can conclude that all four OPA1 transcript species harbour the mitochondrial leader sequence. Thus, all putative OPA1 protein isoforms in the human brain are imported into mitochondria.

A missense mutation (I314L) in the homeodomain of HOXD13 results in both gain- and loss of DNA binding activity. *S. Kan*¹, *D. Johnson*^{1,2}, *H. Giele*², *A.O.M. Wilkie*^{1,2}. 1) Weatherall Institute of Molecular Medicine, The John Radcliffe, Oxford, UK; 2) Plastic & Reconstructive Surgery, Radcliffe Infirmary, Oxford, UK.

The HOX genes encode a highly conserved family of transcription factors, several of which act in a sequential and concerted manner to play fundamental roles in limb development. To date, two HOX genes have been proven to be mutated in human limb disorders: *HOXD13* in synpolydactyly (SPD) and *HOXA13* in hand-foot-genital syndrome.

We screened for mutations of the *HOXD13* open reading frame in patients with limb malformations, and identified a novel heterozygous mutation (940A>C, I314L) in all affected members of two pedigrees. The hand phenotypes of the two families are variable, including brachydactyly of the 5th digit, partial duplication of the 4th digit, and shortening of the 3rd metacarpal. The I314L mutation locates in the α -helix III of the conserved homeodomain at position 47. This is one of the four amino acid residues shown to make specific protein-DNA contacts in a variety of homeodomain-DNA crystal structures. Biochemically, isoleucine and leucine share many similar characteristics; however, in a cross-species line up of 364 different homeodomain-containing genes, leucine was never observed at homeodomain position 47.

Previous work has identified a core 5'-TTAC/T-3' (b-strand) consensus binding motif for proteins encoded by the 3' HOX genes. We compared the binding activity of the I314L mutant HOXD13 with wild type using gel shift assays. The I314L mutant bound the TTAC motif with higher affinity, but TTAT with lower affinity, compared to wild type. These findings suggest that the I314L mutation may differentially enhance or diminish the binding of HOXD13 to different DNA sequences and thereby exert both gain- and loss-of-function effects through different pathways; this explains why the phenotype associated with this mutation differs from SPD. The finding that the Leu47 HOXD13 homeodomain retains DNA binding activity raises interesting questions about why it is not observed in nature.

Characterization of missense mutations in the forkhead transcription factor FOXC1, a gene mutated in Axenfeld-Rieger malformations. *R.A. Saleem, F.B. Berry, T.C. Murphy, M.A. Walter.* Medical Genetics/Ophthalmology, Univ Alberta, Edmonton, AB, Canada.

FOXC1 is a developmentally important transcription factor. Mutations in FOXC1 lead to aberrant development of the anterior segment of the eye and increase the risk of glaucoma. We have previously determined the consequences of 5 missense mutations on FOXC1. Recently, five new FOXC1 missense mutations underlying AR malformations have been identified (P79L, P79T, I91S, I91T, R127H). The effects of these FOXC1 mutations on the ability of the FOXC1 protein to bind and bend DNA and activate gene expression were investigated. Site-directed mutagenesis was used to introduce these missense mutations into the FOXC1 cDNA. The effect of each additional missense mutation on FOXC1-DNA interactions was tested by electrophoretic mobility shift assays (EMSAs) and DNA-bending assays, while the effect of each missense mutation on the transactivation ability of FOXC1 was tested using a dual luciferase reporter assay. Preliminary results indicate that while all the missense mutations tested demonstrate reduced transactivation of a luciferase reporter gene in comparison to wild type FOXC1, the levels of residual activity of the mutant forms of FOXC1 vary greatly. Additionally, EMSAs have revealed that FOXC1 carrying P79L, P79T, I91S, or I91T is still able to bind an *in vitro* derived FOXC1 binding site at near wt FOXC1 levels. Further analyses of the effects of these missense mutations on FOXC1 binding specificity and the nature of the transactivation disruption are underway. Combined with our previous work, these experiments show that missense mutations in FOXC1 are able to disrupt the stability of FOXC1 protein, the interaction of FOXC1 with DNA, and/or the transactivation potential of FOXC1. This study will provide an understanding of how disease-causing mutations perturb FOXC1 function and will define critical thresholds of FOXC1 function. These studies indicate that FOXC1 protein levels and activity are tightly controlled and will provide a basis for understanding the role of FOXC1 in normal development.

Analysis of candidate genes for Crohn's disease: association with IL-4R and STAT6 genes from the IBD1 and IBD2 region. *B. Franke*¹, *D.J. de Jong*², *A.H. Naber*², *J.J. Willemen*¹, *J.G. Heister*¹, *H.G. Brunner*¹, *F.A. Hol*¹. 1) Department of Human Genetics, University Medical Centre Nijmegen, Nijmegen, The Netherlands; 2) Department of Gastroenterology and Hepatology, University Medical Centre Nijmegen, Nijmegen, The Netherlands.

BACKGROUND: Genetic susceptibility plays an important role in the etiology of Crohn's disease. Linkage studies indicate that genes in the IBD1 locus on chromosome 16 and (to a lesser extent) in the IBD2 locus on chromosome 12 are involved. Within the IBD1 region, NOD2 was recently identified as the gene of interest. However, linkage to the broad IBD1 region appears not to be explained by NOD2 alone. In IBD2, no involved genes have been described, yet. **AIMS:** In this study we tried to assess the relation of putative candidate genes in IBD1 (other than NOD2) and IBD2 with Crohn's disease. **METHODS:** Polymorphisms in the genes coding for IL-4R, CD11b, NOD2 (all three in IBD1) and STAT6 (in IBD2) were tested for association with Crohn's disease, using Transmission Disequilibrium Tests in patient-parent triads. **RESULTS:** In IBD1 we observed significant association with the Q576R polymorphism in IL-4R and a trend towards significance for the C-insertion allele of NOD2. IL-4R results remained significant upon exclusion of families with this NOD2 allele. No association was observed with the CD11b gene in IBD1. In IBD2 we found significant association of Crohn with a polymorphism in the STAT6 gene. **CONCLUSION:** IL-4R in the IBD1 region and STAT6 in the IBD2 region are associated with Crohn's disease. Both genes are functionally related in T lymphocyte differentiation and may play a role in the etiology of Crohn's disease. Our results indicate that IL-4R and NOD2 constitute independent risk factors for Crohn's disease in IBD1.

Two familial autosomal-dominant hemochromatosis cases associated with mutations in the SLC11A3 gene. V.

Douabin-Gicquel¹, P. Brissot^{2,3}, C. Halimi⁴, J. Rochette⁵, J.Y. Le Gall⁶, V. David^{1,6}, A.M. Jouanolle¹. 1) Laboratoire de Genetique , CHU Pontchaillou, Rennes, France; 2) Inserm U522, Rennes, France; 3) Clinique des maladies du foie, CHU Pontchaillou, Rennes, France; 4) Medecine Interne, CH Senlis, France; 5) Service de Genetique, CHU Amiens, France; 6) UMR 6061, Rennes, France.

Hemochromatosis is a progressive iron overload disorder frequent among subjects of European descent. It is generally inherited in an autosomal recessive pattern and most cases are related to homozygosity for the C282Y mutation in the HFE1 gene. We report here two familial cases of non HFE1 iron overload ; clinical symptoms of affected individuals were similar to those observed in HFE1 hemochromatotic patients but they did not have mutations in HFE1. Taking into account their particular genetic, biological and histological features, respectively 1) autosomal dominant inheritance, 2) marked increase in serum ferritin but moderate transferrin saturation, 3) iron accumulation in hepatocytes but also in Kpffer cells, the best candidate gene seemed to be SLC11A3 (Ireg1) recently implicated in similar cases. SLC11A3 encodes ferroportin, a basolateral membrane protein involved in the export of iron from the enterocyte to the circulation. Results : in the first family the proband and his son shared the same heterozygous deletion in exon 5, val162del. In the second one the three affected subjects (the mother and her two daughters) presented with the same heterozygous substitution in exon 8 resulting in the replacement of glycine 490 with aspartate. Conclusion : The involvement of the SLC11A3 gene should be evoked in autosomal dominant iron overload with major increase of serum ferritin.

Novel anterior segment phenotypes resulting from forkhead gene alterations: evidence for cross-species

conservation of function. *O.J. Lehmann*¹, *S. Tuft*², *G. Brice*³, *R. Smith*⁴, *A. Blixt*⁵, *A. Child*³, *T. Jordan*¹, *R.A. Hitchings*², *P.T. Khaw*², *S. John*⁴, *P. Carlsson*⁵, *S.S. Bhattacharya*¹. 1) Dept Molecular Genetics, Inst Ophthalmology, London, England; 2) Moorfields Eye Hospital, London, England; 3) Department of Cardiological Sciences, St. George's Hospital Medical School, London; 4) The Jackson Laboratory, Bar Harbour, Maine, USA; 5) Department of Molecular Biology, Gothenburg University, Gothenburg, Sweden.

Mutations in murine and human orthologs usually result in similar phenotypes. However with mutations in two forkhead transcription factor genes (*FOXC1* and *FOXC2*), inter-species differences include corneal or anterior segment phenotypes, respectively. To determine whether such discrepancies provided an opportunity for identifying novel human/murine ocular phenotypes, pedigrees with early onset glaucoma phenotypes secondary to segmental chromosomal duplications/deletions encompassing *FOXC1* and 18 individuals with *FOXC2* mutations underwent detailed ocular phenotyping. Mice with mutations in either *Foxc1* or *Foxe3*, were assessed for features of the human phenotypes. A significant increase in central corneal thickness was present in affected individuals from the segmental duplication pedigrees compared with their unaffected relatives (mean 13%, maximum 35%, $P < 0.05$). Alterations in corneal thickness were present in mice heterozygous and homozygous for *Foxe3* mutations but neither in *Foxc1* heterozygotes nor the small human segmental deletion pedigree. Mutations in *FOXC2* resulted in ocular anterior segment anomalies. These were more severe and prevalent with mutations involving the forkhead domain. Normal corneal development is dependent upon the precise dose and levels of activity of certain forkhead transcription factors. The altered corneal thickness attributable to increased forkhead gene dosage is predicted to affect clinical management of certain glaucoma subtypes through increasing recorded intraocular pressure. Taken together with the *FOXC2* mutation ocular phenotype, whose genotype-phenotype correlation may represent a feature common to other forkhead genes, these results highlight the remarkable cross-species conservation of function amongst forkhead genes.

Expression of mutant *JAGGED1*, which encodes a Notch ligand, in a fetus with Alagille syndrome. *M. Meunier-Rotival¹, C. Driancourt¹, J. Boyer¹, N. Raynaud¹, C. Crosnier¹, J. Deschatrette¹, M. Gonzales², M. Hadchouel^{1,3}.* 1) Genetique et maladies du foie de l'enfant, INSERM U347, Kremlin-Bicetre,; 2) Unite de Foetopathologie, Hopital Saint-Antoine, Paris; 3) Service d'Hepatologie pediatrique, Hopital de Bicetre, France.

Heterozygous mutations of *JAGGED1*, encoding a ligand for Notch receptors, are responsible for Alagille syndrome (AGS), a developmental disorder mainly affecting liver, heart and vasculature, vertebra, kidney and eye. The phenotype is variable even among patients with the same mutation. The mutations are found in the part of the gene encoding the extracellular and transmembrane domains of the protein. The majority of the mutations lead to a premature termination codon, which could produce a truncated protein. We previously demonstrated that both mutant and wild-type *JAGGED1* alleles are transcribed in lymphoblastoid cell lines of AGS patients, carrying missense, nonsense, frameshift, and splice site mutations. By studying a fetus carrying a frameshift mutation in the *JAGGED1* gene, we show that this is also the case in vivo. Prenatal molecular diagnosis was performed on a mother with AGS, due to a 4-bp deletion in exon 9 of *JAGGED1*. The fetus carried the same mutation. The parents elected to terminate the pregnancy. The 24-week-old fetus exhibited pulmonary stenosis, cystic right kidney, and thymic hypoplasia. We measured, by real time RT-PCR, the expression of *JAGGED1* in the liver, the kidney, and a cell line established from the aorta. The level of expression was 20 times higher in the kidney than in the liver. Both the wild-type and mutant *JAGGED1* RNAs were present in the 2 tissues, albeit at different concentrations. Similarly both wild-type and mutant alleles were transcribed in the cell line from aorta. These results are in good agreement with the expression pattern of *JAGGED1* in normal human embryos and fetuses, showing a strong expression pattern of *JAGGED1* in the cardiovascular system and in kidney, but no label in the bile ducts. The presence of the mutant transcript, even in relatively small quantities, indicates that the mutant (soluble) protein may be synthesised and act via a dominant negative mechanism.

Novel Missense Mutation Suggests the Heart is More Sensitive to JAG1 Dosage than the Liver. *J.J.D. Morrissette, F.M. Lu, R.P. Colliton, N.B. Spinner.* Division of Human Genetics, Children's Hospital of Phila., Philadelphia, PA.

Alagille syndrome (AGS) is caused by haploinsufficiency for JAG1, a ligand that functions in the Notch signaling pathway, which is involved in cell fate determination. AGS, is a variably expressed, dominant disorder affecting the liver, heart, eye, skeleton and face. The molecular basis for the variable expressivity is unknown, but no genotype phenotype correlation has been demonstrated. JAG1 mutations in AGS include whole gene deletions, protein truncating, splicing and missense mutations, suggesting that haploinsufficiency is the mechanism of disease causation. A few missense mutations have been studied, and were found to result in failure of the protein to be transported to the cell surface, consistent with a mechanism of haploinsufficiency. A unique JAG1 missense mutation (G274D) was previously identified in 13 individuals from an extended family who presented with cardiac defects in the absence of liver dysfunction (Eldadah et al., 2001). We studied the expression, localization and activity of this mutation to explain the organ specific phenotype in affected individuals. The G274D mutation was found to be conditional ("leaky") in that it produces two populations of proteins, normal and abnormal. The mutant population is abnormally glycosylated and is retained intracellularly, rather than being transported to the cell surface, similar to previously studied JAG1 missense mutations. The G274D-JAG1 protein is temperature sensitive, with more abnormal (and non-functional) molecules produced at higher temperatures. Carriers of this mutation therefore have more than 50%, but less than 100% of the normal concentration of JAG1 molecules on the cell surface. The cardiac specific phenotype associated with this mutation leads us to hypothesize that the developing heart has increased sensitivity to changes in JAG1 dosage, compared to the developing liver.

Program Nr: 2119 from 2002 ASHG Annual Meeting

FOXL2 gene deletions in patients with Blepharophimosis Ptosis Epicanthus Inversus Syndrome (BPES). V.S. Yellore, N. Udar, M. Chalukya, S. Yelchits, R. Silva-Garcia, K. Small. Dept Ophthalmology, Univ California, Los Angeles, Los Angeles, CA.

Blepharophimosis-ptosis-epicanthus inversus syndrome (BPES) is an autosomal dominant disorder of the eyelids that occurs in either of two types. Type I BPES, but not type II, is associated with premature ovarian failure. The causative gene FOXL2, is a forkhead transcription factor and is located at chromosome 3q23. We sequenced the entire FOXL2 gene in 40 patients from independent families and found base changes leading to mutations in only 15 of these individuals. Deletion in the 3q23 region have been reported to cause BPES. Large deletions can be identified by FISH analysis but small deletions are more difficult to identify. We used microsatellite analysis to identify deletions in the remaining patients. Using genomic sequence we generated 6 new microsatellite markers flanking the FOXL2 gene extending 0.5 Mb on either side of the gene. We genotyped the 15 probands and their families for these markers. Using haplotype analysis we identified 3 patients to be hemizygous for these markers thereby establishing deletion of this region. The deletion mutations accounts for 7.5 of our patients population. This work contributes further evidence of haploinsufficiency leading to the syndrome.

Human Genome Variation: The Problems and Challenges Ahead. *R.G.H. Cotton*^{1, 2}, *O. Horaitis*¹ and & members of the *Human Genome Variation Society*. 1) Genomic Disorders Research Centre, Melbourne VIC 3065, Australia; 2) The University of Melbourne, Dept. of Medicine, Melbourne VIC 3010, Australia.

Variations in human genes are assuming an increasing importance in all areas of health care. New methods for the detection of mutations and the completion of the human genome sequencing project have seen an exponential rise in variation information that must be collected, quality controlled, documented and stored safely to ensure future availability to health care professionals, researchers and others. This task will be a major challenge for the future of biological and medical science as there may be anywhere from one to greater than 1000 mutations in any given gene. To date this information has been collected by general databases such as OMIM or HGMD that collect only published mutations and in the case of OMIM selected published mutations. Unpublished mutations have made their way into Locus Specific Databases (LSDBs) and these can often contain 50% more mutations than published ones as well as other more detailed gene specific information. LSDBs however do not exist for all genes at this time.

The HUGO Mutation Database Initiative has addressed many problems regarding these issues and at the ASHG 2001 meeting a new society was inaugurated: the Human Genome Variation Society. This society aims to foster discovery and characterization of genomic variations including population distribution and phenotypic associations and promote the collection, documentation and free distribution of genomic variation information and associated clinical variations as well as endeavor to foster the development of the necessary methodology and informatics. The HGVS members have a number of projects, our main one being a new central variation database that will ensure capture of a maximum number of mutations, quality control of data submissions, safe storage and free-of-charge display via the Internet.

We outline the problems with mutation collection, why the current system cannot keep up and propose our solution as well as introduce our Society. **www.hgvs.org**.

Mutations in the *GJB2* gene among Bangladeshi with nonsyndromic hearing impairment. *J.H. Greinwald Jr*^{1,2}, *J.K. Bradshaw*², *L.H.Y Lim*¹, *M. Ali*³, *Y.S Guo*¹, *V. Pilipenko*¹, *D. Ingala*⁴, *M. Keddache*⁴, *D.I. Choo*^{1,2}, *R. Wenstrup*⁴, *R.J.H. Smith*⁵. 1) Center of Deafness and Hearing Research, Cincinnati, OH; 2) University of Cincinnati College of Medicine, Cincinnati, OH; 3) Dhaka Health Care, Dhaka, Bangladesh; 4) Dept of Human Genetics, Childrens Hospital Cincinnati, Cincinnati, OH; 5) Dept of Otolaryngology, University of Iowa, Iowa City, Iowa.

Background. Hereditary hearing impairment (HHI) accounts for approximately 50% of childhood hearing loss. Mutations in the *GJB2* gene are the most common cause of HHI in many countries. **Purpose.** We report the frequency of mutations in the *GJB2* gene in association with non-syndromic hearing impairment (NSHI) from Bangladesh. **Methods.** Fifty-eight patients with NSHI had DFNB1 testing. Thirty-one control subjects were identified with no sensorineural hearing impairment (HI). **Results.** Thirty-one of 58 (53.4%) had idiopathic severe to profound HI, 10 had moderate HI, and 3 had mild HI. Sequence variation was detected from direct sequencing from genomic DNA. One homozygous disease causing *GJB2* mutation (W77X) and one homozygote with a mutation of unknown significance (R127H) were identified in the Bangladesh NSHI population. Additionally several non-disease related polymorphisms were detected (V27I, E114G and V153I) including one control subject homozygous for V27I and heterozygous for E114G. Three affected and 5 control subjects were heterozygous for the R127H mutation. No carriers for known disease causing mutations were identified in the control or HI groups. **Conclusions.** The *GJB2* mutation rate in Bangladesh is considerably lower than previously identified in many other populations studied. These preliminary results indicate the need for further study of the genetic factors of NSHI in Bangladesh and throughout Southern Asia.

Program Nr: 2122 from 2002 ASHG Annual Meeting

MALDI-TOF mass spectrometry implementation for clinical molecular diagnostics. *I.M. Buyse, R.P. Pace, P. Lurix, B.B. Roa.* Baylor DNA Diagnostic Laboratory, Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

A major challenge for clinical molecular genetics is optimization of assay sensitivity/specificity and accuracy. The increasing demand for genetic testing services also requires a quantum leap in testing efficiency and throughput, which is addressed by improved technologies. Along these lines, our laboratory is converting DNA tests for known point mutations from the standard allele-specific oligonucleotide hybridization analysis (ASO) to a matrix assisted laser desorption ionization-time of flight (MALDI-TOF) mass spectrometry platform (Sequenom). This PCR-based assay employs primer-extension using specific combinations of unlabelled dNTP/ddNTP mixes, followed by discrimination of the predicted extension products using mass spectrometry. This study involves the development, validation, and implementation of MALDI-TOF assays for new and existing tests. These include an Ashkenazic disease screening panel for common mutations in Tay-Sachs disease, Canavan disease, and cystic fibrosis (CF). Similarly, Ashkenazi mutation panels for Gaucher disease, Bloom syndrome, Familial Dysautonomia and Niemann-Pick Type A disease have also been developed. MALDI-TOF assays are in the process of implementation for cystic fibrosis, using an augmented CF panel for diagnostic testing and pan-ethnic carrier screening that exceeds the current recommended core panel of CF mutations. Assay design is greatly facilitated by the provided software, and testing efficiency is substantially improved by assay multiplexing which typically involves the use of 3 to 5-plex assays. Pilot studies and validation data from our laboratory indicate an extremely high level of assay sensitivity/specificity and accuracy, coupled with a marked increase in throughput. Challenges encountered in the conversion process include process automation for a 384-well PCR format, and MALDI-TOF integration with our existing lab information system to provide for continuous sample tracking. Implementation of the MALDI-TOF platform will address current and future needs for high-throughput genotyping in a DNA diagnostic laboratory setting.

RPGR gene mutations are clustered at the 5'end of an evolutionary diverged coding minisatellite in exon ORF15.

*I. Bader*¹, *M. Hergersberg*², *E. Apfelstedt-Sylla*³, *B. Wissinger*³, *B. Lorenz*⁴, *A. Meindl*⁵, *T. Meitinger*¹. 1) GSF National Research Center for Environment and Health, Neuherberg, Germany; 2) Kantonsspital Aarau, Switzerland; 3) Department of Ophthalmogenetics, University of Tuebingen; 4) Department of Ophthalmogenetics, Regensburg, Germany; 5) Department of Medical Genetics at the University of Munich, Germany.

Mutations in the RPGR (retinitis pigmentosa GTPase regulator) gene are known to be causal for the majority of X-linked retinitis pigmentosa (xLRP). However, there was a striking discrepancy between the proportion of families linked to the RP3 locus and those having mutations in the RPGR gene. Most of the missing mutations were shown to be situated in a mutational hotspot in a novel alternatively spliced RPGR exon (ORF15). Screening 58 xLRP families we found RPGR gene mutations in 71% of families with definite X-linked inheritance, with a clustering of RPGR gene mutations at the 5'end of the most repetitive sequence of exon ORF15. The comparison of these results with the distribution of ORF15 mutations in two further comprehensive mutational screens in large xLRP cohorts, reveals a strong polarity of frameshift mutations towards the 5'end of the most repetitive sequence in exon ORF15 in all three populations investigated. Subsequent detailed computerized analysis of the human coding sequence of exon ORF15 and the orthologous sequences in mouse, dog, cattle and pufferfish show that the most repetitive sequence in exon ORF15 is an evolutionary diverged coding minisatellite. Polarity of frameshift mutations towards the 5'end and frequent in-frame alterations within the tandem repeat array are reminiscent of mutation events in non-coding human minisatellites and indicate increased germline instability. The tandem repetitive structure conserved across species puts this unusual coding sequence in the context of repeats of base oligomers as the primordial coding sequences and their vestiges in modern genes.

Fine mapping and prevalence of *FOXC1* and *PITX2* dosage alterations. *M.A. Lines¹, F. Mirzayans¹, O.J. Lehmann², M.A. Walter¹.* 1) Med Genetics / Ophthalmology, University of Alberta, Edmonton, AB, Canada; 2) Institute of Molecular Biology, London, UK.

Mutations and deletions of the eye-expressed transcription factors *FOXC1* and *PITX2*, as well as duplications of *FOXC1*, are each potential causes of anterior segment developmental anomalies including Axenfeld-Rieger (AR) malformations and related clinical disorders. While the pathologic significance of mutations of these genes has been well demonstrated, the mechanism and frequency of occurrence of *FOXC1* and *PITX2* dosage alterations remains unclear. We are currently conducting mapping and cohort experiments aimed at assessing the extent and prevalence of 6p25 and 4q25 chromosomal microdeletions/duplications. We present a detailed microsatellite-based map of distinct but tightly clustered 6p25 duplications within three extensive anterior segment dysgenesis (ASD) pedigrees, complemented by real-time PCR-based screening of a panel of 70 sporadic ASD patients for similar findings. Attempts are underway to characterise the boundaries of each duplicated region in order to determine if genomic features may suggest a mechanism for this event. *FOXC1*, in particular, maps to the 6p subtelomere. Subtelomeric regions are GC-poor, repeat-rich, and increasingly appreciated as hotspots of chromosomal rearrangement. *FOXC1* dosage alterations may therefore be more common causes of AR than is currently appreciated.

Azoospermia Factor Microdeletions in Cryptorchidism, Varicocele and Idiopathic Infertility. *R. Dada¹, N. Gupta², K. Kucheria¹*. 1) Genetic Division, Anatomy, AIIMS, New Delhi, 110029, Delhi, India; 2) Urology Department, Anatomy, AIIMS, New Delhi 110029. India.

Deletions of the Azoospermia Factor (AZF) on the long arm of Y chromosome are an important cause of male infertility. AZF is located on deletion interval 5 and 6 and is associated with spermatogenic failure and has been used to define three regions on Yq (AZFa, AZFb and AZFc) which are critical for spermatogenesis and are recurrently deleted in infertile males. This loci contain genes and gene families critical for germ cell development and differentiation and deletion of these loci cause spermatogenic arrest at different stages of germ cell development. Infertility affects 10-15% couples attempting pregnancy and in about half the cases sperm production is defective either qualitatively or quantitatively. One hundred and twentytwo infertile males with oligozoospermia and azoospermia were included in this study. Semen analysis was done in each case to determine the spermatogenic status- normospermic (>20million sperms/ml), oligozoospermic (<20million sperms/ml) or azoospermic (no sperms in the semen). They were subjected to detailed clinical examination, endocrinological and cytogenetic study. Thirty G-banded metaphases were analyzed in 122 infertile males and PCR microdeletion analysis was done in 70 cytogenetically normal cases. For this genomic DNA was extracted using peripheral blood. The STS primers tested in each case were sY84, sY86 (AZFa); sY127, sY134 (AZFb); sY254, sY255 (AZFc). PCR amplifications found to be negative were repeated at least 3 times to confirm the deletion of a given marker. The PCR products were analyzed on a 1.8% agarose gel. Eight of the seventy cases showed deletion of at least one of the STS markers. Review of literature has shown that the overall frequency of microdeletions varies from 1 to 55%. In the present study the frequency of microdeletion in was 11.4%. AZF microdeletions were seen in both idiopathic and in non- idiopathic cases with Cryptorchidism and varicocele.

High-throughput SNP genotyping to identify genetic modifiers of complex multigenic mechanisms underlying severe CF liver disease. *K.J. Friedman¹, S.C. Ling², A.H. Handler¹, M. Macek Jr³, J. Zielenski⁴, P.R. Durie⁴, L.M. Silverman¹, M.R. Knowles¹ and CF Liver Disease Consortium.* 1) Depts Pathology & Lab Medicine, & Medicine, Univ North Carolina, Chapel Hill, NC; 2) Royal Hosp for Sick Children, Glasgow, Scotland; 3) Dept Pediatrics, Charles Univ, Prague, Czech Republic; 4) Depts Molecular & Medical Genetics, Pediatrics, Univ of Toronto, and Program in Genetics & Genomic Biology & Program in Integrative Biology, Hosp for Sick Children, Toronto, Canada.

CFTR mutations have limited predictive value in forecasting disease severity in CF, as patients with identical genotypes may or may not develop severe CF liver disease (CFLD). Data have implicated mutations in the alpha-1-antitrypsin (PI) and mannose binding lectin (MBL2) genes as risk factors for CFLD. In truth more complex interactions may influence development of hepatic fibrosis. Our data suggest these interactions exist, as the risk conferred by PI gene mutations is compounded by a high expression promoter variant (T @ -509) in the transforming growth factor beta (TGFB1) gene (OR 3.2 95%CI 1.2-8.2 P=.01). Dual presence of PI & MBL2 mutations also confers increased risk for CFLD (OR 4.6 95%CI 1.2-16.9 P=.038). Combination of mutations/variants in all three genes confers the greatest risk (OR 11.4 95%CI 1.3-104 P=.01). Additional genes are likely to contribute to CFLD. Approx. 100 genes have been identified as candidate modifiers for this outcome. These include genes underlying other inherited liver disorders, or mediate fibrogenesis, inflammation, immune or oxidative stress response, metabolism of the ECM, or influence hepatocellular proliferation. We have identified 193 validated single nucleotide polymorphisms (SNPs) linked to 85 of these candidate modifier genes. Many are functional while others are anonymous, and each will permit detection of risk-associated haplotypes. High-throughput assays for these SNPs are underway. Aggressive international recruitment of more patients has identified ~400 CFLD patients likely to meet our criteria. We anticipate analysis of 95 CFLD patients and ~200 matched controls will shortly identify additional genes that modify risk for CFLD.

Variation of FMR1 mRNA levels by repeat size and X-inactivation pattern. *E.G. Allen, S.L. Sherman.* Department of Human Genetics, Emory University School of Medicine, Atlanta, GA.

The fragile X syndrome, a type of inherited mental retardation, is due to the silencing of the FMR1 X-linked gene as a result of an expansion of an unstable CGG repeat sequence located in the 5 untranslated region (UTR) of the gene. Once expanded to over 200 repeats, the FMR1 gene is hypermethylated and consequently no message is transcribed and no protein produced. There are essentially four allelic forms of the gene with respect to the repeat length and they are referred to as normal, intermediate, premutation and full mutation. The defined repeat lengths are 40 repeats, 41-60 repeats, 61-199 repeats and 200 repeats, respectively, although there is overlap at the boundaries of these definitions. Until recently, the unmethylated, long CGG repeat track found in premutation carriers was thought to have little phenotype consequence. Now there is convincing evidence that female premutation carriers have an increase risk for premature ovarian failure (POF) whereas full mutation carriers have the same risk as the general population. However, the increased risk does not appear to be correlated with the size of the premutation. Recent reports have indicated that FMR1 mRNA levels are increased among premutation carriers compared with non-carriers and suggest that increased mRNA levels may be involved in the risk for POF. Thus, we are studying a large population of intermediate and premutation carriers to characterize the distribution of mRNA levels by repeat size in order to better define this molecular correlate. The population consists of blood samples drawn from 15, 15 and 15 non-carrier, intermediate and premutation males, respectively, and 20, 25 and 25 non-carrier, intermediate and premutation females. All subjects have been assessed with a large battery of neuropsychological measures and, for females, with a reproductive history, hormone levels and X-inactivation pattern. A clear understanding of the variation in levels of FMR1 mRNA will potentially provide a more powerful molecular correlate. This can be used to test the hypothesis of a direct relationship between increased mRNA levels and the risk for clinical involvement.

No Genotype-Phenotype Correlation in Holt-Oram Syndrome. A. Brassington¹, S. Sung¹, R. Toydemir¹, T. Le¹, A. Roeder¹, L. Jorde¹, M. Bamshad^{1,2}. 1) Department of Human Genetics, University of Utah, Salt Lake City, UT; 2) Department of Pediatrics, University of Utah, Salt Lake City, UT.

TBX5 is one of a family of genes encoding transcription factors that share a unique DNA-binding domain called the T-box. Mutations in *TBX5* cause malformations of the heart and upper limbs in Holt-Oram syndrome (HOS). It has been suggested that mutations in the 5' end of the T-box are associated with severe heart but mild limb defects, while mutations in the 3' end of the T-box cause mild heart and severe limb defects. We screened the entire coding region of *TBX5* in 45 families meeting the diagnostic criteria for HOS and discovered 15 mutations in 9 familial and 6 sporadic cases. Eight of these were missense mutations that cause amino acid substitutions in the T-box. Three missense mutations occurred at a previously described mutational hotspot (Arg237), and 3 were found at a newly described hotspot Thr233. Each of the missense mutations in the T-box is predicted to disrupt binding of TBX5 to its target site by changing an amino acid residue in direct contact with the target DNA or reducing the stability of the secondary structure required to maintain residues in a continuous DNA recognition surface. In 3 of 6 families with missense mutations in the T-box, both mild and severe defects of the heart and limbs were observed. Only 2 of 16 individuals with missense mutations in the T-box had the expected pattern of limb and heart defects, and in 7 of 16 individuals, we observed the converse of the expected pattern. Moreover, the spectrum and severity of malformations was similar between individuals with missense, nonsense, and frameshift mutations. We conclude that there is little evidence to support a genotype-phenotype correlation between mutations in *TBX5* and the variable expression of malformations in HOS.

Modifier genes in Cystic Fibrosis. *F. Belpinati*¹, *G. Malerba*¹, *C. Quinzii*¹, *C. Patuzzo*¹, *C. Bombieri*¹, *C. Castellani*², *B.M. Assael*², *P.F. Pignatti*¹. 1) Sec. Biology & Genetics, DMIBG, University of Verona, Verona, Italy; 2) Cystic Fibrosis Veneto Regional Centre, Hospital of Verona, Italy.

Cystic Fibrosis is an autosomal recessive disease caused by mutations in the Cystic Fibrosis Transmembrane Conductance Regulator (CFTR) gene. The severity and onset of clinical presentation in CF are highly variable, and the variability is explained only partially by allelic heterogeneity at the CFTR gene. Literature data suggest that the severity of pulmonary manifestation in CF may be correlated with other genetic factors. We have genotyped 83 CF patients attending the Veneto Regional CF Centre of Verona with defined genotypes carrying severe-severe CFTR gene mutations, for genes involved in inflammatory response (TNF α , LT α , FCeRIb), protease/antiprotease imbalance (a1AT, a1ACT) and host defense (MBL) candidate gene for disease modulation in CF. All the patients were clinically evaluated for respiratory parameters, gastrointestinal and nutritional status parameters, and other clinical variables. We have typed the following functional polymorphisms: TNF α -308; LT α NcoI; FCeRIb RsaI; a1AT A1237G, S, Z; a1ACT Thr-15Ala; MBL R52C, G54N and G57E. We found evidence for an association between TNF α -308 genotypes and distal occlusion obstruction syndrome ($p=0.0024$; OR=10, CI:1.0-460). The data also confirm the strong linkage disequilibrium between LT α NcoI* and TNF-3082* alleles ($p=0.00016$) as reported by the literature. A possible association between the R52C polymorphism of the MBL gene and multiresistant Staphylococcus infections was also detected ($p=0.0319$; OR=3.3, CI: 0.8-13.9).

Involvement of the *abca4* gene in autosomal recessive cone-rod dystrophies. *D. Ducroq¹, J.M. Rozet¹, S. Gerber¹, I. Perrault¹, F. Barbet¹, S. Hanein¹, S. Hakiki¹, J.L. Dufier², A. Munnich¹, C. Hamel³, J. Kaplan¹.* 1) INSERM U393, Hopital des Enfants Malades, Paris, France; 2) Service d'Ophtalmologie, Hopital des Enfants Malades, Paris, France; 3) INSERM U245, Montpellier, France.

In order to evaluate the implication of the ABCR gene in 16 autosomal recessive families and 13 sporadic cases of cone-rod dystrophy (CRD), 48 affected individuals were screened for mutations. All patients fulfilled the minimal criteria for diagnosis of CRD (ophthalmoscopic and electrophysiologic data). Using Denaturing High Pressure Liquid Chromatography (DHPLC) and direct sequencing techniques, we searched for mutations in the 50 exons and flanking intron sequences of the ABCA4 gene, in one affected patient per family. Sixteen different mutant alleles were identified in 12/29 patients. Among these 12 patients, 2 were homozygotes (2 consanguineous families), 4 were compound heterozygotes and 7 single heterozygotes. Among the 29 patients screened, 16 were affected with autosomal recessive CRD (ARCRD) and 13 were sporadic cases. ABCA4 mutations were found in 6/16 ARCRD (37.5%) and in 6/13 sporadic CRD (46.1%). The ABCA4 gene which has been identified in 1997 as the unique Stargardts (STGD) causing gene, has been later recognized as responsible for some forms of RP (RP19) and some CRD, depending on the nature of the ABCA4 mutations and on the remaining protein activity. Recently, A.Maugeri reported on the frequent implication of the ABCA4 mutations in patients affected with autosomal recessive CRD (65%) and speculated that Mutations in the ABCA4 (ABCR) gene are the major cause of autosomal recessive Cone-Rod Dystrophy. Considering that in all series, the screening of the ABCA4 gene failed to detect mutations in 20% of STGD patients, we made the assumption that the ABCA4 gene account for 46.9% of all autosomal recessive CRD and is indeed the major disease-causing gene in our series. In addition, we can calculate the risk that a sporadic case of CRD is an isolated form of autosomal recessive CRD when no mutation has been found in the ABCA4 gene. This risk is estimated to 10.5% according to a Bayesian calculation.

Novel insights in genotype-phenotype correlations in BPES through in-depth *FOXL2* mutation analysis. E. De Baere¹, D. Beysen¹, C. Oley², P. De Sutter¹, A. Garza³, C. Jonsrud⁴, P. Koivisto⁵, B. Leroy¹, B. Lorenz⁶, F. Meire¹, A. Plomp⁷, L. Van Maldergem⁸, A. De Paepe¹, J. Cocquet⁹, M. Fellous⁹, R. Veitia⁹, L. Messiaen¹. 1) Dpt of Med Genet, Gynaecol and Ophthalmol, Ghent University Hospital, Belgium; 2) Queensland Clin Genet, Royal Children's Hosp, Brisbane, Australia; 3) Grupo Trans-Americano de Esteril y Fertil, Mexico; 4) Univ Hosp of Tromsø, Dept of Med Genet, Norway; 5) Dept of Clin Genet, Tampere Univ Hosp, Finland; 6) Dpt of Ped Ophthalmol, Strabismol and Ophthalmogenet, Klin der Univ Regensburg, Germany; 7) AMC, Univ of Amsterdam, Clin Genet, The Netherlands; 8) Dpt of Hum Genet, Loverval, Belgium; 9) Hum Immunogenet, Inst Pasteur, Paris, France.

The blepharophimosis syndrome (BPES) is an autosomal dominant syndrome in which a complex eyelid malformation is associated (type I) or not (type II) with premature ovarian failure (POF). Both types have recently been ascribed to mutations in *FOXL2*, a forkhead transcription factor. We and others demonstrated a genotype-phenotype correlation: predicted truncated proteins lead to BPES type I, while particular predicted extended proteins cause BPES type II. In this study we extensively analyzed *FOXL2* in a series of unrelated BPES patients through (i) sequencing of ORF, 5' UTR and putative core promotor, (ii) Q-PCR, (iii) Southern blot (iv) FISH and (vi) microsatellite analysis of the *FOXL2* flanking regions. We have found 20 additional *FOXL2* mutations, most of which are novel. Upon revision of the genotype-phenotype correlation we found that: (i) the distinction between BPES type I and II is not so strict as previously stated as we observed the occurrence of an intermediate phenotype; (ii) the current genotype-phenotype correlation should be modified since we found exceptions against it in several families. As a consequence the predictive value of molecular testing concerning female infertility is still limited. Finally, in several well-established BPES families where no causal mutation was found, a position effect or mutations in another gene might be present and further attempts are underway to elucidate the defects in these families.

The contribution of genotypes at the MEFV and SAA1 loci to amyloidosis and disease severity in patients with Familial Mediterranean fever. *R. Gershoni-Baruch¹, R. Brik¹, M. Sinawi¹, M. Lidar², A. Livneh².* 1) Dept Human Genetics, Rambam Medical Ctr, Haifa, Israel; 2) Dept of Internal Medicine, Sheba Medical Center, Tel-Aviv, Israel.

Familial Mediterranean fever (FMF) is an autosomal recessive disorder characterized by recurring attacks of fever and serositis and predisposition to renal amyloidosis. Five sequence alterations (M694V, V726A, M680I, M694I and E148Q) in the pyrin/marenostrin (MEFV) gene account for the majority of FMF chromosomes. The wide clinical variability of the disease has been related to MEFV allelic heterogeneity. M694V homozygotes have a severe form of disease. Otherwise, a role for additional genetic and/or environmental has been proposed. Recently, polymorphisms at the SAA1 (serum amyloid A1) locus, or rather the SAA1/ genotype, were found to influence susceptibility to renal amyloidosis. We evaluated the contribution of genotypes at both the MEFV and the SAA1 loci to disease severity and amyloidosis. DNA samples from 274 FMF patients (152 males; 122 females), in whom two mutant FMF alleles have been identified, were further analyzed for genotypes at the SAA1 locus. The study group included 61 individuals with renal amyloidosis. We found that the SAA1/ genotype was strongly associated with renal amyloidosis but did not bear on disease severity (calculated using the Tel-Hashomer severity score). The majority of individuals with renal amyloidosis were homozygous for either the M694V or the complex V726A-148Q allele. The overall, male/female ratio was significantly higher among patients with amyloidosis than among patients without amyloidosis. The results of this study agree with the observation that the SAA1 locus plays a key role in conferring genetic susceptibility to amyloidosis. The contribution of male gender and genotypes at the MEFV locus to renal amyloidosis are equally significant.

Identification of modifying pathways involved in the phenotypic variability of spinal muscular atrophy (SMA). C. Helmken¹, Y. Hofmann¹, H. Raschke¹, S. Rudnik-Schöneborn², K. Zerres², B. Wirth¹. 1) Dept. Molecular Genetics, Institute of Human Genetics, Bonn; 2) Institute of Human Genetics, Aachen.

Proximal spinal muscular atrophy (SMA) is a neuromuscular disorder, caused by homozygous absence /mutations of the survival motor neuron gene 1 (SMN1). SMN1 is part of an 800 kDa protein complex ("gems") with a crucial role in snRNP biogenesis, pre-mRNA splicing and a presumable function in neural transport. SMN2, a nearly identical copy of SMN1, predominately produces exon 7-skipped transcripts, whereas SMN1 mainly produces full-length transcripts. The SR-like splicing factor Htra2-b1 was shown to interact with SMN and to restore full-length SMN2-mRNA to more than 80%. In rare cases siblings with identical 5q13-homologs and homozygous absence of SMN1 show variable phenotypes - affected or unaffected -, suggesting that SMA is modified by other, yet unknown factors. By analyzing seven such families, we demonstrated that in EBV-transformed cell lines homozygously deleted unaffected individuals not only display significantly higher levels of SMN protein, but also exhibit high expression levels of SMN-interacting proteins present in gems (Gemin2, Gemin3, and ZPR1) as compared with their affected siblings. In contrast, in primary fibroblast cultures no protein expression differences could be observed. Interestingly, other SMN-interacting proteins, which are not components of gems, such as p53, are not subject to a SMN-dependent regulation. Furthermore, Htra2-b1 was found to be up-regulated similarly as SMN. Since we could not find any sequence or transcription differences among intrafamilial siblings within SMN, Gemin2, Gemin3, ZPR1 or Htra2-b1, we postulate that the SMA phenotype is modified by a factor that influences the SMN complex, most probably acting upstream of Htra2-b1, which for its part up-regulates SMN, which then up-regulates other "gems"-complex members. Furthermore, this modulating effect is tissue-specific. The identification of the SMA modifying factor could represent an additional key-element on the way to develop a therapy in SMA patients based on the up-regulation of the SMN protein.

SMARD gene scan in patients with non-5q SMA. *A.Q. Hejmanowski¹, A.H.M. Burghes², T.W. Prior¹.* 1) Department of Pathology, Ohio State University, Columbus, OH; 2) Department of Molecular and Cellular Biochemistry, Ohio State University, Columbus, OH.

Spinal Muscular Atrophy with Respiratory Distress (SMARD) causes respiratory distress early in life and death occurs after the diaphragm is paralyzed. SMARD patients share some clinical features with SMA type I patients, including anterior horn cell loss, early age of onset, and short life expectancy. Recently, gene mutations have been identified in SMARD patients. We have thus begun screening our patient population with symptoms consistent with SMA who have been shown to be negative for the standard SMA deletion for SMARD related mutations.

Using fluorescent sequencing, a novel missense mutation, K220N, in exon 5, has been identified in 2 siblings. Although these patients do suffer from respiratory insufficiency and have distal muscle weakness, they have reached the ages of 9 and 11. Based on these initial findings, we feel that SMARD may exhibit a broader clinical phenotype, which includes patients with milder respiratory distress, and some shared SMA features.

It is imperative to determine whether a relationship exists between various gene mutations and disease severity. To that end, we are beginning a comprehensive DHPLC screening of the SMARD gene in our 410 SMA-like patients. To date, we have found 40 heterozygotes and 1 homozygote of a previously described SNP, S201L, also in exon 5, and numerous other polymorphisms throughout the gene.

Mutational spectrum of Pallister-Hall and Greig cephalopolysyndactyly syndromes. *J.J. Johnston, J. Turner, I.M. Olivos-Glander, L.G. Biesecker.* GDRB, NHGRI, NIH, Bethesda, MD.

Mutations in the zinc finger transcription factor GLI3, on chromosome 7p13, cause the Greig cephalopolysyndactyly (GCPS) and Pallister-Hall syndromes (PHS). PHS and GCPS are variable but distinct entities with numerous non-overlapping features. We hypothesized that GCPS is caused by functional haploinsufficiency of GLI3, while PHS is caused by the production of a truncated GLI3 protein that retains DNA binding activity. To test this hypothesis we analyzed patients with GCPS or PHS for GLI3 mutations. Individuals diagnosed with GCPS were first analyzed for deletions of the GLI3 locus. GCPS patients who were not deleted and all PHS patients were subjected to sequencing and/or dHPLC analysis to identify point mutations in GLI3. Our patient group consisted of 70 patients, 32 with GCPS and 38 with PHS. Eleven GCPS patients had large GLI3 deletions (>150 kb), leaving 59 patients to screen for mutations. A total of 34 mutations were identified and four additional patients have sequence alterations that predict amino acid substitutions that may be causative. Of the 22 mutations identified in PHS patients, all but one predicted a truncated protein 3' of the zinc finger domain and 5' to codon 1152 within the putative activation domains. These mutations fell in exons 13, 14 and the 5' end of exon 15. An additional PHS patient had a Pro>Arg alteration in exon 15 with no other alteration identified. Mutations in GCPS patients were more varied than those in PHS patients and occurred over a greater extent of the gene. No mutations were found in exons 13, 14, or the 5' end of exon 15 in GCPS patients. Alterations identified in GCPS patients included frame shift and stop mutations 5' to the zinc finger domain, frame shift and stop mutations at the 3' end of exon 15, in addition to the 11 large deletions. Three GCPS patients had sequence alterations of unknown significance. The distribution of mutations in these two phenotypes is significantly associated with the phenotypes ($p < .01$). These data support the hypothesis of a distinct pathogenetic mechanism for GCPS and PHS.

Snowflake vitreoretinal degeneration is genetically distinct from Stickler syndrome and Wagner disease. *M.M. Lee¹, C.J. Coulson¹, R. Ritter III¹, T. Hirose², A.O. Edwards^{1,3}*. 1) Department of Ophthalmology, UTSW Medical Center, Dallas, TX; 2) Schepens Eye Research Institute and Department of Ophthalmology, Harvard Medical School, Boston, MA; 3) McDermott Center for Human Growth and Development, UTSW Medical Center, Dallas, TX.

Purpose: To determine if Snowflake vitreoretinal degeneration is clinically and genetically distinct from Stickler syndrome and Wagner disease. **Methods:** Clinical data were collected on family members by history and examination. Thirteen family members underwent prospective examination and an additional twelve members were ascertained. Linkage analysis was performed with MLINK. **Results:** Six of the thirteen prospectively examined subjects had Snowflake vitreoretinal degeneration. Early onset cataract (5/6;83%), fibrillar vitreous degeneration (6/6;100%), and peripheral retinal abnormalities (5/6;83%) including minute crystalline deposits called snowflakes (4/6;67%) were common. Retinal detachment was seen in 1 of 6 (17%) of these prospectively examined subjects. A total of fourteen affected subjects were identified within the family and 3 (21%) had developed retinal detachment. Orofacial features such as cleft palate and midface hypoplasia and early onset hearing loss and arthritis typical for Stickler syndrome were absent. Linkage analysis excluded known vitreoretinal degeneration loci including the collagen 2A1 (*COL2A1*), collagen 11A1 (*COL11A1*), and Wagner disease loci. **Conclusions:** The absence of a retrolenticular membrane and presence of fibrillar vitreous degeneration were consistent with the vitreous structure reported for *COL11A1* and not *COL2A1* mutations. The absence of systemic features was characteristic of the vitreoretinopathies linked to chromosome 5q13 (e.g. Wagner disease) and mutations in exon 2 of the *COL2A1* gene. The absence of nyctalopia, posterior chorioretinal atrophy, and tractional retinal detachment were inconsistent with the chromosome 5q13 vitreoretinopathies. The clinical findings and linkage analysis demonstrate that Snowflake is a distinct vitreoretinal degeneration.

Phenotype and genotype characteristics of Korean patients with Gaucher Disease. *H.J. Kim, J.A. Yang, S.J. Park, I.S. Park, J.Y. Cho, G. Lee.* Dept Medical Genetics, Ajou Univ Col Medicine, Suwon, Korea.

Gaucher Disease (GD), a most common lysosomal storage disorder due to deficient activity of Glucocerebrosidase (GC), has been well known for its phenotypic variations and allelic heterogeneity. We found that non-neuronopathic form of GD (type1) to be rather aggressive with early childhood onset and rapid progression of massive organomegaly and skeletal complications leading to high morbidity and mortality, and high preponderance of neuronopathic(NP) form in Korean GD pts (more than 50%). To understand the molecular basis of the phenotypic characteristics of Korean GD, we performed mutational analysis of GC gene in 23 unrelated Korean GD pts (10 type1, 6 type2, 4 type3A, 3 type3B) by direct sequencing of PCR amplified genomic DNA and NciI restriction enzyme digestion methods. 15 different mutations were identified in 37 alleles; 10 alleles for L444P mutation, 4 alleles each for G46E, F213I and R257Q, 3 alleles for N188S and G202R, and 9 rare mutations of R48W, L160V, V191G, A232P, F331L, V375V, G377S, D409H and V460V were detected an allele for each. The spectrum of GC mutations found in Korean GD is rather unique compare to that of Jewish & Caucasian population. N370S, the most common GC mutation among Jewish (70%) and other Caucasian ethnic group (60-30%), is not found in Korean. The N370S is well established for its association with mild non-NP and the protective mutation from NP. Thus, the lack of N370S mutation among Korean may explain being severe type 1 and high preponderance of NP form (types 2 & 3). L444P, a common mutation (40%) among non-Jewish Caucasian and Japanese, is known to be associated with NP phenotype, esp. homoalleles in particular. However among 13 Korean NP pts, only 4 alleles (15%) and no homoalleles were detected. Among next common mutations, F213I, reported 14% in Japanese GD, was detected in both type I and NP pts, but G46E, never reported in Japanese GD, was detected only in type I pts, and G202R was only in NP. R257Q mutation previously known to be associated with mild phenotype, was detected both type1 and type2 pts. Comparison of the Korean GC mutations and phenotypes to that of Caucasian and Japanese will be presented.

Genotypic and phenotypic heterogeneity of DFNB1-related hearing impairment in the MidWestern US. *L.H.Y. Lim¹, J.K. Bradshaw^{1,2}, Y.S. Guo¹, V. Pilipenko¹, C. Madden¹, D. Ingala³, M. Keddache³, D.I. Choo^{1,2}, R. Wenstrup³, R.J.H. Smith⁴, J.H. Greinwald^{1,2}.* 1) Center for Hearing and Deafness Research, Children's Hospital Cincinnati, (CHMCC), Cincinnati, OH; 2) University of Cincinnati College of Medicine, Cincinnati, OH; 3) Department of Human Genetics, CHMCC, Cincinnati, OH; 4) Department of Otolaryngology, University of Iowa, Iowa.

Purpose. To determine the heterogeneity of, and correlation between the genotype and phenotype of DFNB1-related hearing impairment (HI) in a Midwestern USA population. **Methods.** Retrospective review of 160 consecutive children with idiopathic SNHL with DFNB1 testing. **Results.** The White: Black: Asian: Others distribution was 22: 1: 1:3. Correcting for 3 sib pairs, the prevalence of DFNB1 HI subjects having biallelic mutations was 15.3% (24/157). 37.5% (9/24) were homozygous 35delG, 25% (6/24) had other nonsense/nonsense mutations, and 37.5% (9/24) had a missense mutation in at least one allele. The allelic prevalence of 35delG was 8.6% (27/314) in the study population and 47.9% (23/48) in the DFNB1 group. The M34T allele mutation was next most prevalent at 2.2% (7/314) and 10.4% (5/48) respectively. Two novel mutations K15T and L90V were identified. Severe-profound HI occurred in 59.2% of DFNB1 subjects. Genotypes with biallelic nonsense mutations had a higher risk of severe-profound HI (88.2%). DFNB1 HI was usually bilateral, symmetric, non-progressive, and have flat audiograms. However, asymmetric HI (22.2%), sloping audiograms (25.9%), and even borderline-normal hearing in 1 ear was seen. These subjects were more likely to have at least 1 missense mutation. All 4 DFNB1 subjects with the M34T allele had mild HI in at least 1 ear. **Conclusions.** Our DFNB1-related HI, 35delG mutation and severe-profound HI rates were lower than previously described. Our missense mutation and M34T allelic prevalence were higher. Mild, asymmetric HI and sloping audiograms were more often associated with missense alleles. Two novel missense mutations coding for significant amino acid changes were found.

Characterization of a novel rhodopsin mutation (Pro170Arg) in a family with autosomal dominant retinitis pigmentosa (adRP). *D.K. Hughbanks-Wheaton¹, L.S. Sullivan², S.J. Bowne², S.P. Daiger², D.G. Birch¹.* 1) Retina Foundation of the S.W., Dallas, TX; 2) Human Genetics Center, Univ. Texas-Houston, Houston, TX.

Retinitis pigmentosa (RP) is a genetic eye disease characterized by progressive retinal degeneration. Degeneration typically occurs first in the peripheral retina, affecting the rod photoreceptors, and progresses inward toward the macula. This leads to restriction of the peripheral visual field (i.e., tunnel vision) and night blindness. RP is genetically heterogeneous and can be inherited in an autosomal dominant, autosomal recessive, X-linked recessive, or sporadic manner. Mutations in the rhodopsin gene are thought to account for approximately 30% of adRP cases. In an effort to identify mutations responsible for adRP we have identified a novel rhodopsin mutation. Using single-strand conformational polymorphism (SSCP) analysis followed by direct sequencing we identified a missense mutation at codon 170 resulting in a proline to arginine amino acid substitution within the 4th transmembrane domain of the rhodopsin gene. The residue at 170 is highly conserved in all vertebrates and mutations in this codon have not been described previously. In addition, this mutation has not been observed in 1,000 chromosomes tested. Affected family members (n=5) report first being aware of poor night vision in their late teens. Subjective peripheral field loss is first evident in the third decade. ERGs from four siblings aged 33-38 years revealed non-detectable rod responses in the two males. Both females retained rod a- and b- waves. The gain of rod photoreceptor transduction estimated from rod a-waves was reduced, suggesting that the mutant rhodopsin traffics to the outer segment and participates in the visual cycle. Cone b-waves were reduced in amplitude and delayed in implicit time in all patients with the mutation. The high conservation of the Pro170 residue, together with the cosegregation of this missense mutation with adRP in the affected family members supports the pathogenicity of this mutation.

Charcot-Marie-Tooth disease: A novel Tyr145Ser mutation in the Myelin Protein Zero (MPZ, P0) gene causes different phenotypes in homozygous and heterozygous carriers. *A. Leal^{1,2}, C. Kayser³, M. Berghoff⁴, E.*

Hernandez², R. Barrantes², A. Reis¹, G. Del Valle², D. Heuss³, B. Rautenstrauss¹. 1) Inst Human Genetics, Univ Erlangen-Nbg, Erlangen, Germany; 2) INISA and School of Biology, Univ of Costa Rica, San Jose, Costa Rica; 3) Neurological Department, Univ Erlangen-Nbg, Germany; 4) Neurological Department, Univ Wuerzburg, Wuerzburg, Germany.

Mutations in the MPZ gene cause Charcot-Marie-Tooth type 1B (CMT1B), a demyelinating hereditary motor and sensory neuropathy (HMSN). Mutations in MPZ have been related also with axonal neuropathy (CMT2), particularly due to a T124M mutation in exon 3. Patients who carry this mutation are additionally affected with Argyll Robertson-like pupils and frequently with deafness and dysphagia. Here we present a Costa Rican family affected mainly with CMT1B; the parents presented a mild neuropathy with a late age of onset (50 years), whereas the two children presented an earlier age of onset (late 30 years) and a more severe neuropathy. Clinical signs are distal sensory deficits and absent ankle jerks. Pupillary abnormalities, distal weakness and atrophies are restricted to the children. Electrophysiological studies revealed axonal degeneration and demyelination. A sural nerve biopsy from one of the children showed signs of axonal degeneration as well as demyelination. Both in the maternal and the paternal family histories other patients with this type of peripheral neuropathy exist. After sequencing of all 6 coding MPZ exons for the parents and children, a Y145S mutation in exon 3 was found; the parents are heterozygous for this mutation, whereas the children are homozygous carriers. In contrast to the T124M mutation, only the homozygous Y145S carriers are affected with pupillary anomalies, and the Y145S heterozygous patients are less affected than the T124M heterozygous. We propose that by the exchange of similar side chains (uncharged polar) the slightly altered protein conformation has only low impact on the protein function; this could explain the mild phenotype of heterozygote carriers. However, a homozygous change could be sufficient to cause a neuropathy associated with pupillary anomalies.

Repeated Pregnancies Associated with Late Term Fetal Loss Malignant Ventricular Arrhythmias in a Mother Mosaic for an SCN5A Mutation. T. Miller¹, L. Baumbach¹, N. Moreno¹, E. Estrella¹, M.E. Ahearn¹, P. Rusconi¹, G. Wolff¹, P. Kurlansky², R. Myerburg¹, N. Bishopric¹. 1) Univ. of Miami School of Medicine, Miami, FL; 2) Miami Heart Research Institute, Miami, FL.

Germline mosaicism is a rare but important mechanism of genetic disease. Somatic mosaicism can explain some instances of reduced penetrance of disease-causing mutations, such as those detected in cardiac ion channel genes (*KVLQT1*, *HERG*, *SCN5A*, *KCNE1* and *KCNE2*) associated with Long QT syndrome (LQTS). We investigated a 19-month African-American male with severe ventricular arrhythmias and his asymptomatic mother for LQTS. The child had fetal distress at 7 months gestation with *in utero* ventricular arrhythmia and postnatal *torsade des pointes* refractory to drug therapy, requiring delivery at 32 weeks and heart transplant at 6 months of age. He has had no further arrhythmias. His mother's previous pregnancy ended in late term stillbirth. She is asymptomatic, has normal EKGs, and denies consanguinity and has no known family history of heart disease, syncope or sudden death. We analyzed the child and his mother for mutations in all *KVLQT1* exons, and the most mutable *HERG* and *SCN5A* exons using exon-specific PCR, SSCP analysis, and direct DNA sequencing of SSCP variants. Importantly, we identified a heterozygous *SCN5A* mutation in the child, *R1623Q*, which has been previously reported as a *de novo* mutation in two unrelated Asian patients with LQTS. Initial sequence analysis of genomic DNA from the mother's peripheral blood suggested that she did not carry the mutant allele. We then employed an additional mutation detection technique that exploits the fact that *R1623Q* destroys a *HinfI* restriction site in *SCN5A*. We determined that ~ 10% of the mother's exon 28 PCR product was resistant to digestion. Sequencing of the undigested PCR product revealed exclusively the *R1623Q* allele, suggesting that the mother is a mosaic for this mutation. We are currently assessing the extent of somatic mosaicism in the mother. Our results suggest that maternal mosaicism for LQTS-associated mutations should be considered in cases of recurrent fetal loss and/or sudden infant death with normal parental phenotypes.

The effect of genetic modifiers on phenotypic variation in cystic fibrosis-associated pulmonary disease. *S.C. Hilmer¹, C.A. Merlo², R.A. Enke², M.E. Couch², E.P. Hoffman¹, J.G.N. Garcia², M.P. Boyle²*. 1) Ctr for Genetic Medicine, Children's Natl Medical Ctr, Washington, DC; 2) The Johns Hopkins Hospital, Baltimore, MD.

Cystic fibrosis (CF) is a lethal, multi-system autosomal recessive genetic disorder primarily affecting Caucasian populations. CF is caused by mutations in the cystic fibrosis transmembrane conductance regulator (CFTR), leading to the disruption of ion transport in epithelial lined organs and resulting in the plugging of ducts with obstinate, difficult-to-clear secretions. Over 1,000 mutations in CFTR have been identified, the most common of which is a deletion of a 3 base pair region resulting in the loss of a phenylalanine in the first nucleotide binding domain (DF508). Despite multisystem involvement, including lungs, sinuses, pancreas, bile ducts, sweat glands, intestines, bones and the reproductive tract, the majority of morbidity and mortality of CF patients is due to CF-associated lung disease. Recently, it has become apparent that CF patients with identical genotypes (specifically DF508 homozygotes) have considerable phenotypic variation, especially within the pulmonary system. We propose that this variation is the result of modifier genes that can be identified by use of oligonucleotide high-density microarray analysis of nasal epithelial cells. Gene expression analysis was performed using the Affymetrix GeneChip Human Genome U133 set on cells isolated from 15 CF patients with mild pulmonary disease, 10 patients with severe pulmonary disease, and 10 sex and age-matched controls. This technique allows for quantitative expression of 33,000 well-substantiated human genes. Genes involved with immune function, inflammation and transcription were found to be significantly up regulated in severe patients relative to mild. Additionally, 2 previously described CF phenotype modifiers (histone deacetylase and interleukin-8), were found to be differentially expressed in severe CF patients relative to mild patients. This data proves that candidate genetic modifiers can be identified through whole-genome expression profiling of small samples from primary scrapings of patient nasal epithelium.

Single nucleotide substitution in the COL1A1 gene (IVS13-10T®A) results in use of a new splice acceptor site, mRNA instability, and mild osteogenesis imperfecta. *I.A. Schafer^{1,2}, J. Stein², J.C. Hyland³, U. Schwarze⁴, P.H. Byers⁴, B.A. Clark².* 1) Metro Health Med Ctr, Cleveland, OH; 2) Cleveland Clinic Foundation, Cleveland, OH; 3) Center for Gene Therapy, Tulane University, New Orleans, LA; 4) University of Washington, Seattle, WA.

Osteogenesis imperfecta (OI) usually results from heterozygosity for mutations in the type I collagen genes, COL1A1 and COL1A2, which encode the pro α 1(I) and pro α 2(I) chains, respectively of type I procollagen. The analysis of the production of type I collagen by cultured skin fibroblasts is an adjunct to the identification of OI in children thought to have been abused. Cultured skin fibroblasts from a 27 day old girl who had a spiral fracture of the right femoral shaft and blue sclerae synthesized less than the normal amount of type I collagen but a definitive diagnosis of OI type I could not be established because informative markers that distinguished the two coding sequences were not found. The coding and exon-flanking sequences of the two type I collagen genes were screened by CSGE and a variant was identified in one COL1A1 allele (IVS13-10T®A) that introduced a new acceptor site at the -10, -9 positions of the intron and was not seen in 500 previously characterized alleles. If used, this would introduce an 8 nucleotide insertion that leads to a frameshift and creation of a premature termination codon in exon 25 of this 52 exon gene. RTPCR of RNA isolated from the cells identified a small amount of a fragment consistent with use of a new acceptor site. It was not clear if all transcripts from this allele used the new site or if some used the constitutive site. The 24 year old father and 61 year old paternal grandfather of the index patient both had blue sclerae, a history of fractures, and were heterozygous for the IVS13-10T®A mutation, consistent with the diagnosis of OI. These findings suggest that a spectrum of severity of bone fragility from normal to that seen in OI type I could be explained by "leaky" splice site mutations that lead to some normal splicing from the altered allele and titrate the amount of normal type I collagen in bone between control levels and those seen with OI type I.

Genotype/Phenotype Correlations in X-Linked Hypophosphatemic Rickets. *L.I. Valentine¹, T.J. Kirkpatrick¹, K.-S. Au¹, V.M. Rose¹, P.G. Brosnan^{1, 2}, B.W. Dominguez¹, D.A. Johnston³, H. Northrup^{1, 2}.* 1) Pediatrics, Univ of Tex Med School, Houston, TX; 2) Shriners Hospital for Children, Houston, Texas; 3) Univ of Texas MD Anderson Cancer Center, Houston, Texas.

X-linked hypophosphatemic rickets (XLH), a sex-linked dominant disorder of phosphate homeostasis, is the most common form of inherited rickets with an incidence of 1 in 20,000. XLH is characterized by defective renal phosphate handling and vitamin D metabolism leading to growth retardation, rachitic and osteomalacic bone disease, and hypophosphatemia. Conventional combined treatment of 1,25 dihydroxyvitamin D₃ (Rocaltrol) and inorganic phosphate salts has been well established to improve linear growth and heal rachitic skeletal abnormalities. Medication dosage is adjusted based on multiple laboratory parameters and linear growth. Inactivating mutations in the neutral endopeptidase gene, *PHEX*, are responsible for the XLH phenotype. We investigated whether type of *PHEX* mutation correlated with laboratory results and/or the development of therapy induced complications (nephrocalcinosis and hyperparathyroidism). Participants included 30 patients equally divided between Hispanics of Mexican descent (a previously unstudied group with XLH) and non-Hispanic Whites. Twenty different families were represented (20 individuals from 10 families with multiple affected individuals and 10 sporadically affected individuals). Eleven different mutations were detected with mutation identification in 80% of the multigenerational families and 50% of the sporadic cases. Multiple mutation types (missense, nonsense, splicing error, frameshift and deletion) were detected with seven novel mutations (not reported in the PHEXDB or medical literature). Mutation types were divided into two main types: missense and protein truncation. Ten patients with protein truncation mutations had a history of elevated PTH levels compared to only two patients with missense mutations. No correlation was observed with development of nephrocalcinosis. Testing additional patients for *PHEX* mutations and correlating with treatment regimen and laboratory values is needed to determine the significance of our genotype/phenotype observation.

***Rpp21* and *Rpp38* allele variants occur at different frequencies in severely and mildly affected CHH patients.** *M. Ridanpää*^{1,2}, *R. Fagerholm*^{1,2}, *I. Kaitila*^{2,3}, *O. Mäkitie*⁴. 1) Folkhälsan Institute of Genetics, Helsinki, Finland; 2) Department of Medical Genetics, University of Helsinki, Finland; 3) Department of Clinical Genetics, Helsinki University Hospital, Finland; 4) Hospital for Children and Adolescents, Helsinki University Hospital, Finland.

The RNase MRP has at least two functions required for cell growth, namely nucleolar cleaving of pre-rRNA and sequence-specific cleavage of RNA in mitochondrial DNA synthesis. All proteins and an RNA component are essential for the functional enzyme. We have recently described mutations in *RMRP*, encoding for the RNA component, in Cartilage-hair hypoplasia (CHH). A substitution A70G comprises 91% of the mutations in Finnish CHH patients and is the most common mutation worldwide. Despite of the same mutation in *RMRP* patients, even siblings at young age, can represent marked differences in the phenotype, indicating a role of genetic modifiers. We have studied three genes encoding for the proteins of RNase MRP in two Finnish CHH patient groups representing the most utmost phenotypes, all homozygous for A70G in *RMRP*. The 11 patients with severe phenotype had severe growth failure and complete alopecia (6) or severe hair hypoplasia (5). Six of them had hypoplastic anemia in infancy, 4 had Hirschsprung disease and 9 an increased susceptibility to infections. The patients with mild CHH had less severe growth failure and normal (2), mildly hypoplastic (6) or severely hypoplastic (1) hair. None of them had hypoplastic anemia, Hirschsprung disease or increased susceptibility to infections. In a search of polymorphisms in *Rpp20*, *Rpp21* and *Rpp38*, we found twelve base substitutions. In exon 2 of *Rpp21*, allele G was more common than allele A in severe CHH cases (12/20 vs. 7/16; 60% vs. 44%). Allele C in exon 2 of *Rpp38* was more common than allele G in severe cases (19/22 vs. 9/16; 86% vs. 56%). Both changes are predicted to cause an amino acid substitution. In addition, an intronic change of G for A in *Rpp38* was more common in severe than in mild cases (7/22 vs. 2/16; 32% vs. 13%). These results suggest that polymorphisms in the genes encoding for the protein components of RNase MRP may contribute to the phenotypic variability in CHH.

Dominant X-linked RP is frequently accounted for by truncating mutations in the exon ORF15 of the RPGR gene. *J.M. Rozet¹, I. Perrault¹, N. Gigarel¹, E. Souied¹, I. Ghazi², S. Gerber¹, J.L. Dufier², A. Munnich¹, J. Kaplan¹.* 1) INSERM U393, Hopital des Enfants Malades, Paris, CDX 15, France; 2) Service d'Ophtalmologie, Hopital des Enfants Malades, Paris, CDX 15, France.

In order to determine whether dominant X-linked retinitis pigmentosa (DXLRP), a condition previously described as different from the recessive XLRP (RP3), are due to mutations in the retinitis pigmentosa GTPase-regulator (RPGR) gene, we screened this gene for mutations in 14 families with severe expression in carrier females. Sequencing of the RPGR gene in affected individuals allowed the identification of 8 different null mutations in 9/14 families. All mutations were found to lie in the ORF15 exon. Interestingly, in 2/9 families, the mutation was found in an asymptomatic potential carrier. On the other hand, in-frame deletions or duplications reported earlier as polymorphisms were identified in 2/5 families with no mutation and direct sequencing of the RPGR exon ORF15 failed to detect any base change in the three remaining families. Nevertheless, linkage analyses confirmed the localisation of the gene in all families at the RP3 locus, suggesting that in these last 5 families, the disease might be caused by a mutation located in an unexplored region of the RPGR gene such as the promoter or the introns. In conclusion, we report here on the identification of null RPGR alleles in patients affected with DXLRP. Although, the age at onset of the disease in females is delayed compared to males (20-40 years versus 10-20 years, respectively), the visual impairment, the fundus alteration and the visual field reduction can be as severe in heterozygous females as in hemizygous males. In these females whose ERG is non-recordable, no preferential X-inactivation was observed. It would be extremely interesting to know the exact phenotype of females harbouring truncating mutations in the RPGR exon ORF15 in the XLRP families recently reported. Indeed, if some of the women were more severely affected than what is usually described for carrier females in recessive XLRP, we would have to consider RP3 as an incomplete dominant X-linked disease such as it is now reported for ornithine transcarbamylase deficiency.

Biochemical and genomic analysis of *ABCR* in STGD patients. *A.N. Yatsenko, N.F. Shroyer, R.A. Lewis, J.R. Lupski.*
Human Molecular Genetics, Baylor College of Medicine, Houston, TX.

Stargardt disease (STGD1, OMIM#248200) is an autosomal recessive retinal dystrophy classically observed at an early age. The prevalence of STGD1 in the United States is estimated at 1 in 8,000 or less. The causative gene for STGD1 is located on chromosome 1p21 and has been cloned. This gene, *ABCR* (also called *ABCA4*), contains 50 exons and encodes a photoreceptor-specific ATP-binding cassette transporter. *ABCR* protein appears to function as an outwardly directed flippase for retinoids. Despite the confirmed linkage to the single *ABCR* locus, *ABCR* coding mutations account for only 66% - 80% of Stargardt disease chromosomes. The remaining 20-34% STGD alleles are unknown. We hypothesized a potential role for genomic rearrangements within *ABCR* region for these alleles. We have performed genomic Southern analysis for 100 STGD families with either one or no identified *ABCR* mutations. We found one deletion allele that eliminates *ABCR* exon 18 among the 200 chromosomes evaluated (~0.5%). STGD subjects with this deletion have a second mutant *ABCR* allele 2588G->C. The deletion spanning 1030 bp yields an in-frame deletion of 30 amino acids at positions 885-915 of the putative *ABCR* protein and is located at the linker region between transmembrane 1 and ATP-binding 1 domain, suggesting that this *ABCR* deletion is a disease-associated allele. Our breakpoint analysis of deletion region revealed a nonhomologous recombination with potential DNA topoisomerase I sites at both breakpoints. By deletion-specific PCR assay, we found the same allele deleted in 2 of 384 random controls (768 chromosomes, 0.26%) and 1 in 96 (~0.5%) AMD patients, but not in 96 age-matched controls with normal eye examinations or in 288 other STGD subjects. To understand the biochemical nature of this 1030 bp *ABCR* deletion, we created a plasmid construct with this *ABCR* alteration and performed transient transfection in 293 HEK cells. Biochemical analysis progresses. Our data indicate that genomic alterations of this type are a minor contribution to STGD mutant alleles. The remaining 20-34 % of Stargardt disease alleles remain unidentified.

Gene Expression in Inherited Human Craniosynostosis. *T.S. Zorick¹, L. Alonso², N. Alonso³, H. Matsushita⁴, M.R. Passos-Bueno¹.* 1) Biology, Univ Sao Paulo, Sao Paulo, Brazil; 2) Clinical Genetics, Escola Paulista Medicina, Sao Paulo, Brazil; 3) Dept of Plastic Surgery, Univ Sao Paulo, Sao Paulo, Brazil; 4) Dept of Neurosurgery, Univ Sao Paulo, Sao Paulo, Brazil.

Craniosynostoses are common congenital human birth defects, occurring 1 in 3000 live births. Craniosynostosis is caused by premature ossification of the cranial suture growth regions, which results in characteristic craniofacial abnormalities. Reconstructive surgeries are often necessary to alleviate the resultant clinical sequelae. Craniosynostoses are recognized as belonging to one of over 100 described genetic syndromes based upon the type of craniosynostosis observed, along with other dysmorphologies in other organ systems. About half of these are thought to have a monogenetic basis, which are generally autosomal dominant. The majority of the identified causative mutations have been found to map to genes for Fibroblast Growth Factor Receptors types 1-3. Although great progress has been made in recent years in molecular characterization of the primary genetic changes responsible for many cases of severe congenital craniosynostoses, the underlying mechanism for how these changes result in a particular disease phenotype remains largely unknown. The object of this research proposal is to identify genes that are differentially regulated in patients with Apert and Pfeiffer syndromes. We are collecting tissue samples isolated during corrective surgeries for patients with craniosynostoses, and culturing fibroblasts from these tissues. These cultured fibroblasts are then used to perform global analyses of gene expression on these cells in comparison to normal subject controls using SAGE (serial analysis of gene expression). Although many investigators have established clinical guidelines for grading the severity of the craniosynostoses, it is evident that the primary causative mutations are pleiotropic in their phenotypic expression. Therefore, an understanding of the downstream gene expression changes which occur among the various craniosynostosis syndromes will be much more informative and offers the promise of being able to improve clinical outcome prediction.

Epsilon-sarcoglycan mutations in three ethnically diverse families segregating Myoclonus-Dystonia. A.

Dagvadorj¹, B.I. Karp¹, N. Sambuughin², A. Shatunov¹, W. Bara¹, M. Hallet¹, L.G. Goldfarb¹. 1) NINDS, National Institutes of Health, Bethesda, MD; 2) Barrow Neurological Institute, Phoenix, AZ.

Myoclonus-dystonia (M-D) is an autosomal dominant disorder characterized by bilateral alcohol-sensitive myoclonic jerks involving arms and axial muscles. Dystonia, usually torticollis and/or writer's cramp, occurs in most patients and may occasionally be the only symptom. Patients often show prominent psychiatric abnormalities, including panic attacks and obsessive-compulsive behavior. Studies of M-D families demonstrated linkage to a locus on chromosome 7q21. Using positional cloning approach, Zimprich et al. (2001) have recently identified heterozygous loss-of-function mutations in the Epsilon-sarcoglycan (SGCE) gene. We evaluated 3 unrelated North- and South-American families with M-D for the presence of mutations by sequencing all eleven SGCE exons. In a family from Bolivia with early-onset M-D observed in four affected members, a G-to-A transition at nucleotide position 232 resulted in glycine-to-serine substitution at codon 78. A large North-American family of British descent with 12 known patients suffering from alcohol-sensitive M-D showed a G-to-A change at the highly conserved position +1 of the intron 1 splice donor site (IVS1+1G>A). Studies of functional consequences of this mutation are in progress. Finally, in an American family of German-Italian origin with five individuals affected with early-onset M-D, a mutation was detected at nucleotide 289 replacing C with T and resulting in termination of translation at codon 97. This latter mutation was previously described in a German M-D family.

A prevalent founder mutation among Ashkenazi Jews with Usher syndrome type 1. *T. Ben-Yosef¹, S.L. Noss², A.C. Madeo¹, A. Bar-Lev², J.H. Wolfman¹, Z.M. Ahmed¹, J.P. Willner², R.J. Desnick², K.B. Avraham³, H. Oster⁴, C. Oddoux⁴, A.J. Griffith¹, T.B. Friedman¹.* 1) Laboratory Molecular Genetics, NIDCD/NIH, Rockville, MD; 2) Department of Human Genetics, Mount Sinai School of Medicine, New York City, NY; 3) Department of Human Genetics and Molecular Medicine, Sackler School of Medicine, Tel Aviv University, Tel Aviv, Israel; 4) Human Genetics Program, New York University School of Medicine, New York City, NY.

Usher syndrome is the most common cause of combined sensorineural deafness and blindness, and is a clinically heterogeneous disorder. The most severe form, Usher type I (USH1), is characterized by profound prelingual hearing loss, vestibular areflexia, and prepubertal onset of retinitis pigmentosa. Genes for six of twelve autosomal recessive USH loci have been identified. We studied the genetic basis of USH1 in the Ashkenazi Jewish population. Study subjects were 18 USH1 probands from 12 unrelated Ashkenazi families. DNA samples from four families were analyzed for the presence of shared haplotypes of genetic markers linked to six USH1 loci. A conserved haplotype and a homozygous recessive nonsense mutation were found for all affected individuals in these families. Of 12 unrelated USH1 probands, seven were homozygous for the nonsense mutation (58.3%); one was a compound heterozygote with a second putative mutation in the same gene (8.3%); and four were homozygous for the wild type allele (33.3%). Carrier frequencies of 0.79% (95% C.I. 0-1.8%) and 2.47% (95% C.I. 0.1-4.9 %) for the nonsense mutation were found among Ashkenazi Jews from New York and Israel, respectively. Based upon our findings, one prevalent nonsense mutation appears to account for the majority of USH1 cases in Ashkenazi Jews. The high carrier frequency of this mutation in this population predicts a prevalence of 0.15-1.5 affected persons per 10,000. Since the mutation was found in only 62 percent of USH1-bearing chromosomes from our Ashkenazi Jewish patients, the actual USH1 incidence risk is probably higher. The identification of this founder mutation will allow for better genetic counseling, carrier screening and molecular diagnosis, enabling hearing rehabilitation before loss of sight occurs.

Spontaneous mutations in CIAS1 gene cause neonatal onset multisystem inflammatory disease

(NOMID/CINCA). *I. Aksentjevich¹, F. Austin¹, J. Balow¹, J.J. Chae¹, E. Remmers¹, W.T. Watford², S.R. Hofmann², J.J. O'Shea², H. Komarow¹, N. Shoham¹, H. Hoffman⁴, R. Goldbach-Mansky³, D.L. Kastner¹.* 1) Genetics & Genomics Branch, NIAMS, NIH, Bethesda, MD; 2) Molecular Immunology and Inflammation Branch, NIAMS, NIH, Bethesda, MD; 3) Office of Clinical Director, NIAMS, NIH, Bethesda, MD; 4) Division of Rheumatology and Allergy/Immunology, University of California, San Diego, California.

Neonatal onset multisystem inflammatory disease (NOMID), also known as a chronic infantile neurological cutaneous and articular syndrome (CINCA), is a rare autoinflammatory disease characterized by skin rash, epiphyseal bony overgrowth, CNS involvement (chronic meningitis, sensorineuronal hearing loss, chorioretinitis), and other systemic features of inflammation. Most of the patients have presented as sporadic cases due to low reproductive fitness. We investigated whether patients with this disorder have mutations in the CIAS1 gene (encoding cryopyrin; PYPAF1; NALP3) which was recently identified as a gene causing the clinically similar Muckle-Wells syndrome (MWS). We have collected samples from 13 NOMID patients, and have identified 5 new missense substitutions: L264H, A374N, F523L c>a, F523L c>g, Y570C, and one mutation, D303N, which was recently reported by another group. None of these nucleotide changes were observed in any of over 700 control chromosomes, strongly supporting the hypothesis that they are mutations and not benign polymorphisms. In 3 patients where parental DNA was available, we showed that mutation arose de novo. Mutations in this gene have recently also been reported by others in seven additional European patients with NOMID /CINCA. Our findings reported here also rise the possibility of genetic heterogeneity, because 7/13 patients were negative for mutations, even after complete sequencing of CIAS1. Consistent with recent data linking cryopyrin to cytokine processing, monocytes bearing the D303N mutation showed increased level of IL-1 precursor by Western blotting. Peripheral blood mononuclear cells of this patient showed increased IL-3, IL-5, and IL-6, but not TGF(*)1 mRNA expression by Taq Man analysis.

Severe myoclonic epilepsy of infancy is caused by *de novo* mutations in *SCN1A*. *L.R.F. Claes, D. Audenaert, B. Ceulemans, K. Smets, A. Löfgren, J. Del-Favero, C. Van Broeckhoven, P. Dejonghe.* Department of Molecular Genetics, Flanders Interuniversity Institute for Biotechnology, University of Antwerp, Antwerpen, Belgium.

Severe myoclonic epilepsy of infancy (SMEI) is a rare disorder occurring in patients with no family history of a similar disorder. Early manifestations are tonic, clonic and tonic-clonic seizures in the first year of life. Seizures are often prolonged, generalized and associated with fever. Later in life, SMEI patients suffer from afebrile seizures. Early psychomotor and speech development is normal, but in the second year of life developmental stagnation occurs. Patients often become ataxic and speech development is delayed. There is no treatment that alters the patients outcome significantly. We screened the neuronal sodium channel α -subunit gene *SCN1A* in 16 unrelated SMEI patients and their parents and identified a single heterozygous *de novo* mutation in each patient: 4 frameshift, 3 nonsense, 2 splice donor and 7 missense mutations. For each patient paternity was confirmed, and none of the mutations occurred in 184 control chromosomes. All missense mutations were clustering in the S4-S6 region of *SCN1A* containing the channels voltage sensor and pore. There was no clear genotype/phenotype correlation since all SMEI patients had a severe phenotype independently of the type of mutation. Our data provide evidence that *de novo* mutations in *SCN1A* are the major cause of SMEI. Further, SMEI most likely results from *SCN1A* haploinsufficiency.

Phenotypic and genetic heterogeneity of autosomal recessive Limb Girdle Muscular Dystrophy (LGMD) in the Hutterite population. P.D. Frosk¹, A. Hoke³, K. Morgan², T.M. Fujiwara², C.R. Greenberg¹, K. Wrogemann¹. 1) Biochemistry and Med. Genetics, University of Manitoba, Winnipeg, MB; 2) Human Genetics and Medicine, McGill University, Montreal, PQ; 3) Clin. Neurosciences, University of Calgary, Calgary, AB.

Limb girdle muscular dystrophy is genetically heterogeneous and relatively common in the Hutterite population of North America with over 60 patients identified so far. Using samples from Hutterite families from Canada and the US we identified two loci for LGMD: *LGMD2H* (9q31-33) and *LGMD2I* (19q13.3). The putative disease-causing mutations occur in *TRIM32* (c.1459G>A, D487N) and *FKRP* (c.876C>A; L276I), respectively. To date these mutations account for all known cases of LGMD in this population. Therefore, we can provide accurate carrier testing and diagnosis for all the Hutterite patients with an LGMD phenotype. Given accurate molecular diagnosis, we have now begun to differentiate the two types of LGMD at the phenotypic level. Clinical differences are apparent between the two groups, with the *LGMD2I* patients having an earlier mean age at diagnosis, variable calf hypertrophy, a more severe course, and higher serum creatine kinase (CK) levels. Carriers of *LGMD2I* may have mildly elevated serum CK but are asymptomatic with respect to muscle weakness. Two of 15 *LGMD2I* patients have severe dilated cardiomyopathy and two others presented with reactions to general anesthetics. *LGMD2H* patients have lower serum CK levels, generally have a milder clinical course with respect to their myopathy, and none have shown muscle pseudohypertrophy nor have developed signs of cardiomyopathy or rhabdomyolysis. No patient homozygous for mutations in both *TRIM32* and *FKRP* has been identified although we have identified one patient homozygous for the *FKRP* mutation and heterozygous for the *TRIM32* mutation. This patient appears clinically indistinguishable from *LGMD2I* patients who are homozygous for the *FKRP* mutation and have no *TRIM32* mutation. These phenotypic observations will allow better clinical delineation and prospective management of Hutterite patients with LGMD and may help in our efforts to discern the pathogenesis in these two disorders.

Detection of mutations in the translation initiation factor eIF2B in a white matter disorder, the CACH/VWM

syndrome. *O. BOESPFLUG-TANGUY*¹, *A. FOGLI*¹, *E. EYMARD-PIERRE*¹, *D. RODRIGUEZ*², *E. BERTIN*³, *M. PINEDA*⁴, *R. SURTEES*⁵, *G. UZIEL*⁶, *E. MALASPINA*⁷, *R. SCHIFFMANN*⁸. 1) Fac de Medecine, Inserm U384, Clermont-Ferrand, France; 2) Hopital Trousseau, INSERM U546, Paris, France; 3) Dept of Neurosciences Bambino Gesu Children's Hospital, Rome, Italy; 4) Hospital San Joan de Deu, Barcelona, Spain; 5) Institute of Child Health, University College, London, United Kingdom; 6) Carlo Basta Institute, Milano, Italy; 7) Istituto di Clinica Padiatrica, Bologna, Italy; 8) National Institutes of Health, Bethesda, USA.

The Childhood Ataxia with diffuse Central nervous system Hypomyelination (CACH) or Vanishing White Matter (VWM) syndrome is an autosomal recessive leukodystrophy characterized by a progressive spastic ataxia with episodes of rapid deterioration following febrile infection or head trauma. Age of onset and disease severity are variable. MRI shows a diffuse abnormality of the cerebral white matter with an increasing number of cavitations. Genetic heterogeneity of this syndrome was recently confirmed by the description of mutations in the five subunits of the eIF2B translation initiation factor (alpha, beta, gamma, delta, epsilon). We analyzed the five EIF2B genes in 33 CACH families by genomic or cDNA sequencing. Missense mutations were detected in the EIF2B5 gene in 74% of families (in exons 3(60%), 2 (20%), 7 and 4 (10% each)). 52% of patients carried a R113H mutation in exon 3. Patients homozygote for this mutation express a mild form of the disease. Patients heterozygote composite with a R113H mutation have a milder phenotype than those without this mutation. Mutations in the beta, gamma, delta subunits of the eIF2B were detected respectively in 10% 8% and 10% of families. Mutation in the alpha subunit was found in only one family. In conclusion, EIF2B mutation represents a major genetic marker for the diagnosis of CACH/VWM, easy to detect in more than 50% of patient by testing the presence of the R113H mutation. Work is in progress to determine the consequences of these eIF2B mutations on the protective cellular mechanisms that respond to heat stress.

Identification of the Hydrolethalus Syndrome Gene on 11q23-25. *L. Lanyi*¹, *S. Finnila*¹, *I. Visapaa*^{1,2}, *J. Lee*¹, *R. Salonen*³, *L. Peltonen*^{1,2}. 1) Dept. of Human Genetics, David Geffen School of Medicine, UCLA, Los Angeles, CA; 2) Dept. of Molecular Medicine, National Public Health Institute and Dept. of Medical Genetics, University of Helsinki, Finland; 3) Dept. of Obstetrics and Gynecology, Helsinki University Central Hospital.

Hydrolethalus Syndrome (HLS) is a recessive lethal malformation syndrome characterized predominantly by hydrocephaly with absent midline structures of the brain. The disease is enriched in the Finnish population with an incidence of 1:20,000. We mapped the HLS 11q23-25 by linkage analysis and restricted the region to a critical 1cM interval using linkage disequilibrium (LD) and shared ancestral haplotype analysis. The coding region of all known genes and predicted transcripts on the critical region were sequenced. LD and haplotype analysis of informative SNP markers on the coding regions of the ten candidate genes further restricted the locus to 600 kb between markers D11S4258 and D11S975. A nucleotide variant was identified in a predicted transcript (Celera:hCG1644899) and showed complete association and cosegregation with the disease alleles. This variant is located in the coding region of a novel, predicted transcript with no known functional domains. The A to G mutation results in Asp221Gly change in the predicted 299 amino acid polypeptide. Mutation analysis in HLS families and 400 control DNA samples collected from Middle and Eastern Finland revealed that all affected individuals are homozygous for this variant and that the observed carrier frequency well agrees with the expected carrier frequency of 0.02 in these regions of Finland. No carriers were found in the European control sample of 200 chromosomes. The presence of the steady state transcript of this predicted gene was confirmed with Northern and RT-PCR analyses. The HLS gene is expressed and alternatively spliced in various tissues, transcript level being highest in brain and spleen. Northern analyses revealed no significant changes in the steady state transcript level in available tissues from affected individuals. Ongoing analyses are targeted to characterize the cellular and tissue localization of the HLS transcript and polypeptide.

The Expanding World of Molecular Mechanisms Involved in the Pathogenesis of Limb-Girdle Muscular Dystrophies. *V. Nigro*^{1, 2, 3}, *S. Aurino*^{1, 3}, *A. Belsito*^{1, 3}, *F. D'Amico*¹, *V. Ventriglia*¹, *M. Dionisi*³, *M. Esposito*³, *E. Marra*³, *V. Saccone*³, *G. Piluso*¹. 1) Dipartimento di Patologia Generale, Seconda Universita' degli Studi di Napoli, S. Andrea delle Dame, 80138 Napoli, Italy; 2) Centro di Eccellenza per le Malattie Cardiovascolari, Seconda Universita' degli Studi di Napoli, S. Andrea delle Dame, 80138 Napoli, Italy; 3) Telethon Institute of Genetics and Medicine (TIGEM), via P. Castellino 111, 80131 Napoli, Italy.

Limb-girdle muscular dystrophies (LGMDs) are progressive Mendelian disorders of proximal skeletal muscles. They are extremely heterogeneous both clinically and genetically. At least sixteen autosomal genes are involved in dominant and recessive forms. Our objectives are the identification of genes mutated in additional forms of LGMD and the identification of common pathways involved in the pathogenesis of muscle wasting. We assume that some of them can be found among the partners of gene products deficient in known LGMDs. Our strategy was: 1) bioinformatic scanning of the public and Celera databases by homology and electronic expression data. 2) Interaction screening of skeletal and cardiac muscle yeast two-hybrid cDNA libraries using the following bait cDNAs: dysferlin (LGMD2B), calpain-3 (LGMD2A), telethonin (LGMD2G), TRIM-32 (LGMD2H) and fukutin-related protein (LGMD2I) using each cDNA with causative missense mutations, as negative controls. 3) High-throughput mutation analysis, using DNA pools containing balanced mixes of two-three DNA from unrelated LGMD patients. These pools were PCR amplified for each exon of each gene and subjected to automated heteroduplex analysis by dHPLC (Transgenomic). We identified twenty putative LGMD candidate cDNA by yeast two-hybrid and several specific interactions were observed. By dHPLC we assigned patients to known LGMD loci and created a large pool of unassigned LGMD. We are identifying new genes possibly involved in the pathogenesis of LGMDs. This could improve both diagnosis and therapy approaches.

TDP1 mutations cause autosomal recessive spinocerebellar ataxia with axonal neuropathy and further illuminate the pathway for topoisomerase I dependent DNA damage repair. *H. Takashima*¹, *C.F. Boerkoel*¹, *J. John*^{1,2}, *G.M. Saifi*¹, *M.A.M. Salih*⁷, *D. Armstrong*⁶, *Y. Mao*⁴, *F.A. Quijcho*⁴, *B.B. Roa*^{1,3}, *M. Nakagawa*⁸, *D.W. Stockton*^{1,2}, *J.R. Lupski*^{1,5}. 1) Mole Human Gen.; 2) Kleberg Genotyp Ctr.; 3) DNA Diag. Lab.; 4) Howard Hughes MI, Baylor Col Med; 5) Pediatrics.; 6) Pathology, Texas Child Hosp, Houston, TX; 7) Pediatrics, Col Med, Riyadh, Saudi Arabia; 8) Third Dept Int Med, Kagoshima Univ, Japan.

Tyrosyl-DNA phosphodiesterase 1 (Tdp1) repairs covalent topoisomerase I (Topo I) DNA complexes and is essential for preventing the formation of double strand breaks resulting from the interference of stalled Topo I complexes with DNA replication in yeast. Surprisingly, we find that deficiency of such DNA repair in humans does not predispose to neoplasia or dysfunction of rapidly replicating tissues, but rather causes spinocerebellar ataxia with axonal neuropathy (SCAN1) apparently by affecting large terminally differentiated essentially non-dividing neuronal cells. Using genome-wide linkage mapping and a positional candidate approach in a Saudi Arabian family segregating autosomal recessive SCAN1, we identified a homozygous mutation in TDP1 (1478A>G, H493R). The His493 residue is conserved across species, and resides in the enzyme active site. Mutation of this amino acid to arginine predicts disruption of the symmetric active site structure by protein modeling. We suggest that loss-of-function mutations in TDP1 could cause SCAN1 either by interfering with DNA transcription or by inducing apoptosis in post-mitotic neurons. Intriguingly, the repair of Topo I induced DNA damage involves a coordinated biochemical reaction requiring the following enzymes: a proteolysis enzyme, Tdp1, the single-strand break repair complex (SSBR) [PNKP, DNA polymerase, DNA ligase III, XRCC1]. Aprataxin, causes early-onset ataxia with ocular motor apraxia and hypoalbuminemia (EAOH) when mutated, has been postulated to interact with SSBR. The similarity in phenotype between SCAN1 and EAOH could arise either because accumulation of DNA breaks gives rise to a common phenotype or because aprataxin acts in the same pathway as Tdp1 and is involved in the repair of Topo I induced DNA breaks.

Mandibuloacral dysplasia is caused by R527H mutation in lamins A/C gene. *F. Sangiuolo¹, G. Novelli¹, A. Muchir², A. Helbling-Leclerc², M.R. D'Apice¹, C. Massart², F. Capon¹, A. Botta¹, F. Amati¹, P. Sbraccia³, M. Federici³, R. Lauro³, C. Tudisco⁴, R. Pallotta⁵, G. Scarano⁶, B. Dallapiccola⁷, L. Merlini⁸, G. Bonne².* 1) Dept Biopathology Tor Vergata Univ, Rome,Italy; 2) INSERM U523, Inst de Myologie, Gr. Hospitalier Pitie-Salpetriere Paris,France; 3) Dept Int. Medicine Tor Vergata Univ,Rome,Italy; 4) Dept of Surgery Tor Vergata Univ,Rome,Italy; 5) Dept of Medicine,Univ Chieti,Italy; 6) Med.Genet.Division,Hosp.Benevento, Italy; 7) Dept Exper. Medicine Univ La Sapienza and CSS-Mendel,Rome,Italy; 8) Neuromuscular Unit,Rizzoli Inst, Bologna,Italy.

Mandibuloacral Dysplasia (MAD;MIM 248370)is a rare autosomal recessive disorder characterized by craniofacial anomalies,skeletal malformations and mottled cutaneous pigmentation.Through a homozygosity mapping we demonstrated linkage of MAD to chromosome 1q21 in 5 consanguineous Italian families.All patients shared a common haplotype(from markers D1S2715 to D1S2721),absent in 96 healthy controls.Multipoint analysis identified in this interval a maximum LOD score of 9.05.We identified in this region as candidate genes the lamins A/C(LMNA)on the basis of its involvement in Dunnigan-type familial partial lipodystrophy(FPLD)showing a partial overlapping phenotype with MAD.We sequenced LMNA gene and identified in all 9 patients the same homozygous transition, 1580GA (R527H).The mutation was absent in 300 unaffected individuals.In order to confirm the pathogenic effect of R527H mutation in MAD, we have analyzed cultured skin fibroblasts from a patient,using lamin specific antibody.MAD cells present lobulation of their nuclear envelope and abnormal lamin distribution.The R527 amino acid is located at external surface of C-terminal domain.Thus, R527H substitution would disrupt the surface structure of the protein altering binding fundamental sites. LMNA mutations cause other five distinct diseases:AD/AR Emery-Dreifuss muscular dystrophy,limb-girdle muscular dystrophy 1B,dilated cardiomyopathy type 1A,AR Charcot-Marie-Tooth disease type 2,and FPLD.This observation expand our knowledge on laminopathies and provide evidence for a wide range of effect of this protein on human development and differentiation.

The human homologue of the mouse *zfh-4* gene is a candidate gene for congenital bilateral isolated ptosis. *D.O.*

Robinson¹, R. Keay¹, J.A. Crolla¹, A.G. Tyers², T.F.W. McMullan¹. 1) Wessex Regional Genetics Laboratory, Salisbury District Hosp., Wiltshire, SP2 8BJ, England; 2) Dept. of Ophthalmology, Salisbury District Hosp., Salisbury, Wiltshire, SP2 8BJ, England.

Ptosis (blepharoptosis) is the abnormal drooping of the upper eyelid and can impair full visual acuity. Two linkage loci have been reported for congenital bilateral isolated ptosis, an autosomal dominant locus at 1p32-p34.1 and an X-linked dominant locus at Xq24-Xq27.1. A patient with isolated ptosis was identified with a de novo balanced translocation, 46, XY, t(1;8) (p34.3;q21.12). Sequence analysis of the translocation breakpoints showed that the chromosome 1 breakpoint does not disrupt a gene, however the chromosome 8 breakpoint interrupts a human homologue of the mouse *zfh-4* gene, encoding a zinc finger homeodomain transcription factor. Human ZFH-4 consists of 10 exons spanning ~161kb of DNA and the translocation breakpoint occurs in intron 4 resulting in truncation of the gene and its protein product. In mice it is known that *zfh-4* is expressed in neurones in the mid and hind-brain during embryogenesis. It is therefore possible that reduction in expression may affect the development of the oculomotor nuclei situated in the midbrain. The oculomotor nerves could be affected including the innervation of the levator palpebrae superioris (LPS), which is defective in inherited ptosis in humans. To determine whether ZFH-4 is truly associated with ptosis, we are currently investigating a cohort of patients with congenital bilateral isolated ptosis in an attempt to identify additional ZFH-4 mutations.

Identification and molecular characterization of a ring chromosome 18 associated with a vascular disease. A.A.

Timur^{1,2,3}, *A. Sadgephour*^{1,2,3}, *M. Graf*⁴, *S. Schwartz*⁴, *D. Driscoll*⁵, *Q. Wang*^{1,2,3}. 1) Center for Molecular Genetics; 2) Department of Molecular Cardiology, Lerner Research Institute, The Cleveland Clinic Foundation, Cleveland, OH; 3) Center for Cardiovascular Genetics, Department of Cardiovascular Medicine, The Cleveland Clinic Foundation, Cleveland, OH; 4) Center for Human Genetics, University Hospitals of Cleveland, Department of Genetics, Case Western Reserve University, Cleveland, OH; 5) Division of Pediatric Cardiology, Mayo Clinic, Rochester, MN.

Klippel-Trénaunay Syndrome (KTS) is a congenital vascular disorder comprised of capillary, venous and lymphatic malformations associated with overgrowth of affected tissues. In this study, we report the identification of a *de novo* ring marker chromosome in a patient with a vascular disease with some features of KTS. The ring chromosome is derived from chromosome 18, and appears to be mosaic with 25% of cells containing it. Fluorescence *in situ* hybridization (FISH) technique was used to define the chromosome 18 breakpoints associated with the ring chromosome. The chromosome 18p breakpoint was localized between the markers *WI-9619* and *D18S1150*, and is estimated to be less than 8.7 cM to the centromere. The 18q breakpoint was localized between the markers *UniSTS:148508* and *UniSTS:154383* and estimated to be less than 2.3 cM to the centromere. We conclude that the r(18) contains the chromosome 18 centromere and its size is estimated to be less than 11 cM. These studies define a new cytogenetic abnormality associated with KTS, and establish a framework for finding a potential vascular gene located close to the chromosome 18 centromere.

Disruption of Troponin-Tropomyosin Complex Causes Distal Arthrogryposis. *S. Sung*¹, *A. Brassington*¹, *K. Simpson*¹, *L. Jorde*¹, *J. Carey*², *M. Bamshad*^{1,2,3}. 1) Department of Human Genetics, University of Utah, Salt Lake City, UT; 2) Department of Pediatrics, University of Utah, Salt Lake City, UT; 3) Shriners Hospitals for Children, Intermountain Unit, Salt Lake City, UT.

The distal arthrogryposes (DAs) are a group of disorders characterized by congenital contractures of the hands and feet. We discovered that variant Freeman-Sheldon syndrome (FSS), the most common DA, is caused by mutations in *TNNI2*. *TNNI2* encodes an isoform of troponin I (TnI) that is a component of the troponin-tropomyosin (Tc-Tm) complex specific to fast-twitch myofibers. TnI prevents muscle contraction by inhibiting actomyosin ATPase activity. Binding of Ca⁺² ions to the Tc-Tm complex reverses this inhibition and causes muscle contraction. Each of the mutations in *TNNI2* is predicted to disrupt the carboxy-terminal domain of TnI. In the cardiac isoform of TnI, perturbation of this domain diminishes the sensitivity of TnI to Ca⁺² ions, reduces contractility, and impairs movement. This appears to be caused by mutant TnI interacting with normal molecules of TnI or other thin filament proteins. Mutations in *TNNI2* may cause congenital contractures by a similar mechanism. Variant FSS is a genetically heterogeneous disorder. Thus, we sought additional candidate genes by examining the modifiers of mutant isoforms of TnI in *Drosophila*. One of these modifiers is tropomyosin, another component of the Tc-Tm complex. A human homologue of tropomyosin is encoded by *TMP2*, located in the critical interval of another form of DA, distal arthrogryposis type 1 (DA1). Subsequently, we discovered that DA1 is caused by substitution of a highly conserved amino acid residue in tropomyosin. These findings suggest that DAs, in general, may be caused by mutations in genes encoding proteins of the contractile apparatus specific to fast-twitch myofibers. This would be analogous to the observation that mutations in the genes encoding cardiac-specific isoforms of the Tc-Tm complex cause a cardiomyopathy. Our discoveries provide us with an opportunity to directly study the etiology and pathogenesis of multiple congenital contracture syndromes and to consider novel therapeutic interventions.

Lay Advocacy Owned Blood and Tissue Banks. *S.F. Terry^{1, 2}, V.H. Whittemore³, C.T. Driscoll⁴, E.W. Johnson⁵, M.E. Davidson¹, P.F. Terry^{6,2}.* 1) President, Genetic Alliance, Sharon, MA; 2) Executive Director, PXE International, Washington, DC; 3) Tuberous Sclerosis Alliance, MD; 4) NHGRI, Bethesda, MD; 5) Barrow Neurological Institute, Phoenix, AZ; 6) Genomic Health, Redwood City, CA.

International lay advocacy groups accelerate and focus research efforts. Some international advocacy organizations, including those falling under the umbrella of larger groups such as the Genetic Alliance, have created small, niche repositories of biological materials. These banks provide an invaluable asset to the research community by streamlining some of the most logistically difficult aspects of searching for a gene, mutations and subsequent phenotype genotype correlations. Lay advocacy groups provide the basis for the informed decision making process, accessing and collecting appropriate DNA samples, protecting patient confidentiality, recontacting/redrawing patients as needed, collecting epidemiological data and reporting progress, or the lack of it, to research participants, in a culturally sensitive manner. The organizations are also uniquely able to safeguard confidentiality by acting as both a bridge and a 'firewall' between researchers, participants, and other organizations. The lay advocacy groups facilitate research by requiring collaboration, refining the focus and reducing the number of overlapping projects. These groups and the communities that support them are empowered in the process and foster the global effort to find the causes and cures for these diseases. Lessons learned from these banking efforts, all born of advocacy, for different diseases, using different models, will be discussed.

Identification and Haplotype Analysis of Single Nucleotide Polymorphisms in AMPD1 Gene. *K. Toyama¹, H. Morisaki¹, Y. Kitamura², N. Kamatani², T. Morisaki^{1, 3}.* 1) Dept. Bioscience, NCVC Research Institute, Suita, Osaka, Japan; 2) Inst. Rheumatology, Tokyo Women's Medical University, Tokyo, Japan; 3) Dept. Molecular Pathophysiology, Osaka University School of Pharmaceutical Sciences, Osaka, Japan.

AMPD1 deficiency, which shows relatively mild clinical phenotypes, is one of the most common enzyme deficiency in Caucasian. In addition to hereditary metabolic myopathy, this enzyme defect has been reported to be associated with improved cardiovascular survival in patients with chronic heart failure and coronary artery disease. However, the common type of AMPD deficiency has not been found in certain population including Japanese. Recently, we have identified a compound heterozygote of AMPD1 deficiency in Japanese myopathic patient. These findings suggest that the common variants are restricted to some population, and possibly one haplotype would account for the ancestral AMPD1 deficiency. We have identified 35 polymorphisms in and around the AMPD1 gene, including newly identified nonsynonymous variations. One of the new AMPD1 mutants showed reduced activity and different characteristics. By using LD Support software, we defined the typical haplotypes of AMPD1 locus and identified the ancestral haplotype responsible for the most common AMPD1 variant.

***ROR1* gene is mutated in the dominant form of Robinow syndrome.** *A.M. Vianna-Morgante*¹, *H.G. Brunner*², *H. van Bokhoven*², *B. Hamel*², *J.F. Mazzeu*¹. 1) Department of Biology, Universidade de São Paulo, São Paulo, Brazil; 2) Department of Human Genetics, University Medical Center, Nijmegen, The Netherlands.

Robinow syndrome (RS) is characterized by facial dysmorphisms, mesomelic shortening and hypoplastic genitalia. Both dominant and recessive forms of RS have been described that can be distinguished by the presence, in the recessive form, of costovertebral segmentation defects. The gene mutated in the recessive form, *ROR2*, is mapped at 9q22 and codes for an orphan tyrosine kinase receptor. Another member of the orphan tyrosine kinase receptor family is *ROR1*. We have previously described a partial duplication of chromosome 1p in a patient with the dominant form. One of the breakpoints at 1p31 disrupted the *ROR1* gene. We considered this gene as a candidate for the dominant form of Robinow syndrome and started a trial for mutations in *ROR1* gene in 36 unrelated patients in which *ROR2* mutations had been excluded. Exons 8 and 10 were partially analyzed. SSCP analysis of exon 8, which codes for the cysteine-rich domain, revealed altered patterns in five patients. In another patient we detected an insertion of 90 bp in exon 10, affecting the tyrosine-kinase domain. The cysteine-rich and tyrosine-kinase domains are those most frequently mutated in *ROR2* gene in patients with the recessive form of the syndrome. These results indicate that mutations in *ROR1* gene cause the dominant form of Robinow syndrome.

A silent coding change altering splicing of ATR, a DNA repair gene, is a cause of Seckel syndrome. *V. Ruiz-Perez¹, M. O'Driscoll², P. Jeggo², J. Goodship¹*. 1) Institute of Human Genetics, University of Newcastle upon Tyne, UK; 2) Genome damage and stability unit, University of Sussex, UK.

We have previously reported autozygosity mapping of a Seckel syndrome [MIM210600] locus to chromosome 3q22.1-q24. Additional family members enabled us to reduce the region of homozygosity and a candidate gene, ATR, remained within the region. Mutations were sought by cDNA amplification and direct sequencing. We observed skipping of exon 8 in an affected individual, introducing a frameshift and stop codon immediately after exon 7. Further cDNA analysis revealed a very low frequency of exon 8 skipping in normal controls in addition to the expected product. In the affected individual the proportions of the two products are inverted and two additional intermediate faint bands were seen. Sequencing these intermediate bands showed use of two alternative splice donors in exon 8. Genomic sequence analysis identified a silent single base change in exon 8. Wild type and mutant HIV-ATR hybrid minigenes were transfected into cos-7 cells. Analysis of the cDNA revealed two products with the wild type, corresponding to normal splicing and exon 8 skipping but found only the shorter allele with the mutant sequence. Hence splicing of exon 8 seems to be leaky in normal individuals and this silent base change has further decreased splicing efficiency. Ataxia telangiectasia related protein (ATR) and ataxia telangiectasia mutated (ATM) are related phosphatidylinositol 3-kinase-like kinases (PIKKs). ATM phosphorylates multiple substrates in response to DNA double strand breaks. ATR, in contrast, responds to other forms of DNA damage and to stalled replication forks. Cell lines derived from a patient from this family showed undetectable levels of ATR by western blotting. Additionally, we find that the phosphorylation of known ATR substrates is impaired in these cell lines. Whilst mutations in ATM cause ataxia telangiectasia, this represents the first report of patients defective in the ATR signalling pathway.

Angiotensin II Type 2 Receptor (AGTR2) Mutations Cause X-linked Mental Retardation. A.K. Srivastava^{1,2}, V.S. Vervoort¹, M.A. Beachem¹, P.S. Edwards¹, S. Ladd¹, K.E. Miller¹, X. de Mollerat^{1,2}, G.F. Guzauskas¹, K. Clarkson¹, C.E. Schwartz^{1,2}, B. DuPont^{1,2}, E. Boyd³, R.E. Stevenson^{1,2}. 1) J.C. Self Research Institute of Human Genetics, Greenwood Genetic Center, Greenwood, SC; 2) Department of Genetics & Biochemistry, Clemson University, Clemson, SC; 3) Fullerton Genetics Center, Asheville, NC.

X-linked mental retardation (XLMR) is the most common cause of inherited mental retardation in males. Linkage of several XLMR families to a large genetic interval, Xq23-q25, suggests the presence of one or more MR genes in the region. So far one MRX gene, the *PAK3* gene, has been identified within this interval. To identify other candidate MR genes, we analyzed a de novo balanced translocation [46, X, t(X;7)(q24;q22)] in a female patient with MR. We mapped the X chromosome breakpoint and analyzed the expression of the genes from the breakpoint region for functional nullisomy in the female patient with the translocation. We found that expression of the *AGTR2* gene in Xq24 is absent in this female patient. Additionally, we screened for mutations of the *AGTR2* gene in 5 probands from XLMR families putatively assigned to genetic intervals that encompass the *AGTR2* gene, in 33 probands from families with possible X-linked MR but no definitive linkage data, and in a large cohort of 644 unrelated male patients with MR of unknown causation but negative for Fragile-X. We identified eight mutations among these 682 MR males in the *AGTR2* gene including one frame-shift and three missense mutations. We also identified four polymorphic variants of the gene. The mammalian brain expresses two angiotensin II (Ang II) specific receptors, AGTR1 and AGTR2. Ang II actions on blood pressure regulation, water electrolyte balance, and hormone secretion are primarily mediated by AGTR1. The function of AGTR2 remains unclear. Our findings indicate a role for AGTR2 in brain development and cognitive function. If confirmed by further studies, this would indicate that mutations in the *AGTR2* gene is an important cause of mental retardation in males, accounting for 1% or more of mental retardation in males.

Adult-Onset Primary Open Angle Glaucoma (POAG) Caused by Mutations in Optineurin: A TNF-alpha-inducible protein that interacts with Huntingtin, RAB8, TFIIIA and E3-14.7K. *T. Rezaie*¹, *A. Child*², *R. Hitchings*³, *G. Brice*², *L. Miller*⁴, *M. Coca-Prados*⁵, *E. Héon*⁶, *T. Krupin*⁷, *R. Ritch*⁸, *D. Kreutzer*⁴, *R. Pitts Crick*⁹, *M. Sarfarazi*¹. 1) Molecular Ophthalmic Genetics Laboratory, University of Connecticut Health Center, Farmington, CT; 2) St. George's Medical School, London; 3) Moorfields Eye Hospital, London; 4) Pathology, UCONN Health Center, CT; 5) Ophthalmology and Visual Science, Yale University, CT; 6) Ophthalmology & Vision Research, Toronto, Canada; 7) University Eye Specialists, Chicago, IL; 8) New York Eye and Ear Infirmary, NY; 9) International Glaucoma Association, London.

We identified Optineurin (*OPTN*) as the mutated gene for adult-onset POAG, the *GLC1E* locus on 10p14. Screening of optineurin in 54 families with at least one low-pressure glaucoma subject identified one truncating (g.691insAG) and 2 missense (E50K and R545Q) mutations in 9 (16.7%) families. E50K was present in 7 families with 38 living glaucoma subjects, 18% of whom had high intraocular pressure. Another risk-associated change (M98K) was identified in 13.6% of glaucoma subjects and 2.1% of controls. Optineurin encodes for 577 a.a., contains 2 putative bZIP motifs, a C2H2-ZF type and several leucine-zipper domains. Two transcripts of 2.0 and 3.6-kb were present in trabecular meshwork (TM) and non-pigmented ciliary epithelium (NPCE). A 66-kDa protein was detected in TM, NPCE and aqueous humors of human and 7 other species. Immunocytochemistry showed a perinuclear localization of endogenous protein in the Golgi apparatus. Cloning of the mouse and monkey genes identified proteins with 584 and 571 a.a. and 78% and 96% identity to human *OPTN* respectively. Each of these 3 genes has 13 coding exons and their intron-exon boundaries are fully conserved. Optineurin shows similar intracellular localization in human, monkey and mouse. Immunohistochemistry identified optineurin in the anterior segments and optic nerves of human and monkey. Optineurin interacts with a number of proteins to regulate apoptosis, inflammation and vasoconstriction and it may have a neuroprotective role in glaucoma optic neuropathy. Supported By: EY-09947 and IGA.

Clinical and molecular characterisation of Frontotemporal dementia linked to Human Chromosome 3. G. Skibinski, L. Chakrabarti, and FReJA (Frontotemporal Research in Jutland Association). MRC Prion Unit, Institute of Neurology, London, UK.

Frontotemporal dementia linked to chromosome 3 (FTD-3) is an autosomal dominant pre-senile dementia. It is associated with a large Danish pedigree that spans 6 generations with over 1000 known individuals. Early onset (below 65 years) includes changes in personality, disinhibition, dyscalculia and hyperorality, progressing to a non fluent aphasia, speech disturbances and dystonic posturing. There is generalised cerebral atrophy with occasional frontal predominance and in one patient, a reduction in widespread cortical blood flow. Through haplotype analyses we have restricted the dementia locus to a 4cM region within chromosome 3. Using the current human genome sequence, candidate genes are being sequenced to identify any mutation that segregates with the disease, with particular attention being given to genes expressed in the brain. High-resolution FISH technology and Southern blot analysis are being used to identify genomic differences and chromosomal anomalies. Comparison of gene expression from FTD-3, Alzheimer and non-neurodegenerative brains will indicate aberrations in molecular pathways and complement the proteomic studies that are underway to investigate disruption to protein expression levels. In addition the development of an information extraction program will provide a novel in silico approach to obtain previously undiscovered molecular components and pathways from the literature relating to FTD-3.

In search of the forgotten exon of the human crumbs homolog 1 and its implication in LCA. *S. Gerber¹, I. Perrault¹, S. Hanein¹, S. Shalev², J. Zlotogora³, J.M. Rozet¹, F. Barbet¹, D. Ducroq¹, J.L. Dufier⁴, A. Munnich¹, J. Kaplan¹.* 1) Genetics, INSERM U393, Paris, France; 2) Genetic Unit, Haemek Medical Center, Afula, Israel; 3) Dpt of Community Genetics, Public Health Services, Ministry of Health, Ramat Gan, Israel; 4) Service d'Ophtalmologie, Hpital Necker - Enfants Malades, Paris, France.

In order to identify the gene responsible for Leber congenital amaurosis in a very large consanguineous family originating from Palestine. A genome wide search for homozygosity was undertaken in the nine affected patients of the family. The fluorescent oligonucleotides of the Genescan Linkage Mapping Set, version II (Perkin Elmer Cetus) were used. Amplified fragments were analysed on an automatic sequencer (ABI377). Genes lying in the candidate region were screened by direct sequencing in affected individuals. Novel CRB1 exons were searched by the screening of the Human Genome Working Draft and confirmed by RT-PCR of retinal mRNA. Homozygosity was found in several regions of the genome. Further analyses allowed to exclude these regions except one since homozygosity for the markers only reflected the lack of informativity in the parents. Conversely, we found evidence for homozygosity for markers of the 1q31 region. Recombination events in two affected individuals allowed us to reduce the genetic interval containing the disease-causing gene between D1S1723 and D1S2668. The CRB1 gene was found to map in this 4 cM interval. However, prior to this genome wide search for homozygosity, a screening of the six already known LCA-causing gene including CRB1 was performed and no mutation was found. The mapping of the disease-causing gene in this family prompted us to consider that the mutation might lie in a forgotten exon of the CRB1 gene. Subsequently, we screened the Human Genome Working Draft in order to identify novel CRB1 exons. This study revealed that a 12th exon lies in the 3'end of the gene. The sequence of this exon revealed that the disease in this family is accounted for by a homozygous 10 bp deletion leading to apparition of a premature Stop codon. Further study of this exon in 80 untreated LCA patients was therefore undertaken.

Novel mutations and genetic markers in Fabry disease. *K. Azibi^{1, 2}, C. Caillaud^{1, 2}, C. Heltianu³, J. Dussau¹, J.P. Puech¹, L. Poenaru^{1, 2}.* 1) Laboratoire de Genetique, Universite Paris V, CHU Cochin, Paris, France; 2) Institut Cochin, Inserm, CNRS, Paris, France; 3) Institute of Cellular Biology & Pathology N. Simionescu, Bucharest, Romania.

Fabry disease is an X-linked glycosphingolipid storage disease resulting from deficient activity of the lysosomal alpha-galactosidase A (GLA). This enzyme defect leads to the accumulation of globotriaosylceramide in the lysosomes of vascular endothelial and smooth muscle cells, but also in plasma. Therefore, clinical manifestations in the classical form are due to pathology of small vessels resulting in angiokeratoma, renal failure and heart and brain ischemia. Death occurs from renal or cardiac complications.

To clarify the molecular mechanism causing the enzyme defect, the alpha-galactosidase gene was amplified and sequenced for each 43 patients and 25 carriers from 59 families. 30 mutations (14 novel and 16 previously described) were identified. The novel mutations were : two nonsense mutations (W245X and W262X), five missense mutations (A156N, S297C, P265R, I354K and Q279H), a small nucleotide insertion (InsG10678) and six deletions (1235del15, 5113delA, 10593delAT, 7316delA, 7335delG and delATCA). Our study defines the previously reported heterogeneity of mutations causing Fabry disease, but no strict genotype-phenotype correlation was found. It has also permitted to clarify the carrier status in females and to offer them prenatal diagnosis.

Recently, polymorphisms of endothelial dysfunction markers genes, eNOS, angiotensin-converting enzyme (ACE), angiotensinogen (AGT) and the type 1 (AT1) and type 2 (AT2) angiotensin II receptors, have been considered to play a role in the pathophysiology of vascular, heart and renal diseases. Thus, alteration of the nitric oxide pathway has been previously shown in Fabry disease. Analysis of different genetic markers of the endothelium dysfunction may allow to determine the role in the clinical heterogeneity of Fabry disease.

Novel mutations in type B Niemann-Pick disease: Implications for phenotype/genotype correlations. *C.M.*

Simonaro¹, M. McGovern¹, M. Wasserstein¹, R. Giugliani², A. Al Aqeel³, P. Ozand⁴, R.J. Desnick¹, E.H. Schuchman¹.

1) Dept Human Genetics, Mount Sinai Sch Medicine, New York, NY; 2) Dept Genetics, Hospital de Clinicas de Porto Alegre, Porto Alegre, Brazil; 3) Dept Pediatrics, Riyadh Armed Forces Hospital, Riyadh, Saudi Arabia; 4) Metabolic Disease Center, King Faisal Specialist Hospital, Saudi Arabia.

Types A and B Niemann-Pick disease (NPD) result from deficient acid sphingomyelinase (ASM) activity. Type A NPD is characterized by neurodegeneration that leads to death by ~3 years of age, whereas patients with Type B NPD have little or no neurological involvement and may survive into adulthood. Enzyme replacement therapy has been evaluated in a mouse model of NPD, and markedly improves the visceral organ pathology. These studies provided "proof of principal" that this approach will be beneficial for Type B NPD patients, and a clinical trial is currently being planned. We have therefore been performing ASM genotype analysis on Type B NPD patients from around the world, including over 40 patients evaluated at Mount Sinai. Over 80 novel mutations have been identified in over 150 Type B NPD patients. Among these are several common mutations not previously reported, including a point mutation found in 10 patients of Scottish descent, three point mutations in 16 Type B patients from Saudi Arabia, and several point or frame-shift mutations found in patients of Turkish descent. We have also extended previous analyses of the common deltaR608 mutation, and found that throughout the United States, Brazil, and several countries in Western Europe it accounts for about 30% of the Type B NPD alleles. Phenotype analysis of the patients revealed that the Saudi mutations were associated with an aggressive, but non-neurological, form of Type B NPD, whereas the Scottish mutation was associated with a milder form. Continued analysis of the deltaR608 mutation confirms that this mutation is also associated with a less severe form of Type B NPD. These ongoing studies provide a basis for phenotype/genotype correlations in Type B NPD, and should aid in the selection of appropriate patients for the enzyme therapy clinical trials.

Program Nr: 2172 from 2002 ASHG Annual Meeting

A novel mutation in the X-linked form of Charcot-Marie-Tooth neuropathy. *G. Karadima, M. Panas, P. Floroskoufi, N. Kalfakis, D. Vassilopoulos.* Dept Neurology, Athens National University, Athens, Greece.

X-linked Charcot-Marie-Tooth disease (CMTX) is a sensorimotor peripheral neuropathy linked to mutations in the gene encoding connexin 32. In the present study DNA-based mutation analysis on the connexin 32 gene (Cx32) was performed in 5 patients with CMT type 1 phenotype but without duplication involving the chromosomal region 17p12-p11.2. The coding region of the connexin 32 gene, entirely contained in exon 2, was screened for mutations. Mutation screening was performed by SSCP analysis after PCR amplification of the coding region. Automated sequencer performed sequencing of the candidate fragments. We found 5 missense mutations of which 1 is new: Val38Ala. Restriction enzyme digestion was used to confirm the sequencing results of the new mutation. The mutant allele was absent in 100 healthy controls. The identification of this new CMTX causing mutation is a critical step for carrier detection and presymptomatic diagnosis.

Contribution of two X-linked loci, FRAXE and XNP to mental retardation in South Africa. *F.B. Essop, A. Krause.*
Human Genetics, NHLS, Johannesburg, Gauteng, South Africa.

Mental retardation (MR) affects 1-2% of the general population. About 50% of severe cases of MR have a genetic cause, and almost half of these are said to be due to X-linked mental retardation (XLMR). XLMR can be subdivided into syndromic XLMR (MRXS) and nonspecific XLMR (MRX). MR is usually a secondary feature in MRXS. MR is the only feature seen consistently in MRX. This study aims to investigate the contribution of two X-linked loci associated with XLMR, viz. the XNP gene and the FRAXE, FMR-2 gene to MR in South Africa, with a view to improving diagnostic services for MR. The contribution of the locus to MR in South African populations is currently being assessed by screening males with a range of MR- either from institutions or routine referrals for fragile X A syndrome testing who tested negative for the FRAXA mutation. FRAXE syndrome, the most commonly identified MRX gene, is associated with a mild form of MR. At least 255 MR individuals have been tested for the FRAXE mutation. Of these, 182 have tested negative for FRAXE and 73 samples are currently being retested. Mutations in XNP have been shown to be relatively commonly involved in severe XLMR. The zinc finger helicase-coding region of XNP is a hot spot for mutations. As mutations in the XNP gene lead to a severe MR phenotype, screening for XNP mutations in MR males who have a negative family history was suggested. At least 187 MR males have been screened for mutations in the hot spot region. These results are currently being analysed. If the two new markers are shown to contribute significantly to the causes of XLMR in the South African population, they will be implemented as new diagnostic tests.

The novel Rho-GTPase activating gene *MEGAP* has a putative role in severe mental retardation. V. Endris¹, B. Wogatzky¹, U. Leimer², D. Bartsch², M. Zatyka³, F. Latif³, E.R. Maher³, G. Tariverdian¹, G.A. Rappold¹. 1) University of Heidelberg, Institute of Human Genetics, Heidelberg, Germany; 2) Central Institute of Mental Health, Mannheim, Germany; 3) Section of Medical and Molecular Genetics, Department of Pediatrics and Child Health, University of Birmingham, Birmingham, UK.

In the last few years, several genes involved in X-specific mental retardation have been identified using genetic analysis. Although it is likely, that additional genes responsible for idiopathic mental retardation are also localized on the autosomes, cloning and characterisation of such genes have been elusive so far. Here we report the isolation of a novel gene, *MEGAP*, which is disrupted and functionally inactivated by a translocation breakpoint in a patient, who shares some characteristic clinical features, such as hypotonia and severe mental retardation, with the 3p- syndrome. By FISH and LOH analysis, we demonstrated that this gene resides on chromosome 3p25 and is deleted in 3p- patients. *MEGAP* mRNA is predominantly and highly expressed in fetal and adult brain and specifically in the neurons of the hippocampus and cortex, structures known to play a pivotal role in higher cognitive function, learning and memory. We describe several *MEGAP* transcript isoforms and show that *MEGAPa* and *b* represent functional GAP proteins by an in vitro GAP-assay. *MEGAP* has recently been shown to be part of the Slit-Robo pathway regulating neuronal migration and axonal branching, highlighting the important role of *MEGAP* in mental development. We propose that haploinsufficiency of *MEGAP* leads to abnormal development of neuronal structures that are important for normal cognitive function.

Identification of autosome-linked mental retardation (MR) mutations: mapping and characterization of balanced autosome;autosome translocations associated with MR. *M.A. Beachem, S. Ladd, V.S. Vervoort, L.R. Taylor, G.F. Guzauskas, R.J. Schroer, R.E. Stevenson, B. DuPont, A.K. Srivastava.* J.C. Self Research Institute of Human Genetics, Greenwood Genetic Center, Greenwood, SC.

Mental retardation (MR) is the most common developmental disability affecting about 2-3% of the human population. Genes that cause inherited MR are distributed throughout the human genome. In recent years several MR genes, especially on the X chromosome, have been isolated but success in identifying autosomal MR gene has been very limited. So far only few suggestive autosomal MR loci have been reported based on studies of a limited number of familial cases and studies of patients with MR and balanced chromosomal rearrangements. Extending the latter approach, we have characterized the chromosomal breakpoints in several patients with MR and autosome;autosome translocations. In principle, at least one of the two chromosome breakpoints is likely to disrupt or alter expression of a specific gene, thus producing the MR phenotype in these patients. We defined seven potential chromosomal regions on chromosome 3q12, 5q15, 6q22, 16q24, 17q23 and 21q22 potentially harboring candidate MR genes. In five patients, we have identified clones/markers flanking one of the two translocation breakpoints. We have identified the genomic contigs that span one of the two breakpoints in two patients. FISH and PFGE analyses have narrowed the critical breakpoint regions associated with MR to less than 1 Mb in five cases. One autosomal breakpoint mapped within the Down syndrome critical region on chromosome 21. Due to the lack of large familial autosomal cases with MR, which normally assist in defining linkage intervals associated with MR on the genome, the balanced translocations associated with MR analyzed here provide a most valuable resource for the mapping of MR loci. The mapping information presented here will be useful in the identification of the genes associated with human cognitive functions.

ARX mutations frequently cause X-linked mental retardation. *M.E. Mangelsdorf^{1,2}, M. Finnis¹, L. Hobson¹, B. Hodgson¹, G. Turner³, M. Partington³, C. Schwartz⁴, R.E. Stevenson⁴, H. Lubs⁵, E. Holinski-Feder⁶, J. Mulley^{1,7}, J. Géczy^{1,2}.* 1) Department of Cytogenetics and Molecular Genetics, Women's and Children's Hospital, Adelaide, Australia; 2) Department of Paediatrics, University of Adelaide, Adelaide, Australia; 3) Hunter Genetics and University of Newcastle, New South Wales, Waratah, Australia; 4) Greenwood Genetic Center, Greenwood, SC 29646, USA; 5) University of Miami School of Medicine, Miami, FL; 6) Medizinisch Genetisches Zentrum, Bayerstrasse 53, D-80335, Munchen, Germany; 7) Department of Molecular Biosciences, University of Adelaide, Adelaide.

We have recently described mutations in the *Aristaless*-related homeobox (*ARX*) gene which cause both syndromic and non-syndromic X-linked mental retardation (XLMR) (Strømme et al, 2002). Our initial studies showed that 9/11 families that mapped to Xp22, in which *ARX* is located, contained a mutation in this gene. One mutation (428-451 dup(28bp)), which results in expansion of a polyalanine tract (12-20 alanines) made up more than half of the mutations found. This duplication causes both non-syndromic as well as a variety of syndromic XLMR (X-linked infantile spasms syndrome [ISSX], Partington Syndrome). Haplotype analysis suggests that these mutations are separate events and are not due to a founder effect, and that this polyalanine tract represents a mutation hotspot within the gene. In the past genes implicated in non-syndromic MR have only been found in few of the families mapping to the region in which the gene resides. In order to determine the frequency of *ARX* mutations causing MR we have screened, by SSCA, (1) additional families which have been mapped to the region, (2) boys with familial MR suggesting X-linked inheritance but too small for linkage and (3) boys representing sporadic cases previously shown not to contain expansions at the *FRAXA* CCG repeat. Additional 428-451 dup(28bp) mutations were found in these groups. Apart from CCG expansions associated with *FMR1* and *FMR2*, only *ARX* accounts for a significant proportion of MR families mapping to a specific region of the X. Furthermore, *ARX* mutations may be present in some of the patients usually referred for fragile X syndrome testing.

Impaired fuel homeostasis leads to defective non-shivering thermogenesis in the 70kDa Peroxisomal Membrane Protein (PMP70) deficient mouse. *I. Silva-Zolezzi*^{1,2}, *K.J. Hebron*¹, *G. Thomas*³, *D.S. Millington*⁴, *V. Valle*¹, *G. Jimenez-Sanchez*¹.

1) HHMI and Inst of Genetic Medicine, Johns Hopkins Univ, Baltimore, MD; 2) Programa Doctoral en Biomedicina Molecular, CINVESTAV, Mexico; 3) Kennedy Krieger Institute, Baltimore, MD; 4) Duke University Medical Center, Durham, NC.

PMP70 is one of four known half ABC transporters in mammalian peroxisomes. To better understand its function and implications for human disease, we produced *PMP70* knockout mice (*PMP70*^{-/-}) by standard methods. These mice are viable and exhibit impaired peroxisomal β -oxidation of phytanic and pristanic acids and a variety of metabolic abnormalities including reduced hepatic glycogen in the fed state; a medium chain dicarboxylic aciduria that increases with fasting; and increased expression of peroxisomal proliferator-activated receptor alpha (PPAR α) target genes such as *MCAD*, *ACOX* and *ACAA1* in the liver. Surprisingly, the *PMP70*^{-/-} mice also have a defective non shivering thermogenesis (NST) as shown by a drop in body temperature to $<15^{\circ}\text{C}$ after 2-6h at 4°C (controls $35\pm 3^{\circ}\text{C}$), similar to that of mice with defects in mitochondrial β -oxidation (eg. *LCAD*-deficient mice). In contrast to these other models, *PMP70*^{-/-} mice have normal brown adipose tissue (BAT) lipid content and normal levels of BAT *UCP-1* expression. *PMP70*^{-/-} mice do however have a reduction in plasma carnitine (total carnitine 22.8% of controls). Moreover, blood glucose levels are normal in the fed state but are $\sim 50\%$ of control after a 4.5h cold exposure (99 ± 21 vs $193\pm 37\text{mg/dl}$). To study the role of fuel homeostasis in NST of *PMP70*^{-/-} mice, we determined cold tolerance before and after 10 days of a high carbohydrate (CHO) (70%) diet or 4 weeks of a carnitine-supplemented (0.5g/Kg/day) diet. Both diets delayed the onset of hypothermia from $\sim 3\text{-}4\text{h}$ to $\sim 9\text{-}11\text{h}$. Furthermore, after returning to a standard CHO diet for 2 weeks, *PMP70*^{-/-} mice again evidence a profound defect in NST. Similar studies with carnitine repletion are underway. Our results suggest that accumulation of phytanic and pristanic acids in the *PMP70*^{-/-} mouse activate PPAR α , leading to inappropriate activation of the fasting fuel homeostasis that may limit energy substrates leading to NST in this mouse.

RNA Instability in Carbamyl Phosphate I (CPS-1) Deficiency Resulting from Intronic and Exonic Mutations Results in Message Homozygosity for the Other Mutation in at Least One Third of Patients. *M.L. Summar^{1,2}, L. Hall¹, A. Payne², A. Willis².* 1) Dept Pediatrics/Div Genetics, Vanderbilt Univ Medical Ctr, Nashville, TN; 2) Molecular Physiology & Biophysics.

CPS-1 deficiency (CPS1D) is a rare autosomal recessive disorder which causes either a lethal or severe defect in the function of the urea cycle. As part of our mutation studies of CPS1D we have studied mRNA and Genomic DNA in all patients where both were available. We have noted that over 1/3 of patients analyzed for both tissues are homozygous for a missense or nonsense mutation in RT/PCR products of CPS-1 but heterozygous for these mutations in PCR products of genomic DNA. We hypothesized that the missing allele might be the result of genomic changes which result in an unstable transcript. We studied 24 patients for whom both RNA and DNA were available. We screened all 37 exons and sequence 5' and 3' of the transcript by PCR of genomic DNA. At least 50 bases of flanking intron sequence was included in each amplified exon. RT/PCR products were obtained from liver, lymphoblastoid, or fibroblast samples. Sequencing was performed using radiolabelled dNTPs and cycle sequencing. 12 of the patients were homozygous for both their cDNA and genomic DNA changes. 3 patients were heterozygous in both tissues. 9 patients were homozygous for changes in cDNA which were heterozygous in genomic DNA (Hom/Het). We determined changes in these Hom/Het patients from genomic DNA that were not detected in mRNA. We found 2 premature stop codons from single base substitutions, 3 out of frame deletion/insertion changes resulting in premature stop codons, 1 5' UTR change, 1 mid-exon missense mutation, and 2 intron/exon boundary changes near the 3' end of the intron. These findings demonstrate that changes observed in genomic DNA may often have their effect on the transcript rather than the translation process. These findings also suggest robust cellular mechanisms for degrading flawed RNA. This study suggests that whenever practicable mRNA should be studied alongside genomic DNA to better understand the mechanisms of proposed mutations.

A robust multiplex minisequencing assay for rapid screening of common *HBB* and *HBA2* thalassemia mutations.

S.S. Chong^{1,2,3}, W. Wang¹. 1) Pediatrics; 2) Ob/Gyn, Lab Med/MDC, Nat'l Univ Singapore, Singapore; 3) Pediatrics, Johns Hopkins School of Medicine, Baltimore, MD.

The thalassemias are the most common monogenic disorders in the world, and are endemic to many regions in Southeast Asia. We previously developed a rapid single-tube multiplex PCR test to detect the most common deletional determinants of α -thalassemia. We have now developed a complementary assay to enable rapid screening of the most common thalassemia point mutations. The *HBB* and *HBA2* genes were amplified separately or multiplexed together. Excess PCR primers and unincorporated dNTPs were enzymatically degraded. Multiplex minisequencing was then performed on the purified PCR products, using mutation-specific primers containing non-specific 5' tails of differing lengths and the SNaPshot™ reaction mix containing DNA polymerase and ddNTPs, each labeled with a different fluorophore. Minisequencing primers were designed to anneal next to each mutation site, and comprised a total of 7 common *HBA2* mutations (codon0D1bp, Constant Spring, Paksé, Quong Sze, Suan Dok, codon30D3bp, codon59) and 15 common *HBB* mutations (panel I: codon41/42, IVSIIInt654, IVSI nt5, codon17, -28, -29, codon71/72, codon26; panel II: IVSInt1, codon19, codon0, codon43, codon27/28, codon8/9 and codon35). Minisequencing products were separated and detected by capillary electrophoresis on an ABI PRISM™3100, and analyzed using GeneScan™ and Genotyper™3.7 software. Homozygous wild-type or mutant DNA samples displayed only a single colored peak for each mutation site on the electropherogram, reflecting incorporation of either normal or mutant fluorescent ddNTPs. Samples heterozygous for a specific mutation displayed two different-colored peaks for that mutation site, reflecting incorporation of two different fluorescent ddNTPs by the primer. A double blind analysis of 96 thalassemia patient DNA samples of known genotype was performed, of which 87 samples yielded amplified product and all samples were correctly genotyped. We have thus developed a robust, rapid and reliable minisequencing assay to detect the most common non-deletional Southeast Asian thalassemia mutations.

A novel biomarker: somatic transversion mutations of mitochondrial DNA increased in patients with diabetes mellitus. *J. Kamiya¹, Y. Aoki¹, K. Kiyosawa¹, Y. Fukushima².* 1) Dept 2nd Internal Med, Shinshu Univ Sch Medicine, Nagano, Japan; 2) Dept Medical Gen, Shinshu Univ Sch Hospital, Nagano, Japan.

Augmented oxidative stress induced by hyperglycemia possibly contributes to the pathogenesis of diabetic complications. Oxidative stress is known to increase the conversion of deoxyguanosine to 8-oxo-2'-deoxyguanosine (8-oxodG) significantly in the DNA of patients with diabetes mellitus (DM). 8-oxodG can form Watson-Crick pairs with both cytosine (C) and adenine (A), and therefore, it can give rise to guanine (G):C to thymine (T):A or T:A to G:C transversion mutations. Hence, we investigated what kind of somatic mutations actually occurred in the mitochondrial DNA (mtDNA) of diabetic patients, which is thought to be more vulnerable to oxidative damage than nuclear DNA. We studied five diabetic patients (HbA1C = $8.27 \pm 0.60\%$), and five age-matched healthy control subjects. We subcloned and sequenced two parts of mtDNA (control region (nt15996-16401, segment A) and the segment encompassing t-RNA^{Leu(UUR)} (nt3149-3404, segment B)) in the peripheral blood, and identifying somatic mutations from 20 colonies each, while assaying urinary 8-oxodG by the ELISA detection method. The number of total somatic mutations, each of which was not over 5% in heteroplasmy, had no difference between patients with DM and control subjects (19, 16 in DM patients vs 23, 11 in healthy controls, in Segment A, B respectively). However, transversion somatic mutations of the mtDNA significantly increased in patients with DM (5, 6 vs 1, 0; $P < 0.001$, according to two-sided Fisher's exact test), including the three mutations presumably due to 8-oxodG; while transition mutations did not significantly increase. The amount of transversion mutations was not correlated with the content of 8-oxodG in the urine, which tended to increase in diabetic patients, without a significant difference. This is the first report to show somatic transversion point mutations of mtDNA increase in patients with DM, even when not associated with urinary 8-oxodG. Such transversion mutations can become a novel biomarker of mtDNA damage associated with hyperglycemia, and possibly with oxidative stress which is not reflected by urinary 8-oxodG.

Thanatophoric dysplasia type II mice generated using cartilage-specific cre. *T. Lin, S.B. Sandusky, Z. Zhang, C.A. Francomano.* Laboratory of Genetics, National Inst on Aging/NIH, Baltimore, MD.

Fibroblast growth factor receptors (FGFR) are tyrosine kinase receptors, which bind extracellular FGF ligands. FGFR3 is of particular interest since numerous mutations in this gene give rise to human skeletal dysplasias. Specific mutations have already been identified in hypochondroplasia (HCH), thanatophoric dysplasia (TDII), and severe achondroplasia with developmental delay and acanthosis nigricans (SADDAN). Two dysplasias of interest to our laboratory, TDII and SADDAN, are caused by mutations in K650 of human FGFR3 in the second tyrosine kinase domain. To gain a better understanding about their phenotypic differences and to elucidate the underlying molecular bases of these growth disorders, TDII and SADDAN mouse models of FGFR3 were designed with point mutations (K644E and K644M) accurately reflecting the phenotype of the particular skeletal dysplasia. In order to overcome lethal effects caused by the mutation, an in vivo Cre-loxP recombination strategy was used where neo was used to suppress the mutation that the mice were carrying, (FGFR3^{+/neo-K644E})(FGFR3^{+/neo-K644M}) thus generating mice that were phenotypically normal. We have generated our first tissue specific TDII mice by crossing FGFR3^{+/neo-K644E} transgenic mice with cartilage specific COL2A1-Cre mice. The profound phenotype is similar to that of the TDII with K644E expression in all cells. These tissue specific TDII pups had a shorter tail (half of the length of their wild type litter mates) with caudal widening, extremely short, curved forelimbs and hind limbs, and a slightly enlarged head. Upon dissecting the ventral portion of their rib cage, the TDII pups showed features including a much smaller and narrower rib cage than their wild type littermates. Little or no milk was observed in their stomach, indicating decreased viability, while some of their littermates had milk 2 hours after birth. Currently, we are growing the isolated chondrocytes in vitro in alginate beads from these postnatal TDII pups for cellular and molecular characterization.

Modeling Spinal and Bulbar Muscular Atrophy in a Mouse. *C.J. O'Brien, E. Chevalier-Larsen, H. Wang, S. Jenkins, D.E. Merry.* Dept. of Biochemistry & Molecular Pharmacology, Thomas Jefferson University, Philadelphia PA.

Spinal and Bulbar Muscular Atrophy (SBMA) is an adult onset, progressive motor-neuronopathy attributable to the expression of an expanded polyglutamine tract in the N-terminal region of the androgen receptor (AR) protein. Symptoms include bulbar and proximal limb muscular atrophy with fasciculations, and mild androgen insensitivity. Histology reveals neuronal intranuclear inclusions (NII) and the depletion of motor neurons residing in the spinal cord and brainstem. We created a model of SBMA, using transgenic (TG) mice that bear the full-length mutant AR112Q cDNA driven by the prion protein (PrP) promoter. Characterization of the model reveals a gender dependent neurologic disease, suggesting a ligand dependent process. By two months of age, TG males exhibit motor deficits and NII formation. TG females display a mild and delayed phenotype, without notable muscular impairment and few NII. TG AR24Q animals are phenotypically normal and lack NII. Immunohistology (IHC) of brain and spinal cord from TG AR112-34 animals reveals neuronal nuclear staining in brain and spinal cord. Punctate NII are detected in TG males at two months of age with the N-terminal antibodies AR (N-20) and AR318. IHC with antibodies AR441 and AR (C-19) diffusely illuminate the nucleus, but failed to detect these same NII. Protein analysis of AR112 reveals that AR (N-20) positive NII are insoluble in Triton, and are rendered only partially soluble in 4% SDS, suggesting biochemical differences between these NII, and the SDS-insoluble NII seen in previous models using a truncated AR. NII in the TG PrpAR112Q mice resemble those seen in SBMA patients, which are characterized by the absence of C-terminal epitopes. The presence of selected epitopes in NII provides a system with which to investigate the role of AR proteolysis in the onset and progression of SBMA. The gender preference of onset and progression in our model likely results from the same pathogenic mechanism as in SBMA. Ours is an appropriate model for the further examination of ligand dependent mutant AR proteolysis, and the effects of AR ligands on the onset, progression, and phenotype of this neuromuscular disease.

A Murine Model for Hereditary Hemorrhagic Telangiectasia Type 2. *S. Srinivasan¹, T. Dickens¹, L.P. Hale², D.A. Marchuk¹*. 1) Department of Genetics; 2) Department of Pathology, Duke University Medical Center, Durham, NC, 27710.

Hereditary Hemorrhagic Telangiectasia (HHT) is an autosomal dominant disorder characterized by multi-systemic vascular lesions that are prone to hemorrhage. The hallmark vascular lesions, arteriovenous malformations (AVMs), can occur in major organs such as the brain, lung, gastro-intestinal tract, liver, and skin (especially muco-cutaneous tissues). Penetrance is age-dependent and nearly complete only by the 4th decade. HHT type 2 is caused by loss of function mutations in activin-receptor-like kinase-1 (Alk-1). Disruption of the murine Alk-1 gene results in embryonic lethality in the homozygotes due to severe vascular abnormalities (Oh et al., Proc Natl Acad Sci USA 2000, 97:2626-31). We have investigated whether mice heterozygous for Alk-1 deletion will serve as an appropriate animal model for HHT type 2. Alk-1 heterozygotes were maintained for a period of up to 15 months in order to permit the development and progression of an HHT-like phenotype. Five Alk-1 heterozygotes died prematurely, of which, two exhibited vascular abnormalities and severe hemorrhage in a variety of organs. Hemorrhage was evident in the nailbeds, the spleen, and the liver. In addition, dilated and entangled vessels were observed in the paws and on the tongue. Mice were sacrificed at various ages (6-15 months) and examined for the presence of vascular anomalies. Vascular lesions and hemorrhage were identified in 1 of 8 heterozygotes. The anatomical locations of these lesions resemble those of the human disorder. These results suggest that despite the possibility of reduced penetrance, Alk-1 heterozygous mice are an appropriate animal model to investigate the pathogenesis of HHT type 2.

Inducible mice model of Spinocerebellar Ataxia Type 3. *Th. Schmidt¹, J. Boyl¹, C. Holzmann², S. Ibrahim³, U. Grasshoff¹, I. Schmitt⁴, F. Zimmermann⁵, S. Prusiner⁶, O. Riess¹.* 1) Department of Medical Genetics, University of Tübingen, Germany; 2) Department of Medical Genetics, University of Rostock, Germany; 3) Department of Immunology, University of Rostock, Germany; 4) Department of Neurology, University of Bonn, Germany; 5) ZMBH, University of Heidelberg, Germany; 6) Department of Neurology, University of California, San Francisco, CA.

Spinocerebellar Ataxia Type 3 (SCA3) or Machado-Joseph-Disease (MJD) is an autosomal dominantly inherited neurodegenerative disorder caused by the expansion of a CAG stretch in the *MJD1* gene encoding a polyglutamine repeat in the respective ataxin-3-protein. In order to study the course of the disease we generated an inducible transgenic mouse model using the Tet-Off-System developed by Dr. Bujard (Heidelberg). This system is based on two constructs: The promoter construct controls the expression of the so called tTA (Tetracycline transactivator) gene product. The binding of this protein to a Tetracycline responsive element (TRE) in the responder construct induces the transcription of the gene of interest. The expression can be blocked by the addition of Tetracycline which allosterically inhibits the tTA protein. For the ataxin-3-responder mouse lines two different full length constructs containing 15 repeats (control lines) and an expanded repeat with 77 glutamines (disease model) were used.

So far three founders for the control line and six founders for the disease model were generated and stable mouse lines established. In order to verify the function of these mouse lines we crossbred the ataxin-3 responder lines with a well-characterized prion protein promoter mouse line (kindly provided by Dr. S. Prusiner). Double transgenic mice of two disease model mouse lines express the ataxin-3 protein with an expanded polyglutamine repeat. Studies are ongoing to characterize these mouse lines and to define their suitability as a model of SCA 3. These models will allow us to turn off or on ataxin-3 expression at different developmental stages and will demonstrate whether or not the disease phenotype will be reversible.

Functional analysis of lamin A mutations underlying Emery-Dreifuss muscular dystrophy. *C.A. Brown¹, I. Motsch², C. Hartmann³, J. Zhang³, J.A. Ellis².* 1) Dept Lab Med & Pathology, Univ Minnesota Med Sch, Minneapolis, MN; 2) Kings College, London, UK; 3) Carolinas Medical Center, Charlotte, NC.

Emery-Dreifuss muscular dystrophy (EDMD) is characterized by slowly progressive muscle wasting and weakness, early contractures of the elbows, Achilles tendons and spine, and cardiomyopathy associated with cardiac conduction defects. Mutations in the LMNA gene, encoding lamins A and C, have been reported in patients with autosomal dominant, autosomal recessive, and sporadic forms of EDMD. We have examined the effect of nine mutations found in EDMD patients on subcellular localization of mature lamin A, and/or of endogenous nuclear antigens such as emerin, lamin C and lamin B. Transient expression of pEGFP constructs was performed in the mouse myoblast cell line C2C12 and the monkey fibroblast cell line COS-7. Confocal microscopy was used to determine the location of the synthesized EGFP-lamin A fusion protein in these cells. Constructs carrying the lamin A mutations R453W, R527P, L530P were localized normally to the nuclear envelope and neither endogenous emerin or lamin C localization were affected. The G602S and 190+R mutations were also localized normally to the nuclear envelope. Mutations E358K and T150P produced a mislocalization of exogenous lamin A and a rearrangement in endogenous emerin and lamin C localization. The E358K mutant produced a diffuse nucleoplasmic staining, and caused endogenous lamin C to take up a similar appearance. Endogenous emerin in this instance was less distinct in the nuclear envelope. The T150P mutant lost nuclear lamina and nucleoplasmic punctate staining, and became completely punctate and polarized to one side of the nuclear envelope. Endogenous lamin C took up a more punctate appearance within the nucleoplasm. The E361K and R133P constructs demonstrated intranuclear foci, consistent with the inability of the altered lamin A to incorporate into the nuclear lamina. These results indicate the variable effect of pathogenic forms of lamin A at the cellular level.

A unique structure-function analysis of a mutation in the androgen receptor gene that causes complete androgen insensitivity. *B. Gottlieb*^{1,5}, *J.H. Wu*^{3,5}, *T.C. Scanlon*^{1,2}, *S. Ghali*^{1,2}, *L.K. Beitel*¹, *M.A. Trifiro*^{1,4}. 1) Dept Cell Genetics, Lady Davis Inst Medical Res, Montreal, PQ, Canada; 2) Department of Human Genetics, McGill University, Montreal; 3) Department of Oncology, McGill University, Montreal; 4) Department of Medicine, McGill University, Montreal; 5) Center for Translational Research in Cancer, McGill University, Montreal.

An androgen receptor (AR) gene mutation (R774C) in the ligand binding domain (LBD) of the AR results in complete androgen insensitivity due to the receptor's inability to bind ligand. This is typical of many AR LBD mutations that are either not in the putative ligand binding pocket (LBP), or do not result in gross structural LBD alterations. To understand the possible mechanism of action of such mutations, the structure/function relationship of R774C has been analyzed by performing a molecular dynamic simulation of 1.4 ns using the Generalized Born model 2 as implemented in the Amber 7 package. The average structure of the mutant showed that the mutation had local structure distortion in the LBD. Part of AR helix 5 rewinds into a loop, which in turn causes movement of loops 759-772 and 682-695. The movement of loop 682-695 in particular, results in a change in shape of the LBP, and movement of the bound ligand within the pocket. This result is significant, as this is the first case of modeling showing an effect on ligand binding, of a mutation not within the LBP, that has a subtle effect on LBD structure. To confirm the validity of this observation, photoaffinity cross-linking experiments are underway. The normal and mutant AR LBDs were cloned into a GST bacterial expression system. Following protein expression, the cell cultures were incubated with the synthetic ligand [³H] R1881, the cells exposed to UV radiation and the GST-fusion proteins purified. The cross-linked fusion proteins were then cleaved with trypsin and Asp-N, run on a SDS-PAGE gel, which was exposed to film. Any resulting differences in R1881 cross-linking between normal and mutant receptors would validate the modeling technique and allow for analysis of many more non-LBP LBD mutations, not just in AR, but also in other members of the super-family of steroid receptors.

Hearing loss: frequency and functional studies of the most common CX26 alleles. *P. Gasparini*¹, *V. Veronesi*², *M. Bicego*², *S. Melchionda*³, *L. Zelante*³, *E. Di Iorio*⁴, *R. Bruzzone*⁵, *P. D'Andrea*². 1) Medical Genetics, SUN-TIGEM, Napoli, Italy; 2) Dip Biochimica, Biofisica e Chimica delle Macromolecole, Univ Trieste, Italy; 3) Serv Genet Med, IRCCS-CSS, San Giovanni R, Italy; 4) TIGEM (Telethon Institute of Genetics and Medicine), Naples, Italy; 5) Dpt Neurosci, Institut Pasteur, Paris, France.

Despite the large genetic heterogeneity in hearing loss, mutations in GJB2 (connexin 26) account for the majority of recessive and some of dominant cases of deafness. After a large screening of deaf patients we were able to define the frequency of GJB2 alleles in our Italian population. Six of them are missense mutations. In these cases functional studies have been carried out using biochemical and cell biological approaches. Briefly, the coding region of either wild-type (wt) or mutated Cx26 was subcloned into pIRES-EGFP, which permits both the gene of interest and the enhanced form of *Aequorea victoria* GFP gene to be translated from a single bis-cistronic mRNA, allowing an efficient selection of transfected cells for functional studies. To study the cellular localization of mutated Cx26 proteins, HeLa cells were transiently transfected with the cDNA for wtCx26 and relative mutations. To examine to which extent Cx26 mutations affected the level of protein expression, Western blot experiments were performed on total lysates of transiently transfected cells. Finally, to examine whether the mutant connexins could form functional gap junctions, the intercellular transfer of Lucifer yellow was analysed in cells transiently expressing the mutated connexins. As expected, absence of the protein was detected with the most common 35delG mutation. Regarding missense mutations, our data demonstrate that S19T, G12V, M34T, L90P, R184P and R127H lead to abnormal protein in terms of expression, localization and/or functionality. Moreover, M34T acts as a dominant inhibitor of wild type Cx26 channel activity when co-expressed in communication-deficient HeLa cells. These data are an useful step towards a complete understanding of the role of GJB2 in causing hearing loss.

Molecular basis of Peters' anomaly in a cohort of Saudi Arabian patients: expanding the phenotypic spectrum of *CYP1B1* mutations. *B.A. Bejjani*¹, *S.M. Curry*¹, *R.A. Lewis*¹, *A. Al-Rajhi*², *D. Edward*³. 1) Dept Molecular/Human Genetics, Baylor Col Medicine, Houston, TX; 2) King Khaled Eye Specialist Hospital, Riyadh, Saudi Arabia; 3) University of Illinois in Chicago, Chicago, IL.

Peters' anomaly (PA) is a developmental defect of the anterior segment that may occur as an isolated event or that may be associated with ocular and systemic defects. It is phenotypically and genotypically heterogeneous. We sought to determine the role of *CYP1B1* mutations in a cohort of 10 Saudi Arabian families segregating PA in 11 subjects. Experienced ophthalmologists diagnosed all subjects. The diagnosis was confirmed by pathological examination of corneal buttons in 5 subjects. Three subjects from 2 large families had siblings and cousins affected with Primary Congenital Glaucoma (PCG). Purified DNA was prepared from peripheral blood samples and *CYP1B1*-coding exons were amplified and sequenced. The molecular bases of PA and PCG were determined in 6 individuals from 5 families: A) a single missense mutation in *CYP1B1* (G61E) was identified in 5 individuals with PA in 4 families. This is a common in PCG mutation described previously in PCG patients from many ethnic backgrounds; B) a homozygous 10 base-pair deletion that yields a null allele by conceptual translation was detected in a patient with PA and in his siblings with PCG. Importantly, These 2 large families include 3 individuals (2 in one family, 1 in another) with homozygous *CYP1B1* mutations and no ocular anomalies (nonpenetrant). Sequence analysis of coding exons of genes known to be associated with PA (*PAX6*, *FOXC1*, and *FOXE3*) revealed no mutations in any subjects tested. Thus, mutations in *CYP1B1* may be a major cause for PA in this population and also, PA and PCG may share common molecular pathways. We also suggest that PA and PCG may represent variable severity in the same spectrum of anterior segment dysgeneses. The occurrence of PA, PCG, and unaffected individuals with identical homozygous *CYP1B1* mutations in the same sibship could suggest the presence of modifiers that modulate the clinical severity of the phenotypic expression of the same *CYP1B1* mutation(s).

Genetic Homogeneity of G6PD Deficiency in Bahrain. *N.M. Jassim, S.S Al Arrayed.* Genetic department, Salmaniya Medical Complex, Manama, Bahrain.

Glucose 6-Phosphate Dehydrogenase is an enzyme that is essential for protection of red blood cells from oxidation. Deficiency of G6PD activity is presumed to be the most common enzymopathy in man, with over 100 mutant alleles causing the phenotypic deficiency. Estimation of G6PD deficiency in Bahrain showed high prevalence of deficient subjects rating up to 26% of the whole population. Previous PCR-based DGGE, and RFLP molecular investigations, we found that the main causal defect of G6PD deficiency in Bahrain is the common variant G6PD Mediterranean (nt 563 C-T). Here, we studied 60 unrelated phenotypically deficient subjects (48 males and 12 females). We found that 70 out of 72 X-chromosomes (97%) are bearing the G6PD Med variant. Further analysis of the silent polymorphism at nucleotide position 1311 of this gene revealed quite homogeneity for this mutation in Bahrain. Out of 46 subjects (34 males and 12 females) bearing the G6PD Med mutation. 56 X-chromosomes (97%) showed thymine (T) at nt 1311, while it is cytosine (C) in two X-chromosomes (3%). In contrast, we studied 87 X-chromosomes for this silent polymorphism from subjects of normal phenotype and genotype for this enzyme. We found 52 X-chromosomes (60%) having "C" at nt 1311 and 35 X-chromosomes (40%) having "T". In conclusion these findings revealed high genetic homogeneity for G6PD deficiency in Bahraini people. Furthermore, the presence of thymine at nt 1311 for the vast majority of mutant chromosomes might suggest a possible unicentric source of this mutation in Bahrain.

Program Nr: 2190 from 2002 ASHG Annual Meeting

Carrier frequency of DF508 mutation in the CFTR gene in Indian population. *V. Kapoor, M. Kabra, S.S. Shastri, R. Vijaya, S. Arora, B. Prahlad, S.K. Kabra, A.K. Deorari, V.K. Paul, P.S.N Menon.* Department of Pediatrics, All India Institute of Medical Sciences, New Delhi, Delhi, India.

Cystic Fibrosis (CF) is a chronic, progressive, autosomal recessive disease of the exocrine glands involving multiple organs resulting in diverse phenotype. Mutations in Cystic Fibrosis Transmembrane conductance Regulator (CFTR) gene cause altered function of chloride channels on the apical membrane of the epithelial cells. More than 1000 mutations in the CFTR gene have been reported to the Cystic Fibrosis Genetic Analysis Consortium, of which DF508 mutation is the commonest accounting for 70-80% of all mutations causing CF in the Western population. CF is considered to be rare in Asians (i.e. 1/10,000) based in Goodchild et al study in the migratory Asian population of UK. The prevalence of DF508 mutation in Asians is 19-44% based on a few case reports. There are no population based studies on the prevalence of CF in India. This study was undertaken to estimate the carrier frequency of DF508 mutation in the Indian population. Nine-hundred and fifty five samples were collected in EDTA vacutainers. DNA was extracted by phenol-chloroform method and tested for DF508 mutation by PCR according to the protocol of Chris Mathews et al. The PCR products were analysed in 8% polyacrylamide gel followed by silver staining. On testing 955 cord blood samples, 4 samples were heterozygous for DF508 mutation. The place of origin of the parents in these four cases was Uttar Pradesh, Jammu, Karnataka and Pakistan respectively. Though the majority of the parents were from North India, mainly from Delhi and the adjoining States we had one case from South India. Based on this data, the carrier frequency of DF508 mutation was 1/238 (i.e. 0.42%). With the available data, using the Hardy-Weinberg principle the frequency of CF disease caused by DF508 homozygosity was calculated to be 1/2,28,006. The estimated prevalence of CF in Indian population ranges from 1/43,321 to 1/1,00,443. Thus CF does occur in the Indian population though the frequency is less as compared to the Caucasians. Considering the genetic diversity of the Indian population, further studies are required on a larger sample size.

cDNA microarray analysis of single patient with Duchenne muscular dystrophy. *S. Noguchi*^{1,2}, *T. Tsukahara*¹, *R. Kurokawa*^{1,2}, *M. Fujita*^{1,2}, *Y.K. Hayashi*¹, *Y. Goto*¹, *I. Nonaka*¹, *A. Tujimoto*³, *I. Nishino*^{1,2}. 1) Natl Inst Neuroscience, NCNP, Kodaira, Tokyo, Japan; 2) CREST, JST, Kawaguchi, Saitama, Japan; 3) DNA Chip research Inc, Yokohama, Kanagawa, Japan.

We newly developed a microarray containing 4224 human cDNA clones representing 3500 genes expressed in skeletal muscles. Our cDNA microarray system provides both high sensitivity and reproducibility with only 1 microgram of total RNA which first allowed us to study gene expression in a single patient specimen. We analyzed six muscle specimens from patients with Duchenne muscular dystrophy (DMD) both to deduce common pathognomonic features in DMD and to highlight difference among patients at the molecular level. The genes associated with myofiber degeneration, cell infiltration, inflammation, and muscle development, were significantly upregulated, while those related to muscle homeostatic function were downregulated. Among the genes regulated differently among the patients, we focused on the expression of the genes encoding HLA-related proteins, and the myosin light chain and troponin T isoforms as parameters for necrotic and regenerating process. The expression pattern of these genes was in accordance with the severity of dystrophic changes on muscle pathological examination. Our new cDNA microarray provides a molecular basis of muscle pathology.

CARTILAGE HAIR HYPOPLASIA (CHH) AND THE RNASE MRP (RMRP) GENE. *P. Hermanns¹, A. Bertuch¹, E. Munivez¹, A. Mian¹, V. Lundblad¹, J. Leroy¹, B. Zabel², B. Lee¹.* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Children's Hospital of the University of Mainz, Mainz, Germany.

Cartilage Hair Hypoplasia (CHH) is an autosomal recessive disorder characterized by, short stature, blond sparse hair, defective cellular immunity and predisposition to several cancers. CHH patients have mutations in the RNase MRP (RMRP) gene and one Finnish allele accounts for a majority of mutations. RMRP is the RNA component of a ribonucleoprotein which functions as an endonuclease and is thought to be involved in processing of the pre-rRNA in the nucleolus, cleavage of mitochondrial RNA, and priming of mitochondrial DNA replication. Its function in vertebrates and the pathogenesis of CHH is unknown and it is the first nuclear encoded RNA to be linked to a Mendelian genetic disease. In a cohort of 14 patients we found mutations in both alleles in 12 patients. Two patients had no mutations in the RMRP gene. Ten mutations have not been previously described. The mutations include insertions in the promoter region, missense substitutions of evolutionarily conserved as well as divergent bases. We have not found high numbers of polymorphism in outbred populations. The transcribed part of the RMRP gene is highly conserved among different species; however, the only mutation which is conserved between human and yeast is the main Finnish mutation (A70G). This mutation has been reported NOT to reduce the RMRP levels or to alter protein-RMRP level and protein-RMRP binding. The RMRP protein complex still forms (Ridanp et al. Cell 2001). To further understand the potential function of RMRP in cellular metabolism, we introduced the A70G mutation into the yeast ortholog of RMRP (NME1). The NME1 null allele causes lethality in yeast. In contrast, the A70G allele did not exhibit differences regarding growth rate, nutritional requirement, or chromosomal stability at different temperatures. Current studies are focused on generational differences for these parameters.

The Pyrin Pathway of Inflammation: Arthritis-Associated Mutations in PSTPIP1 Cause Hyperphosphorylation and Increased Binding to Pyrin. *N.G. Shoham¹, E. Mansfield¹, M. Centola¹, G. Wood¹, C.A. Wise², D.L. Kastner¹.* 1) Genetics and Genomics, NIAMS, NIH, Bethesda, MD; 2) Molecular Genetics and Cellular Biochemistry, center for musculoskeletal research, Scottish Rite Hospital, Dallas, Texas.

Pyrin, the FMF protein, is the prototype of a family of proteins that share an N-terminal death domain fold motif (the pyrin domain) and have been implicated in apoptosis and inflammation. To identify other associated proteins, we used pyrin as the bait in a yeast two-hybrid assay. One of the pyrin-interactors was proline serine threonine phosphatase-interacting protein (PSTPIP1), a tyrosine-phosphorylated protein previously shown to interact with PTP-PEST, c-Abl, CD2, and the Wiskott-Aldrich syndrome protein (WASP). PSTPIP1 and pyrin were found at high levels in monocytes, and, when cotransfected in HeLa cells, they colocalized by fluorescence microscopy and could be coimmunoprecipitated. Deletion mutants demonstrated that the B-box/coiled-coil segment of pyrin is necessary and sufficient for this interaction. In contrast, we found that the SH3 and coiled-coil domains of PSTPIP1 are both necessary, but neither is sufficient, for pyrin-binding. The Y344F point mutation, which blocks the tyrosine-phosphorylation of PSTPIP1, was associated with a marked reduction in pyrin-binding in pervanadate-treated HeLa cells. Further, we found that the A230T and E250Q PSTPIP1 mutations, which were recently shown to cause the dominantly inherited syndrome of pyogenic arthritis, pyoderma gangrenosum, and acne (PAPA), caused increased pyrin-binding as assayed by immunoprecipitation. Relative to wild-type, these PSTPIP1 mutants were hyperphosphorylated when coexpressed with c-Abl kinase. Taken together, these data suggest that PAPA-associated mutations increase PSTPIP1 phosphorylation and consequently pyrin-binding, thus providing a possible mechanism for the PAPA syndrome.

Mutations in the small GTPase late endosomal protein RAB7 are associated with Charcot-Marie-Tooth type 2B neuropathy. V. Timmerman¹, K. Verhoeven¹, K. Coen¹, N. Verpoorten¹, M. Auer-Grumbach³, J.M. Kwon⁴, D. FitzPatrick⁵, E. De Vriendt¹, A. Jacobs¹, V. Van Gerwen¹, K. Wagner³, H.P. Hartung⁶, P. De Jonghe^{1,2}. 1) Molecular Genetics Department, Flanders Interuniversity Institute for Biotechnology, Born Bunge Foundation, University of Antwerp, Antwerpen, Belgium; 2) Division of Neurology, University Hospital Antwerpen, Antwerpen, Belgium; 3) Institute of Medical Biology and Human Genetics, Karl-Franzens University Graz, Austria; 4) Department of Neurology, Washington University School of Medicine, St. Louis, MO, USA; 5) South East Scotland Clinical Genetic Service, Western General Hospitals, Edinburgh, Scotland; 6) Department of Neurology, Heinrich-Heine University, Dusseldorf, Germany.

Ultero-mutilating neuropathies are characterised by prominent sensory loss, often complicated by severe infections, arthropathy and amputations. So far, two loci and one gene have been reported for autosomal dominant ultero-mutilating neuropathies. However, molecular genetic studies have demonstrated that a third locus has to exist. Hereditary sensory neuropathy type I (HSN I) maps to 9q22.1-q22.3 and is caused by mutations in the SPTLC1 gene. The locus for hereditary motor and sensory neuropathy type IIB (HMSN IIB) or Charcot-Marie-Tooth type 2B (CMT2B) maps to 3q13-q22. CMT2B is clinically characterised by marked distal muscle weakness and wasting, a high frequency of foot ulcers, infections and amputations of the toes due to recurrent infections. We found two missense mutations (L129F and V162M) in the small GTP-ase late endosomal protein RAB7 associated with the CMT2B phenotype in three families. The alignment of RAB7 orthologs shows that both missense mutations target highly conserved amino acid residues. The V162M mutation affects a valine that is conserved among all species. The L129F mutation is localised next to a conserved GTP-binding domain. RAB7 is known to be ubiquitously expressed, and we found expression in mouse E13 sensory and motor neurons. Why mutations in an universally expressed protein as RAB7 lead to an axonal pathology in CMT2B is currently unknown.

Disease-specific changes in facioscapulohumeral muscular dystrophy by expression profiling. *Y.-W. Chen¹, P. Masny², K.M. Flanigan³, J. Martin², H. Qian¹, T. Mozaffar⁴, S.T. Winokur².* 1) Center for Genetic Medicine, Children's National Medical Center, and George Washington University, Washington, DC; 2) Department of Biological Chemistry, University of California, Irvine, CA; 3) Department of Human Genetics, University of Utah School of Medicine, Salt Lake City, UT; 4) Department of Neurology, University of California, Irvine, CA.

Facioscapulohumeral muscular dystrophy (FSHD) is an inherited muscle disorder resulting from deletions of the 3.3 kb D4Z4 repeat units on 4q35. Although a position effect hypothesis is proposed to be the cause of the FSHD, the primary and downstream gene changes of the disease are not clear. To identify FSHD-specific expression changes, we report expression profiling of FSHD muscles using Affymetrix HGU133 set representing 42,000 transcripts. By comparing profiles of 5 FSHD to 4 normal controls, we identified 1014 genes and ESTs significantly ($p < 0.05$) misregulated in the FSHD muscles. After subtracting genes differentially expressed in the Duchenne muscular dystrophy and dysferlin deficiency from that of the FSHD, we identified 668 FSHD-specific changes. The largest functional group of the 374 down-regulated genes was involved in protein synthesis and processing including methionyl aminopeptidase 2, amino acid transporter 2, and ribosomal proteins. As FSHD often has an inflammatory component, it is interesting to note that several immune response genes (eg. CD14, immunoglobulin kappa constant, and complement component 3a receptor 1) were up-regulated more than two fold. In addition, a custom glass slide array consisting of ~200 genes and ESTs from 4q35 and 10q26 was constructed, and 35 genes differentially expressed (31 up- and 4 down-regulated) more than 2 fold were identified in the FSHD samples. Among them, 15 genes and 9 genes were located at the 4q35 and 10q26 regions, respectively. Our results suggest that the 4q35 deletion in FSHD causes primary up-regulation of a subset of genes at both the 4q35 and homologous 10q26 loci, with subsequent downstream dysregulation of a series of disease-specific transcripts. The late onset and asymmetric distribution of muscle involvement may be mediated by metabolic and immune downstream changes.

Microarray analysis of Emery-Dreifuss muscular dystrophy. *Y.K. Hayashi^{1,2}, S. Noguchi^{1,2}, M. Fujita^{1,2}, R. Kurokawa^{1,2}, K. Goto^{1,2}, T. Tsukahara^{1,2}, I. Nishino^{1,2}.* 1) Neuromuscular Research, National Institute of Neuroscience, NCNP, Tokyo, Japan; 2) CREST, Japan Science and Technology Corporation, Saitama, Japan.

Emery-Dreifuss muscular dystrophy (EDMD) is slowly progressive muscular disorder characterized as scapulothoracic-peroneal muscle weakness and atrophy, early joint contractures, and cardiomyopathy with conduction block. X-linked recessive form (X-EDMD) is caused by mutations in the emerin gene on Xq28, and autosomal dominant form is caused by mutations in the lamin A/C gene on 1q21. Mutations in the lamin A/C gene also cause clinically distinct disorders including limb-girdle muscular dystrophy, familial dilated cardiomyopathy, familial partial lipodystrophy, and hereditary axonal neuropathy. Both emerin and lamin A/C are nuclear envelope proteins, however their detailed functions are not known yet. In this study, we characterized the expression pattern of over 5,000 genes in human skeletal muscle using our original cDNA microarray. Our microarray was designed to select genes expressed in human skeletal muscle. Further, this microarray can analyze the gene expression profiles of each patient since only small amounts of total RNA are required. We examined biopsied skeletal muscle specimens from two X-EDMD and one AD-EDMD patients. Human skeletal muscle total RNA (ORIGENE) was used as the reference and the gene expression level was calculated as relative ratio to the reference. Gene clusters were also generated and the gene expression pattern differences between X- and AD-EDMD were compared. The down-regulated 200 genes were involved in 19 energy metabolism, 18 sarcomeric, 20 transcription/translation and 10 DNA binding proteins. The genes of titin and nebulin were down-regulated that were observed in other muscular dystrophies. The up-regulated 200 genes included 31 energy metabolism, 28 sarcomeric and 15 signal transduction. Actin genes, tropomyosin 1, and muscle specific enolase were increased. Immune response genes were not significantly increased which suggested to reflect the pathological changes with no active muscle fiber necrosis. We are now performing detailed analysis of the data.

Malignant Hyperthermia Susceptibility: diagnosis in the South African context. *F.F. Maree^{1,2}, B. Wedge¹, D. Prosser¹, G.S. Gericke³, A. Olckers^{1,2}.* 1) Centre for Genome Research, Potchefstroom University, Pretoria, South Africa; 2) DNAbiotech, Pretoria, South Africa; 3) Medical Research Council, South Africa.

Malignant Hyperthermia (MH) is an autosomal dominant genetically and clinically heterogeneous pharmacogenetic disorder. Traditionally the diagnosis of MH was based on the highly invasive in vitro contracture test (IVCT). This type of diagnostic testing is expensive and cumbersome to provide to the South African population. The promise of an unequivocal molecular test, requiring a mere blood sample, or blood spot, is attractive and logistically feasible in our developing country. The high level of genetic heterogeneity in MHS has prompted active debate on the suitability of a molecular strategy as the sole diagnostic approach for MH. In South Africa the two IVCT diagnostic centres which were operational in the past have closed down, leaving us with no alternative but to embrace a molecular diagnostic strategy. Samples referred to us, from both private and public clinics, are subjected to the screening of the 15 causative mutations within the RYR1 gene, as outlined by the European MH Group. Failing the detection of any of these mutations, samples are subjected to a mutation screening strategy in order to identify novel mutations associated with MH in the South African population. To date, we have received 208 samples, of which 11 (all from the same family SA105) has been identified to harbour the Arg614Cys mutation in the RYR1 gene on chromosome 19q. Seven MH loci have been reported in the human genome. Our initial approach was to classify families, after haplotype analysis, as displaying linkage to either of these loci. Via this approach one family, SA102, has been identified to link to a novel locus on chromosome 2q, as reported earlier. Here, our in silico approach to elucidate the genetics of MH holds promise but, to date, no candidate gene for MH has been identified at this locus. The strategy to screen for MH on the molecular level has also been adopted by other countries in Europe and North America. However, the genetic heterogeneity of MH argues in favour of high throughput facilities where multiple mutations can be screened simultaneously.

Molecular exploration of the Dysferlin gene in LGMD2B and Miyoshi myopathy in a large cohort of patients. K.

NGUYEN¹, M. Krahn¹, R. Bernard¹, D. Figarella-Branger², F. Leturcq³, G. Bassez⁴, J. Pouget⁵, B. Eymard⁴, N.

Levy^{1,6} and French Dysferlin Study group. 1) Departement de Genetique Medicale, Hopital d'enfants de la Timone, Marseille; 2) Biopathologie Nerveuse et Musculaire, Hopital Timone, Marseille; 3) Laboratoire de Biochimie Gntique, Hopital Cochin, Paris; 4) Institut de myologie, Hopital de la Salpetriere, Paris; 5) Service des maladies neuromusculaires, Hopital Timone, Marseille; 6) Inserm U491, Genetique et Developpement, Marseille, FRANCE.

Limb Girdle Muscular Dystrophies (LGMD) are clinically heterogenous disorders with different modes of inheritance. Among the autosomal recessive forms of LGMD, LGMD2B involving proximal muscles at the onset, and distal Miyoshi myopathy are due to mutations in the same gene dysferlin. This gene encompasses 55 exons spanning over 150 kb of genomic DNA. It encodes a membrane associated protein of unknown function containing 2088 aminoacids. Our purpose was to perform a mutational analysis in a serie of patients presenting with a proximal phenotype (LGMD2B) or a distal myopathy of Miyoshi type. All patients had a deficiency in protein dysferlin showed in immunohistochemistry or Western-blot analysis. Mutational screening was done in the 55 exons followed by sequencing for exons with abnormal migration profile. This analysis revealed 8 new homozygous or compound heterozygous mutations in LGMD and Miyoshi patients. Phenotype-genotype correlations have been established and revealed that variable phenotypes may be associated to a same mutation in unrelated patients as well as in a same family. Among these mutations, a homozygous (1765-1766 insA) in exon 15 leading to a premature stop codon (R589fsX608) was found in a patient with atypical Miyoshi myopathy. This mutation is predicted to result in a complete loss of function of the dysferlin protein and will be particularly discussed. Also, a splicing mutation has been found in 3 different French patients, suggesting a mutation "hotspot" in this population. This study shows that a clinical approach followed by a protein analysis are absolutely necessary before performing mutational screening in the general strategy of diagnosis of the LGMD.

Fukutin is required for maintenance of muscle integrity, cortical histiogenesis, and normal eye development. S.

*Takeda*¹, *M. Kondo*¹, *J. Sasaki*², *K. Arai*³, *M. Imamura*⁴, *T. Fujikado*⁵, *K. Matsumura*³, *T. Terashima*⁶, *T. Toda*². 1) Otsuka GEN Research Institute, Tokushima, Japan; 2) Department of Post-Genomics and Diseases, Osaka University Graduate School of Medicine, Osaka, Japan; 3) Department of Neurology, Teikyo University School of Medicine, Tokyo, Japan; 4) Institute of Neuroscience, National Center for Neurology and Psychiatry, Tokyo, Japan; 5) Department of Ophthalmology and Visual Science, Osaka University Graduate School of Medicine, Osaka, Japan; 6) Department of Anatomy and Neurobiology, Kobe University Graduate School of Medicine, Kobe, Japan.

Fukuyama-type congenital muscular dystrophy (FCMD) is characterized by congenital muscular dystrophy associated with brain malformation (polymicrogyria) due to a defect during neuronal migration. We previously identified the gene responsible for FCMD, which encodes the fukutin protein. Most FCMD patients carry an ancestral mutation, which arose as a consequence of the integration of a 3-kb retrotransposon element into the 3' untranslated region of the fukutin gene. No FCMD patients have been identified with non-founder (point) mutations on both alleles, suggesting that such patients are embryonic-lethal and fukutin is essential for normal development. Here we report that chimeric mice generated using ES cells targeted for both fukutin alleles develop severe muscular dystrophy, with the selective deficiency of alpha-dystroglycan and its laminin-binding activity. They showed laminar disorganization of the cortical structures in the brain with impaired laminin assembly, focal interhemispheric fusion and hippocampal and cerebellar dysgenesis; and anomaly of the lens, loss of laminar structure in the retina, and retinal detachment. These results indicate that fukutin is necessary for the maintenance of muscle integrity, anchorage by radial cells, neuronal intercellular adhesion, and normal ocular development.

Comparative cross-species profiling of human DMD and mouse models for muscular dystrophy helps identify downstream pathways of disease pathogenesis. *L. Pasquali¹, M. Bakay¹, F.W. Booth¹, Y. Chen², K. Gorni³, B. Tseng¹, P. Zhao¹, E.P. Hoffman¹.* 1) Research Center for Genetic Medicine, Children's National Medical Center, Washington, DC; 2) Department of Veterinary Biomedical Sciences, University of Missouri at Columbia, Columbia, MO; 3) Department of Neurology, University of California, San Francisco, CA.

DMD patients lack dystrophin, and they present chronic degeneration/regeneration of the muscle, with progressive muscle wasting and early death. The *mdx* mouse, despite the complete loss of dystrophin, after initial necrosis, at 3-4 weeks of age, shows successful muscle regeneration, muscle hypertrophy and increased strength. Our goal was to identify compensatory mechanisms induced in the mouse but not human, by comparing the genome-wide expression profiles. The hypothesis is that differentially expressed genes in DMD and *mdx* mouse may confer protection to the murine dystrophin deficient model. We used as a starting point a "late muscle regeneration cluster" generated from a 27 time-point murine regeneration series. We then compared the expression of these genes in dystrophin-deficient *mdx* and experimental muscle regeneration (U74 GeneChip series) and human DMD muscle (U95 GeneChip series and custom Affymetrix MuscleChip). We generated a list of genes that were upregulated in both mouse models, but not upregulated in DMD. We then produced antibodies against each of the gene products to confirm the expression profiling and identify cell types expressing the differentially regulated proteins. These genes, that are inhibitors of negative regulators of skeletal muscle mass, specific cell division and differentiation genes, and specific connective tissue modulatory genes, are pharmacological targets for modulation of the progressive pathology of the human disease.

Identification of a novel frame shift mutation in RSK2 gene from a Coffin-Lowry syndrome family. *T.-J. Chen¹, GL. Wilson¹, Y. Wang¹, P. Maertens², W. Wertelecki¹, J. Martinez¹*. 1) Dept Medical Genetics, Univ South Alabama, Mobile, AL; 2) Dept Neurology, Univ South Alabama, Mobile, AL.

Coffin-Lowry syndrome (CLS) is a X-linked mental retardation syndrome caused by defects on the RSK2 gene. We have previously reported a CLS family with four patients in two generations (AJHG, 61(4): A106, 1997). The patients in this family, a mother and her 3 children (a male and two females), have severe mental retardation with typical CLS phenotype. In addition, brain MRI studies on these patients revealed abnormalities in the deep subcortical white matter, thinning of the corpus callosum, hypoplastic cerebellar vermis, and asymmetry of the lateral ventricles. The severity of the MRI findings correlated with the severity of mental retardation within these patients. Recently, we performed extensive mutation screening on the whole RSK2 gene on this family. Twenty-two exons including the intron/exon junctions have been amplified by PCR and subsequently, sequenced on both strands using ABI 310 automatic sequencer. A novel mutation of two nucleotide insertion (298 ins TG) has been identified on the patient's RSK2 gene. The insertion creates a stop codon on codon position 100, and the truncated RSK2 protein only has 99 amino acids. All patients have the same mutation and no other mutation could be found in the RSK2 gene. Thus, this novel mutation is likely to be responsible for the unusual clinical presentation in this family that includes full phenotypic expression in females and unique brain MRI abnormalities. The pathological function for the mutant to result in this clinical presentation as well as genotype/phenotype correlation awaits further clarification.

Detection of PLP duplications in Pelizaeus-Merzbacher Disease: Comparison of multiple methodologies in measurement of gene copy number. *Q. Gao, V.C. Thurston, G.H. Vance, S.R. Dlouhy, M.E. Hodes.* Dept Medical & Molecular Gen, Indiana Univ school of Medicine, Indianapolis, IN.

Pelizaeus-Merzbacher disease (PMD) is a rare, X-linked neurological disorder characterized by dysmyelination of the central nervous system (CNS). The genetic etiology of this disease is associated with mutations in the gene encoding proteolipid protein (PLP), the most abundant protein in the CNS myelin. In addition to a wide spectrum of point mutations and frameshift mutations, duplications involving the entire PLP gene appear to be the major cause of PMD, accounting for 50%-70% of cases with a family history of PMD or X-linked spastic paraplegia (SPG2). Techniques used to identify duplications of PLP include Southern blot, densitometric RFLP, semiquantitative comparative multiplex PCR (CM-PCR) and fluorescence in situ hybridization (FISH). However, each technique has certain limitations in clinical testing for PMD. In the current study, we investigated a relatively new technology, real-time PCR for the detection of duplications of the PLP gene. Forty-two patients with clinical and neurological features of PMD/SPG2 were included in this study. The data generated from real-time PCR was compared blindly to data obtained from FISH and CM-PCR. All three methods identified PLP duplications in sixteen of the samples and one sample had a deletion of the PLP gene. One sample was duplicated by real-time PCR, but not by FISH and CM-PCR. Possible explanation for this discrepant sample might be the detection of low-level mosaicism by the extremely sensitive real-time PCR. Twenty-four samples were negative for duplications of PLP by all three methods. The advantages, limitations and clinical applications of each method are compared and discussed.

Characterisation of mutations in patients with low level mosaicism by fraction collection of dHPLC separated heteroduplex peaks. *P. Emmerson¹, J. Maynard¹, R. Butler², J.R. Sampson¹, J.P. Cheadle¹.* 1) Institute of Medical Genetics, University of Wales College of Medicine, Cardiff, UK; 2) Medical Genetics Service for Wales, University Hospital of Wales, Cardiff, UK.

Somatic mosaicism is a frequent phenomenon in mendelian disorders that exhibit a high proportion of new mutations. However, mutant alleles present at low frequency may escape detection. We have previously shown that denaturing high-performance liquid chromatography (dHPLC) can detect TSC1 and TSC2 mutations in tuberous sclerosis patients with low-level somatic mosaicism, even when direct sequencing can not identify the causative lesion. Characterisation of these mutations currently involves extensive sequencing of cloned products. To overcome this limitation, we have utilised dHPLC with an in-line fraction collector to isolate low-level heteroduplex peaks which can be sequenced directly to reveal the mutation. We have successfully applied this technique to identify the mutations 2724-1G>C in TSC1 and 1772del4bp in TSC2 which were present in only 6 percent of the patient's peripheral blood lymphocytes.

A new homozygous mutation of the Lipoprotein Lipase Gene: (D174V) The first Lebanese mutation. M.

Abifadel^{1,2}, JP. Rabes^{1,3}, L. Villegier¹, M. Varret¹, N. Salem², E. Choueiri², A. Derre¹, H. Aydenian², C. Junien^{1,3}, S. Jambart², C. Boileau^{1,3}. 1) INSERM U383, Hosp Necker-Enfants Malades, Paris, France; 2) Saint-Joseph University, Beirut, Lebanon; 3) Hosp Ambroise Pare, AP-HP, Paris, France.

Many diseases including chylomicronemia, pancreatitis and atherosclerosis are directly or indirectly related to abnormalities in the lipoprotein lipase (LPL) function. This enzyme plays a major role in lipid metabolism by regulating the catabolism of triglycerides rich lipoprotein particles. The human LPL gene is located on chromosome 8p22. Several mutations of LPL have been identified so far and influence LPL function in different ways. We report the first mutation of the LPL gene found in the Lebanese population. We investigated the molecular defect resulting in fasting hyperchylomicronemia, and recurrent severe pancreatitis in a Lebanese patient of consanguinous parents by sequencing the 10 exons of LPL. We identified a new homozygous missense mutation in exon 5 resulting in the substitution of Val for Asp at position 174 of the mature LPL protein. Mutations in exon 5 are the most commonly reported cause of LPL deficiency. As no enzyme restriction site was changed by this mutation we designed modified primers mismatching with the normal LPL gene and introducing a unique BclI restriction site in the normal sequence that is not generated when the mutation is present. This PCR-mediated site-directed mutagenesis allowed segregation study of the mutation in the proband's family and rapid screening of 100 Lebanese normolipidemic patients in which the mutation was not found. The identification of this new mutation and this rapid screening method will help diagnosis of LPL deficiency in the Lebanese population, consanguinous and known for its high dyslipidemia incidence. The possibility of a founder effect for this LPL mutation and its link with the Lebanese founder mutation (C660X) of the LDLR (low density lipoprotein receptor gene), are under investigation. In conclusion we report a new mutation (D174V) in LPL gene and a rapid screening method. This is the first mutation of the LPL gene found in the Lebanese population.

Program Nr: 2205 from 2002 ASHG Annual Meeting

Analysis of eight exons of the CFTR gene in 65 Iranian Cystic Fibrosis patients by DHPLC and sequencing. *E. Elahi*^{1, 2}, *B. Alinasab*², *G. Esson*², *F. Ghassemi*¹, *M. Houshmand*⁴, *A. Khodadad*³, *P. Oefner*², *F. Reihani-Sabet*¹, *M. Ronaghi*², *M. Shahabi*¹, *Y. Thorstenson*². 1) Dept Biological Sci, Tehran University, Tehran, Iran; 2) Stanford Genome Technology Center, Stanford University, Palo Alto, CA; 3) Pediatric Polyclinic, Children's Hospital Medical Center, Tehran University, Tehran, Iran; 4) National Research Center of Genetic Engineering and Biotechnology, Tehran, Iran.

Exons 3,4,6b,10,12,17b,19 and 20 and neighboring intron sequences of the Cystic Fibrosis Transmembrane Regulator (CFTR) gene were analyzed in 65 Iranian Cystic Fibrosis patients by Denaturing High Pressure Liquid Chromatography (DHPLC). The PCR products of exons harboring mutations were sequenced by the dideoxy protocol. The sequences were compared to wild type sequences using the Sequencher sequence analysis software. In the eight exons analyzed, 24 different variations were detected. Five of these appear to be changes not previously reported: N408®G (E92E), deletion of GATT between N867-33 and N867-6 (deletion of one of seven repeats in intron 6b), N1655T®A (F508I), N1716+8A®G, and N3811T®G (L1227V). We are in the process of completing mutation analysis in all the exons of the Iranian patients.

Low proportion of dystrophin gene deletions among Filipino Duchenne and Becker Muscular Dystrophy patients. *E.C. Cutiongco¹, B.C. Cavan¹, E.C. Abaya¹, C.L. Silao¹, C.D. Padilla¹, H. Nishio², M. Matsuo².* 1) Institute of Human Genetics, Manila, Philippines; 2) International Center for Medical Research, Kobe University Graduate School of Medicine, Japan.

Duchenne muscular dystrophy (DMD), an X-linked progressive neuromuscular disorder, affects 1 in 3500 male livebirths. The milder allelic form, Becker muscular dystrophy (BMD), occurs in 1 in 20,000. Both are caused by mutations in the dystrophin gene. In DMD, affected individuals have little or no functional dystrophin while BMD cases may have a partially functional dystrophin giving rise to milder clinical manifestations. Mutations causing DMD/BMD are deletions of one or more exons of the dystrophin gene, exon duplications, or point mutations. The proportion of deletions among mutant dystrophin alleles in North American and European studies is 55-65% while a lower proportion (37%) of dystrophin gene deletions among Israeli DMD and BMD patients has been described. Other Asian populations have likewise shown a lower proportion of deletions among mutant dystrophin: 40-43% in Japanese and 45-50% in Chinese populations. A racial difference in the proportion of deletions may exist. We examined DNA samples of 35 unrelated Filipino patients diagnosed with DMD and BMD. Of these patients, 13 have been included in a previous report; this is an extension of that study. Deletions were detected using the multiplex DNA amplification procedure which permits rapid identification of 80-90% of all dystrophin gene deletions. Our results show that 8 of the 35 patients (22.8%) have deletions in at least one of the 23 exons of the dystrophin gene examined using multiplex PCR. This proportion of dystrophin gene deletion is the lowest reported so far in comparison to other populations. This low proportion makes diagnosis using the current PCR techniques particularly difficult. We also found that deletions among Filipino DMD/BMD patients were more common in the 5' end (62.5%) than in the central rod domain (37.5%). The findings suggest the presence of genetic variability among DMD/BMD patients in different populations.

Improvement of the scanning of the *CFTR* gene by multiplexing DHPLC analysis. *C. Ferec*^{1,2,3}, *K. Rouault*², *M.P. Audrezet*^{1, 2, 3}, *C. Le Marechal*^{1, 2, 3}. 1) Lab de Biogenetique, Universite de Bretagne Occidentale, Brest, France; 2) INSERM EMI 0115, molecular and epidemiological genetic, Brest, France; 3) CHU Brest, France.

We have recently shown that DHPLC is a powerful scanning technique for identification of point mutations in the *CFTR* gene (Le Marechal et al. 2001). Up to now all mutations tested were detected. To improve the speed of the complete analysis of the 27 exons we have developed a multiplexe strategy. Taking into account the oven temperature deduced from the melting profile of each amplicon, and the acetonitril concentration for their elution, we designed 7 multiplexe PCR. We report the PCR conditions and DHPLC settings to achieve these analysis. Only 20 DHPLC injections are now necessary for studying the coding sequence of the *CFTR* gene. The multiplexing of two amplicons can save 25% analysis time and allows to reduce the cost bellow one US dollar per amplicon scanned. One need rapid (few days) and accurate technique to scan the complete coding sequence in emergency situation such as prenatal diagnosis requested after the discovery of a hyperechogenic bowell during ultrasonnd screening. Quick typing with specific tests looks for only 30 most frequent mutations compared to more than one thousand described in the CF database (www.genet.sickkids.on.ca). The residual risk for CF in a couple with one unidentified allele is decreased from 1/10 to 1/60 if the technique used has 98% detection rate which is DHPLC performance.

Program Nr: 2208 from 2002 ASHG Annual Meeting

Validation of the novel WAVE-MD™ System technology for Mutation detection screening by DHPLC for Cystic Fibrosis. *C. Griffiths¹, G. Restagno², S. Papadimitriou¹, J. Walter¹*. 1) Transgenomic Ltd., UK; 2) Dipartimento di Patologia Clinica, Settore Genetica Molecolare Azienda Sanitaria Ospedaliera O.I.R.M.S.ANNA, Torino, Italy.

The WAVE-MD™ System is a new platform for mutation detection by Denaturing High Performance Liquid Chromatography (DHPLC). It can be used to identify known mutations or to detect unknown mutations, and offers a number of key innovations to the previously reported methods. The primary advantages of the WAVE -MD™ System are the disposable cartridge used for DNA analysis underlying the DHPLC technique, simplification of the gradient with regards to method development, and an advanced software incorporating automated mutation calling. We detail here initial experiments to validate the technology platform by screening a panel of previously characterised mutations and demonstrate the same high efficiency of mutation detection as reported with the conventional instrumentation and cartridge technology. In addition, applications specific work is performed to screen the CFTR gene, emphasising the transferability of previously characterised DHPLC methods for detection of specific mutants and providing data as to the accuracy of the mutation calling capability.

An homozygous mutation in the Fukitin-related protein gene(FKRP) causing a severe MDC1C form with mental retardation and cerebellar cysts:(Founder affect in Tunisian families). *F. FAKHFAKH¹, N. LOUHICHI¹, C.*

TRIKI², P. RICHARD³, S. QUIJANO⁴, H. AYADI¹, P. GUICHENEY⁵. 1) Laboratoire de genetique molcu, Faculte de Medecine , SFAX, SFAX, TUNISIA; 2) Service de neurologie,CHU Habib Bourguiba,SFAX,TUNISIE; 3) Service de biochimie,groupe hospitalier Salpêtrière,Paris, France; 4) Service de pediatrie,Hopital Raymond Poincaré,Garches,France; 5) Inserm ,U523,institut de myologie,Paris,France.

The congenital dystrophies(CMD)are a heterogeneous group of autosomal recessive disorders presenting in infancy with muscle weakness, contractures and dystrophic change on muscle biopsy.Approximately 40%of patients with CMD have a primary deficiency (MDC1A)of laminin alpha 2 chain (merosin) due to mutations in LAMA2 . In addition, a secondary deficiency of laminin alpha2 is associated with some CMD forms, including MDC1B, MEB, FCMD and MDC1C mappedrespectively to chromosomes 1q42, 1p3, 9q3 and 19q13.Mutations in the FKRP gene have been identified in patients affected with a severe form of MDC1C, which is characterized by inability to walk, muscle hypertrophy ,marked elevation of serum creatine kinase and normal brain structure and function.We have performed immunohistochemical and genetic analyses for five patients belonging to five consanguineous Tunisian CMD families presenting muscle hypertrophy, marked elevation of serum creatine kinase,cerebellar cysts and mental retardation. Immunohistochemical analysis revealed a partial deficiency of merosin in all the patients.Linkage analysis showed an exclusion of FCMD, MEB, MDC1A and MDC1B loci but linkage to MDC1C locus.Mutation screening of the whole FKRP coding region revealed a new homozygous C1363A (Ala/Asp)missense mutation in the five patients. This mutation was not found in more than 200 control chromosomes.The presence of the same mutation in these 5 patients suggests a founder affect which has been confirmed by haplotype analysis. This is the first homozygous mutation in FKRP causing CMD with mental retardation and brain abnormalities.

Comparison of two methods for routine accurate determination of the two mutations in the *IKBKAP* gene causing Familial Dysautonomia. A. Blumenfeld¹, M. Idelson¹, L. Reznik¹, I. Bejarano-Achache¹, C. Maayan¹, F.B. Axelrod², A. Yakir³, A. Bessudo³, Y. Furman³, N. Navot³. 1) Hadassah Univ Hosp, Jerusalem, Israel; 2) NYU Med Center, New York; 3) Savyon Diagnostics Ltd, Ashdod, Israel.

Familial dysautonomia (FD) is an autosomal recessive disorder, caused by poor development, poor survival, and progressive degeneration of the sensory and autonomic nervous system, affecting many other body systems. FD is inevitably fatal, with only 50% of patients reaching the age of 30. The frequency of the disease among Ashkenazi Jews is about 1:3,700, which corresponds to a carrier rate of 1:32. All cases were due to two mutations in the *IKBKAP* gene: one in intron 20 with a frequency >99%, and the other in exon 19, with a frequency of less than 1%. The disease was also observed among non-Ashkenazi Jews, mainly among Sephardic Jews. All but one non-Ashkenazi patients and carriers have the major mutation. Detailed haplotype analysis of these individuals showed that they are all of the same ancestral origin, and share the same haplotype over several centimorgans. One non-Ashkenazi carrier has the minor mutation / typical minor haplotype. To date, no other mutations in the *IKBKAP* gene, causing FD, have been identified.

We have developed two simple screening methods for these mutations. The first is based on digestion of PCR-amplified FD gene fragments with a restriction enzyme followed by gel electrophoresis, and the other - on a single nucleotide primer extension reaction, followed by ELISA in a kit format. Comparison of the two methods on the same set of samples provided identical results. The results correspond to those obtained by haplotype analysis.

Lately, there has been a dispute regarding the actual frequency of the minor FD mutation: though observed in less than 1% of FD families, the possibility of a higher carrier frequency of this mutation in the Ashkenazi Jewish population, has been raised. The availability of our two methods for detection of mutations causing FD, can serve as an important tool in resolving this dispute. These detection methods allow fast, precise and cost-effective population screening tool for this devastating disorder.

A family with episodic ataxia type 2; no evidence of genetic linkage to the CACNA1A gene on chromosome

19p13. *Y. Nagao*^{1, 2}, *H. Hirose*², *J. Takita*², *T. Arayama*³, *T. Igarashi*², *Y. Hayashi*². 1) Department of Pediatrics, Social Health Insurance Medical Center, Tokyo, Japan; 2) Department of Pediatrics, University of Tokyo Hospital, Tokyo, Japan; 3) Department of Pediatrics, Kikkoman Hospital, Chiba, Japan.

Episodic ataxia type 2 (EA2) has been reported to result from mutations in the CACNA1A gene, located on chromosome 19p13. We report a family with episodic ataxia, clinically indistinguishable from EA2, that was not caused by CACNA1A gene mutation. The proband is a 10 y-old boy, who has had 6 cerebellar ataxic attacks since 8 y. His attacks occurred almost monthly, lasting for 2 to 3 days. He was treated successfully with acetazolamide. His maternal grandmother, mother and twin brother had similar attacks since they were 50 y, 34 y and 10 y, respectively. The symptoms in his grandmother improved gradually without medication. His mother and twin brother took acetazolamide with a good response. We examined the CACNA1A gene for this family but did not detect any mutations. Furthermore, there was no evidence of genetic linkage between the CACNA1A gene and the symptomatic patients in this family. These suggest that the cause of EA2 can be heterogeneous, that is, defects of genes other than CACNA1A might also be the cause of EA2.

Comprehensive screening of the RYR1 gene by denaturing high-performance liquid chromatography. S.

McWilliams¹, T. Nelson², M. Cavender¹, L. Goldfarb³, K. Sivakumar¹, N. Sambuughin¹. 1) Barrow Neurological Institute, Phoenix, AZ; 2) Wake Forest University, Winston Salem, NC; 3) National Institute of Neurological Disorders and Stroke, NIH, Bethesda, MD.

Malignant Hyperthermia (MH) is a life-threatening hypermetabolic crisis following exposure to commonly used anesthetics. In the majority of cases, MH results from a defect in regulation of calcium release in skeletal muscle due to dominant mutations in the calcium channel of the sarcoplasmic reticulum, ryanodine receptor (RYR1 at 19q13). Because of the large size of the RYR1 gene, most genetic screening studies have targeted few known mutational hot spots and as a result mutations were identified in only about 25% of studied patients. The aim of this study was to develop an efficient method of finding most, if not all mutations in the RYR1 gene. We analyzed the entire coding region of the RYR1 gene in eight MH patients using denaturing high-performance liquid chromatography (DHPLC). One known mutation and five novel amino-acid substitutions were found in the RYR1 gene. The four amino acid changes were considered as likely candidate mutations for MH, based on their cosegregation with MH, absence among 50 healthy controls and location at conserved residues within RYR1 proteins. Two novel candidate mutations were located outside of known mutational hot spots. Our preliminary data suggest that mutations in the RYR1 gene are distributed throughout the gene and the efficiency of mutation detection in patients with MH can be increased from 25% to greater than 60% with the use of highly sensitive DHPLC screening technique.

Mutation Analysis of Sex Determined Genes in Korean Patients with Sex-Reversal Disorders. *S.C. Jung¹, K.S. Lee¹, Y.J. Lee¹, J.A. Park², J.S. Lee².* 1) Division of Genetic Disease, Korea National Institute of Health, Seoul 122-701, Korea; 2) Department of Pediatrics (Medical Genetics), Yonsei University College of Medicine, Seoul 120-752, Korea.

The XY chromosome configuration determines male and the XX female, but in sex reversal syndrome a male with XY will develop female sex organs or a woman with XX will have male characteristics. All of steps of sex differentiation are under genetic control. Therefore mutations of the corresponding genes can cause the failure of sex differentiation. Genomic DNA was extracted from the lymphocytes of patients and their family, with sex-reversal disorders who presented with 46, XY, phenotypic female or 46, XX, phenotypic male. We have performed molecular studies of sex determined genes; *sex-determining region Y (SRY)*, *anti-Müllerian hormone (AMH)*, *steroid 21-hydroxylase*, *androgen receptor (AR)*, *steroidogenic factor-1 (SF-1)*, *doublesex*, *mab-3 related in testis-1 (DMRT-1)* and *Wnt-4*. Using PCR and direct-sequencing method, we identified 2 insertion or deletion mutations in the whole sry open reading frame (ORF), 8 missense mutations - Pro31Leu, intron2 splice site, Ile173Asn, Val282Leu, Gly292Ser, Leu308insT, Gln319Stop, Arg357Trp - in *steroid 21-hydroxylase* gene. In addition, 3 mutations in *AR* gene and duplication of *Wnt-4* gene were identified. For *AR* gene, there were a single nucleotide C deletion at amino acid 39, resulting in frameshift mutation and two missense mutations; Leu57Gln, Ala596Thr. Ala596Thr mutation was found in two brother patients, whose mother showed heterozygosity at the same position. In *SF-1* and *DMRT-1* genes, no mutations have been detected yet. We are going to analyze more candidate genes to find causative mutations of sex reversal disorders.

Spontaneous tandem-base mutations in mouse and man: rare occurrence in the germline and similar mutation types in the soma. K.A. Hill, J. Wang, K. Farwell, S.S Sommer. Dept Molecular Genetics, City of Hope Natl Med Ctr, Duarte, CA.

The frequency, pattern and spectrum of spontaneous tandem-base mutations (TBM) have not been well characterized. We previously analyzed spontaneous TBM in a transgenic mouse model for detection of *in vivo* somatic and germline mutations (Big Blue). The frequency of TBM showed age and tissue specific differences. TBM had a unique pattern of mutation types with a predominance of G:C to T:A (70%) and specifically GG to TT and GG to AT mutations (58%). To explore the relevance of spontaneous TBMs, we sequenced 2,593 additional mutants from 11 tissues, tripling the sample size. Forty-four TBM were identified. The previous findings were confirmed and several new observations were made. TBM were most frequent in the kidney (3.45×10^{-6}), accounting for 7.6% of all mutational events in kidney. TBM were also frequent in liver and adipose and infrequent in most other tissues. The frequency of TBM in liver increased dramatically with age. TBM frequency in kidney is at least 60-fold higher than in the germline. TBM are also rare in the human germline (one occurrence in 5,142 germline mutations present in human Factor IX, Factor VIII, HNPCC, and P53 mutation databases). Somatic TBM were more frequent in humans (P53, supF, HPRT and APRT databases). The pattern of somatic TBM mutations in the P53 gene was similar, although not identical in mice and humans (TBM related to UV-induced skin cancer were excluded). In general, the types of TBM were similar in mice and humans except for an excess of CA to TG TBM in humans. The data indicate that TBM are a significant fraction of mutations in certain somatic tissues and that the unknown endogenous mechanisms for TBM may be similar in mice and man.

Routine analysis of the CFTR IVS(8)T polymorphism discloses two pathogenic mutations. *C. Kraus¹, L. Naehrlich², S. Mattes³, A. Reis¹.* 1) Institute of Human Genetics, University of Erlangen-Nuremberg, Erlangen, Germany; 2) Pediatric Hospital, University of Erlangen-Nuremberg, Erlangen, Germany; 3) Pediatric Hospital of the Thuringen-Clinic, Salfeld, Germany.

Cystic fibrosis (CF) is the most common autosomal recessive disorder in the Caucasian population, caused by hundreds of mutations in the cystic fibrosis conductance transmembrane regulator (CFTR) gene. Routinely, we use an Oligonucleotide ligation assay (Applied Biosystems) to screen for 31 mutations in the CFTR gene, including 24 of the most common. Additionally, CFTRdele2,3(21kb), which occurs with a frequency of 1% in our population is analyzed by multiplex PCR. The application of these methods allows us to identify both disease causing mutations in 111 (87%) out of 127 proven CF patients. With regard to CBAVD the polymorphism IVS(8)T were examined by PCR/restriction analysis and subsequent PAGE. Generally, the poly-T tract in intron 8 exists in three variants, 5T, 7T, and 9T. The 7T and 9T variants generate a predominantly normal transcript, whereas the 5T allele reduces the level of functional CFTR and is associated with an inherited form of infertility in males (CBAVD). The existence of further allelic variants (3T, 6T and 8T) was shortly mentioned by Doerk et al. (2001). From our CF patients four out of 127 exhibited an abnormal migration pattern in the PAGE of IVS(8)T. In two patients PAGE results suggested a 6T allele in addition to a 9T and 7T allele, respectively. Sequencing, however, disclosed the 6T allele of one patient as a 7T allele carrying a splice site deletion (IVS8-1delG). In the other two patients PAGE displayed a 7T and 9T allele with an abnormal heteroduplex formation. In these cases a IVS8-2A->C transversion was discovered in cis with the 7T allele. By carefully evaluating the migration patterns we were able to identify the second disease allele in three additional patients. Thereby both disease causing mutations could be identified in 90% versus 87 % of our patients analyzed. We therefore conclude that any atypical T variant has to be carefully analyzed for the underlying mechanism.

Identification of a Putative New Hypochondroplasia Mutation in the Intracellular Juxtamembrane Domain of

FGFR3. *F.G. Lux III¹, A.S. Aylsworth², S.H. Blanton³, T.E. Kelly³, G.A. Bellus⁴ and The Genentech Hypochondroplasia Study Group.* 1) Dept Biol, Lander Univ, Greenwood, SC; 2) Dept. Pediatrics & Genetics, Univ. North Carolina, Chapel Hill, NC; 3) Dept. Pediatrics, Univ. Virginia, Charlottesville, VA; 4) Depts Dermatology, Pediatrics and Human Medical Genetics Program, University of Colorado, Denver, CO.

Dominant point mutations in the fibroblast growth factor receptor 3 (FGFR3) gene are known to cause several different forms of human dwarfism. Hypochondroplasia is one of the milder forms and it is estimated that 50 - 70% of all cases are caused by 2 point mutations (C1620A & C1620G) that result in an N540K amino acid substitution in the exon 13 proximal tyrosine kinase domain. There have been reports of rare cases of hypochondroplasia resulting from other FGFR3 amino acid substitutions occurring in exon 13 (N5540T, N540S, I538V), exon 15 (K650N, K650Q) and exon 9 (N328I). The underlying genetic etiologies in the remaining 30 -50% of hypochondroplasia diagnoses remain unknown and some genetic heterogeneity has been demonstrated. We have begun a screen for novel FGFR3 mutations employing the WAVE DNA Fragment Analysis System (Transgenomic, Santa Clara, CA) in hypochondroplasia patients in whom known FGFR3 mutations have been excluded. An examination of up to 12 exons from 42 individuals has resulted in the identification of a number of putative new polymorphisms or mutations in several FGFR3 exons. One putative new mutation (C1346T) results in a P449L substitution in exon 11, which encodes the intracellular juxtamembrane domain. This proline codon is highly conserved among all FGFR genes in chordates. We speculate that this amino acid substitution causes constitutive activation of FGFR3 and results in a hypochondroplasia phenotype.

Determination of the mutation spectrum in Dutch patients with Maturity Onset Diabetes of the Young (MODY).

M. Losekoot¹, A.W. de Visser¹, H.H.P.J. Lemkes², A.L.J. Kneppers¹, E. Bakker¹, J.A. Romijn², M. Breuning¹, J.A. Maassen³. 1) Centre for Human and Clinical Genetics, Leiden Univ Medical Ctr, Leiden, Netherlands; 2) Dept of Endocrinology, Leiden Univ Medical Ctr, Leiden, Netherlands; 3) Dept of Molecular Cell Biology, Leiden Univ Medical Ctr, Leiden, Netherlands.

Type 2 diabetes shows multifactorial aetiology with strong evidence for an inherited component. Several monogenic, highly penetrant type 2-like diabetes subtypes have been defined, accounting for about 5% of the Dutch diabetic patients. Among these, the most important is Maturity Onset Diabetes of the Young (MODY). MODY shows an autosomal dominant pattern of inheritance and can be divided in at least 7 subtypes (MODY1-7), each subtype being caused by mutations in a specific gene. The unambiguous molecular diagnosis of the specific MODY subtype allows the early diagnosis of diabetes that can help to prevent the development of diabetic complications. Also does it allow risk assignment for diabetic complications to particular diabetic subtypes. Presymptomatic testing in relatives at-risk allows an early diagnosis of their diabetes and close monitoring and treatment will help to prevent the development of diabetic complications. The DNA of a group of 81 patients, fulfilling the criteria for MODY, e.g. autosomal dominant pattern of inheritance and early-onset type 2 diabetes, was scanned by automated direct sequence analysis for the presence of mutations in the HNF-1alpha, glucokinase, HNF-4alpha, IPF-1, and HNF-1beta genes known to be involved in MODY types 1-5. In 28% of the patients a mutation in one of these genes was found. In 19% the HNF-1alpha gene was mutated, while in 5% a mutation in the glucokinase gene was found and in another 5% a mutation in the HNF-4alpha gene was present. No mutations in either the HNF-1beta or IPF1 gene were detected. *This study is financially supported by the Diabetes Fonds Nederland.*

Molecular investigation of Alagille syndrome in patients candidated to liver transplantation. *G. Massazza¹, P. Stroppa², M. Iascone¹, M. Poma¹, A. Sonzogni¹, A. Parma¹, B. Gridelli³.* 1) UO Anatomia Patologica; 2) UO Pediatria; 3) Centro Trapianti Fegato, Ospedali Riuniti, Bergamo, Italy.

Alagille syndrome (AGS) is an autosomal dominant developmental disorder, characterised by bile ducts paucity and resultant liver disease in association with cardiac, skeletal, ocular and craniofacial abnormalities. It is caused by deletions or mutations in the Jagged 1 (JAG1) gene located on chromosome 20p12, which encodes a ligand for Notch family receptors. In 15% of the AGS patients, hepatic involvement progresses to liver failure that requires organ transplantation. AGS shows highly variable penetrance, and diagnosis in mildly affected patients can be difficult. The JAG1 gene spans 36kb and consists of 26 exons, encoding a 5,5 kb transcript. The aim of our study was the screening of JAG1 alterations in paediatric patients with unexplained cholestasis, waiting for liver transplantation. Seven patients with strong clinical evidence of Alagille syndrome (AGS) and 9 children with unexplained cholestasis with some features of Alagille (p-AGS) together with their respective parents were enrolled in the study. The overall median age was 12,5 months (range: 50days-11years). We performed the screening of 20p12 deletions by STRP analysis, mapping into the region. SSCP analysis of JAG1 gene was carried out in no-deleted patients. We did not find any deletions but we detected 15 DNA alterations in JAG1 by SSCP analysis. DNA sequencing revealed presence of 2 nonsense, 2 missense, 7 silent and 4 intronic sequence variations. The sequence variations, causing an aminoacid substitution or truncation of the protein, were tested in the parents and in fifty unrelated and healthy controls. R235X and Q304X were de novo, instead P871R and R937Q were paternally inherited. The missense mutation P871R was a known polymorphism while R937Q was not found in 100 control chromosomes. In conclusion, we identified 3 mutations among the 7 AGS patients (43%) and no significative alterations in pAGS patients.

Identification of Novel CLN2 Mutations Reveals Canadian-Specific NCL2 Alleles. *W. Ju^{1,2}, R. Zhong⁴, S. Moore⁵, D. Moroziewicz^{1,2}, J. Currie², P. Parfrey⁵, W.T. Brown², N. Zhong^{1,2,3}.* 1) SCL-Molecular Neurogenetic Diagnostic Laboratory; 2) Dept. Human Genetics, New York State Inst Basic Res, Staten Island, NY; 3) Dept. Neurology, SUNY Downstate Health Center, Brooklyn, NY; 4) Stuyvesant High School, New York, NY; 5) Clinical Epidemiology Unit, Health Sciences Center, Memorial University of Newfoundland, St. Johns, NF, Canada.

Late-infantileonset neuronal ceroid lipofuscinosis (LINCL or NCL2) is among the most common childhood neurodegenerative disorders. It has been reported in the Canadian population. Among 23 Canadian families studied with molecular approaches, 20 were confirmed as having NCL2, the late-infantile onset NCL underlied by gene CLN2. The mutation G284V, which is found only in Canadian NCL2 and accounts for 55% of the NCL2 families and 32% of the mutant alleles, indicates that G284V presents as a founder mutation. Along with two other common CLN2 mutations IVS5-1GC, which accounts for 25% (10/40), and R208X (636CT), which accounts for 10% (4/40), of Canadian mutant NCL2 alleles, G284V should be applied to clinical molecular diagnosis for Canadian NCL2. As a result, molecular study of the three mutations for Canadian LINCL would detect 85% of NCL2 families and 67% of mutant NCL2 alleles. In addition, several novel mutations that are clustered in the distal coding sequence of the CLN2 gene have been identified in Canadian NCL2 alleles. The G284V mutation appears to interfere with normal protein folding and thus might cause the loss of function of the lysosomal enzyme tripeptidyl peptidase1 (TPP1), which is deficient in individuals with NCL2.

Program Nr: 2220 from 2002 ASHG Annual Meeting

Characterization of a Bgl I RFLP in DMPK gene and its implications in molecular diagnosis of Myotonic dystrophy. *L.N. Hjelm, K. Muralidharan.* Department of Pediatrics, Division of Genetics, Emory University School of Medicine, Atlanta, GA 30322.

Myotonic Dystrophy (DM) is an autosomal dominant muscle disorder caused by expansion of the CTG trinucleotide repeats in the DMPK gene. Point mutations, deletions, insertions in the DMPK have not been reported. PCR and Southern Blot analysis are used to determine CTG repeat sizes in DMPK gene. Southern blot analysis is used to detect large expansions not detectable by PCR amplification. We detected a novel Bgl I polymorphism in DMPK gene that could be mistaken for an expansion of CTG repeats. It was detected in a patient who had two normal size alleles in PCR but showed an 'expanded' allele in Southern analysis. Testing with other restriction enzymes did not detect an expanded allele. This variation does not appear to be pathogenic as it was also found in the father who was not symptomatic. A Hha I polymorphism in intron 5 and a Hinf I polymorphism in intron 9 of DMPK gene have been reported earlier. The site of the Bgl I polymorphism lies in the DMAHP gene at the 3' end of DMPK gene. This polymorphism could be source of false positive result in molecular diagnosis of DM using Bgl I restriction digestion.

Spectrum of mutations in the CLN6 gene. *C.A.F. Teixeira*^{1,2}, *J.E. Espinola*³, *C.J.P Bessa*², *A. Guimares*^{4,5}, *M.C.S Miranda*^{2,6}, *M.E. Mcdonald*³, *M.G. Ribeiro*^{2,6}, *R.M.N. Boustany*¹. 1) Pediatrics and Neurology, Duke University, Durham, NC; 2) Departamento de Neurobiologia Genetica do Instituto de Biologia Molecular e Celular da Universidade do Porto, Portugal; 3) Molecular Neurogenetics Unit, Massachusetts General Hospital, Charlestown; 4) Unidade de Neuropatologia, Hospital Geral de Santo Antnio, Porto, Portugal; 5) Departamento de Patologia e imunologia, Instituto de Cincias Biomdicas Abel Salazar, Universidade do Porto, Portugal; 6) Unidade de Enzimologia do Instituto de Genetica Medica do Porto, Portugal.

The neuronal ceroid lipofuscinoses (NCLs) are a genetically and clinically heterogeneous group of autosomal recessive neurodegenerative diseases. This group of diseases is characterized by the accumulation of autofluorescent lipopigment in various tissues, and by progressive cell death in brain and retina. Recently the CLN6 gene causing variant late infantile NCL in Costa Rican and Portuguese patients was identified (pLINCL; OMIM 601780). The number of mutations found suggests that the CLN6 gene may be a highly mutable gene. We summarize previously described mutations, and describe three novel mutations in the CLN6 gene. An American patient was found to be heterozygous for a 4bp insertion in exon 3. The mutation in the other allele consists of a point mutation in exon 7. The third novel mutation was identified in a Portuguese patient heterozygous for the I154del Portuguese CLN6 mutation. This third mutation is a double mutation of a 4pb deletion and a 1bp deletion in exon 7. Three Portuguese patients with a clinical profile similar to CLN6 patients, but no defects in the CLN6 gene or any other known NCL gene were identified. Our work has led to these conclusions: (1) variant late infantile Batten disease in Portugal is genetically heterogeneous (2) the CLN6 gene is mostly likely a highly mutable gene and (3) the I154del accounts for the CLN6 defect in 79% of Portuguese alleles studied (4) three variant late infantile Portuguese patients may have defects in a new NCL gene.

SHOX deletions and point mutations in 56 patients with short stature. *L. Stuppia*^{1,2}, *G. Calabrese*^{1,3}, *E. Morizio*^{1,3}, *V. Gatta*¹, *S. Pintor*¹, *P. Guanciali Franchi*^{1,3}, *D. Fantasia*^{1,3}, *G. Palka*^{1,3}. 1) Dept di Science/Biomed, Univ G D Annunzio, Chieti, Italy; 2) Istituto di Citomorfologia Normale e Patologica, CNR, Chieti, Italy; 3) Servizio di Genetica Umana, Ospedale di Pescara, Italy.

Stature is the result of interactions of several factors including those of genetic origin. About 3% of people suffer of short stature and in most of them the cause is unknown. Recently, the SHOX gene (Short Stature Homeobox containing gene), mapped on the pseudoautosomal region (PAR1) of the X and Y chromosomes, was specifically associated with the short stature of patients with Turner syndrome and those with Leri Weill dyschondrosteosis (LWD). Few data are reported about the relationship between SHOX mutations and idiopathic short stature. We investigated 56 patients with short stature of unknown origin, using FISH analysis for the detection of SHOX deletions, and direct sequencing of exons 2-6a for the screening of point mutations. With these approaches, we detected SHOX deletion in 4 cases (7.1%) and SHOX point mutation in 3 patients (5.3%). The mutations consisted of a C-G transversion on nucleotide 548 (C548G) within exon 3 leading to an Arg-Gly change within the SHOX homeodomain. The prevalence of SHOX deletions/mutations in this study are higher in respect to those present in the literature. These discrepancies are likely due to the limited number of reported cases and to the different techniques employed, particularly to the use of direct sequencing analysis, more sensitive than SSCP in detecting point mutations. Two patient with SHOX deletion and one with point mutation were submitted to rhGH treatment, showing a good response. Thus, it is possible to recommend the use of rhGH therapy in patients with SHOX rearrangements, since these have to be considered as Turnerian patients, who show a positive response to this treatment.

Maple syrup urine disease: A Common Novel Mutation Identified Among Affected Individuals of the Philippines.

C.L.T. Silao^{1,2}, *C.D. Padilla*², *H. Nakamura*³, *M. Matsuo*¹. 1) Division of Molecular Medicine, International Center for Medical Research, Kobe University Graduate School of Medicine, Kobe, Japan; 2) Department of Pediatrics, University of the Philippines College of Medicine-Philippine General Hospital, Manila, Philippines; 3) Department of Pediatrics, Kobe University Graduate School of Medicine, Kobe, Japan.

BACKGROUND OF THE STUDY: Defective function of the branched chain α -ketoacid dehydrogenase complex [BCKD] produces the clinical phenotype of Maple syrup urine disease [MSUD]. Several causal mutations have been identified in the 3 catalytic components comprising this enzyme complex, one of which is the dihydrolipoyl transacylase [E2] subunit. A study to determine the molecular basis of MSUD was carried out on 15 subjects belonging to 13 unrelated families from the Philippines. **METHODS:** The approach consisted of: (1) isolating DNA from peripheral blood of clinically diagnosed MSUD affected individuals and a normal control; (2) performing PCR amplification of the entire E2 subunit of the BCKD enzyme complex in both patient and normal control DNA; and (3) subsequent direct sequence analysis of the regions flanking the E2 gene defect. **RESULTS:** We identified the same novel molecular lesion in a large proportion of the subjects studied (10 of 15) with 7 of them, belonging to 5 unrelated families, being homozygous for the mutation. Two of the 3 compound heterozygote patients presenting with this common novel mutation had novel missense mutations. Another previously reported missense mutation was also found in 2 other compound heterozygotes. **CONCLUSION:** This study provides the molecular basis for understanding this genetic disorder among Filipino MSUD patients. The novel mutation in our subjects suggests that identification of this mutation will facilitate, if it is an option, prenatal diagnosis of affected families. Effective carrier detection may decrease the incidence and/or the morbidity associated with delayed diagnosis of this disorder among future Filipino MSUD patients.

***NROB-1* Intragenic Inversion Causes Adrenal Hypoplasia Congenita (AHC).** *Y. Zhang, U. Bhardwaj, B.H. Huang, M. Karpodinis, E.R.B. McCabe.* Departments of Pediatrics and Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA 90095-1752.

X-linked Adrenal Hypoplasia Congenita (AHC) is a rare developmental disorder of the adrenal cortex. It is caused by molecular defects in the *NROB1* gene, which result in primary adrenal insufficiency and Hypogonadotropic Hypogonadism encoding DAX1 (HH). Most commonly, mutations of the *NROB1* gene include frameshifts and single nucleotide substitutions or large intergenetic contiguous gene deletions. Although more than 85 such mutations have been reported for *NROB1* to date, no large intragenic rearrangements have been documented. Here, we report the first case of AHC due to an interstitial inversion with breakpoints within exon 1 and the intron. The full coding region and the intron/exon boundaries of the *NROB1* gene were amplified into overlapping segments and sequenced. Dot blot hybridization was used to confirm the results. Using long PCR we were able to amplify exon 2. However, we could only amplify the 5 regions of exon 1 and the intron. The inconsistency of amplification in the 3 regions suggested the possibility of an inversion in this region. The exact breakpoints were precisely determined by PCR amplification and sequencing. Two pairs of primers were designed across the possible 5 and 3 junction, and subsequent PCR analysis indicated a nearly 3.5 kb inversion with a 3 contiguous 3 bp deletion (CTT) involving breakpoints within exon 1 and the intron: g.673_4161inv3488; 4162_4164delCTT. Knowing that intragenic inversions may occur within the *NROB1* gene raises important diagnostic issues. If one breakpoint is within an exon, as in our patient, the inversion should be identified when PCR amplification of the coding region fails. However, if breakpoints occur in the non-coding region, an inversion may be missed by PCR assays that are designed to analyze the coding region. If AHC is diagnosed clinically and no deletion or *NROB1* mutation is identified, then the possibility of an inversion should be considered.

Mutation Analysis and Genotype -Phenotype Correlation in a family with Mutations in *DNAH5* and Primary Ciliary Dyskinesia (PCD). M. Zariwala¹, P.G. Noone¹, A. Sannuti¹, S.L. Minnix¹, M. Hazucha¹, J.L. Carson¹, M.W. Leigh¹, H. Olbrich², H. Omran², M.R. Knowles¹. 1) Pulmonary / CF Research and Treatment Center, University of North Carolina at Chapel Hill, NC. USA; 2) Universitats-Kinderklinik, Freiburg, Germany.

Primary ciliary dyskinesia (PCD) is an autosomal recessive disorder associated with chronic sino-pulmonary infection. ~ 50% of the patients have situs inversus (SI) (Kartagener's syndrome). Clinical phenotype is caused by abnormalities of ciliary structure/function. *DNAH5* mutations have been shown to cause PCD and randomization of left/right asymmetry in patients with outer dynein arm defects (ODA). Recently, a homozygous splice mutation [IVS74-1G->C] in *DNAH5* has been identified in 2 siblings with PCD born to consanguineous couple (Olbrich et al. 2002). This mutation is predicted to cause loss of exon 75, and result in a truncated protein with loss of 72 amino acids. Both males (10 & 5 yr.) presented with recurrent oto-sinu-pulmonary infections. The younger sibling was born with SI and neonatal respiratory symptoms. This led to the diagnosis in him, plus an older sib without SI. Both had normal lung function. Carrier analysis was carried out in 13 family members. Parents, two maternal aunts, one maternal uncle and maternal grandfather harbored the mutation on one allele. The parents and unaffected sibling (7 yr.) were clinically normal. Nasal NO (nl/min; normal 36925) levels were severely reduced in patients (2 and 7), and intermediate in the parents (215, 212). Ciliary ultrastructure showed absent/shortened ODA (IDA) in both affecteds; the parents had mild shortening of DA (nm) relative to normal (IDA=12.2 vs 16.0, ODA 17.5 vs 21). This suggests obligate carriers may have sub-clinical biologic defects, such as lower than normal levels of nasal NO and slight shortening of DA. This family with clinical PCD provides an ideal opportunity to test the hypothesis that this splice-site mutation may results in a very reduced (or absent) level of expression of full-length transcript, and thus a truncated protein, manifested by shortened, stubby ODA. Quantitative estimates of *DNAH5* mRNA are underway. Supported by "CRU#RR00046".

A novel CACNA1A missense mutation in a family with EA-2 results in complete loss of P/Q-type calcium channel function. *K.A. Scoggan^{1,3}, J.E. McRory⁴, C.M. Santi⁴, T.P. Snutch⁴, J.H. Friedman⁵, D.E. Bulman^{1,2}.* 1) Ottawa Health Research Institute, Ottawa, ON, Canada; 2) Division of Neurology, Ottawa Hospital-General Campus, Ottawa, ON, Canada; 3) Nutrition Research Division, Health Canada, Ottawa, ON, Canada; 4) Biotechnology Laboratory, University of British Columbia, Vancouver, BC, Canada; 5) Brown University, Division of Neurology, Memorial Hospital of Rhode Island, Pawtucket, Rhode Island, NY, USA.

Episodic ataxia type-2 (EA-2) is an autosomal dominant neurological disorder that is usually caused by mutations in the CACNA1A gene that result in premature termination of translation. Affected individuals experience discrete episodes of cerebellar ataxia usually associated with migraine symptoms and respond to acetazolamide. We identified a 27 year old woman who began exhibiting signs of episodic ataxia at age 12. The "attacks" lasted about 20 minutes, were occasionally precipitated by stress, and sometimes preceded by a headache. Family history was positive for episodic ataxia, although a number of affected individuals in this family were originally thought to have some form of epilepsy. Initially the proband was placed on acetazolamide, but over time the attacks returned to their normal frequency. A combination of acetazolamide and valproic acid provided effective relief from attacks. At present her daughter, who appears to have similar symptoms, is responsive to acetazolamide treatment alone.

Mutational analysis of the CACNA1A gene revealed a novel missense mutation in exon 12, which was found only in affected family members. This G to A transition changes a highly conserved glutamic acid residue to a lysine residue in domain II S2 of the P/Q-type calcium channel α_{1A} ($Ca_v2.1\alpha_1$) subunit. Expression of the mutant channel *in vitro*, resulted in complete loss of channel function.

Clinical and Molecular Studies in 5 families with Limb Girdle Muscular Dystrophy/Hereditary Inclusion Body Myopathy, Paget disease of Bone and Frontotemporal dementia. *G.D.J. Watts¹, M. Thorne¹, M.J. Kovach², A. Pestronk³, V.E. Kimonis¹.* 1) Department of Genetics, Children's Hospital Boston, Harvard Medical School, Boston, MA; 2) Department of Biological and Environmental Sciences, University of Tennessee at Chattanooga, Chattanooga, TN; 3) Dept. of Neurology, Washington Univ. School of Med., St Louis, MO.

We have previously demonstrated linkage to 9p 13.3-p12 in a large family with Limb Girdle Muscular dystrophy and Paget disease of bone and an additional 3 families with autosomal dominant inclusion body myopathy (HIBM), Paget disease of bone (PDB) and frontotemporal dementia (Kovach et al 2001). Linkage in these families and an additional one with this unique combination identifies a critical locus on 9p 13.3-p12 spanning 4-6 MB.

Clinical features in 57 affected individuals in 5 families indicate that 51 had muscle weakness in variable patterns involving proximal, and, occasionally, distal muscles. With disease progression, the weakness became more generalized, often resulting in respiratory failure.

Muscle histology reveals myopathic changes and rimmed vacuoles. PDB caused by overactive osteoclasts was present in 51/57 primarily involving the spine and hip, causing pain, elevated alkaline phosphatase, and urine pyridinoline/ deoxypyridinoline and is responsive to bisphosphonates. Frontotemporal dementia associated with relative sparing of memory and impairment of executive skills occurred in 21/57 at a mean age of 54 y.

Recently mutations in the GNE (UDP-N-acetylglucosamine 2-epimerase) gene which maps to 9p13-p12 have been found in IBM2, an autosomal recessive inclusion body myopathy associated with quadriceps sparing. No mutations were found in the GNE gene in affected individuals in our families indicating that LGMD/HIBM/PDB/FTD is not allelic with IBM2. Candidate gene tropomyosin 2, NDUFB6 and SMU1 were also not implicated. Identification of the genes for this complex disorder is a priority in understanding these common pathways/ pathogenetic mechanisms.

Three-Year Experience with Mutation Studies for the International Long QT Syndrome Registry at Rochester: Screening, Molecular Spectrum, Mutation "Hot-spots", Phenotypic Variations, and Genotype-Phenotype

Correlation. *M. Qi*^{1,2}, *A. Moss*³, *L. Ning*^{1,2}, *W. Zareba*³, *J. Robinson*³, *Y. Xu*^{1,2}, *S. Rosero*³, *E.S. Kaufman*⁴, *C. Ohle*⁵, *T. Kelly*⁵, *D. Ryan*¹. 1) Dept Pathol/Lab Med; 2) Center for Cardiovascular Research; 3) Dept Med, Univ Rochester, Rochester, NY; 4) Heart & Vasc Res Ctr, MetroHealth Campus, Case Western Reserve Univ, Cleveland, OH; 5) Dept Ped (Genet), Univ Virginia, Charlottesville, VA.

Multiple cardiac ion channel genes have been identified in the hereditary long QT syndrome (LQTS), an arrhythmogenic disorder characterized by an unusual electrocardiographic abnormality (QT prolongation) and a propensity to syncope, polymorphous ventricular tachycardia (torsade de pointes), and sudden death. Since the establishment of the molecular genetics LQTS research program at URMC in 1999, we have set up molecular testing for all 6 known LQT genes and over 400 patients have been analyzed. Multiple novel mutations responsible for LQTS have been identified. Due to their multiple loci and considerable size, mutation detection in these genes represents a challenge that is only partially met by the conventional screening method of single stranded conformational polymorphism (SSCP). We tested the applicability of dHPLC in the molecular diagnosis of LQTS by assessing a cohort of 194 patients with 12 previously identified mutations (including 8 different missense mutations, 1-bp, 2-bp, 3-bp and 9-bp deletion mutations), and 2 polymorphisms in the LQTS genes. All mutations/SNPs were readily detected, including one undetectable by SSCP previously. Our data showed that the dHPLC technology is highly sensitive and efficient and it is now routinely used in our molecular analysis of LQTS. Multiple types of pathogenic mutations have been identified, including missense, nonsense, splice site, in-frame deletions, and frameshift mutations. While those mutations could be found in nearly all coding regions of the responsible genes, they were particularly frequent in the pore regions. The mutations in the HERG pore region manifest most severe clinical phenotypes for LQTS2. LQTS shows considerable variation in reduced penetrance and expressivity, even within families.

Pantothenate kinase associated neurodegeneration: *PANK2* gene structure, mutations, and molecular diagnosis.

*S.K. Westaway*¹, *B. Levinson*², *K.H.L. Ching*¹, *B. Zhou*², *M.A. Johnson*¹, *R.J. Coryell*¹, *J. Gitschier*², *S.J. Hayflick*¹. 1) Departments of Molecular and Medical Genetics, Pediatrics and Neurology, School of Medicine, OHSU, Portland, OR; 2) Howard Hughes Medical Institute & Departments of Medicine and Pediatrics, University of California, San Francisco, CA.

Pantothenate kinase associated neurodegeneration (PKAN), previously known as Hallervorden-Spatz syndrome, is an autosomal recessive neurodegenerative disorder caused by mutations in the pantothenate kinase 2 gene (*PANK2*). The *PANK2* sequence was obtained from two adjacent chromosome 20p clones. The mRNA is approximately 1.85 kb by Northern blot analysis. The cDNA is predicted to be 1383 nt from start to stop codon, encoding a protein of 460 amino acids with a predicted molecular weight of 50.6 kDa. Details on the structure of the gene were determined from RACE PCR and bioinformatics research. *PANK2* mRNA has 7 exons, initiated by several alternative first exons. Tissue expression analyzed by PCR from cDNA collections indicates a global expression pattern.

To date, 64 distinct *PANK2* mutations and 8 variations have been identified. All but 2 of 16 deletion or insertion mutations cause frameshifts resulting in a premature stop codon. These mutations, along with 7 nonsense and 5 splice site mutations, are predicted to result in no protein product. The G411R and T418M missense mutations in exon 6 are the most common mutations found in PKAN patients, together representing over 30% of mutant alleles. G411R occurs on a common haplotype of markers in 15 of 19 haplotyped patients. This suggests a founder effect about 400-1600 years ago. G411 is conserved among all human and mouse PANK paralogs and many pantothenate kinases from other species. Most other mutations in PKAN patients are present only in a single family. A screening protocol for genetic testing and prenatal diagnosis using PCR and sequencing has been developed. Information obtained from the study of *PANK2* mutations in PKAN patients may provide clues to the function, structure, catalysis, localization and intermolecular interactions of the PANK2 protein and the importance of specific amino acids or domains in fulfilling those roles.

Deletion analysis of the 15q11-q13 region by real-time quantitative PCR. *G. Raca*¹, *R. Brown*¹, *K. Buiting*², *S. Das*¹. 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Institut für Humangenetik, Universitätsklinikum Essen, Essen, Germany.

Large gene deletions, particularly intragenic deletions, are often difficult to detect by standard PCR-based mutation detection methodologies. A promising approach to the identification of gene deletions is by real-time quantitative PCR (QPCR). We have applied this technique to the identification of deletions in the imprinting control center (IC) region on chromosome 15 in patients with Prader-Willi (PWS) and Angelman syndrome (AS), as a model for the study of gene and intragenic deletions by real-time QPCR. The PCR was performed in real-time using fluorescent hybridization probes for detection, in a duplex reaction with a control gene, using the LightCycler system. The *SNRPN* exon 1 and IC3 regions, which represent the smallest region of overlap for the PWS-IC and AS-IC regions respectively were the targeted regions for analysis and the b-globin gene was used as the control. We have analyzed over 50 normal DNA samples, 15 samples with known AS-IC deletions, and 15 samples with known PWS-IC deletions. For all the normal DNA samples the ratio of AS-IC or PWS-IC to b-globin was between 0.8 and 1.3. All samples with a deletion gave a ratio of 0.4 to 0.6, indicating a decrease in the relative concentration of the IC region as compared to the b-globin control. In addition, we have analyzed a series of 13 blinded samples and correctly identified the deletion status of all the samples. This assay will be important for the deletion analysis of the IC region in patients with PWS and AS and can be used for diagnostic purposes. We are currently performing a study to determine the incidence of intragenic deletions in the *UBE3A* gene in patients with AS. Mutations in the *UBE3A* gene have only been found in 14-38% of AS patients with normal methylation and it is possible that large intragenic deletions of the *UBE3A* gene are being missed in this group of patients. We are analyzing a series of patients with an AS phenotype and no identifiable molecular abnormality for deletions in the *UBE3A* gene by real-time QPCR. Results of our deletion analysis will be presented.

Ellis-van Creveld: A genetically heterogenous syndrome? *S.W.J. Tompson¹, V. Ruiz-Perez¹, E. Oliveira da Silva², L. Algazali³, M. Wright¹, J. Goodship¹*. 1) Institute of Human Genetics, University of Newcastle, Newcastle upon Tyne, UK; 2) Instituto Materno-infantil de Pernambuco, Recife, Brazil; 3) Faculty of Medicine, United Arab Emirates University, UAE.

Ellis-van Creveld syndrome [MIM 225500], an autosomal recessive skeletal dysplasia, is characterized by short limbs, short ribs, postaxial polydactyly, dysplastic nails and teeth and congenital cardiac defects. We have now screened 58 samples for mutations by direct sequencing of coding exons and fluorescent dosage PCR analysis. In total we have identified mutations in 13 patients (4 previously reported) which include deletions, insertions, missense, nonsense and splicing mutations. In all of these patients both changes have been identified and three mutations were seen in more than one family (S307P, 873insT, 1694delC). The lack of mutations in 45 patients (77%) raises the possibility of genetic heterogeneity. We have, therefore, carried out microsatellite analysis in 7 consanguineous pedigrees with no identified mutation. Affected individuals in each of these families were homozygous across the EvC gene and surrounding region. In a large consanguineous Brazilian family with six affecteds included in the analysis, an unaffected individual placed the mutation upstream of exon 12 and yet the causative mutation remains elusive. The mapping is therefore consistent with EvC being a single gene disorder; the fact that we have not identified mutations in the majority of patients suggests a common mutation mechanism that is missed by exon sequencing, such as an inversion. We obtained fibroblasts from two patients and the cDNA sequence was normal arguing against this hypothesis and again raises the possibility of genetic heterogeneity. This issue is yet to be resolved. We have also undertaken microsatellite analysis in consanguineous families with the phenotypically overlapping disorders, Jeunes asphyxiating thoracic dysplasia and short-rib polydactyly type III syndrome (SRPIII), and found that affected individuals are not homozygous for this region indicating that these disorders are not allelic with EvC.

Gross rearrangements in the *MECP2* gene in two patients with Rett syndrome. *E. Schollen, E. Deflem, E. Smeets, J.P. Fryns, G. Matthijs.* Center for Human Genetics, Univ Leuven, Leuven, Belgium.

Since the identification of *MECP2* as the disease gene in Rett syndrome in 1999 (MIM #312750), numerous publications describe mutations in this gene. Depending on the clinical selection criteria, mutations are found in 60-85% of the patients with typical Rett syndrome. The mutation spectrum in *MECP2* is mainly composed of single base changes, and small deletions in the C-terminal region. A limited number of more complicated rearrangements or bigger deletions (up to 400 bp) have been described. Most of the screenings are PCR based and restricted to the coding region. Therefore, major rearrangements or mutations in the regulatory regions might be missed.

Routine DHPLC screening of *MECP2* identified mutations in 43 of 68 Belgian patients with typical Rett syndrome. All frequent mutations were represented in this group as well as some C-terminal deletions and 4 new point-mutations. In a further attempt to find the molecular defect in a selection of 15 patients with a typical Rett presentation but no mutations upon routine screening, Southern blot was performed with a probe encompassing the coding region of exon 4 and part of the 3'UTR. Abnormal patterns were detected in two patients, suggesting major rearrangements of this region. These most probably result in disruption of the 3'UTR of the *MECP2* gene. Although the exact function of the long 3'UTR is not yet known, the strong conservation of this region between mouse and human as well as the tissue dependent expression of the two *MECP2* transcripts point to an important regulatory function. Further experiments are ongoing to identify the precise genetic defect.

These observations are unique but underline the limitations of the PCR-based diagnostic approaches.

MECP2 mutation screening in Brazilian patients with Angelman syndrome-like phenotype. *C. Fridman, M.C. Varela, C.P. Koiffmann.* Dept Biol, Univ Sao Paulo, Sao Paulo, Brazil. cintiafri@hotmail.com.

Angelman syndrome (AS) is characterized by hypotonia, severe mental retardation, absent speech, seizures, ataxia, outbursts of laughter, macrostomia and prognathism. Most of the cases present genetic abnormalities at chromosome 15q11-q13 (70% maternal deletion, 1-5% paternal uniparental disomy and ~8% UBE3A mutations), in ~10% of patients the genetic mechanism is unknown. Rett syndrome (RTT) is one of the main cause of severe mental retardation in girls and is characterized by autism, apraxia, seizures, stereotypic hand movements, and deceleration of head growth. After a period of normal development, the patients show a regression of motor and mental abilities (between 6 months and 3 years); they gradually lose speech and purposeful hand use. It is a dominant X-linked disorder, usually associated with male lethality, caused by mutations in the MECP2 gene. MECP2 mutations may occur in patients with typical and also atypical RTT phenotype showing that there is a broader spectrum of the disease. Since one of the differential diagnosis of AS is RTT, we have screened for mutations in the MECP2 gene 28 female patients with a clinical course compatible with AS in whom SNRPN methylation and UBE3A mutation analysis were normal. The main phenotypic and behavioral characteristics considered for AS inclusion criteria were mental retardation, neurodevelopmental delay, language impairment, happy demeanour and/or outbursts of laughter. PCR amplification was done with primers covering the MECP2 coding exons and the products were sequenced on an automated sequencer using the Dye Terminator method; the results were compared with the reference human MECP2 sequence (GenBankX99686). Two missense mutations (R306M, T158M) and two polymorphisms (S411) were identified. One of the polymorphisms was also present in the patient with T158M mutation. Since methylation analysis of SNRPN gene does not allow diagnosis in 10% of the AS patients, female patients with neurodevelopmental delay, mental retardation, language impairment, happy demeanour, inability to walk or ataxic gait and normal methylation pattern should be tested for MECP2 mutations. Support: FAPESP, CEPID, CNPq.

Identification of a novel mutation in *FBNI* in a patient with tall stature and ectopia lentis lacking marfanoid habitus. *M. Mamada, T. Yorifuji, K. Kurokawa, M. Kawai, T. Nakahata.* Pediatrics, Kyoto University Hospital, Kyoto, Japan.

Introduction: Marfan syndrome (MFS) is an autosomal dominant heritable disorder of connective tissue. The defective protein is fibrillin-1, the 350-kDa extracellular glycoprotein, encoded by *FBNI* mapped to chromosome 15q21.1. Mutations in *FBNI* give rise to not only MFS but also other related disorders such as isolated ectopia lentis, Shprintzen-Goldberg syndrome and MASS phenotype. We report a case characterized by tall stature and ectopia lentis with a defect in *FBNI*. **Patient Profile:** Patient is a 9-year-old boy who was born to clinically normal parents. Bilateral ectopia lentis was diagnosed at the age of 3 years. He has no cardiac manifestations other than annuloaortic ectasia. As skeletal features he has only tall stature (3.5SD), completely lacking marfanoid habitus and other skeletal anomalies. He does not fulfil the Gent criteria for MFS. **Materials and Methods:** Mutation in the *FBNI* mRNA was detected by RT-PCR amplification and direct sequence analysis. Southern blot analysis was carried out to confirm the mutation in the genomic DNA. **Results:** Direct sequence analysis revealed the 459 bp in-frame deletion covering a part of exon 6, whole of exons 7 and 8 and a part of exon 9. What was a distinctive feature was the same 12 bp sequence appeared at both ends of the deletion. Southern blot analysis did not reveal any difference of the band pattern compared to the control, showing the deletion was existed only in patients mRNA, not in genomic DNA. No sequence alteration was detected in exons 6 to 9, suggesting that the splicing error did not explain the mechanism of this mutation. **Discussion:** In this study we identified a novel mutation in *FBNI* with a patient of unique phenotype that has not been reported to date. The phenotype is very interesting when we consider the genetic factors to affect stature, because the defect of *FBNI* is associated with tall stature showing no typical skeletal features of MFS. This suggests that tall stature and Marfan-like skeletal form can be separated in the fibrillinopathy. To our knowledge this type of mutation has not been reported to date. Its mechanism gives us a great interest and is now elucidating.

Haplotype analysis of the tyrosinase (*TYR*) gene. *R.A. King, J.E. Pietsch, J.D. Lande, J.P. Fryer, W.S. Oetting.*
Department of Medicine and Institute of Human Genetics Univ Minnesota, Minneapolis, MN.

Tyrosinase is the major enzyme involved in pigmentation in all animal species, and the human *TYR* gene and its protein product show great homology to lower organisms. Mutations of the *TYR* gene produce oculocutaneous albinism type 1 (OCA1) and more than 100 different mutations in OCA1 have been identified. We have now created extended haplotypes of the *TYR* gene to analyze the evolution of the human gene and the origin of the mutations. Four single nucleotide polymorphisms (SNPs) were identified in the 5' region of the *TYR* gene by sequencing 4000 bp of the 5' promoter region in DNA from 13 families [-3879 (g->a), -3748 (a->c), -3421 (g->a), and 3046 (g->a)]. A polymorphic LINE insertion (at 2093) was also identified. Extended haplotypes were then constructed from analysis of 159 chromosomes from probands and parents of 54 OCA families, and 151 chromosomes from 59 control normally-pigmented trios (child and parents). All samples were predominantly Caucasian. The extended haplotypes included the 4 new SNPs, the insertion, and the known polymorphisms at 301 (c->t), -199 (c->a), codon 192 (C->A), codon 402 (G->A), and the *Taq* I site in intron 1. The chimpanzee *TYR* gene was used to determine the root ancestral haplotype. A total of 21 extended haplotypes were identified in 310 chromosomes. The haplotype distribution of 31 different mutations associated with OCA1 showed that all but one mutation occurred on a single haplotype indicating that most were founder and not recurrent mutations; one mutation was found on 2 distinct haplotypes. Components of the Phylip analysis package were used to construct the most parsimonious phylogenetic haplotype tree, showing three major evolutionary branches in the development of this gene. 21/31 (68%) of the mutations were on 3 haplotypes. We conclude that tyrosinase gene haplotypes associated with OCA1 mutations provide a historical view of this gene in humans.

Analysis of CFTR gene mutation frequency in a random European population. *G. Modiano*¹, *C. Bombieri*², *M. des Georges*³, *V. Scotet*⁴, *M. Toepfer*⁵, *B.M. Ciminelli*¹, *F. Belpinati*², *C. Guittard*³, *M.P. Audrezet*⁴, *S. Giorgi*¹, *A. Begnini*², *M. Koudova*⁵, *F. Pompei*¹, *C. Ciccacci*¹, *M. Macek jr*⁵, *FC. Ferec*⁴, *M. Claustres*³, *P.F. Pignatti*². 1) Dpt. Biology E Calef, Univ. Rome Tor Vergata, Italy; 2) Sec. Biol. Genet, DMIBG, Univ. Verona, Italy; 3) Inst. Biol., Univ. Montpellier, France; 4) Centre de Biogenetique CDTS, Brest, France; 5) Dpt. of Mol. Genet. CF-Centre Charles Univ., Prague, Czech Rep.

In a study on 2530 CFTR alleles from random individuals from Italy, France, and Czech Republic, we have identified 16 CFTR Single Nucleotide Substitutions (10 of which in the coding sequence: cSNS) which are certainly non CF-causing because for each of them the frequency ($q - 2.5$ se) is higher than the combined frequency for Europe of the non well characterized CF-causing alleles (ca. 0.004). The sample size required for this approach has been so large as to make possible to study the pattern of variation of the CFTR genes carrying the M470 allele (the ancestral one) separately from those with the 470V allele. It turned out that all types of variation are preferentially located in the M470-CFTR genes; indeed some of them are even 'M470 allele-restricted'. Due to this heterogeneous distribution of the CFTR gene variability among its two M470V alleles it is possible to estimate from the present data that the probability of being a CF risk couple for the MM x MM couples is about 130 fold higher than for the VV x VV couples. The present study has been concerned with the coding sequence of only one gene. However, the sample size was so large as to allow one to examine a range of variability (the sub-polymorphic quasi-polymorphic range) never explored before. The main findings of this large scale study have been the following: 1) the number of detected cSNS is proportional to the square root of n genomes; 2) the cSNS-MS (MisSense) have a probability of occurring with a sub-Polymorphic frequency equal to that of the cSNS-SS (SameSense), whereas the probability of the cSNS-MS of being polymorphic is about fourfold lower than that of the cSNS-SS. This implies that selection has prevented the vast majority of the cSNS-MS from becoming polymorphic.

Evidence of a founder effect for the RETGC1 (GUCY2D) 2943delG mutation in Leber congenital amaurosis pedigrees of finnish origin. *S. Hanein¹, I. Perrault¹, P. Olsen², T. Lopponen², M. Hietala³, S. Gerber¹, M. Jeanpierre⁴, F. Barbet¹, D. Ducroq¹, S. Hakiki¹, A. Munnich¹, J.M. Rozet¹, J. Kaplan¹.* 1) INSERM U393, Hopital des Enfants Malades, Paris CDX15, FRANCE; 2) Dpt of Clinical Genetics, Oulu University Hospital, Oulu, Finland; 3) Clinical Genetics Unit, Turku University Hospital, Turku, Finland; 4) INSERM-EMI 0005, Hopital Cochin, Paris CDX14, France.

Leber congenital amaurosis (LCA) is the earliest and most severe form of all inherited retinal dystrophies. It is a genetically heterogeneous condition as six disease-causing genes have been hitherto identified. RETGC1 (GUCY2D) is more frequently implicated in our series of LCA patients. Interestingly, 70 % of the families with RETGC1 mutations are originating from Mediterranean countries, the remaining families (30 %) originating from various regions worldwide. Here, we report the screening of the RETGC1 gene in three unrelated and non consanguineous families of Finnish origin. The 21 exons of the RETGC1 gene as well as intron-exon boundaries were screened for mutations in one affected patient of the three families using DHPLC and direct sequencing. Linkage disequilibrium studies were performed by haplotyping all available family members of the three using polymorphic markers flanking the RETGC1 gene. All patients of the three Finnish families studied here were found to carry the same homozygous delG2943 mutation. The segregation of the mutation with the disease was confirmed in all three pedigrees. The identification of a unique homozygous mutation in three unrelated and non consanguineous families suggests a founder effect. Interestingly, no linkage disequilibrium was found using polymorphic markers flanking the RETGC1 gene, supporting the view that the mutation was very ancient. Bayesian calculations points the founder mutation to 150 generations (95% credible interval 80-240 generations), ie 3000 years ago.

Survey of Molecular Lesions Causing Genetic Disease in the Old Order Amish and Conservative Mennonites of Lancaster County, PA. *E.G. Puffenberger, D.H. Morton.* Clinic for Special Children, Strasburg, PA.

The Clinic for Special Children is a non-profit medical service for patients with inherited metabolic disorders. The clinic mainly serves Old Order Amish and conservative Mennonite families in eastern Pennsylvania. These Plain sects have an unusually high incidence of specific genetic diseases. In a continuing effort to provide molecular diagnostic services, we have identified and/or verified the molecular lesions which segregate in these populations. We and others have identified 34 molecular lesions in 26 different genes which cause disease in these two groups. For each disease, we have verified the published mutations in our patient population. For diseases where the mutation had not been previously identified, we sequenced the genes and identified mutations. In our survey, 20 disorders were caused by a single mutation segregating in the population. However, 6 monogenic diseases exhibited mutation heterogeneity. Notably, we sequenced the SLC3A1 and SLC7A9 genes in five Mennonite cystinuria patients. We were surprised to identify 4 separate mutations (2 at each locus), 3 of which were novel. Other disorders demonstrating mutation heterogeneity include congenital nephrotic syndrome, mevalonate kinase deficiency, phenylketonuria, and familial hypercholanemia. Several diseases are found in both populations. This is not wholly unexpected as there are known genealogical ties and they have a shared Anabaptist history. In Crigler-Najjar syndrome, the same mutation in UGT1A1 segregates in both populations. We confirmed a common haplotype by microsatellite marker analysis of the UGT1A1 region on chromosome 2. Conversely, 3-methylcrotonylglycinuria is found in both populations, but a different mutation in MCCB causes disease. Assessment of mutation frequency was performed for several diseases using disease incidence and genotyping. For example, we estimated the incidence of maple syrup urine disease (MSUD) in the Mennonites for the period 1985-1994. The incidence, 1/378 births, yielded a carrier frequency of 9.8% (without correction for inbreeding) and a carrier frequency of 7.7% with an inbreeding coefficient of 0.0219.

The dominant-negative action of mutant SOX10 seen in patients with simple WS4 is potentially diminished apparently due to nonsense-mediated decay. *M. Khajavi, K. Inoue, J.R. Lupski.* Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

Waardenburg's syndrome (WS) is an autosomal dominant disorder which causes deafness and pigmentary disturbances due to defective function of the embryonic neural crest. In association with sensorineural deafness and pigmentary abnormalities, congenital aganglionosis has been reported, a combination called Waardenburg-Hirschsprung syndrome type 4 (WS4). The involvement of two neural crest derived lineages indicates a common regulatory pathway shared between enteric ganglia and melanocytes. In the heterozygous state, spontaneous mutation of *SOX10* which results in premature terminations has been identified in patients afflicted with WS4. Each of these mutations is likely to result in a null allele, suggesting haploinsufficiency of the *SOX10* product. Interestingly, in a more severe neurocristopathy, including leukodystrophy compatible with Pelizaeus-Merzbacher disease (PMD) and CMT1-type peripheral myelinopathy accompanying WS4, were reported in which an extended proline rich tail that was added to the transactivation domain of the *SOX10* protein was observed. This led to the hypothesis that this mutant may give an additional or different function to the transactivation domain of *SOX10* and result in a dominant negative allele. Further mutations of *SOX10*, each of which results in premature terminations in the last exon of *SOX10*, have been reported in WS4 patients with both CNS and PNS myelinopathy. We hypothesized that the dominant-negative action of *SOX10* nonsense mutations in patients with simple WS4 is mitigated by the nonsense-mediated decay pathway. To address this hypothesis, we have characterized *SOX10* mutations found in WS4 patients with or without myelinopathies by introducing such disease associated mutations in an expression vector and using transiently transfected U138/cos7 cell lines. Both mutation types interfere with the wild-type *SOX10* transcription activity, suggesting dominant-negative functions. Current experiments are addressing a potential role for nonsense-mediated decay in the abrogation of dominant-negative effects of selected mutant alleles.

Non-classic cystic fibrosis phenotypes in the absence of *CFTR* mutations. *J.D. Groman*^{1,2}, *B. Karczeski*¹, *M.E. Meyer*¹, *P.L. Zeitlin*³, *R.W. Wilmott*⁴, *G.R. Cutting*^{1,2,3}. 1) McKusick-Nathans Inst. of Gen. Med., Johns Hopkins Sch. of Med., Baltimore, MD; 2) Training Program in Human Genetics, Johns Hopkins University Sch. of Med., Baltimore, MD; 3) Dept. of Pediatrics, Johns Hopkins Sch. of Med., Baltimore, MD; 4) Dept. of Pediatrics, Saint Louis Univ. Sch. of Med., St. Louis, MO.

Identification of *CFTR*, the gene responsible for Cystic Fibrosis, is regarded as one of the triumphs of positional cloning. Subsequently, mutations causing loss of function were identified in each *CFTR* gene in patients with classic CF, while mutations that reduce but do not eliminate *CFTR* function were found in patients with non-classic forms of CF. Patients with the classic form of CF have manifestations in the sweat gland, pancreas, respiratory tract, and male reproductive tract, whereas patients with non-classic CF have manifestations limited to a subset of the aforementioned organ systems. To determine the entire spectrum of mutations associated with non-classic CF phenotypes, we performed extensive analysis of the *CFTR* gene on 99 non-classic CF patients who failed to test positive for two CF causing mutations prior to referral. Mutations in each *CFTR* gene were identified in 35 of 49 patients referred with one previously identified mutation, but in only 6 of 50 patients referred without a mutation. Twenty-three patients had one, and 35 patients had no *CFTR* mutations. Haplotype analysis revealed lack of linkage to *CFTR* in two unrelated families with affected siblings. Although each of the affected siblings had elevated pilocarpine induced sweat Cl⁻ concentrations, measurements of cAMP-mediated ion and fluid transport demonstrated the presence of functional *CFTR*. No significant clinical differences were found among patients with or without *CFTR* mutations, except pancreatic insufficiency was less common in patients with two *CFTR* mutations (5%) compared to those with one (22%), or without *CFTR* mutations (31%; $p = 0.006$). These findings suggest that factors other than mutations in the *CFTR* gene can produce phenotypes clinically indistinguishable from CF caused by *CFTR* dysfunction.

Trans-splicing of mRNA precursor results in duplication or triplication of exon 2 in dystrophin mRNA and is responsible for Duchenne muscular dystrophy. *Y. Takeshima*¹, *T. Ito*², *A. Surono*², *H. Nakamura*¹, *M. Matsuo*². 1) Department of Pediatrics, Kobe Univ. Grad. Sch. Med, Kobe, Japan; 2) Division of Molecular Medicine, Kobe Univ. Grad. Sch. Med, Kobe, Japan.

Splicing is divided into two patterns; one is cis-splicing, where two exons located same pre-mRNA, and the other is trans-splicing, where the two exons are initially parts of two separate pre-mRNA molecules. The dystrophin gene, which is mutated in Duchenne muscular dystrophy (DMD), is the largest human gene and consists of 79 constitutive exons and two cryptic exons X and 2a located in introns 1 and 2, respectively. In the present study, we isolated several dystrophin cDNAs with different 5'-terminal structure which were caused by trans-splicing in Japanese DMD case.

When a region encompassing exons 1 to 5 was amplified from dystrophin cDNA in his lymphocytes, only one cDNA consisting of exons 1-X-2-2-3 was identified. From his skeletal muscle, remarkably several different dystrophin cDNAs were isolated in different amount. Two major cDNAs consists of exons 1-2-2-3 or 1-X-2-2-3, and the others consists of exons 1-2-X-2-2-3, 1-2-2a-3, 1-X-2-3, 1-2-3. Since these cDNAs suggested duplication or triplication of exon 2 in his genomic DNA, genomic DNA was examined by Southern blot analysis and PCR amplification. Unexpectedly it was disclosed that only single copy of exon 2 was present and nucleotide sequence of exon 2 and exon/intron boundary is normal.

These results indicate that duplication or triplication of exon 2 in mRNA of index case is due to the trans-splicing between different pre-mRNA molecules of dystrophin. And this is a novel molecular mechanism of human genetic disorders.

Identification of Novel Mutations in Two Amelogenesis Imperfecta Families. *P.S. Hart¹, T.C. Hart², K.W. Seow³, A.J. Aldred⁴, M.D. Michalec¹, J.T. Wright⁵*. 1) Dept Human Gen, Univ Pittsburgh, Pittsburgh, PA; 2) Dept Oral Med/Pathology, Univ Pittsburgh, Pittsburgh, PA; 3) Dept Ped Dent, Univ Queensland, Queensland, Australia; 4) Dept Dent and Murdoch Children's Research Institute, Royal Children's Hospital, Melbourne, Australia; 5) Dept Ped Dent, Univ North Carolina, Chapel Hill, NC.

The Amelogenesis Imperfectas (AI) are inherited disorders that adversely affect enamel development causing abnormalities in amount, structure and composition of enamel. The genetic basis for three forms of AI are known. The X-linked form, AIH1, results from amelogenin gene (AMELX) mutations. 2 clinically distinct forms of autosomal dominant AI, smooth hypoplastic AI and local hypoplastic AI, are due to enamelin gene mutations (ENAM) on 4q21. We present mutational analyses of 2 families with AI: one with the X-linked and one with an autosomal dominant form. The X-linked form is due to an AMELX exon 2 C to G transversion (g.52C>T; c.52C>T). This mutation changes a highly conserved proline to an alanine (p.P18A), and heterozygous females exhibited vertical grooves of hypoplastic enamel. This brings the number of described amelogenin gene mutations to 13, with 54% being deletions, 31% missense mutations and 15% nonsense mutations. The family segregating autosomal dominant AI presented a smooth hypoplastic AI phenotype. Enamelin gene analysis revealed a deletion of a G in exon 8 (c.588delG). This frameshift creates a smaller (276 amino acid) chimeric protein with 80 novel amino acids before premature termination (p.197fsX277), compared to the wild-type 1142 amino acids protein. This is the third mutation described in ENAM. The previously reported c.157A>T (p.K53X) mutation results in a localized hypoplastic phenotype. The c.534+1G>A (p.A158_178Qdel) mutation results in a more severe smooth hypoplastic phenotype. The more severe hypoplastic phenotype with the p.197fsX277 mutation described here may indicate a dominant negative effect of the mutant protein interfering with function of the wild-type protein. Mutational analysis of AI families provides insight into normal enamel development as well as demonstrating genotype-phenotype correlations.

Spinocerebellar ataxia type 10 ATTCT repeat expansions in Brazilian patients and in a patient with early onset ataxia. P. Fang¹, T. Matsuura², H.A.G. Teive³, S. Raskin⁴, P. Jayakar⁵, E. Schmitt¹, T. Ashizawa², B.B. Roa¹. 1) Dept Molec Human Genetics, Baylor Col Medicine, Houston, TX; 2) Dept Neurology, Baylor Col Medicine, Houston, TX; 3) Dept Medicine, Federal Univ Parana, Brazil; 4) Laboratorio Genetika, Brazil; 5) Div of Genetics and Metabolism, Miami Childrens Hospital, Miami, FL.

Spinocerebellar ataxia type 10 (SCA10) is an autosomal dominant neurogenetic disorder characterized by cerebellar ataxia and seizures. SCA10 is associated with a large ATTCT pentanucleotide repeat expansion mutation in the *SCA10* gene. Normal individuals have 10-22 repeats, while SCA10 patients have expansions in the hundreds to thousands of repeats. We report on DNA diagnostic testing for three SCA10 patients. Two patients were from unrelated Brazilian families of Portuguese ancestry who were referred for SCA10 diagnostic testing because of progressive gait ataxia associated with dysarthria; previous molecular testing for SCA1, 2, 3, 6, 7 and 8 were negative. Both patients had one normal allele by PCR analysis of the polymorphic ATTCT repeat region of *SCA10*. Southern analysis found expansions of ~1,500 repeats for patient 1, and ~1,600 repeats for patient 2. The third patient is a 19-year old Hispanic female from the U.S. Southern analysis found an expansion of ~280 repeats in the proband and in her apparently asymptomatic mother, but not in her asymptomatic father. Southern data were corroborated by a modified PCR method which confirmed ATTCT repeat expansions in the two Brazilian patients, the 19-year old patient and her mother. Previous studies had documented SCA10 expansion mutations exclusively in the Mexican population. The incidence for other populations is believed to be low, but is currently unknown. Our study of the Brazilian patients presents the first SCA10 expansion cases identified in non-Mexican ataxia patients, putting Portuguese/Brazilian populations at-risk for SCA10. The ~280-repeat expansion identified in the 19-year old patient represents the smallest SCA10 expansion mutation identified to date. The findings on this family highlight the need for further genotype-phenotype correlation studies for SCA10.

Characterization of mutant TATA-box binding protein (TBP) containing expanded polyglutamine tracts. *M.J. Friedman*^{1,3}, *K.J. Dougherty*², *S.H. Li*³, *X.J. Li*³. 1) Graduate Program in Genetics and Molecular Biology; 2) Graduate Program in Neuroscience; 3) Dept Human Genetics, Whitehead, Emory Univ, Atlanta, GA., USA.

Nine inherited neurodegenerative diseases have been found to associate with polyglutamine expansion in the respective disease proteins including TBP, the TATA binding protein that is essential for the basal transcription of genes. Expanded polyglutamine in TBP causes a neurodegenerative disorder (SCA17) with symptoms similar to Huntington's disease. Since TBP is a well-characterized protein, study of how polyglutamine expansion affects the function of TBP would provide insight into the mechanism(s) by which polyglutamine expansion mediates selective neurodegeneration. We have generated cDNA constructs by replacing the normal CAG repeat with expanded CAA/CAG repeats in the TBP gene. The resulting DNA constructs encode TBP containing 15, 38, 60, and 98 glutamines, and thus cover both the normal (15-40 glutamines) and pathogenic (42-67 glutamines) ranges observed in humans. Expression of these cDNAs in HEK 293 cells demonstrated that only pathogenic repeats caused TBP to form aggregates. While these aggregates were unable to react with 1C2 antibody that was generated against TBP, western blots showed that 1C2 preferentially reacted with soluble TBP containing expanded polyglutamine, suggesting that polyglutamine expansion confers different protein conformation and immunoreactivity. HEK 293 cells expressing mutant TBP also had reduced viability as compared with those expressing normal TBP. The TBP disease cell model will allow us to study further how polyglutamine expansion alters protein conformation and the function of TBP.

Mutant huntingtin forms aggregates differently in the nucleus and neuropil. *J.R. McGuire^{1,2}, Z.X. Yu², H. Zhou², S.H. Li², X.J. Li².* 1) Graduate Program in Genetics and Molecular Biology, Emory Univ, Atlanta, GA; 2) Dept Human Genetics, Emory Univ, Atlanta, GA.

Huntington disease is caused by polyglutamine expansion in the disease protein, huntingtin, a 350 kDa protein of unknown function. Expanded polyglutamine causes huntingtin to kill neurons and forms aggregates in the nucleus. While the role of intranuclear aggregates is unclear, our recent studies suggest that the formation of neuropil aggregates is more correlated with disease progression in HD mice and that neuropil aggregates are associated with axonal degeneration. To examine whether these two types of aggregates are formed differently, we examined HD repeat knock-in mice that express full-length mutant huntingtin and show both intranuclear and neuropil aggregates. We first used the antibody EM48 that reacts with the first 253 amino acids of huntingtin. EM48 recognizes aggregates in both the nucleus and neuropil. Our newly developed antibody EM121, which reacts with amino acids 359-429 of huntingtin, was unable to react with nuclear huntingtin aggregates despite its strong reaction with diffuse cytoplasmic huntingtin. PC12 cells were then transfected with N-terminal huntingtin (1-505 amino acids) that contains the HA epitope at its C-terminus. Mutant huntingtin containing a 120 glutamine repeat formed aggregates in the cytoplasm and neuritis, which could be labeled by both EM48 and the anti-HA antibody. Some transfected mutant huntingtin also formed intranuclear inclusions that were intensively labeled by EM48 but not anti-HA. In HD repeat knock-in mice, nuclear huntingtin aggregates were ubiquitinated while neuropil aggregates were negative to anti-ubiquitin. These studies suggest that intranuclear aggregates are formed by huntingtin fragments smaller than those for neuropil aggregates and therefore are more readily ubiquitinated.

Implementation of Long PCR for the Detection of a Very Large Trinucleotide Repeat Expansion in a 3-Year-old with Juvenile Huntington's Disease. *T.A. Maher¹, M. Ito¹, B.A. Loose¹, B.T. Darras², J.M. Milunsky^{1,3}*. 1) Center for Human Genetics, Boston University School of Medicine, Boston, MA; 2) Department of Neurology, Children's Hospital, Harvard Medical School, Boston, MA; 3) Department of Pediatrics, Boston University School of Medicine, Boston, MA.

A 3-year-old female with juvenile Huntington's disease (HD) and a family history is described. To our knowledge, she is one of the youngest children reported with juvenile HD and molecular confirmation. Symptoms of developmental regression, seizures and rigidity were noted at 18 months. HD, a progressive disorder of motor, cognitive, and psychiatric disturbances, is inherited in an autosomal dominant manner with paternal anticipation. The prevalence is between 3 and 7 per 100,000 in populations of western European descent. Juvenile HD has onset of symptoms before age 20 and is documented in less than 10% of all cases. The diagnosis of HD rests on family history, characteristic clinical findings, and the detection of an expansion of a CAG polyglutamine tract in the Huntingtin gene on chromosome 4p16. The CAG repeat length in affected individuals ranges from 36 to more than 200. The expansion of the CAG triplet repeat in the IT-15 (Huntingtin) gene of this patient was determined by a modified PCR analysis to be approximately 265 repeats, the largest CAG repeat ever reported in a HD allele. Currently, many molecular diagnostic laboratories in the US offer HD testing using a widely available PCR-based molecular test that is 98.8% sensitive, however, often the largest repeats are missed because of inefficient amplification of the large CAG repeat expansion. The Southern blot method is more reliable for such cases, however, only a few laboratories in the US have adopted this method. We have developed an easy, rapid and reliable modified PCR method using XL PCR that can detect up to at least 265 CAG repeats. This assay was shown to be reproducible, very reliable, and this report suggests implementation of this assay procedure as part of a standard protocol for HD testing in the molecular diagnostic community.

Huntington's disease-like 2 (HDL2): Frequency, genotype-phenotype relationships, and neuropathological characterization. *R.L. Margolis^{1,2}, J. Troncoso³, S.E. Holmes¹, E. O'Hearn^{4,5}, A. Rosenblatt¹, C. Callahan¹, J. Hwang¹, D. Rodnicki¹, C.A. Ross^{1,2,5}, A. Krause⁶, W. Seltzer⁷.* 1) Dept of Psychiatry; 2) Program in Cellular and Molecular Medicine; 3) Dept of Pathology; 4) Dept of Neurology; 5) Dept of Neuroscience, Johns Hopkins Univ Sch Med, Baltimore, MD; 6) Div of Human Genetics, National Health Laboratory Service, and Sch of Pathology, Univ of the Witwatersrand, Johannesburg, S. Africa; 7) Athena Diagnostics, Inc., Worcester, MA.

We recently reported that a CAG/CTG expansion in a variably spliced exon of Junctophilin-3 on 16q causes a neuropsychiatric disorder, termed Huntington's disease-like 2 (HDL2), that is clinically indistinguishable from Huntington's disease (HD). We have now confirmed the existence of this new disorder in at least seven independent pedigrees. Across all populations so far examined, HDL2 accounts for about 0.5-1% of HD-like cases that test negative for the HD gene, though the frequency of HDL2 is higher if cases are limited to those with an autosomal dominant inheritance and a phenotype typical of HD. Most pedigrees are of African descent, and a particularly high number of cases have been ascertained in S. Africa. Repeat length is tightly correlated with younger age of onset. Individuals with shorter expanded repeats (about 42-49 triplets) tend to present with prominent chorea, while those with longer expansions (50 or more triplets) tend to have more rigidity and dystonia (similar to juvenile onset HD). Almost all affected individuals have psychiatric symptoms or syndromes. The two brains available for autopsy both show an HD pattern of neurodegeneration and intranuclear inclusion bodies similar to those seen in HD.

CAG/CTG expansions are rare among patients with familial SCA not assigned to the SCA1-3,6-8,10,12,17 loci. A. Saluto¹, C. Cagnoli¹, C. Michielotto¹, C. Gellera², A. Castucci², C. Mariotti², S. DiDonato², L. Orsi³, A. Franco³, E. Rota³, F. Taroni², N. Migone¹, A. Brusco¹. 1) Genet.Biol.Bioch.& U.O.Genet Med,Osp.G.Battista,Torino,Italy; 2) Dip.Biochem.&Genetics-Ist.C.Besta,Milano,Italy; 3) Dip Neurosc.,Torino,Italy.

A CAG/CTG repeat expansion has been involved in 8 of the 9 known spinocerebellar ataxia (SCA) genes. We investigated the contribution of this expansion in orphan SCA genes, by using the RED technique. We selected 139 unrelated familial SCA patients of Italian origin, negative for expansions at the SCA1-3,6-8,10,12 and 17 genes: 52 were autosomal dominant and 87 with an uncertain transmission. Patients carrying 40 or less CAG/CTG were not considered for further analyses, since this size is present also among healthy controls. Twenty-four had an expansion of 50 or more triplets, and were screened for two polymorphic regions containing CAG/CTG, SEF2-1B and ERDA1 loci, not involved in the SCA pathogenesis. In 19 cases the expansion was attributed to the ERDA1, and in two to the SEF2-1B locus. Among the remaining cases, one (130 repeats) revealed to be an SCA8 case, escaped to the previous screening. The remaining two were evaluated for the DRPLA expansion, and indeed, one had a value in the full pathological range (63 triplets). The last patient was at the end suspected to be compatible with Huntington's disease (HD): in fact an expansion of 57 repeats was detected in the corresponding gene. Our screening on a large group of 139 familial SCA patients let us to conclude that orphan SCA genes have probably a pathogenic mechanism different from the CAG/CTG expansions. Alternatively we could hypothesize the existence of genes like TBP, where a mix of CAG/CAA triplets, which cannot be detected by RED, codes a pathogenic stretch of polyglutamines, or the presence of pathogenic ranges below 40 repeats. The involvement of repeat expansions in at least a part of these patients cannot be ruled out, also considering the presence of anticipation in at least ~10% of our families. Furthermore, a few cases diagnosed as SCA are probably due to mutations in the DRPLA, and eventually the HD gene.

Program Nr: 2249 from 2002 ASHG Annual Meeting

Huntington's disease-like 2 (HDL2): Preliminary exploration of pathogenesis. *D. Rudnicki¹, E. O'Hearn^{2,3}, S.E. Holmes¹, A. Sawa^{1,3}, Z. Kaminsky¹, J. Kleiderlein¹, J. Troncoso⁴, C.A. Ross^{1,3,5}, H. Takeshima⁶, T.H. Moran¹, R.L. Margolis^{1,5}.* 1) Department of Psychiatry; 2) Neurology; 3) Neuroscience; 4) Pathology and; 5) Program in Cellular and Molecular Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 6) Department of Biochemistry, Tohoku University, Japan.

Last year our laboratory identified a disorder, termed Huntington's Disease-Like 2 (HDL2; Margolis et al., 2001, Holmes et al., 2001), with clinical and pathological findings essentially indistinguishable from Huntington's disease (HD). The mutation causing HDL2 is a CAG/CTG expansion in the CTG orientation within a variably spliced exon of junctophilin-3 (JPH3). The position of this mutation suggests several possible hypotheses for HDL2 pathogenesis, including 1) the presence of a cryptic CAG repeat encoding glutamine on the reverse strand; 2) haploinsufficiency of the JPH3 gene resulting from interference of transcription, splicing, or translation by an expanded repeat; and 3) toxicity of an expanded polyalanine or polyleucine repeat encoded by a splice variant of JPH3. Using RT-PCR of normal and HDL2 brain tissue, we have yet to find evidence of the first hypothesis. To test the second hypothesis, haploinsufficiency of JPH3, we are examining the behavior and neuropathology of junctophilin-3 knockout mice (Nishi et al, 2002). Both junctophilin-3 *wt/-* and *-/-* mice show impaired motor function on an accelerating rotarod protocol as early as 6 weeks of age, with increasing deficits with advancing age. Performance was more impaired in the *-/-* mice. We are currently using immunohistochemistry to compare the brain of *wt/-* and *-/-* mouse brains to human HDL2 brain samples, and to search for evidence of polyleucine or polyalanine toxicity (hypothesis 3) in cell models and human HDL2 brain samples. Confirming one (or more) of these hypotheses may provide valuable insight into the mechanisms of striatal vulnerability and the pathogenesis of HDL2, HD and other neurodegenerative disorders. Funding sources: NINDS and the Hereditary Disease Foundation.

Exclusion of maternal uniparental disomy of chromosome 14 in Prader-Willi syndrome referrals using a rapid methylation PCR assay. *L. Dietz*¹, *A.A. Wylie*², *K.A. Rauen*³, *S.K. Murphy*², *R.L. Jirtle*³, *P.D. Cotter*^{1,3}. 1) Medical Genetics, Children's Hospital, Oakland, CA; 2) Department of Radiation Oncology, Duke University Medical Center, Durham, NC; 3) Division of Medical Genetics, Department of Pediatrics, University of California San Francisco, San Francisco, CA.

Maternal and paternal uniparental disomy of chromosome 14 are both associated with abnormal phenotypes. PatUPD14 is characterized by polyhydramnios, low birth weight and skeletal and abdominal anomalies. MatUPD14 has a less severe phenotype including growth retardation, short stature, precocious puberty, obesity, hypotonia and some developmental delay. To date, over twenty matUPD14 patients have been reported. Interestingly, there are some phenotypic features of matUPD14, notably hypotonia, obesity and hypogonadism in some patients, which are suggestive of Prader-Willi syndrome (PWS). Recently, three matUPD14 patients were reported who were originally referred for a possible diagnosis of PWS. The identification of matUPD14 in these patients suggested that there may be some utility in testing for matUPD14 in patients referred for PWS, who were not confirmed by molecular analysis. In order to test this hypothesis, we selected 200 patients who had been referred for molecular diagnosis of Prader-Willi syndrome based on their clinical phenotype, and who were normal by Southern blot or methylation PCR (mPCR) analysis of the SNRPN promoter region. Patients were screened using a rapid bisulfite modification/mPCR method based upon the differential methylation of the imprinted *GTL2/MEG3* gene on chromosome 14. Methylation PCR analysis of normal, patUPD14 and matUPD14 controls all showed the expected PCR fragments. All 200 patient samples showed both the paternal and maternal-specific PCR fragments, consistent with biparental inheritance of chromosome 14 and excluding matUPD14. This data suggests that the incidence of matUPD14 among patients referred for PWS is likely to be low.

Genetic Heterogeneity of Autosomal Recessive Cataract. *G.D. Billingsley¹, R. Sidhu¹, S. Herd¹, A.V. Levin³, F.L. Munier^{4,5}, D.F. Schorderet⁴, A. Balmer⁵, D.A. Mackey^{6,7}, M. Sale⁶, E. Héon^{1,2,3}.* 1) Vision Science Research Program, Toronto Western Hospital; 2) University of Toronto, Department of Ophthalmology; 3) The Hospital for Sick Children Research Institute; Toronto, Ontario, Canada; 4) Unit of Oculogenetics and Division of Medical Genetics, CHUV; 5) Hôpital Ophthalmique Jules Gonin, Lausanne, Switzerland; 6) Menzies Centre for Population Health Research, University of Tasmania, Hobart, Tasmania, Australia; 7) Centre for Eye Research Australia, University of Melbourne, East Melbourne, Victoria, Australia.

Cataracts constitute the leading cause of blindness worldwide and the mechanisms of lens opacification remain unclear. Approximately one-third of all congenital cataracts are familial and recent studies suggest that ~50 % of age-related cataracts could be accounted for by Mendelian inheritance, predominantly autosomal recessive (AR). In contrast to the large number of genes and loci (at least 20) identified in human autosomal dominant cataract, only two genes, *CRYAA* and *LIM2*, and two loci with as yet unidentified genes have been implicated in AR cataract. Eight families were recruited, five of which are consanguineous, with early onset bilateral cataract and at least 2 affected members, in order to further localize and identify the genes responsible for AR cataract. STRP markers for the previously published AR loci (3p21.1 - p21.3, 9q13-q22, 19q13.4, 21q22.3) were chosen for genotyping. For those families not excluded from 19q and 21q, the coding sequences of *LIM2* and *CRYAA* will be screened by SSCP analysis. The disease in one family cosegregated with markers of the 3p loci, but did not narrow the published disease interval. The remaining families have been excluded from three AR loci by genotype/haplotype analysis and SSCP(*CRYAA*). This study provides further evidence for genetic heterogeneity in the AR form of cataract. The molecular characterization of AR cataract is essential in order to better understand the complex cascade of events modulating lens opacification in the more common age-related cataract.

Genetics of X-linked congenital stationary night blindness (CSNB): summary of mutation analysis. *N.T. Bech-Hansen¹, R. Tobias¹, T. Rosenberg², J. Robitaille³, K.D. Unger¹, A. Zaprzelski¹, P.A. Farndon⁴, M. Schwartz², D.G. Birch⁷, J.R Heckenlively⁵, R.G Weleber⁶.* 1) Med Genetics, Univ Calgary, Calgary, AB, Canada; 2) National Eye Clinic, Denmark; 3) Dept. Ophthalmology, Dalhousie Univ, Halifax, NS, Canada; 4) Dept of Genetics, Univ of Birmingham, UK; 5) Jules Stein Eye Institute, Los Angeles, CA; 6) Casey Eye Clinic, OHSU, OR; 7) Retina Foundation of the Southwest, Dallas, TX.

X-linked CSNB represents a rare disorder of retinal neurotransmission. Patients present with a variable phenotype of reduced visual acuity, which may include myopia, night blindness, nystagmus, or strabismus; they all have negative electroretinograms (ERGs). Genetic analysis has revealed genetic heterogeneity, CSNB1 and CSNB2, which correlates with the clinical entities of complete CSNB and incomplete CSNB. Moreover, the causative genes have been identified as *NYX* (CSNB1) and *CACNA1F* (CSNB2). Using direct DNA sequencing, we have expanded the analysis of these two genes to a total of 80 families with X-linked CSNB and identified a total of 53 unique mutations. In patients with complete CSNB from 25 families, we have detected 9 missense, 5 in-frame insertion/deletion, 1 splice-site, 1 nonsense, and 1 frame-shift mutations in *NYX*, which encodes the GPI-anchored proteoglycan nyctalopin. In patients with incomplete CSNB from 44 families, we detected a total of 27 different mutations in *CACNA1F* (7 nonsense, 5 frameshift, 4 splice-site, 7 missense, and 1 in-frame insertion/deletion mutations) which are each predicted to alter or lead to a loss of function of the alpha-1-F subunit that is part of a retinal-specific voltage-gated L-type calcium channel. In addition, patients from 10 different Danish families diagnosed with Aland Eye disease (AED) and a British family diagnosed with Aland Island Eye disease (AIED) were also found to have mutations in *CACNA1F* (5 missense, 1 in-frame deletion, 1 splice-site, 3 nonsense, and 2 frameshift mutations). These findings provide further support for the causative role of *CACNA1F* and *NYX* in X-linked CSNB conditions, including AED and AIED. Supported in part by CIHR, and Foundation Fighting Blindness (Canada).

Fine mapping of the GLC1C locus in a large Greek pedigree segregating primary open angle glaucoma. G. Kitsos¹, K. Rust², R. Sykes², J.R. Samples², E. Economou-Petersen³, M. Grigoriadou⁴, G. Aperis⁴, K. Psilas¹, M.B. Petersen⁴, M.K. Wirtz². 1) Univ. of Ioannina, Greece; 2) Casey Eye Inst., Oregon Health Sciences Univ., Portland, Oregon; 3) Drakopoulion Blood Bank Center, Athens, Greece; 4) Inst. of Child Health, Athens, Greece.

Glaucoma is a heterogeneous group of disorders, the majority of which are associated with an open, normal appearing anterior chamber angle and are termed open angle glaucoma (OAG). OAG is likely to be a genetically heterogeneous disorder that results from the interaction of multiple affected genes and environmental influences. Six loci have so far been mapped by linkage analysis in families with autosomal dominant mode of inheritance of OAG, GLC1A-GLC1F. Only one gene has so far been identified, the TIGR gene responsible for the GLC1A locus. Mutations in the TIGR gene have been detected in most familial cases of juvenile onset OAG as well as in a small proportion of adult onset OAG patients, also known as primary OAG (POAG). We have previously mapped the GLC1C locus to chromosome 3q21-q24 in one large North American pedigree and one large Greek pedigree with autosomal dominant POAG. Haplotype analysis suggested independent origin of the genetic defect in the two families. We here present refined mapping of the GLC1C locus in the Greek family by including more family members and analyzing more markers in the chromosome 3q inclusion region. A total of 89 individuals from 4 generations were clinically examined and genotyped. Clinical findings in affected individuals included characteristic glaucomatous changes in the visual field, increased cup to disc ratio, and intraocular pressure before treatment more than 21 mmHg, with age at diagnosis 31 years and older. DNA microsatellite polymorphism and haplotype analysis together with identification of recombinant individuals narrowed the GLC1C critical region to the interval between markers D3S3637-D3S1555. Two individuals were homozygous for the partial disease haplotype D3S3637-D3S3694 and were unaffected at the age of 65 and 63 years, respectively. This study represents a step further towards the identification of the GLC1C disease causing gene.

RS1 mutations causing X-linked Juvenile Retinoschisis lead to intracellular retention of mutant retinoschisin. D.

Trumpf¹, T. Wang¹, C.T. Waters¹, A.M.K. Rothman¹, T.J. Jakins¹, K. Römisch². 1) Department of Medical Genetics, Cambridge Institute for Medical Research, Addenbrookes Hospital, University of Cambridge, UK; 2) Department of Clinical Biochemistry, Cambridge Institute for Medical Research, Addenbrookes Hospital, University of Cambridge, UK.

X-linked retinoschisis results in visual loss in early life with the characteristic abnormality of schisis within the inner retina. Patients often present at school age but can present within the first few months of life. Many missense and protein truncating mutations of the causative gene RS1 (encoding retinoschisin) have been identified but the disease is variable even within families and severity is not mutation-dependent. Retinoschisin is secreted and predicted to have a globular conformation. Missense mutations would be expected to interfere with protein folding leading to an abnormal conformation and elimination by intracellular protein degradation. To test this we have expressed 7 pathological RS1 mutations (L12H, C59S, G70S, R102W, G109R, R141G, R213W) in Cos-7 cells and investigated their intracellular processing. Constructs of WT RS1 and RS1 mutations in pcDNA3.1 and fusions with EGFP were generated and expressed in Cos-7 cells. Using immunoblotting and confocal fluorescence microscopy we have shown normal secretion of WT RS1, but either reduced (C59S, R141G) or absent (L12H, G70S, R102W, G109R and R213W) secretion of mutant RS1 and retention in the endoplasmic reticulum (ER). We found that WT and mutant RS1 are associated with the molecular chaperones Bip (GRP78 from the HSP70 family) and PDI. In addition, we have shown that L12H RS1 is degraded by the proteasome pathway and in vitro transcription/translation revealed the lack of cleavage of its signal peptide. Our results indicate the pathological basis of RS1 is intracellular retention of retinoschisin and this may explain why disease severity is not mutation dependent.

Mutation Screening of *RPGR* in Male Patients with X-Linked or Sporadic Forms of Retinitis Pigmentosa or Cone-Rod Dystrophy. *A.L. Radak*¹, *F.Y. Demirci*^{1,2}, *B.W. Rigatti*², *E.I. Traboulsi*³, *T. Alitalo*⁴, *T.S. Mah*^{1,2}, *M.B. Gorin*^{1,2}. 1) Dept of Human Genetics, GSPH, Univ of Pittsburgh, Pittsburgh, PA; 2) Dept of Ophthalmology, School of Medicine, Univ of Pittsburgh, Pittsburgh, PA; 3) Center for Genetic Eye Diseases, Cole Eye Inst, Cleveland Clinic Foundation, Cleveland, OH; 4) Dept of OB/GYN, Helsinki University Hospital, Helsinki, FINLAND.

Retinitis Pigmentosa (RP) refers to a heterogeneous group of phenotypically similar hereditary retinal disorders described in several inheritance patterns, as well as sporadically. X-linked (XL) RP (XLRP) is a generally severe form of RP. The *RPGR* (retinitis pigmentosa GTPase regulator) gene isolated from *RP3* region (Xp21.1) was found to be mutated in up to 70% of XLRP families. This includes mutations in exon ORF15 (an alternative 3' terminal exon of *RPGR*) that contains a mutational hot spot. In addition, exon ORF15 mutations have been shown to cause XL-atrophic macular degeneration and a subset (COD1) of XL-cone-rod dystrophy (XLCRD). Using direct PCR sequencing, we screened *RPGR* exons 1-14 and ORF15 for mutations in samples from 4 XLRP and 12 XLCRD families and a total of 20 North American sporadic male patients with either RP or CRD. We found mutations in two XLRP samples (ORF15+483_484delGA and IVS1+1G>A) and in one sporadic RP sample (1404C>T), although analyses of additional samples are still underway. Despite a sampling bias created by our previous efforts to recruit COD1 families (corresponding *RPGR* mutations published elsewhere), more than half of our current XLCRD families have not been mapped to *COD1* and/or lack *RPGR* mutations, supporting the importance of genetic heterogeneity. Further mutation analysis in sporadic samples will help to determine the rate at which mutations in *RPGR* affect these patients. Our data supports the involvement of *RPGR* in sporadic cases, although different criteria in the selection of cases for *RPGR* screening may result in reporting different frequencies. The comparison of phenotypes of *RPGR* mutation positive patients versus mutation negative patients may provide indicators for the prediction of sporadic cases at high-risk for *RPGR* mutations and serve as a valuable guide for future genetic counseling.

Inherited retinopathy causing mutations in the AIPL1 protein interfere with its interaction with the cell-cycle control protein, NUB1. *M.M. Sohocki¹, C.G. Castellano¹, A.F. Sorensen¹, D.T. Akey².* 1) Dept Ophthal, Columbia Univ, New York, NY; 2) Dept of Envrmtl Hlth, Univ Cincinnati, OH.

Mutations in the aryl hydrocarbon receptor-interacting protein-like 1 gene have been found in patients with Leber congenital amaurosis (LCA), a severe, early onset form of inherited blindness. The AIPL1 protein has considerable homology with the aryl hydrocarbon receptor-interacting protein (AIP), which helps to mediate the stabilization and nuclear transport of the aryl hydrocarbon receptor as part of a complex with hsp90. To determine the normal function of AIPL1 and to better understand how mutations in this gene cause disease, we performed a yeast two-hybrid screen to identify AIPL1-interacting proteins. One of the identified interacting proteins corresponds to Nub1 (NEDD8 Ultimate Buster-1), which is thought to control many biological events, including cell-cycle progression. In addition, constructs were designed to determine what regions of the AIPL1 protein were involved in the interaction. To determine the potential impact of LCA-causing mutations on the interaction, nine LCA-associated mutations were introduced into the AIPL1 construct. The ability of the mutant AIPL1 proteins to interact with the NUB1 protein was determined through quantitative b-galactosidase assays and growth in liquid dropout media. While each deletion construct was capable of interacting with NUB1, the construct encoding the C-terminal region of AIPL1 appeared to have the highest binding activity. This is consistent with the finding that the sequence required for interaction of AIP with hsp90 is within the final 20 amino acids of AIP. The majority of the mutations significantly reduced the interaction between these proteins. Therefore, we hypothesize that the majority of AIPL1 mutations cause inherited retinopathy due to loss of function. Due to the likelihood that AIPL1 is functioning as part of a multi-protein complex, it is possible that the mutations not associated with reduced interaction with NUB1 affect the interaction with another component of the AIPL1 complex. Alternatively, it is possible that these mutations result in mislocalization of the protein within the cell.

Abnormal X chromosome inactivation in female patient with partial hypoxanthine-guanine

phosphoribosyltransferase (HGPRT) deficiency. *L. Dvorakova¹, J. Hujova¹, R. Dobrovolny¹, L. Stolnaja¹, E.*

Tietzeova¹, M. Hrebicek¹, M. Kumsta², I. Sebesta^{1,2}. 1) Inst Inherit Metabol Disorders, 1st Faculty of Medicine, Charles University, Prague, Czech Republic; 2) Inst.Clin. Biochem., 1st Faculty of Medicine, Charles University, Prague, Czech Republic.

Partial deficiency of hypoxanthine-guanine phosphoribosyltransferase (HGPRT) described as Kelley-Seegmiller syndrome is an X-linked recessive disorder of purine metabolism associated with gout and urolithiasis. This phenotype occurs almost exclusively in males. We follow a girl who presents gouty arthritis of big toe and hyperuricaemia from the age of 9 years. Biochemical studies revealed partial HGPRT deficiency. Direct sequencing of PCR products prepared from genomic DNA revealed that our female patient inherited mutation c.158T>C (V53A) from her father. This mutation located in the 3rd exon of HGPRT gene was previously described in a patient with similar phenotype. The proband's sister and grandmother (father's mother) are also heterozygous for V53A, although they are asymptomatic. The severe phenotype of the female proband can be explained by the following: 1. There is another mutation on the second allele, or 2. there is an unfavorable skewing in X-inactivation towards the mutant allele. To examine the first possibility we cloned both alleles into a plasmid. The entire sequence of the allele, which did not carry the mutation c.158T>C, was sequenced and no other mutation was detected. X-inactivation analysis in DNA from peripheral leukocytes suggests that our female patient has preferentially activated the mutant allele inherited from her father. On the contrary, her asymptomatic sister and grandmother use almost exclusively the normal allele. The presented data suggest, that in girls with unexplained hyperuricaemia and gout the partial HGPRT deficiency has to be taken into account. While biochemical tests performed in heterozygotes may fail because of X-inactivation status, mutation analysis is a reliable tool for carriers identification. (Supported by grants NE 6557-3-01 of the Czech Ministry of Health and MSM-111100005 of the Czech Ministry of Education).

Molecular basis of Oro-facio-digital type I syndrome. *B. Franco, G. Giorgio, A. Barra, A. Ballabio, M. Ferrante.*
TIGEM, Telethon Inst Gen & Medicine, Naples, Italy.

Oro-Facio-Digital type 1 (OFD1) is an X-linked dominant condition characterized by polycystic kidneys and malformations of the face, oral cavity, digits, and brain. We identified the gene responsible for this disorder, OFD1, and showed that it is an anonymous protein characterized by five predicted coiled-coil domains. We have now collected 23 OFD1 patients (8 familial and 15 sporadic) and found mutations in all cases. These include 3 missense, 14 frameshifts, 3 splice site and 3 non sense mutations. The mutations are distributed along the protein although 6 out of 23 (26%) are located in exon 3. To gain insight into the pathogenetic mechanism underlying OFDI, sub-cellular localization experiments were performed in transfected COS7 cells on wild type and mutated forms of the OFDI protein. Our study showed that the wild type OFD1 displays a punctate distribution, concentrating in speckles of variable size and uniformly distributed in the cytoplasm. On the other hand, constructs carrying the mutated forms showed a more diffuse and granular pattern when compared to the wild-type, as the cytoplasmic speckles disappear, resulting in a more homogeneous distribution of the protein in the cytoplasm. Co-localization experiments with markers defining different organelles have been so far unsuccessful. In order to test whether OFD1 could act via a protein-protein interaction mechanism through its coiled-coil domains, interaction mating and co-immunoprecipitation experiments were performed. Our results showed that the protein does homo-interact through its central region where most of the coiled-coils are located. Two hybrids experiments are currently in progress to identify potential OFD1 interactors. A null targeted mutation of the OFD1 gene is being generated in mouse: preliminary analysis of the chimeras revealed the presence of features typical of the human condition. The availability of a mouse model will be critical for the definition of the OFD1 biological role and to gain insights in the pathogenesis of this developmental disorder. Special thanks to clinicians, who provided patients, and who were not included in the author's list due to space limitations.

Mutations in the X-linked dominant type (CDPX2) of chondrodysplasia punctata. *S.E. Chavez¹, R.I. Kelley², L.E. Kratz², A.B. Metzenberg¹.* 1) California State University, Northridge, CA; 2) Kennedy Krieger Institute Baltimore, MD.

Mutations in the X-linked dominant type (CDPX2) of chondrodysplasia punctata. X-linked dominant chondrodysplasia punctata (CDPX2, OMIM #302960) is a rare disorder of cholesterol metabolism, one of a group of such disorders affecting skin and bone development. CDPX2 is characterized by punctate calcification in cartilage, asymmetric rhizomelia, cataracts, patchy alopecia, ichthyosis and atrophoderma. The phenotype includes high levels of intermediate metabolites of cholesterol biosynthesis in plasma and cultured fibroblasts, which results from a deficiency of sterol-D8, D7-isomerase, that is encoded by the EBP gene, located on Xp11.22-23. Here we present the results of biochemical and sequence analyses of 8 unrelated females with clinical diagnoses of CDPX2, and elevated levels of cholest-8(9)-en-3-ol and 8-dehydrocholesterol. Mutations were found in EBP in 7 of the 8 samples. Of these, two were previously reported missense mutations, predicted to cause the substitutions R147H (seen in two of our patients), and E80K. One previously reported nonsense mutation, W61X, was observed in one patient. Three mutations are novel, and include a missense mutation, P200F, a nonsense mutation, W47X, and one splice donor mutation in intron 2, nt301+1 G>A. We found no evidence for genotype-phenotype correlation in these patients. The patient for which no mutation was found in the coding regions or splice junctions of the EBP gene may have a mutation in a regulatory region or in an unknown gene affecting EBP activity. Through this report and others, a pattern is emerging showing both the importance of biochemical analysis in patients with a clinical diagnosis, and the relatively high frequency of novel mutations in the EBP gene requiring molecular diagnosis through sequence analysis.

Hemiduplication of body organs: A possible disorganization-like syndrome. *M. Thomas¹, K. Chong¹, B. Mullen², A. Pai¹.* 1) Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hosp, Toronto, ON, Canada; 2) Dept of Pathology, University of Toronto, ON, Canada.

The mouse mutant disorganization was first fully described by Hummel (158, 1959). Who stated that it received its name from the fact that it disrupts the orderly process of organogenesis and induces a great variety of developmental anomalies in structure derived from germ layers. We report a fetus with duplication of the external and internal body organ of the right side of the body which resemble the disorganization syndrome reported in the mouse mutant. This was the first pregnancy to a non-consanguineous couple of Anglo-Saxon origin, with negative family and pregnancy history. Fetal ultrasound at 20 weeks gestation revealed two vessel cord, bilateral club foot and right diaphragmatic hernia. The pregnancy was terminated and the autopsy showed hypoplasia of the right face, sternum, right ribs, trunk, labia majora and sternum. There were duplication of right arm, right clavical, right lung, right stomach, partial duplication of the small bowel, duplication of the right iliac wing, right adrenal gland and right kidney. There was a cloacal tag, right diaphragmatic hernia with deviation of the heart to the left, and pulmonary hypoplasia. The female fetus had a bicornate uterus, with segmentation defect in the upper thoracic spine and 11 pairs of ribs. The fetus also had bilateral talipes equinovarus, sandal gap on left foot, anular pancreas and melodysplasia of the spinal cord. There was pterygium involving the right elbow and right knee and a single umbilical artery. No abnormalities were detected in the CNS. The mouse disorganization mutant presents with complete limb duplication as well as other abnormalities. Several human cases with similar findings have been reported mainly with limb duplication and hamartomatous lesions in different parts of the body. To the best of our knowledge, such an extensive hemiduplication of different body organs has not been reported. We think that the findings are consistent with the disorganization-like syndrome.

Casamassima-Morton-Nance syndrome : Another case and review of the literature. *C. Thauvin-Robinet Jr¹, L. Laurent², S. Lionnais³, T. Rousseau³, N. Nadal⁴, F. Mugneret⁴, C. Durand⁵, P.D. Turnpenny⁶, P. Sagot³, L. Faivre¹.* 1) Centre de Genetique, Hopital d'Enfants, Dijon, France; 2) Laboratoire d'anatomopathologie, Hopital du Bocage, Dijon, France; 3) Clinique gynecologique et obstetrique, Maternite du Bocage, Dijon, France; 4) Laboratoire de Cytogenetique, Hopital du Bocage, Dijon, France; 5) Service de Radiologie, Hopital d'Enfants, Dijon, France; 6) Molecular Genetics, School of Postgraduate Medicine and Health Sciences, Barrack Road, Exeter, United Kingdom.

Casamassima-Morton-Nance syndrome (CMN; MIM 271520) is a rare disorder characterized by the association of spondylocostal dysostosis with "crab-like" appearance of the thoracic skeleton, various urogenital abnormalities and anal atresia. Only five cases with CMN have been reported in the literature. Differential diagnose are represented by spondylocostal dysostosis syndromes with "crab-like" appearance of the thoracic skeleton, including Jarcho-Levin syndrome, autosomal dominant spondylocostal dysostosis, and spondylothoracic dysostosis. Here, we report on a fetal case of CMN born from Caucasian non consanguineous parents. Ultrasound survey at 12 weeks of gestation showed severe growth retardation and suspicion of scoliosis. Autopsy performed after spontaneous death at 14 weeks of gestation revealed major scoliosis, asymmetric trunk, anal atresia and agenesis of external and internal genitalia, bladder and kidneys. Radiological features included hemivertebrae and rib abnormalities with crab-like appearance of the thoracic skeleton. These findings fit with the diagnosis of Casamassima-Morton-Nance syndrome. Reviewing the literature, apart from the characteristic clinical features, the five reported cases with CMN also presented atypical signs such as midthoracic meningocele (1/5), polymicrogyria (1/5), preaxial polydactyly (1/5), hypoplastic right femur (1/5) and sacral agenesis (1/5). Sequence analysis of the DLL3 gene involved in Jarcho-Levin syndrome is in progress in the present reported case.

Osteocraniostenosis : Lethal dwarfism with thin bones, craniosynostosis and splenic hypoplasia. Report of a new

case. *S. Patrier*¹, *A. Rossi*², *A. Diguert*³, *D. Eurin*⁴, *E. Verspyck*³, *A. Laquerriere*¹, *A. Verloes*⁵. 1) Dept of Pathology, University Hospital, Rouen, France; 2) Dept of Genet, EFS-Normandie, Bois-Guillaume, France; 3) Dept of Obstetrics and Gynecology, University Hospital, Rouen, France; 4) Dept of Radiology, University Hospital, Rouen, France; 5) Dept of Genet, University Hospital Robert Debre, Paris, France.

A 25 year-old Caucasian woman was referred to our hospital for major intrauterine growth retardation at 20 weeks gestation. Ultrasound examination showed micromelic dwarfism and facial dysmorphism. The parents refused to terminate pregnancy . The fetus died at 36 weeks. The female fetus weighed 447g (compare to an expected average of 2220g). Crown-heel distance was 25cm, crown-rump 19cm, OFC 24cm (compare to an expected average of 45, 31 and 32cm respectively). There was a major micromelic dwarfism with acromicria and stubby as well as short fingers, and hypoplastic nails. The skull was scaphocephalic with a mild cloverleaf deformity and wide prominent forehead. Flat face with microphthalmia and hypertelorism, short nose, short philtrum and micrognathia were noted. Radiological examination showed very thin and sclerotic long bones, and diffuse hypomineralisation. Diaphyses were dense and thin like fishbones with flared metaphyses. Hands showed brachyphalangy and brachymetacarpus. The fibulae were filiform. The cranial vault was not ossified and the spine slightly mineralized with platyspondyly. At the autopsy, the vault was totally membranous. Spleen was hypoplastic. Histological examination displayed severe abnormalities of enchondral ossification. Epiphyseal cartilage contained few chondroblasts. Metaphyseal plate showed rare columns of hypertrophied cartilage, short and irregular primary bone trabeculae. The diaphysis was entirely filled with dense osteoid tissue without bone marrow. This observation matches the description of cases reported by Verloes and al. describing a rare and multiple congenital abnormalities syndrome called osteocraniostenosis. Homogeneity and genetic origin of this rare form of osteochondrodysplasia remains unclear. This fetus observation is worth being reported as an extremely severe form of this syndrome.

Cell free fetal DNA is detectable in the CSF of some pregnant women. *R.M. Angert¹, E.S LeShane¹, R.W. Yarnell², D.W. Bianchi¹*. 1) Genetics, Tufts-NE Medical Center, Boston, MA; 2) Anesthesia, Tufts-NE Medical Center, Boston, MA.

Introduction: Cell-free fetal DNA is detectable in maternal plasma. Its origins, distribution, and metabolism remain a mystery but are an area of active inquiry. We hypothesized that fetal DNA could cross the maternal blood-brain barrier and would be detectable in cerebrospinal fluid (CSF).

Materials and Methods: With IRB approval we obtained up to one mL of discarded CSF from 2 women who were having spinal anesthesia for cerclage placement (first trimester), 20 women who were undergoing routine cesarean section (third trimester, antepartum) and 4 women undergoing tubal ligation (third trimester, 24 hours post-partum). DNA was extracted from spun CSF and amplified using real time PCR for *DYS-1* (representing fetal) and *b-globin* (representing total) to quantitate the cell free DNA.

Results: 26 samples of maternal CSF were collected. There were 19 males, 5 females, one set of triplets, and one unknown. *b-globin* DNA sequences were detected in each of the samples [91 ± 115 genome equivalents(GE)/mL]. In one routine cesarean section with a male fetus there was a significant amount of male cell free DNA present in the CSF (7 GE/mL). A sample from a patient bearing triplets (male, male, female) undergoing cesarean section had male cell free DNA detected (9 GE/mL). One post-partum tubal ligation patient whose baby was male had a significant amount of male cell free DNA present in the CSF (6 GE/mL). The remainder of the CSF samples had no detectable male cell free DNA.

Conclusion: Total cell free DNA is detectable in maternal CSF samples. Male cell free DNA, presumably of fetal origin, was detectable in 3 out of 20 samples (15%). This suggests that male fetal cells or cell free DNA may cross the blood brain barrier in pregnant or post-partum women.

Prenatal diagnosis for deletion of SMN gene: occasional observation? *V. Sokolnik, S. Shreder, A. Spector, G. Tsukerman.* Department for Prevention of Hereditary Diseases, Institute for Hereditary Diseases, Minsk, Belarus.

The survival motor neuron (SMN) gene presents in variable number of two almost identical copies (SMN1-telomeric copy, SMN2-centromeric copy). SMN1 gene is absent in the majority of patients with SMA, whereas SMN2 gene copy number modifies the phenotype. Both genes undergo alternative splicing, however, the full-length (FL) transcript is the major product of SMN1, while SMN2 expresses reduced level of full-length transcript and abundant level of transcripts lacking exon 7 (Lefebvre et al., 1995;). The tissues from SMA-fetus with deletion of SMN1 have more transcripts containing exon 7 than peripheral blood of SMA patients (Jong et al., 2000). SMNDelta7 is potently proapoptotic, causing increased cell-specific neuronal apoptosis, whereas full-length SMN protects primary neurons and differentiated neuron-like stem cells from virus-induced apoptotic death (Kerr et al., 2000). SMN2 deletions may be not biologically inert because can alter the SMNDelta7/FL ratio. Our previous studies, with using of the SSCP, have demonstrated that SMN1 was deletion changed in about 82% of Belarus SMA patients, 1,6% parents, while the SMN2 was deleted in 2,6% SMA patients and in 4,8% parents. About 9,5% random control newborns have deletions in SMN2 that be detected by SSCP analysis of amplified DNA from dried blood spots. Now we report the result of restriction site assay study of chorionic villi SMN genes. The patient was the 11-week fetus with karyotype 46 XX. The mother, 24-year old, is healthy. The father, 23-year old, has spina bifida and congenital heart defect. Ultrasound examination was performed at 11th week of gestation and the patient showed an exencephaly. Under consideration of the poor prognosis the termination of pregnancy was made in accordance with the parents. Analysis of SMN genes from chorionic villi revealed that the fetus was deleted for SMN2 exon 7. As far as we know, it is a first observation of SMN2 gene deletion in exencephaly a condition, in which defect in neural tube closure resulting in an overgrowth of undifferentiated neural tissue? This condition is usually found in embryos as an early stage of anencephaly.

Microchimerism and cervical cancer. *K.L. Johnson, D.H. Cha, H. Stroh, D.W. Bianchi.* Department of Pediatrics, Division of Genetics, Tufts-New England Medical Center, Boston, MA.

Background: Fetal cell microchimerism has been shown to be associated with autoimmune disease through a graft-versus-host like response. Microchimerism has also been described in non-autoimmune diseases, such as infectious hepatitis. Microchimerism may result from other sources, including through the persistence of spermatozoa or semen leukocytes following sexual intercourse. The current study was performed to determine if microchimerism is seen in cervical cancer.

Methods: Fluorescence in situ hybridization (FISH) using X and Y chromosome-specific probes was performed on paraffin-embedded cervical tissue sections to allow for the identification of microchimeric male cells within a tissue specimen from a female. Sections from five women with cervical cancer and known pregnancy histories that included at least one live born male were analyzed.

Results: Male cells were observed at low numbers (2-5 cells per section) in one patient with squamous cell carcinoma and in one patient with adenocarcinoma. In both cases, the tissue sections that were analyzed were ~ 1 x 2 cm in area. Microchimeric cells were not observed in the other cases, all of which were represented by smaller specimens (e.g. ~ 1 x 5 mm area).

Conclusions: Microchimerism may be associated with cervical cancer, possibly resulting from fetomaternal cell trafficking or from the presence of semen-associated nuclei. These data, combined with additional data from our laboratory, suggest that microchimerism may be a widespread phenomenon involving many types of disease, including cancer.

22q11 Deletions in Fetuses with Conotruncal Anomalies or Interruption of the Aortic Arch: morphogenetic mechanisms and implications for patient management. *M. Gentile^{1,2}, P. Volpe², M. Marasini³, A.L. Buonadonna¹, M.C. Valenzano¹, F.M. Boscia².* 1) Medical Genetics, IRCCS S de Bellis, Castellana , Bari, Italy; 2) Obstetrics and Gynecology, A.O. Di Venere, Bari, Italy; 3) Pediatric Cardiology, IRCCS Gaslini, Genoa, Italy.

We investigated 100 cases of conotruncal anomalies (CTA) or interrupted aortic arch (IAA), identified in prenatal age, in order to detect the prevalence of 22q11 microdeletion, evaluate the relationship between embryological development of these anomalies and microdeletion of 22q11, and make a comparison between US/FISH results and neonatal clinical findings and outcomes. Prenatal echocardiography and FISH for the DiGeorge critical region (22q11) were performed in all cases. In positive cases the findings were confirmed by autopsy (6 cases) or at post-natal echocardiography and surgery (12 cases). On fetal echocardiography we detected 9 cases of IAA, 12 of Truncus Arteriosus (TA), 31 of Tetralogy of Fallot (TOF), 12 of Pulmonary Atresia with Ventricular Septal Defects (PA with VSD), 15 of Double Outlet Right Ventricle (DORV) and 21 of Transposition of Great Arteries (TGA). FISH detected microdeletions in 22q11 in 18 of 100 fetuses. Our study confirms the feasibility of prenatal diagnosis of heart defects, based on echocardiographic examination, and the high prevalence of 22q11 microdeletion in cases of CTA or IAA. Furthermore our data support the role of 22q11 microdeletion in clinical management of fetuses affected by conotruncal and/or aortic arch anomalies.

Truncus arteriosus in a 45,X male fetus with SRY;autosome translocation. A.K. Yenamandra¹, L. Hentze¹, E. Krim², I. Sadr³, A. Ahmed⁴, W. Fried², P. Koduru¹, L. Mehta³. 1) Cell Genetics, North Shore Univ. Hosp., Manhasset, NY; 2) Dept. Ob/Gyn., North Shore Univ. Hosp., Manhasset, NY; 3) Med. Genetics & Ped. Cardiology, Schneider Children's Hosp. at North Shore, Manhasset, NY; 4) Dept. Pathology, Tampa General Hospital, Tampa, Fla.

A 26 y.o G1P0 woman at 30 weeks gestation was found to have fetal growth retardation and oligohydramnios on ultrasound. The fetus had a single umbilical artery and a heart defect was suspected. Fetal echocardiogram showed truncus arteriosus type I (TA) and a large ventricular septal defect (VSD). Amniotic fluid interphase FISH showed a single X chromosome signal with normal signals for chromosomes 13, 18 and 21. Turner syndrome was presumed, however the fetus had male genitalia on sonogram. Karyotype was confirmed to be 45,X and a FISH study with the SRY probe (located at Yp11.3) showed translocation of SRY to the terminal region of the long arm of chromosome 4. A diGeorge syndrome critical region (22q11.2) FISH study was normal. The biophysical profile of the fetus worsened and the patient opted to undergo late termination of pregnancy. Autopsy confirmed TA type I, a dysplastic semilunar valve, membranous VSD and a left persistent superior vena cava. The right kidney and ureter were hypoplastic. No other birth defects or dysmorphisms were noted. Normal male genitalia were present. Both parents had normal blood chromosome studies. Previous reports of 45,X males with Y;autosome translocations include patients with mental retardation (Y;15), cri-du-chat syndrome (Y;5), trisomy 18 (iso18p) and features of 18p deletion (Y;18). In this case the Y;4 translocation had to be followed by loss of the rest of the Y chromosome. An abnormality at the site of translocation on chromosome 4q could have caused the heart defects as no other etiology was apparent. Though left-sided heart defects are well known in 45,X Turner syndrome patients, TA is only reported in one other patient. Chromosome 4q deletions are associated with heart defects, though not specifically TA. Submicroscopic loss or intersection or inactivation of genes at the site of SRY translocation may determine phenotype in 45,X males with SRY;autosome translocations.

Matthew-Wood syndrome: Prenatal diagnosis and further delineation of a rare condition. *H. Sroka*¹, *G. Ryan*², *S. Keating*³, *A. Pai*¹, *D. Chitayat*¹. 1) Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hosp, Toronto, ON, Canada; 2) Dept. of Obstetrics and Gynecology, Mount Sinai Hosp, Toronto, ON, Canada; 3) Dept. of Pathology, University of Toronto, Toronto, ON, Canada.

Matthew-Wood syndrome is rare condition consisting of pulmonary agenesis, microphthalmia/anophthalmia, and a diaphragmatic abnormality. This unique syndrome is presumably autosomal recessive based on a case report of affected siblings born to unaffected parents (Seller et al. 1996). We report the prenatal diagnosis of Matthew-Wood syndrome based on the fetal ultrasound findings of primary pulmonary hypoplasia, microphthalmia, eventration of the diaphragm and a cardiac abnormality at 25 weeks gestation. The mother was a 26-year-old G4P3L2 woman of English/French Canadian descent and her husband was 27 years old and of French Canadian/English descent. The couple was healthy and non-consanguineous. The couple has two healthy daughters and lost a pregnancy at 34 weeks gestation due to an entangled cord. A fetal ultrasound done at 24.5 weeks gestation in the couples fourth pregnancy revealed left diaphragmatic eventration, bilateral microphthalmia/anophthalmia and cardiac abnormality. Amniocentesis demonstrated a normal female karyotype (46, XX) with no deletion detected at 22q11.2. A fetal echocardiography revealed that the heart occupied most of the left chest. There was a subaortic VSD with mild degree of aortic overriding which could present a mild TOF or a VSD with aortic overriding. Fetal MRI showed bilateral anophthalmia and a cystic structure in the region of the left orbit. The left lung was not identified, the right lung was very small and there was a left diaphragmatic eventration. A female was delivered at 38 weeks gestation and died shortly after birth. An autopsy showed bilateral anophthalmia, diaphragmatic eventration, a hypoplastic heart, hypoplastic lungs more marked on the left than the right, a bicornuate uterus, and a gliopendymal cyst of the corpus callosum.

Ambiguous genitalia in a prenatally diagnosed case of 45,X/46,X,psu idic(Y)(p11.32)karyotype. *S.K. Dhandha, E.W. McPherson, W.A. Hogge.* Dept Genetics, Magee Hosp, Univ Pittsburgh, Pittsburgh, PA.

We report a prenatally diagnosed case of a mosaic karyotype with a 45,X cell line and another cell line consisting of 46,X,idic(Y) karyotype. Prenatally, the majority of the cells (90%) were 45,X on amniocentesis. Therefore, the family was counseled on the Turner phenotype, with the possibility of ambiguous or male genitalia. Follow up ultrasounds showed ambiguous genitalia.

At birth the infant had a bifid scrotum with palpable testes, hypoplastic penis, and hypospadias. Peripheral blood karyotype showed a reversal of the proportions of the cell lines, with 80% of cells containing the extra idic(Y). This case illustrates the difficulty of counseling patients prenatally with mosaic karyotypes (especially those involving sex chromosomes) due to uncertainties involving tissue specific mosaicism. It also raises issues of gender assignment in infants with ambiguous genitalia.

The clinical utility of karyotyping spontaneous abortions. *A.L. Byrnes¹, W.A. Hogge^{1,2}, M.C. Lanasa¹, U. Surti³.* 1) Department of Genetics, Magee-Womens Hospital, Pittsburgh, PA; 2) Department of Obstetrics, Gynecology, and Reproductive Sciences, Magee-Womens Hospital, Pittsburgh, PA; 3) Department of Pathology, Magee-Womens Hospital, Pittsburgh, PA.

Objective: Recurrent pregnancy loss (RPL) affects approximately 1% of couples. Karyotyping of spontaneous abortion material has been advocated as a cost-effective tool in the evaluation of RPL. The objective of this study was to assess the clinical utility of routinely karyotyping spontaneous abortion material. Study Design: We retrospectively reviewed the records of the Pittsburgh Cytogenetics Laboratory from January 1, 1998 through December 31, 2001 for tissues from spontaneous losses at 20 weeks gestation or less for which complete cytogenetics and pregnancy medical records were available. Pregnancy history and maternal demographics were obtained from hospital records. Results: There were submitted samples from 517 individuals of which 28 (5%) failed to grow in culture. Overall, 56% of samples were abnormal. Fifty-two percent of normal results were male. In samples from pregnancies at 13 weeks or less the rate of abnormality was 69%. When analyzed by maternal age, the rate of abnormality in first trimester losses was 57% in women less than 35 years of age, and 82% in those 35 years of age or older. For all losses, there was no difference in the rate of abnormality when comparing first loss versus two or more losses, first pregnancy versus two or more pregnancies, or the presence or absence of at least one live birth. In 82 women with presumed non-chromosomal etiology for a first trimester loss, the rate of chromosome abnormality was 65%. Conclusion: Chromosome abnormalities are the etiology for pregnancy loss in 50-80% of cases, depending on maternal age. There is no association with number of previous losses. Karyotyping of first trimester spontaneous losses beginning with the patient's second loss would provide precise etiologic information, and decrease the number of evaluations necessary for presumptive recurrent pregnancy loss.

TRENDS IN LIVE BIRTH PREVALENCE OF CONGENITAL ANOMALIES 1979-1999 : THE IMPACT OF PRENATAL DIAGNOSIS. *Y. ALEMBIK, M.P. ROTH, B. DOTT, C. STOLL.* Medical Genetics, Hpital de Hautepierre, STRASBOURG, France.

Objectives To describe the impact of prenatal diagnosis on the birth prevalence of congenital anomalies during 21 years (1979-1999) in a well defined population. **Design** A descriptive population-based study. **Setting** Northeastern France (13,500 births per year). **Methods** Analysis of data from multiple sources on births and terminations of pregnancy after prenatal diagnosis of congenital anomalies in 265,679 consecutive pregnancies of known outcome. The study period was divided into 3 subgroups 1979-88, 1989-93 and 1994-99. **Results** Between 1979 and 1988 and 1993 and 1999 prenatal detection of congenital anomalies increased from 11.7% to 25.5% and to 31.9%. Termination of pregnancy (TOP) increased in the same proportions during the 3 time periods. However the increase of TOP was much higher for chromosomal anomalies than for non chromosomal congenital anomalies : 21.7, 43.9 and 64.0 vs 4.8, 7.3, and 10.2 respectively. The birth prevalence of Down syndrome fell by 80% from 1979-88 to 1994-99. Sensitivity of prenatal detection of congenital anomalies and TOPs were lower for isolated cases (only one malformation present in the fetus) than for multiple malformations in the same fetus. Sensitivity varied with the type of malformations : it was high for neural tube defect (79.7%) and urinary anomalies (54.8%) and low for congenital heart defects (25.3%) and for oral clefts (27.6%) **Conclusions** The introduction of routine prenatal diagnosis has resulted in a significant fall in the birth prevalence of congenital anomalies. However this fall varied with the types of congenital anomalies.

Prenatal detection of an interstitial deletion in 4p15 in a fetus with an increased nuchal skin fold measurement.

V.L. Corson, S.T. South, J.L. McMichael, K.J. Blakemore, G. Stetten. Dept. Gyn/Ob, Johns Hopkins University, Baltimore, MD.

The detection of a thickened fetal nuchal skin fold measurement is associated with an increased risk of common trisomies, cardiac defects and an expanding list of other genetic syndromes. We report a 19 year old para 1001 woman who was seen at 21 weeks gestation for a routine ultrasound evaluation that revealed fetal nuchal skin fold measurements of 6.5-8.9mm and a possible pericardial effusion. Following genetic counseling about the possible implications, amniocentesis was performed. A small, interstitial deletion in the short arm of one chromosome 4 was reported, 46,XX,del(4)(p15.2p16.1). Fluorescence in situ hybridization (FISH) using the Wolf-Hirschhorn syndrome probe showed clear signals at the tip of the p arm of both chromosomes 4, confirming that 4p16.3 was present. The maternal karyotype was normal. Paternal blood was unavailable for analysis. The patient elected to terminate the pregnancy and autopsy revealed no major malformations. Dysmorphic features noted included epicanthal folds, a prominent nasal bridge, micrognathia and low-set, posteriorly rotated ears. A series of BAC clones (ResGen Inc.) were prepared and used as FISH probes to refine the breakpoints in chromosome 4. The distal breakpoint lies within a 4Mb region between BAC RP11-81L15 (4p15.33) and BAC RP11-683L20 (4p15.31). The proximal breakpoint lies within a 6Mb region between BAC RP11-660M5 (p15.2) and BAC RP11-53F9 (p15.1).

Chromosome 4p15 deletions have been seen in children with developmental delay, dysmorphic facies, normal-to-accelerated growth and a possible connective tissue disorder. The prenatal finding of an increased nuchal skin fold measurement may be a marker for this particular chromosome abnormality. The pathogenesis of webbing of the neck, a reported feature of 4p deletions postnatally, may involve a gene located at 4p15.1 - 4p15.33. Precise phenotype-karyotype correlations, made possible by cytogenetic resolution using molecular techniques, are crucial in counseling parents when these rare, subtle structural abnormalities are encountered.

CLINICAL-GENETIC STUDY OF SIX FAMILIES WITH RECIPROCAL TRANSLOCATIONS. *R. Baez-Reyes, J.L. Saucedo-Hernandez, G. Razo-Aguilera.* Genetics Department. Instituto Nacional de Perinatologia, SSa. Mexico City.

The incidence of reciprocal translocations in the general population is 1 out of 500 persons (Jacobs,1977). These structural alterations can be detected in parents of children with congenital defects and/or mental retardation, in couples with recurrent spontaneous abortions or sterility. Germ cells produced by carriers of reciprocal translocations can often be unbalanced (Brandiff et al. 1986, Martin 1988), and this fact can lead to embrional and fetal developmental anomalies and limited intrauterine life or neonatal developmental anomalies; segregation of the chromosomes involved as well as the parent who is the carrier of the alteration have to be taken into account in order to figure out the risk in the offspring. Six different reciprocal translocations were observed over a period of two years in the Genetics of Reproduction and Prenatal Diagnosis offices of the Instituto Nacional de Perinatologia, the cytogenetic study indicated in periferal blood cells in 5 case of couples with recurrent gestational loss and in amniotic fluid cells in one case of a fetus with abnormal ultrasonography led to the following findings: t(2;5)mat.; t(3;7)mat.; t(5;7)pat.; t(1;18)mat.; t(1;14)mat and t(2;12)mat. All the couples were given genetic counseling but only four pregnancies were followed to the end, the babies were evaluated at birth and reevaluated periodically to date and even a pedigree studies were achieved. We concluded that the risk of the offspring from carriers of reciprocal translocations should be assessed one by one since it varies in each family depending on the chromosomes involved in the rearrangement, the breakpoints and the degree of genetic imbalance within the carriers germ cells. Prenatal diagnosis, assessment of the baby at birth, and followup checkups should be offered in case of a new pregnancie.

Prospective study of maternal serum screening for fetal chromosomal abnormalities: Clinical importance of false-positive rate. *F. ALVAREZ¹, M.L. SOTO QUINTANA¹, T. PADRON¹, A. ROJAS ATENCIO¹, K. URDANETA¹, A. MORALES MACHIN¹, M. PRIETO².* 1) UNIDAD DE GENETICA MEDICA, UNIVERSIDAD DEL ZULIA, MARACAIBO, ZULIA, VENEZUELA; 2) UNIVERSITY TULANE, NEW ORLEANS, LI.

Background: Maternal serum screening to identify fetal aneuploidy is now routinely offered during second trimester of pregnancy at developed countries. The purpose of this prospective study was to assess the value of maternal serum screening between 15 and 20 week of gestation to detect fetal aneuploidy and to determine the false positive rate (FPR) in a Venezuelan population. Study Design: Blood samples were collected on 1.062 women between 15 and 20 weeks gestation. Samples were assayed for alpha-fetoprotein (AFP), free beta human chorionic gonadotropin (b-hCG) and unconjugated estriol (uE3). Medians were established at each week from 200 normal, singleton pregnancies. Second trimester risk was calculated using the maternal age and different combinations of AFP, b-hCG and uE3. Screening results calculated by likelihood ratio to be equal to or greater than 1:270 were considered positive. If gestational age was confirmed by ultrasonography, genetic counseling and amniocentesis were offered. Results: Ten fetal chromosomal abnormalities were detected with maternal serum screening. Samples size does not allow correct detection rate estimation, but false positive rate (FPR) was found to be in 6,5%. This FPR has one clinical application. At a cut-off of 1:270, second trimester screening best results were obtained using combination of all three biochemical markers. Conclusions: These results confirm the efficacy of maternal serum screening for fetal chromosomal abnormalities with a low FPR. Measurement of AFP, b-hCG and uE3 is an effective prenatal screening test in Latinoamerican population.

Mosaicism for Monosomy 7 and Ring 7 detected through integrated prenatal screening for Down syndrome. *G.E. Johnson, E. Mak-Tam, D. Matias-Impey, H. Dorman, T. Huang, P.R. Wyatt, A.M. Summers.* Genetics Program, North York General Hospital and IODE Children's Centre, , Toronto, Ontario, Canada.

Integrated prenatal screening (IPS) combines first trimester nuchal translucency (NT) and pregnancy associated plasma protein-A (PAPP-A), with second trimester biochemical markers-alpha fetoprotein (AFP), unconjugated estriol (uE3), and human chorionic gonadotrophin (hCG) to screen for pregnancies associated with Down syndrome (DS), neural tube defects (NTD) and trisomy 18. It is expected to detect 85% of cases of DS at term with a false positive rate of 1.5%. Since July 1999, over 7,500 women have been screened using IPS in our centre. Here we report a case of mosaic ring chromosome 7 detected using IPS. A 35 year old Caucasian woman with a negative family history was screen positive for trisomy 18 (risk 1:50) on IPS. An amniocentesis was performed at 17 weeks gestation. Chromosome analysis on 10 metaphase cells showed 45,XY,-7. This karyotype was confirmed on a second amniocentesis; however, FISH analysis using the VYSIS CEP 7 probe on the second sample showed two signals in 90% of the interphase cells examined. The woman had a spontaneous abortion at 20 weeks. The fetus was nondysmorphic but preliminary pathology showed an interrupted aortic arch. Follow-up chromosome analysis of fetal tissue showed the presence of a ring chromosome 7 in 50% of cells in addition to the monosomy 7 cells. Re-examination of the two amniotic fluids did confirm a very low mosaicism for the ring 7 cell line. There are very few cases of mosaic ring 7 reported in the literature. Liveborn patients with the syndrome can have growth deficiency, craniofacial malformations, mental retardation, and pigmentary or vascular skin changes. Cardiac defects have not been reported previously. Our case is unique for 3 reasons: 1) the presence of a monosomy 7 cell line; 2) prenatal detection by IPS screen 3) the different cell line frequencies found in amniotic fluid, fetal tissue, interphase and metaphase analysis. This case illustrates the need for caution when interpreting mosaicism and the need for thorough follow up. These findings provide useful information for prenatal screening and genetic counseling.

Screening for aneuploidy using maternal blood spots in the first and second trimester. *S.B. Melancon¹, S. Demczuk¹, S. Zaor¹, M. Pelletier¹, D.A. Krantz², T.W. Hallahan², J.N. Macri².* 1) Procrea Genetic Services, Mont-Royal, PQ, Canada; 2) NTD Laboratories, Huntington Station, NY, USA.

Prenatal screening for Down syndrome (DS) and open neural tube defects (ONTD) using multiple maternal serum markers is now well established in the second trimester (T2) of pregnancy. Recent data suggest that maternal blood screening in the first trimester (T1) combined with an ultrasound (US) measurement of the fetal nuchal translucency (NT) would allow to reach around 90% sensitivity for DS at a 5% false positive rate. In collaboration with NTD Laboratories, PROCREA has been offering women from Eastern Canada, T1 and T2 maternal screening for DS and ONTD using dried blood spots on filter paper since 1999. NT measurements were selectively offered in T1 and US dating in T2. Before 13 6/7 weeks, PAPP-A and free b-hCG levels were coupled with fetal NT when available. Between 14 and 22 weeks, AFP and free b-hCG were assessed. Following positive screening results, couples were given the choice to follow up in a private or public clinical genetic setting. Until now, 20 640 pregnancies were monitored; 18 970 had T1 (92%) and 1 670 had T2. NT data were provided with 95,5% of T1 samples. There were 38 confirmed cases of DS, 36 in T1 and 2 in T2. In T1, 27/36 (75%) were at risk by blood markers alone, 24/33 (73%) by NT alone and 28/33 (85%) by combined blood/NT results. In one T2 case of DS, blood markers were negative. Using combined blood/NT data in T1, 32 other confirmed aneuploidies were found to be at risk; trisomy 18 in 8, trisomy 13 in 3, Turner syndrome in 10, triploidy in 8 and rare chromosomal anomalies in 3 more. 3 cases of ONTD were found at US in T1. One trisomy 18 and two ONTD were detected in T2. Our results agree with recent combined T1 screening data in DS and T18. In addition, we confirmed the high sensitivity of combined T1 screening in cases of Turner syndrome and in the other less common aneuploidies as well.

Prenatal Diagnosis of Chromosome Abnormalities in Saudi Arabia - A Report of 398 Cases M.A. Iqbal, M. Al-Yousuf, W. Kurdi. DPLM and OB/GYN, King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia. M.A. Iqbal, M. Al-Yousuf, W. Kurdi. DPLM and OB/GYN, King Faisal Specialist Hospital&Research Center, Riyadh, Saudi Arabia.

Although extensive prenatal cytogenetic data is available elsewhere, very few reports are available for Arab countries. The present study describes retrospective data on fetal karyotyping performed on 398 prenatal samples between 1983-2001. The prenatal samples were of amniotic fluid (91%), chorionic villus samples (5%), fetal blood (4%). All of the samples were processed in the laboratory by routine cytogenetic techniques. Clinical indications: abnormal ultrasonographic findings (42.5%), AMA (29.1%), previous child with genetic abnormality (18.8%), carrier of balanced chromosome rearrangement (6.3%), and other indications (3.3%). The mean gestational age at amniocentesis was 24 weeks and at CVS was 12 weeks and 5 days, and cordocentesis was 27 weeks and 5 days. Out of 398 prenatal samples, successful fetal karyotyping was obtained in 385 cases (96.7%). Abnormal fetal karyotype was present in 42 cases (10.6%), and among these, numerical abnormalities were present in 21 cases (50%); autosomal (42.8%); sex chromosome (2.4%) and triploidy (4.8%). Structural chromosome abnormalities were seen in 17 out of 42 cases (40.5%) and mosaicism was observed in 4 cases (9.4%). Out of 169 fetuses with abnormal ultrasound findings, 20 fetuses (11.8%) had an abnormal karyotype, and among these, 17 cases (85%) showed numerical abnormalities. The remaining 15% had structural abnormalities. In the AMA group, 6 out of 116 (5.2%) fetal karyotypes were abnormal; interestingly, trisomy 21 was absent in this group. Out of 75 cases (18.8%) that had a previous child with chromosome abnormality, 70 (93.3%) were normal and 5 (6.7%) were abnormal. Balanced chromosome rearrangement was present in 25 cases (6.3%). Among these, 16 were normal (64%) and 9 (36%) were abnormal. There were 3 cases (0.8%) with a history of recurrent abortions; one of these was normal and 2 were abnormal. The results highlight the importance of fetal karyotyping in high-risk pregnancies. The data will be compared with that of other reported populations in the west.

Evaluation of Ductus Venosus Blood Flow as a Screening Marker for Down Syndrome in the First-Trimester. C. Rossi¹, E. Orlandi¹, F. Orlandi¹, D. Krantz², T. Hallahan², J. Macri². 1) Centro di Diagnosi Prenatale, Palermo, Italy; 2) NTD Laboratories, Huntington Sta, N.Y.

Ultrasound examinations in which crown-rump length, nuchal translucency and ductus venosus (DV) blood flow were evaluated were conducted on 729 first-trimester patients. After the first 78 patients the ductus venosus pulsatility index for the veins (DVPIV) was evaluated. Additionally, a maternal dried blood specimen was analyzed for free Beta human chorionic gonadotropin and Pregnancy Associated Plasma Protein-A. The combination of DV, nuchal translucency and biochemistry was successfully measured in 623 unaffected and 8 Down syndrome cases. The combination of DVPIV, nuchal translucency and biochemistry was successfully measured in 518 unaffected and 6 Down syndrome cases. Abnormal DV blood flow was observed in 26.2% of unaffected cases compared to 62.5% of Down syndrome cases ($P=.07$). The median DVPIV value of 1.15 in unaffected cases was significantly different than the 1.32 observed in Down syndrome cases ($P=.0278$). The false positive and Down syndrome detection rates using DV and DVPIV with maternal age were 15.2% and 75%, and 14.7% and 66.7%, respectively. Including DV into the risk assessment based on nuchal translucency and biochemistry increased the false positive rate from 5.5% (34 of 623) to 6.9% (43 of 623). Including DVPIV reduced the false positive rate from 5.0% (26 of 518) to 3.9% (20 of 518). Applying this approach only to patients whose risk based on nuchal translucency and biochemistry was increased, resulted in 14.7% (5 of 34) and 46.2% (12 of 26) cases being adjusted to within normal range with no loss in detection for DV and DVPIV, respectively. DVPIV, because of its quantitative nature appears to be a better Down syndrome screening marker than DV and should only be used as part of a multiple marker screening protocol. Additional studies are needed to determine if such a protocol should be applied to all patients or only to those with initial false positive results based on the nuchal translucency and biochemistry tests.

A diploid partial hydatidiform mole with microsatellite analysis. *J. Yankowitz, S.M. Zeng, W. Hansen.* Dept OB/GYN, Univ Iowa Hosps & Clinics, Iowa City, IA.

Partial hydatidiform moles (PHM) rarely complicates pregnancy, with an incidence of 0.001% to 0.01% of all pregnancies. PHM is thought to result from a triploid comprising two sets of paternal chromosomes and one set of maternal chromosomes in the fetus and placenta. This can be due to fertilization of a normal egg by two spermatozoa or duplication of a single spermatozoa. The pregnancy is characterized by fetal growth restriction and multiple congenital malformations with cystic changes in the placenta. There have been few reports that describe a normal diploid karyotype in PHM but it has recently been hypothesized that non-triploid PHM does not exist (Genest et al, *J Reprod Med* 2002;47:363-368).

Our patient was a 36 year old gravida 3 para 1. She underwent amniocentesis for maternal age which showed a 46,XX karyotype and normal AFAFP. Ultrasound showed that about 50% of the placenta was composed of confluent cysts. The fetus was normally grown with no anomalies. HCG was 44,257. After counseling about the possibility of partial mole, the patient underwent termination of pregnancy. Histologic evaluation of the placenta showed classic findings of partial mole.

We attempted to determine the genome ploidy and parental origin by analysis of polymorphic markers. Genomic DNA was extracted from molar and normal placenta, four types of fetal tissues (kidney, lung, muscle and eyeball) and parental peripheral blood. 52 polymorphic markers (1-2 markers for each chromosome) were chosen for genotyping. Each polymorphic locus was amplified by PCR and the PCR product was visualized on 6% polyacrylamide gel using silver-staining. Genotyping analysis from 38 informative polymorphic markers disclosed that the fetal tissues, normal placenta and molar tissue were all bi-allelic and of bi-parental origin (one paternal and one maternal). Karyotype of molar tissue also confirmed the original karyotype. Our results indicate that PHM can apparently take place with a diploid genome. These cases represent difficult counseling issues in the presence of normal anatomy and growth of the fetus.

Multiple fetal anomalies associated with subtle subtelomeric chromosomal rearrangements. *I.A. Glass¹, V.L. Souter², D.B. Chapman³, M. Raff¹, M.A. Parisi¹, K.E. Oheim⁴, C.M. Disteché³.* 1) Dept Pediatrics & Medicine, University of Washington, Seattle, WA; 2) Department of Medicine, University of Washington, Seattle; 3) Department of Pathology and Medicine, University of Washington, Seattle; 4) Department of Laboratories, Childrens Hospital and Regional Medical Center, Seattle.

We report two cases of multiple fetal anomalies detected by prenatal ultrasound and associated with subtle subtelomeric chromosomal rearrangements. The first case presented at 25 weeks of gestation with a posterior fossa cyst and ventriculomegaly. Karyotyping of amniocytes showed a subtle terminal abnormality of chromosome 6q. Thereafter, screening of all chromosomal subtelomeric regions using a panel of telomere-specific, fluorescence in situ hybridization (FISH) probes revealed an unbalanced reciprocal translocation between 6q and 17p [46,XX.ish der(6)t(6;17)(q25.3;p13) (TelVysion6q-;TelVysion17p+)]. The second case presented at 25 weeks of gestation with tetralogy of Fallot and at 34 weeks of gestation had additional ultrasound findings of an arachnoid cyst and intrauterine growth retardation. Karyotyping of peripheral blood was performed postnatally and appeared normal. However, a cryptic deletion of the subtelomeric region of the long arm of chromosome 14 was identified when the infants blood sample was used as a control for an oncology FISH probe (IGH-, Vysis Inc). Thereafter screening of all unique chromosomal subtelomeric regions using a panel of telomere-specific, fluorescence in situ hybridization (FISH) probes, revealed an unbalanced reciprocal translocation of chromosomes 14q and 20p [46,XY.ish der(14)t(14;20)(q32.3;p13)(IGH-,D14S308-,TelVysion20p+)mat]. These two cases add to a growing number of reports of cryptic subtelomeric chromosomal rearrangements associated with congenital anomalies. This is also the first report of multiple, simultaneous FISH screening of the subtelomeric regions in amniotic fluid and has demonstrated the technical feasibility of this technique in the prenatal period.

A novel Xp21 contiguous gene deletion associated with Duchenne muscular dystrophy, glycerol kinase deficiency, congenital adrenal hypoplasia and non-specific mental retardation. *S. Baert¹, V. Drouin-Garraud¹, F. Leturcq², P. Marret³, C. Forget⁴, T. Frebourg¹, P. Saugier-veber¹.* 1) Department of Genetics, CHU de Rouen, 76031 Rouen; 2) Laboratory of Biochemistry and Molecular Genetics, Hôpital Cochin, 75014 Paris; 3) Department of Neonatology, CHU de Rouen, 76031 Rouen; 4) Department of Pediatrics, CHG d'Elbeuf, 27000 Elbeuf, France.

The association of Duchenne muscular dystrophy (DMD), glycerol-kinase deficiency (GKD), and congenital adrenal hypoplasia (AHC) results from deletions of the Xp21 region. We report the case of a boy who presented hypotonia at birth and salt wasting at 14 days of life with normal 17 alpha-hydroxy-progesterone. Hypertriglyceridaemia, elevated serum glycerol and CPK (7197 U /L, normal range < 200 U/l) led us to suspect a complex glycerol-kinase deficiency. At 19 months of age, he has a developmental delay and short stature (<3rd percentile) without growth hormone deficiency and mild dysmorphic facial features. G-banding chromosomal analysis was normal. QMPSF (Quantitative Multiplex of Short Fluorescent Fragments) of the Xp21 region revealed that the index case and his mother carried a 3 Mb deletion removing exons 53-79 of *DMD* and the entire *GK*, *DAX-1* and *ILIRAPL1* genes. Partial deletions of the *ILIRAPL1* gene, involved in mental retardation, have already been described, but this report constitutes the first description of a contiguous Xp21 gene deletion removing entirely the *ILIRAPL1* gene. Detection of the *DMD* and *ILIRAPL1* genes deletion in this boy of 19 months of age represents a pre-symptomatic diagnosis of DMD and MR.

Markedly elevated maternal serum alpha-fetoprotein in a twin gestation with both twins heterozygous for Congenital Nephrosis (Finnish Type). *D.N. Saller Jr¹, C.J. Peterson², R.A. Mooney³, P. Martin⁴, S.R. Sanko², E.D. Warner², G. Schwartz⁵, J.A. Canick⁶, W.A. Hogge⁷, J.E. Haddow⁸.* 1) Dept OB/GYN, West Virginia Univ, Morgantown, WV; 2) Dept OB/GYN, Univ of Rochester, Rochester, NY; 3) Dept Pathology, Univ of Rochester, Rochester, NY; 4) Dept Biochemistry, Univ of Oulu, Oulu, Finland; 5) Dept Pediatrics, Univ of Rochester, Rochester, NY; 6) Dept Pathology, Brown Univ, Providence, RI; 7) Dept OB/GYN, Univ of Pittsburgh, Pittsburgh, PA; 8) Foundation for Blood Research, Scarborough, ME.

A 30 year old G3 P2002 female with a twin gestation had a maternal serum alpha-fetoprotein (AFP) at 16.7 weeks of 12.82 MoM. The family history and ultrasound were unremarkable. The amniotic fluid AFPs were 20.65 MoM and 25.01 MoM and the acetyl cholinesterases were both negative. Both karyotypes were 46,XX. DNA testing for Congenital Nephrosis (Finnish Type) (CNF), at the University of Oulu (Finland), indicated both parents were heterozygotes. The father carried a stop codon in exon 8 (previously not identified, but similar stop codons have been found in affected individuals). The mother carried a promoter sequence deletion (previously identified in an affected individual). Analysis of the fetal DNA indicated that both twins were heterozygotes, each carrying the paternal sequence variation only. The amniotic fluid AFP, however suggested an affected pregnancy. The patient was extensively counseled and opted to continue the pregnancy. The remainder of the pregnancy (including serial ultrasounds) was unremarkable. She delivered at 38 weeks by spontaneous vaginal delivery. Initial neonatal urines showed +1 and trace protein. Both twins had trace proteinuria at hospital discharge and have had no proteinuria (negative) on serial urinalysis through 12 months of life. Both twins are healthy and developing appropriately at age 19 months. This case appears to clinically confirm that a single (heterozygote) CNF mutation may affect fetal renal function in the second trimester, causing markedly elevated serum and amniotic fluid AFP, as suggested by Patrakka et al (Lancet 2002;359;1575-7) on terminated pregnancies. Therefore all suspected cases of CNF should be confirmed by molecular studies.

Three consecutive triploidy pregnancies in a 35-year-old woman: genetic predisposition? *B. Huang¹, L. Prensky², M. Thangavelu¹, S. Wang³.* 1) Genzyme Genetics, Orange, CA; 2) California Pacific Medical Center, San Francisco; 3) Harbor-UCLA Medical Center, Torrance, CA.

Triploidy accounts for almost 17% of abortus with chromosome abnormalities. Several mechanisms have been proposed for triploidy including: 1) dispermy; 2) inclusion of polar body during meiosis I or meiosis II and 3) paternal meiosis error resulting in diploid sperms. However, the genetic or environmental factors contributing to the occurrence of triploidy remain unknown. We report a 35-year-old G3P0TAB1SAB2 woman with three consecutive triploidy pregnancies. The patient has a family history of multiple miscarriages (8 miscarriages in paternal grandmother) and infertility (paternal great aunt). She had her first pregnancy at age 31. Ultrasound examination detected multiple abnormalites and the pregnancy was terminated at 16 weeks of gestation. Chromosome analysis of the product of conception revealed a 69,XXX karyotype. The following 2 pregnancies occurred when she was 34 and 35 years of age, respectively. Both pregnancies were miscarried at 8 weeks of gestation. Chromosome analysis of the products of conceptions showed 69,XXY karyotype for both of the pregnancies. There is no other detectable pregnancies. In an attempt to understand the mechanism of repeated triploidy in this couple, microsatellite analysis with DNA markers from multiple chromosomes was performed on the cells from the last pregnancy. The results showed that the fetus inherited two alleles from the mother and one allele from the father, consistent with inclusion of the polar body during maternal meiosis. The information gained from the study will help the family to make informed decisions regarding future reproduction options, particularly in the use of assisted reproductive techniques. In addition, the patient's strong family history of reproductive difficulties and her pregnancy history suggests a possible genetic predisposition to triploidy in this family.

Frequency of congenital defects in newborns of women with diabetes during pregnancy. *M. Aguinaga, I. Llano, C. Hernandez, JM. Garza, DG. Mayen-Molina, R. Garcia-Cavazos.* Departamento de Genetica. Instituto Nacional Perinatologia, Mexico DF, Mexico.

Skipper in 1933 was the first to notice that maternal diabetes was associated with an increased occurrence of congenital malformations. Congenital defects occur 2 to 4 times more frequent in newborns of diabetic women and include cardiopathy, neural tube defects, holoprosencephaly, caudal regression syndrome, renal, gastrointestinal, craneofacial and multiple musculoskeletal abnormalities. The data was collected from the Registry of congenital birth defects of the Instituto Nacional de Perinatologia in Mexico City during the period of 1998 to 2001. Of 504 newborns with congenital defects, we selected only patients with diabetic mothers. There were a total of 70 cases which represents 13.8% of our population. Of these, we detected 27 major congenital defects of which 11 were craneofacial, 5 musculoskeletal, 7 abnormalities of central nervous system, 2 renal and 2 other alterations. Thirty-three minor congenital defects: 21 craneofacial, 7 musculoskeletal and 5 other abnormalities. Ten patients had multiple congenital defects. In our population, newborns of diabetic women account for an important number of patients with congenital defects.

Klippel-Trenaunay Syndrome presenting as possible Amniotic Band Syndrome. *P.L. Devers¹, A.F. Wagner¹, M.C. Treadwell², R. Romero³, G. Conoscenti³, A. Johnson¹.* 1) Div. of Reproductive Genetics, Dept. of Ob/Gyn, Hutzel Hospital, Wayne State University, Detroit, MI; 2) Div. of Maternal-Fetal Medicine, Dept. of Ob/Gyn, Hutzel Hospital, Wayne State University, Detroit, MI; 3) Perinatal Research Branch, NICHD/NIH, Bethesda, MD.

Background: Klippel-Trenaunay syndrome (KTS) is a rare, congenital disorder consisting of combined vascular malformations, varicosities of unusual distribution, and limb enlargement. The antenatal diagnosis of KTS by 2D ultrasound has been well documented. We describe a case of prenatally diagnosed hemihypertrophy suspected to be secondary to amniotic band syndrome (ABS), which was ultimately determined to be KTS.

Case: LM, a 24 y/o G5P2-0-2-2 AA female, presented at 18 2/7 weeks gestation after targeted fetal ultrasound revealed hemihypertrophy of the lt. leg. Both 2D and 3D ultrasound detected thin sheets of amnion extending around the upper and lower leg. Increased vascular resistance was noted in the lt. femoral artery. The remainder of the fetal anatomy appeared normal. The findings were felt to be highly suggestive of vascular obstruction secondary to ABS. Fetoscopy was performed at 21 3/7 weeks gestation for possible excision of the constrictive bands. No identifiable bands were detected; however, multiple bullous lesions and "port-wine" nevi were seen on the edematous leg. Delivery was at 38 2/7 weeks. The lt. leg was noted to have non-pitting edema from thigh to toe with a hemangiomatous lesion extending from the gluteal region to the lateral aspect of the thigh and calf. The diagnosis of KTS was confirmed with the ultrasonic finding of a cavernous hemangioma.

Discussion: The differential diagnosis for prenatally detected asymmetric limb growth would include multiple Mendelian disorders or vascular obstruction secondary to venous thrombosis or ABS. Fetoscopic intervention proved beneficial in eliminating the suggestion of the latter and detection of the dermatologic lesions consistent with KTS.

The role of genetic counseling in assisted reproductive technologies. *A.B. Ilagan¹, T. Hassold¹, P.A. Hunt¹, R. LoretdedeMola², A. Matthews¹.* 1) Human Genetics, Case Western Reserve Univ., Cleveland, OH; 2) Dept. of Reproductive Biology, University Hospitals, Cleveland, OH.

Infertility remains a major health problem affecting 6.1 million people of reproductive age in the United States. Treatment includes a variety of laboratory techniques known collectively as assisted reproductive technologies (ART). Although thousands of children have been conceived by ART since its inception in the late 1970s, associated reproductive risks are continually being assessed and defined. These risks, along with the fact that there are a number of known genetic causes of infertility are compelling reasons why genetic counseling should be an essential part of ART treatment. However, there is no literature that defines the current role of genetic counseling in ART. Therefore, the purpose of this study was to describe how genetic counseling services are currently utilized in reproductive medicine. A total of 406 ART clinics across the United States were sent questionnaires regarding this study. 92 ART clinics completed the questionnaire. Results showed that genetic counselors were employed at 21 clinics. Eleven clinics employed full-time counselors, while counselors worked part-time at 10 clinics. Of the remaining 71 clinics, 67 referred patients to an off-site genetic counselor. Also included in the questionnaire were three vignettes presenting scenarios that involved specific genetic issues, after which participants were asked to describe their current protocol for each situation. Only 50% of respondents indicated that genetic counseling would be included in their protocol for patients with appropriate indications for referral. Given these results, although it was encouraging that genetic counseling was identified as a resource by 96% of participating clinics, it appears that genetic counseling is still underutilized by reproductive specialists in ART. By increasing awareness about the many different roles genetic counseling plays in the ART community, reproductive care would be enhanced for many individuals undergoing ART treatment with underlying genetic causes for their infertility.

b thalassemia prevention program in Iran. *R.R. Karimi-Nejad¹, S. Teimourian¹, F. Sahebjam¹, Y. Shafaghati², S. Hoseini¹, M. Babamohamadi¹, N. Almadani¹, H. Karimi-Nejad¹, H. Najmabadi^{1,2}.* 1) Karimi-Nejad Genetics Ctr, Tehran, Iran; 2) University of Social And Welfare And Rehabilitation sciences.

The most common preventable hereditary disease in Iran is Beta-Thalassemia. The carrier frequency in some regions of the country, is as high as 1 in every 4 individuals. Preventive approach for Beta-Thalassemia started a decade ago as a self-motivated and regulated social need in the form of prenatal diagnosis. Although Iran is a religious country and therapeutic abortions were considered to be unacceptable and against the beliefs of Islam, based on the needs of the society to prevent the widespread of Beta-Thalassemia prevention program was established by the authorities. Iranian geneticists decided to hold a meeting with religious officials to discuss the role of prenatal diagnosis, particularly for B-Thalassemia. It was not until a few years ago when religious leaders accepted that the spread of B-Thalassemia needed to be controlled and issued permission to perform therapeutic abortions up to 16 weeks of gestation for Beta-Thalassemia affected individuals. Simultaneously, the government began to set up an involve systematic approaches for the control and prevention of Beta-Thalassemia. Over the past few years, Iran has also developed a coverage system that forces insurance companies to cover these types of medical expenses; this has been incredibly beneficial in accelerating the prevention program. The government in order to help the prenatal diagnostic program has also approved two national reference laboratories. These reference laboratories are responsible for providing training problem solving, quality control, and quality assurance for themselves and referral laboratories. Today in Iran, effort of the past decade is showing its effect on the society. We are expecting over 1000 prenatal diagnosis to be done this year. Our system is highly efficient and compatible for the neighboring countries. It can be used as a functional adaptive system for any other Islamic countries. In this study we are reporting a total of 2576 chromosome from 2462 individuals of 788 families during 12 years, which has resulted in 541 prenatal diagnosis.

Quantitative Analysis of Fetal DNA in Maternal Serum Before and After Delivery. *M. Hyodo, O. Samura, N. Miharuru, K. Ohama.* Dept.OB/GYN, Hiroshima univ.sch.medicine Japan.

Objective: It has been demonstrated that fetal DNA can be detected in maternal blood during pregnancy and that this DNA can persist for many years after delivery as intact fetal cells and possibly as cell-free fetal DNA. However, it has not been demonstrated how the concentration of fetal DNA in maternal serum change practically before and after delivery, and how long this DNA remains in the maternal circulation. This study was performed to determine the change in the concentration of fetal DNA in maternal serum before and after delivery. **Materials and methods:** The study cases consisted of 20 women carrying male fetuses and 4 women with female fetuses were included as negative controls. Quantitative PCR assay of the sex determining region on the Y chromosome (SRY) was used as a maker of male fetal DNA. We collected peripheral blood from these women at three time points; immediately before delivery, immediately after delivery and one day after delivery. We extracted DNA from 1.2mL of each serum sample and concentrated it into 70L of water. We performed real-time PCR for the SRY gene sequence to detect male fetal DNA in these samples. **Results:** No PCR amplification products of the SRY sequence were detected in the controls. In 20 women carrying male fetuses, the concentration of the SRY sequence in maternal serum before delivery (mean; 85.72copies/mL, range; 16.42-246.96copies/mL) was significantly higher than that after delivery (mean; 64.24copies/mL, range; 2.92-202.53copies/mL)($p=0.03$). One day after delivery, 9 of 20 women with male fetuses had no fetal DNA in their serum, and the mean concentration of the SRY sequence in the other 11 maternal serum was 6.13copies/mL(range; 0.19-15.97copies/mL). **Conclusions:** Fetal DNA was detected in maternal serum before and after delivery, and fetal DNA deceased rapidly by one day after delivery.

Immunofluorescence following FISH: Application to microchimerism studies. *H.P. Stroh, K. Khosrotehrani, D.W. Bianchi, K.L. Johnson.* Division of Genetics, Department of Pediatrics, Tufts-New England Medical Center, Boston, MA.

Objective: Fetal cell microchimerism has been demonstrated in a number of diseases, predominantly autoimmune in nature. The fetal origin of the microchimeric cells has been confirmed by genetic analysis (i.e. PCR and/or FISH). To better understand the functional characteristics of the persistent microchimeric cells, we assessed the feasibility of combining molecular cytogenetic and immunofluorescence methods on archived tissue specimens.

Methods: Paraffin-embedded tissue sections (5 μ M) were subjected to FISH analysis using X and Y chromosome-specific probes, each in a unique fluorescent color. For immunofluorescence analysis, two primary monoclonal antibodies were used: 581 (anti-CD34) and AE1/AE3 (anti-cytokeratin). After performing FISH and without any other pretreatment, slides were washed in PBS, incubated with the primary antibody for one hour (AE1/AE3) or overnight (581), washed and subjected to the detection system. Fluorescent microscopic observation of both histochemical and cytogenetic signals was then performed.

Results: Cytokeratin detection proved successful and stained epidermis in skin and hepatocytes in liver samples, without compromising the FISH signals. CD34 detection failed on spleen, liver and skin samples. Two detection systems were used: a Texas-Red labeled avidin-biotin and a phycoerythrin (PE) goat anti-mouse immunoglobulin antibody. The avidin-biotin detection system resulted in endogenous avidin binding activity with false positive staining. The PE-labeled secondary antibody eliminated this problem.

Conclusions: We have successfully combined immunofluorescence and FISH, using the AE1/AE3 anticytokeratin antibody. In our experience surface markers like anti-CD34 seem to be less effective with this protocol. We believe that internal proteins are best suited for this combined method, although each antibody should be tested empirically.

Recurrent hydatidiform mole: Further mapping and candidate gene analysis on chromosome 19q13.4. P. Panichkul, A. Rajkovic, C.D. Kashork, L.G. Shaffer, I.B. Van den Veyver. Baylor College of Medicine, Houston, TX.

Previous studies support that familial recurrent hydatidiform moles (HMs) have a diploid biparental genomic contribution; affected women carry an autosomal recessive mutation that maps to a region on chromosome 19q13.4 containing imprinted genes. We hypothesized that an oocyte-specific imprinting defect in these women causes their conceptus to behave as a HM with excess paternal genome. Judson, et al. (Nature 2002,416:539-42) found evidence for such an imprinting defect in a patient with 6 recurrent HM. Because familial HM are rare, we hypothesized that patients with sporadic recurrent HM have the same defect and can be studied for additional homozygosity mapping to narrow the critical region. We performed haplotype analysis on two such patients (Mo1 and Mo2) with densely-spaced polymorphic markers in and around the candidate region. Mo1 was homozygous for all markers; Mo2 was homozygous for a smaller interval flanked by D19S418 and D19S404. PCR amplification and direct sequencing of coding exons of *ZIM3* (Zinc-finger gene 3), a paternally imprinted gene and *ZNF264*, a maternally imprinted gene within this region did not reveal mutations in Mo1 and Mo2. A newly identified oocyte-specific gene, *RFPL4* (encoding Ret finger protein-like 4), localized in the candidate region, was also not mutated in Mo1, Mo2. Southern analysis of genomic DNA from Mo1 and Mo2, digested with 6 restriction enzymes and probed with coding exons of these genes did not detect genomic rearrangements. We excluded that a larger deletion was responsible for the apparent marker homozygosity by performing FISH on metaphase spreads from lymphoblasts of patient Mo2 with a BAC clone that maps within the region (no cell lines on other patients were available).

Our findings support that isolated and familial recurrent HM have the same etiology, but additional patients will be studied to confirm this and to narrow the critical region. We further conclude that *ZIM3*, *ZNF264* and *RFPL4* are not mutated in these 2 patients with recurrent HM.

Analysis of imprinted genes on 11p15.5 associated with intrauterine growth. *S. Apostolidou*¹, *A. Williams*¹, *K. O'Donoghue*¹, *Z. Montamedi*¹, *P. Stanier*¹, *P. Loughna*², *G.E. Moore*¹. 1) Maternal and Fetal Medicine, IRDB, Imperial College, Ducane Road, London W12 0NN, United Kingdom; 2) City Hospital, Nottingham NG5 1PB, United Kingdom.

Intrauterine growth restriction (IUGR) contributes greatly to perinatal and childhood morbidity and mortality. IUGR fetuses show ultrasound evidence of slowed growth and are at increased risk of intrauterine hypoxia, acidosis and death. In later life they also have an increased risk of hypertension, glucose intolerance and death from coronary heart disease. The aetiology of IUGR is multifactorial with genetic and environmental factors playing a role. In both mouse and human, disruption of normal imprinting mechanisms has been associated with abnormal growth phenotypes, implicating imprinted genes in the control of size at birth. Chromosome 11p15.5 contains a number of paternally and maternally imprinted genes; *IGF2*, *p57^{KIP2}*, *TSSC3*, *TSSC5*, *H19*, *KCNQ1*, *RNH*. Disruption of *IGF2* imprinting has been found in Beckwith-Wiedemann syndrome and tumours, whereas in transgenic mice deficiency of *Igf2* leads to 60% growth restriction. Quantitative expression analysis of *IGF2* and other imprinted genes on 11p15.5 has been carried out on >200 samples of placenta from consecutive births to compare with fetal growth. Additionally, upstream of *IGF2* is insulin and both genes are regulated by a variable number tandem repeat, the *INSVNTR*. The repeat number or class size and the parent-of-origin of the *INSVNTR* are known to affect both the expression of insulin and *IGF2* in fetal tissues. Smaller repeats increase the risk of type I diabetes and longer repeats are associated with type II diabetes and polycystic ovary syndrome. The same 200 births including parental DNAs (trios) have also been genotyped for the *INSVNTR* class size and parent-of-origin inheritance. Correlations will be drawn between expression levels of the imprinted genes, parent-of-origin, size of the *INSVNTR* and fetal growth in utero.

The genetic contribution to male subfertility: a clinical and molecular genetic study. *C.A. Gardiner¹, K.J. Flintoff², G.R. Taylor², V. Sharma³, A.J. Rutherford⁴, A.H. Balen⁴, C.E. Chu⁵.* 1) Dept Clinical Genetics Service, Nottingham City Hosp, Nottingham, England; 2) Yorkshire Regional DNA Laboratory, Leeds. UK; 3) Assisted Conception Unit, St James University Hospital, Leeds. UK; 4) Assisted Conception Unit, The General Infirmary at Leeds, Leeds. UK; 5) Yorkshire Regional Genetics Service, Leeds. UK.

Approximately 1 in 10 couples seek medical help for subfertility and in about 25% of these cases there is solely male factor subfertility. Epidemiological studies have shown that some male subfertility is familial. Approximately 14% of azoospermic men and 5% of oligozoospermic men have a chromosome abnormality and about 10% of men with azoospermia and 5% of men with oligozoospermia have a Y-chromosome microdeletion. The mean androgen receptor (AR) CAG repeat length has been reported to be significantly longer in male subfertile patients than in fertile controls. Ninety-three men with azoospermia or oligozoospermia and fifty fertile controls agreed to take part in a study, which involved obtaining a three generation pedigree and molecular genetic analysis for Y-chromosome microdeletions and the size of the CAG repeat length in the AR. One man was identified as having a Y-chromosome re-arrangement and one man was identified as having a Y-chromosome microdeletion. There was no statistical difference in the size of the CAG repeat length between the patient and the fertile control population. Five percent of the study population had one first degree relative with subfertility and none of these men had a chromosome abnormality or a Y-chromosome microdeletion. Other genes or environmental factors are involved in male subfertility and family history appears to be currently the only way to identify this group of men. Identification of these families could allow mapping of genes involved in male subfertility or identification of environmental factors that may affect male fertility.

Quantification of gene expression in testicular tissue specimens of idiopathically infertile males. *R. LAVERY¹, J.A Houghton³, A. Nolan², M. Glennon¹, D. Egan³, M. Maher¹.* 1) National Diagnostics Centre, BioResearch Ireland, National University of Ireland, Galway; 2) Fertility Unit, University College Hospital, Galway; 3) Microbiology Department, National University of Ireland, Galway.

Quantitative real-time PCR is increasingly used to quantify copy numbers of nucleic acids for clinical applications. In this study the LightCycler real-time PCR system was used to quantify gene expression levels of selected genes associated with spermatogenesis in a cohort of controls (n=6) and idiopathically infertile males (n=15). The application of quantitative real-time reverse-transcriptase-PCR (RT-PCR) technology for measuring the expression of a number of candidate Y-chromosome genes together with ZNF genes, Protamine-2 and b-actin, the housekeeping gene, was investigated. RNA was extracted from testicular biopsy specimens using Trizol and DNase treated to remove contaminating DNA. LightCycler reactions were prepared using 0.5mg of DNase treated testicular RNA. Quantification of mRNA was performed by comparison to a standard curve generated following RT-PCR amplification and purification of 103,106 and 108 molecules of each gene of interest using the LightCycler - RNA amplification kit SYBR Green 1 (Roche Molecular Biochemicals). To date, Protamine-2 transcribed post-meiotically in the round spermatid stage of spermatogenesis and the ZNF230 gene have been analysed. The Protamine-2 gene was expressed in controls and clinical samples positive for the presence of sperm at biopsy giving mean Ct values of 21.905 and 24.23 respectively. A Ct value of 38.7, below the value of the negative control Ct value, was observed in negative biopsies therefore confirming findings on examination of the biopsy. The newly identified ZNF230 gene (Zhang et al, 2001), previously reported to be undetectable in the testes of azoospermic patients was also analysed by real time RT-PCR. Controls and azoospermic patients had mean Ct values of 18.28 and 20.38 respectively. Histological analysis of testicular biopsy material from patients is also being preformed with a view to suggesting a genotype/ phenotype correlation for the patients.

Identification of the Simpson-Golabi-Behmel Syndrome type 2 gene candidates on chromosome Xp22. *B. Xu*¹, *R.P. Hart*², *Z. Zhang*³, *R. Weksberg*⁴, *L.M. Brzustowicz*^{1,5}. 1) Department of genetics, Rutgers university, Piscataway, NJ; 2) Department of Cell Biology and Neuroscience, Rutgers University Piscataway, NJ; 3) Department of Microbiology and Immunology, Temple University, Philadelphia, PA; 4) Departments of Paediatrics and Genetics, The Hospital for Sick Children and Departments of Paediatrics and Molecular and Genetics, University of Toronto, Canada; 5) Department of Psychiatry, UMDNJ, New Jersey Medical School, Newark, NJ.

The gene for Simpson-Golabi-Behmel syndrome (SGBS) Type 2 has been mapped to an approximately 6 Mb region on chromosome Xp22. This area is predicted to contain 100 to 200 genes, a daunting number to individually mutation screen. The Human Genome Project has sequenced approximately 90% of this region. We have utilized bioinformatics methods to build a catalog of gene structures in this interval. To utilize information generated by the Human Genome Project, the public genomic annotation project, OMIM, and the EST database, a pipe application has been developed to parse genomic annotation data, process EST assemblies and spliced EST/genomic alignments, and simultaneously pipe all data into Artemis, a Java visualization program. This approach has identified 234 candidate sequences in this region. These represent 46 known genes or sequences with strong experimental evidence and 188 EST assembled contigs. These candidates were then used for initial transcript profile screening. Clinic and knock-out mouse studies have demonstrated the importance of the IGF-2 pathway in the overgrowth syndromes. The human HepG2 cell line was employed as a model cell system and utilized to assess the effects of manipulation of the IGF-2 pathway on level of expression of the 234 candidates. Gene expression profiles were established by real-time PCR. Sixty-five of the candidates were detectably expressed in the HepG2 cell line. Among them, 13 genes (4 known genes and 9 EST assembled contigs) showed reproducible expression changes after exposure to IGF-2. These genes are potential candidates for SGBS Type 2, and represent a manageable number to screen for causative mutations. Further study of these candidates will be conducted on samples from a patient with SGBS Type 2 and normal controls.

Preliminary estimate for the detection rate of 45,X pregnancies using the second trimester maternal serum triple test. *P.A. Benn¹, J. Ying²*. 1) Div Genetics, Dept Pediatrics, Univ Connecticut Health Ctr, Farmington, CT; 2) Dept Statistics, Univ Connecticut, Storrs, CT.

Objective: To estimate the detection rate for 45,X pregnancies through second trimester maternal serum Down syndrome and trisomy 18 screening. Also, to evaluate a screening protocol specifically designed to identify 45,X pregnancies. **Methods:** 22 cases of 45,X were ascertained through a cytogenetics database and an additional 51 cases were identified through publications. Screening results (maternal serum alpha-fetoprotein, human chorionic gonadotropin, and uncojugated estriol) were reviewed for cases with fetal hydrops, cystic hygroma alone, and, no evidence of edema. For modeling purposes, 45,X cases were categorized on the basis of their hCG values (Type A >1.0 MoM and Type B <1.0 MoM). Means, standard deviations, and correlation coefficients were calculated and detection rates and false-positive rates established through computer simulations. Second trimester screening cut-offs were 1:270 for Down syndrome and 45,X Type A pregnancies and 1:100 for trisomy 18 and 45,X Type B pregnancies. The 45,X screening protocol was based on modification of a second trimester maternal age-specific prevalence curve for 45,X. Detection rates for Type A and Type B cases were combined and the overall efficacy evaluated for the 1999 U.S. pregnancy population. **Results:** Approximately 49% of all 45,X pregnancies should be identifiable through Down syndrome and trisomy 18 triple testing. The detection rate for cases with hydrops or cystic hygroma was 52% and, when edema was absent, 41%. If offered in conjunction with Down syndrome and trisomy 18 screening, the 45,X screening protocol could identify an estimated 15% more of the affected pregnancies with an incremental gain of 0.9% in the false-positive rate. For women aged <35 years, the incremental gain in detection and false-positive rate was 16% and 1% respectively, while for women aged ≥35 the gain in the detection rate and false-positive was 7% and 0.3% respectively. **Conclusion:** A worthwhile screening algorithm for 45,X could be developed that would primarily benefit younger women.

Accuracy of expected risk of trisomy 18 using the second trimester triple test. *C. Meier, T. Huang, PR. Wyatt, AM. Summers.* Dept Genetics, North York General Hosp, Toronto, ON, Canada.

Since the mid-1990s many centres have used an individual risk method for calculating trisomy 18 risk (Palomaki 1995). Although this method had been widely used, the accuracy of the individual risk has not been well evaluated. Using data from a large provincial programme, we tested the accuracy of estimated risk of trisomy 18 syndrome. The study was based on 382,568 women screened in the Ontario maternal serum screening programme between October 1993 and September 2000. Ninety-four percent of them had known pregnancy outcomes including 108 affected pregnancies. 92,874 were screened using risk cut-off level method (3 1 in 100). The remaining women were screened using a fixed analyte cut-off method. The expected risks for Trisomy 18 for the former group were calculated for this study using AFP Expert (Benetech, ON, Canada) and by applying published population parameters. The age specific prevalence for trisomy 18 was estimated as one tenth of the Down syndrome prevalence for the same age.

Women screened were ranked according to their individual expected risk of Trisomy 18 syndrome. They were divided into nine groups, each group containing 5 to 50 cases of Trisomy 18 pregnancies. The mean expected term risks of having an affected pregnancy were calculated for each group. The risks were then compared with the observed risks (prevalence) of that particular group. Since it is estimated that 70% of Trisomy 18 pregnancies will abort spontaneously subsequent to midtrimester, cases with positive screening results and diagnosed prenatally were multiplied by 0.3 to allow for the spontaneous fetal losses. Close agreement between the mean expected risks and the observed prevalence was seen across lower risk groups, but women identified as having high-risk (by calculation) pregnancies had an actual prevalence that was somewhat less extreme. To our knowledge, this is the first study looking at this question. Our results show the expected risks of Trisomy 18 syndrome assigned to individual women were on average, close to the observed risks across all the risk ranges.

The levels of maternal serum markers for Down syndrome screening in Aboriginal Canadian women. *T. Huang¹, AM. Summers¹, PR. Wyatt¹, C. Meier¹, G. Côté²*. 1) Genetics program, North York Hospital, Toronto, Ontario, Canada; 2) Sudbury Regional Hospital, Sudbury, Ontario, Canada.

In second trimester maternal serum screening (MSS) for Down syndrome, a woman's risks of having a term Down syndrome pregnancy is calculated by combining her age specific risk with her serum marker levels. Previous studies have reported ethnic differences in levels of serum markers, with the major differences seen between Black and Caucasian women. We conducted a study to investigate whether the levels of MSAFP, MShCG, and MSuE3 in Aboriginal women are different from those of Caucasian women. The study was conducted in 7717 Caucasian and 413 Aboriginal women (mostly Ojibway, Oji-Cree and Cree) with singleton pregnancies screened in the Ontario MSS programme between October 1993 and September 1998. Women with multiple pregnancies, pregnancies affected with Down syndrome, neural tube defects, or Trisomy 18, those with insulin-dependent diabetes mellitus and those without weight recorded were excluded from the study. No differences in the levels of maternal serum alpha-fetoprotein and total human chorionic gonadotrophin were observed between the two groups. Maternal serum unconjugated estriol was 15% higher in Aboriginal women. Similar results were seen even after controlling for the influences of age and parity on serum markers. Since Aboriginal women make up only a small proportion of women screened, correcting the level of uE3 for this group will have little effect on screening performance for the whole of Ontario. However, if these results are confirmed by further study, individual centres may consider making this correction, so that similar screening performance can be achieved in Caucasian and Aboriginal women.

Maternal weight impact on maternal triple-marker serum concentrations in a Venezuelan population. *M.L. Hernández, F. Álvarez-Nava, M. Soto, T. Padrón, M.C. Martínez.* Unidad de Genética Médica, Universidad del Zulia, Maracaibo, Venezuela.

Background: Maternal serum screening by means of alpha-fetoprotein (AFP), free b-subunit of chorionic gonadotrophin (b-hCG) and unconjugated estriol (uE3) is broadly consolidated at clinical level allowing to reach a detection rate of 60-70% of syndrome Down fetus. It is known that variables modifying these values exist. The objective of this study is to determine the influence of maternal weight, presence of diabetes mellitus, maternal smoking habits, gravidity, parity and fetal gender on the level of maternal serum markers used in second trimester screening.

Study Design: Maternal serum AFP, b-hCG and uE3 concentrations had been measured in 1062 singleton unaffected pregnancies from 15 to 20 week in two centres of Maracaibo, Venezuela. Information on maternal weight, cigarette smoking, maternal insulin-independent diabetes mellitus, gravidity and parity was available in all pregnancy, fetal gender was only available in 445 amniocentesis was carried. All results were expressed as multiple of the gestation specific median (MoM) values.

Results: All three markers showed a statistically significant negative association with maternal weight ($p < 0,05$) and subsequent analyses MoM values were adjusted using regression analyses. The MoM three serum markers levels in primigravidas was significantly greater than that in non-primigravidas but when it was weight adjusted this differences was not present. Similar results were found for parity. No difference was found in the serum level of all markers in female or male pregnancy.

Conclusions: Maternal weight is most important second trimester screening covariable. Our results emphasize the need for weight correction in serum screening for fetal aneuploidies.

Role of Morbid Obesity and Consanguinity in Maternal Serum Alpha-fetoprotein Screening. *S.B. Reddy¹, S. Reddy², S.S. Reddy³, I. Khanfer³, A.K. Roy³.* 1) Alpha Feto-Protein , Natl Medical Diagnostic Lab, Southfield, MI; 2) Peoples Clinic, Detroit, MI; 3) St. Joseph Medical Center, Detroit, MI.

We have screened African-American and Asian Indian pregnant women for prenatal screening of Neural tube defects and chromosomal defects employing Triple test (MSAFP, MShCG and MSuE3). Our Maternal Serum Alpha-feto Protein (MSAFP) values are adjusted for maternal weight, race and Insulin dependent Diabetes Mellitus (IDDM). In our investigation 97 morbidly obese pregnant women in African-American population weighed 390-402 lbs and 58 in Asian Indian population 270-375 lbs. Out of these 58 morbidly obese Indian pregnant women 22 marriages are consanguineous. They are married either to their first or second cousin or maternal uncle. There have been several reports in the past to show the relationship between maternal weight and MSAFP in different ethnic groups. It has been established that a diluting effect of larger plasma volume is attributed to the lower median values in heavier pregnant women. Thus, heavier women generally have lower concentrations of circulating AFP. That is the reason the weight adjustments are to be made to obtain the precise prenatal risks. The analysis of the outcome data for Neural tube and chromosomal defects we have not found any difference between these two populations of pregnant women. However we found a significant proportion of chromosomal defects was exhibited in the Asian Indian pregnant women in excess of 350lbs with consanguineous marriage. Data and statistics with plausible mechanisms including consanguinity coupled with morbid obesity will be presented.

Antenatal manifestations of Smith-Lemli-Opitz syndrome. A. Goldenberg¹, C. Wolf², F. Chevy², A. Benachi³, Y. Dumez³, A. Munnich¹, V. Cormier-Daire¹. 1) Department of Medical Genetics, Necker-Enfant-Malades Hospital, Paris, France; 2) Laboratory of Mass Spectrometry, Saint-Antoine Hospital, Paris, France; 3) Department of Obstetrics, Necker-Enfants-Malades Hospital, Paris, France.

Smith-Lemli-Opitz syndrome (SLO) is an autosomal recessive multiple malformation and mental retardation syndrome ascribed to a 7-dehydrocholesterol reductase deficiency, usually diagnosed in the early postnatal period. Prenatal diagnosis based on dehydrocholesterol measurement on chorion villi or amniotic fluid is highly reliable. Reviewing a series of 30 cases of SLO, we have addressed the question of the antenatal expression of the disease. Only 10 cases were detected antenatally and 20/30 cases were retrospectively analysed based on antenatal ultrasounds. Intra uterine growth retardation (IUGR) was the most frequent detectable feature (20/30). IUGR was either isolated (9/20) or associated with at least one other anomaly (11/20) including nuchal oedema, renal, cardiac, cerebral malformation, genital anomalies and polydactyly. Among them, 3/11 presented with multiple malformations (> 3 anomalies). In 5/30 cases isolated nuchal oedema (3/30), isolated cardiac (1/30), or renal malformation (1/30) was the only detected anomaly. Finally, ultrasound survey was considered normal in 5/30 cases. We conclude that SLO is frequently expressed antenatally, and we suggest giving consideration to a more systematic sterol screening when dealing with IUGR, especially when associated anomalies are detected.

RARE AND UNEXPECTED MUTATIONS AMONG IRANIAN BETA THALASSEMIA PATIENT AND PRENATAL SAMPLES DISCOVERED BY REVERSE-HYBRIDIZATION AND DNA SEQUENCING. E.

Mehdipour¹, A.A. Pourfathollah², A. Moritz³, M. Neishabury¹, F. Sahebjam¹, A. Tabarroki¹, H. Najmabadi¹, W. Krugluger⁴, C. Oberkanins³. 1) Genetics, University of Social Welfare a, Tehran, Iran; 2) Tarbiat Modarres University, School of Medical Sciences, Tehran, Iran; 3) ViennaLab Labordiagnostika GmbH, Vienna, Austria; 4) Institute of Clinical Chemistry, Rudolfstiftung Hospital, Vienna, Austria.

-Thalassemia is one of the most common hereditary disorders in Iran with an extensive spectrum of mutations. While peripheral diagnostic laboratories are covering the most common mutations known to occur within their respective area, samples remaining unknown mutation are referred to our national reference laboratory for further analysis. We have analyzed 70 previously unresolved cases (thalassemia patient and prenatal samples) by a two-step approach combining reverse-hybridization and DNA sequencing of the entire β -globin gene and 5'-untranslated region. Results: In 60 (86%) of these samples a total of 23 different rare and unexpected β -globin alleles were identified. One of them was a previously unknown transition from AAG (Lys) to TAG (Stop) in codon 95. These results further emphasize the heterogeneity of β -thalassemia in Iran. Refining the knowledge about the distribution of common and rare mutations will further improve our abilities in carrier detection and prenatal diagnosis to prevent this prevalent disorder.

Genetic susceptibility to thrombophilia in women with a past history of pregnancy-induced hypertension. *J. Girouard, N. Bernard, P. Savard, J.M. Moutquin, J. Massé, J.C. Forest, Y. Giguère.* CHUQ, CRSFA, Unité de périnatalogie, Québec, Canada.

Pregnancy-induced hypertension (PIH) is a pregnancy disease characterised by hypertension occurring after 20 weeks of gestation. Some retrospective studies have suggested that women with a past history of PIH could be at increased risk of cardiovascular disease. So far, in a nested case-control study, we are evaluating the cardiovascular risk factor profile (phenotype and genotype) of women with a past history of PIH recruited prospectively 6 to 12 years ago. It is possible that susceptibility to thrombophilia could predispose women to both PIH and long-term cardiovascular disease, but this is not established yet. Polymorphisms of the Factor V Leiden (G1691A), thermolabile MTHFR (C677T), prothrombin (G20210A) and PAI-1 (4G/5G) genes were studied. Cases (n=159) were matched for age and year of delivery with controls (normal pregnancy, n = 106). All genotypes were performed by ASO-PCR. Genotypes distribution followed Hardy-Weinberg equilibrium for all polymorphisms except for the MTHFR polymorphism in cases. This disequilibrium suggests an enrichment of TT-genotype among cases but the odd ratio (OR) for this genotype compare to controls did not reach significance (OR = 1.28; C.I. 95% = 0.65 - 2.53; p = 0.59). Also, for this polymorphism, subgroups analyses based on diagnostic severity did not show any difference between groups. Carrier frequencies of the Factor V Leiden (3.2% vs 4.8 %; p = 0.75) and the G20210A prothrombin (2.5% vs 2.9%; p = 0.83) gene polymorphisms were similar between cases and controls. For the PAI-1 gene polymorphism, genotype and allele frequencies were similar between cases and controls. Using a prospective design, we did not observe any association of the commonly studied polymorphisms associated with genetic susceptibility to thrombophilia in women with a past history of PIH from the French Canadian population.

Linking pregnancy-induced hypertension to cardiovascular disease risk: polymorphisms of the lipoprotein lipase and hepatic lipase genes in French Canadian women. *N. Bernard, J. Girouard, P. Savard, J. Massé, J.M. Moutquin, J.C. Forest, Y. Giguère.* CHUQ, CRSFA, Unité de recherche en périnatalogie, Québec, Canada.

Pregnancy-induced hypertension (PIH) complicates 3-6% of pregnancies and causes increased morbidity for the mother and her fetus. Also, it is suggested that women who suffered from PIH are at increased risk of cardiovascular disease (CVD), but there is little data based on prospective designs. From a cohort of 5543 primiparous women recruited between 1990 and 1996 and diagnosed prospectively, we are studying the link between PIH and long-term risk of CVD. In an ongoing follow up nested case-control study, we are evaluating clinical and anthropometrical profiles of subjects who were pregnant 6-12 years ago, in addition to polymorphisms of the lipoprotein lipase (LPL) and hepatic lipase (HL) genes. We recruited 159 cases (PIH: 34.5 year old) and 106 controls (normal pregnancy: 35.4 year old). We found unfavorable anthropometrical (BMI: 27.5 vs 24.7 kg/m², $p = 0.0002$; abdominal circumference: 101.2 vs 94.9 cm $p = 0.0002$) and lipid (HDL-cholesterol: 1.29 vs 1.40 mmol/L, $p = 0.004$; atherogenic index: 3.8 vs 3.4, $p = 0.004$) profiles in women with a past history of PIH compared with controls. Since the frequency of LPL mutations is increased in French Canadians, we studied by ASO-PCR the risk of PIH associated with the presence of the N291S, D9N, P207L, G188E, D250N and S447X polymorphisms of the LPL gene, as well as the C-514T polymorphism of the HL gene. The combined carrier frequencies of the N291S, D9N, P207L, G188E and D250N mutations (8,1% vs 9.8%; $p = 0.79$) as well as the S447X polymorphism (11% vs 14%; $p = 0.25$) were similar between cases and controls. However, there was a trend for a decreased proportion of 514T allele carriers (HL gene) in the PIH group (odd ratio (OR) = 0.7; 0.4-1.1), especially in the preeclampsia (PIH and proteinuria) subgroup (OR = 0.5; 0.3-1.0) compared with controls. Our results suggest that the lower frequency of HL 514T carriers may explain in parts the increased risk of PIH and the unfavorable CVD risk profile in French Canadian women.

Program Nr: 2304 from 2002 ASHG Annual Meeting

Preimplantation Genetic Diagnosis for Cancer Predisposition. *S. Rechitsky, O. Verlinsky, A. Chistokhina, T. Sharapova, S. Ozen, C. Masciangelo, A. Kuliev, Y. Verlinsky.* Reproductive Genetics Inst, Chicago, IL.

Preimplantation genetic diagnosis (PGD) has recently been offered for couples with inherited predisposition for late onset disorders. We offered this approach for the couples at risk for producing children with cancer predisposition. Using a standard IVF procedure, oocytes or embryos were tested for different mutations predisposing to cancer, preselecting and transferring only mutation-free embryos back to the patients. The procedure was performed for patients with predisposition to familial adenomatous polyposis (maternal 13 bp and 5 bp - deletions in exon 15 and paternal nt2110 insertion G in APC gene), Von Hippel Lindau syndrome (paternal A to T substitution in nt482 of exon 1 in VHL gene), retinoblastoma, Li- Fraumeni syndrome (paternal G524A and maternal 902insC mutations in p53 tumor suppressor gene), neurofibromatosis type I (maternal Trp->Ter (TGG->TGA) mutation in exon 29 of NF1 gene) and type II (L141P mutation in exon 4 of NF2 gene), and familial posterior fossa brain tumor (maternal mutation due to G to A substitution in a donor splice site of Nt443 of exon 7 in hSNF5 gene). Overall, 20 PGD cycles were performed for 10 couples, resulting in preselection and transfer of 40 mutation- free embryos, which yielded 5 unaffected clinical pregnancies and 4 healthy children born by the present time. Despite the controversy of PGD use for late onset disorders, the data demonstrate the usefulness of this approach as the only acceptable option for at risk couples to avoid the birth of children with inherited predisposition to cancer and have a healthy child.

Intact fetal cell isolation from maternal blood using neither MACS nor flow cytometry: Improved isolation using a simple whole blood progenitor cell enrichment approach (RosetteSep™). *F.Z. Bischoff¹, D. Marquez-Do¹, D.I. Martinez¹, C. Horne², D. Dang¹, A. Burke¹, D.E. Lewis², J.L. Simpson^{1,3}.* 1) Depts OB/GYN; 2) Immunology; 3) Molecular/Human Genetics, Baylor Col Medicine, Houston, TX.

Isolation and analysis of intact fetal cells in maternal blood is an attractive method of noninvasive prenatal diagnosis. The frequently observed poor sensitivity and inconsistent recovery is compounded by few circulating fetal cells as well as loss of these fetal cells during enrichment. Optimizing selection criteria and utilizing less complicated methods for target cell enrichment is essential. Hence, MACS and other methods that minimize fetal cell loss have replaced flow cytometry methods. We report salutary results using a simple density-based depletion method that requires neither MACS nor flow separation. **OBJECTIVE:** To determine the sensitivity of fetal cell detection using a density-based method for enrichment of progenitor cells. **METHOD:** Maternal blood samples were obtained prior to amniocentesis/ CVS and then processed randomly within 24 hrs using one of two density-based enrichment methods: 1) For progenitor cell enrichment, samples (n=36; 15.3 mean gestational wks) were labeled with a RosetteSep progenitor antibody cocktail (StemCell, Tech) to remove unwanted mature T-cells, B-cells, granulocytes, natural killer cells, neutrophils and myelomonocytic cells. 2) For enrichment of CD45- cells, samples (n=16; 15.1 mean gestational wks) were labeled with RosetteSep CD45 antibody for removal of maternal white cells. Following antibody labeling, cells were separated on a single Ficoll density (1.077 gm/ml) gradient. The desired non-labeled and less dense cellular fraction was collected and analyzed by FISH using X and Y chromosome-specific probes. **RESULTS:** The detection rate with the progenitor cell enrichment approach was 55% (6/11 male cases) with 4% false-positive (1/25 female cases). No fetal cells (0/7 male cases) were detected with CD45- enrichment. **CONCLUSIONS:** Sensitivity observed using the progenitor cocktail is comparable to that obtained by a single serum analyte with low false-positive detection, and equal or superior to that found with far more laborious flow cytometry or MACS.

Phenotype-karyotype discrepancy in prenatal diagnosis of Turner syndrome: FISH detection of unusual Y chromosome rearrangements. *C. Guze*^{1,3}, *B.J. White*², *J. Kelly*⁴, *A. Anderson*³, *L. Mak*², *R. Hassan*¹. 1) Dept OB/GYN, King Drew Medical Ctr, Los Angeles, CA; 2) Quest Diagnostics, San Juan Capistrano, CA; 3) Calif State Univ Dominguez Hills, Carson, CA; 4) Quest Diagnostics at LA Metro, Van Nuys, CA.

A 27 y.o. Hispanic G5P2A2 requested an amniocentesis at 16 3/7 weeks because of a previous child with Prader-Willi syndrome due to a de novo deletion. She was aware of the low recurrence risk but because of possible gonadal mosaicism she wanted prenatal testing. Following an initial cytogenetic report of 45,X, a fetal ultrasound indicated a male phenotype. When a review of banded slides did not reveal a Y chromosome, FISH of 2 slides was done using X and Y centromeric probes (Vysis, Inc.). The FISH results showed 3 cell lines: one with a single X chromosome signal consistent with the 45,X cell line; a second with an X and a small Y with an absent long arm; and a third with an X and a dicentric Y consisting of two long arms. To assess proportions of the 3 cell lines and Y structure, FISH was performed using Y probes for the sex determining region (SRY) and distal long arm (Yq12). Both the deleted and dicentric Y were SRY positive; both q arms of the dicentric were positive for Yq12. These results from 40 interphases and 2 metaphases indicated a presumptive karyotype of 46,X,dic(Y;Y)(p11.1 or p12;p11.3)[18]/45,X[13]/46,X,del(Y)(q11.1 or q11.21)[9]. The presence of SRY positive cell lines is consistent with the observation of a male phenotype in a fetus with 45,X mosaicism. Examination by a pediatric endocrinologist following delivery revealed normal male external genitalia: rugated scrotum, descended testes and normal penis. These findings generally correlate with future normal male development with little or no risk of gonadoblastoma. The peripheral blood karyotype confirmed the presence of the 3 cell lines: 45,X[8]/46,X,del(Y)(q11.21)[7]/46,X,psu dic(Y)(p11.3)[5]. These Y rearrangements appear to be de novo as the father's chromosomes were normal. This case argues strongly for use of FISH SRY probes on any amniocentesis with a 45,X, to detect mosaicism which may confer potential for normal male development.

A randomized controlled trial (RCT) to evaluate the use of misoprostol for second trimester pregnancy termination associated with fetal malformation. *H. Akoury¹, M. Hannah¹, R. Windrim¹, D. Myles Reid^{1,2}, A. Pai^{1,2}, M. Thomas^{1,2}, G. Seaward¹, E. Winsor², G. Ryan¹, L.E. Ferris¹, T. Einarson¹, A. Willan¹, M. Thomas³, D. Chitayat^{1,2}.*
1) Obstetrics and Gynecology, Mount Sinai Hospital, Toronto, Ontario, Canada; 2) The Prenatal and Medical Genetics Program, Mount Sinai Hospital, Toronto, Ontario, Canada; 3) York University,McLaughlin College, Toronto, Ontario, Canada.

Objective: To compare the effectiveness and safety of misoprostol administered orally (OM) or vaginally (VM) to intra-amniotic injection of prostaglandin F₂ (IAPG) **Methods:** A multi-centre RCT of 3 groups with 217 patients. The primary outcome was the time from start of treatment to placental delivery and the secondary outcomes were the incidence of major and minor maternal complications. OM and VM groups received misoprostol 400 microgram every 4 hr. for 24 hr. IAPG group received 40 mg PGF₂alpha intra-amniotically followed 4 hr. later by oxytocin infusion at 166 mU/min for 24 hr. or until delivery. We performed one interim analysis after 1/3 of patients were enrolled. Before the start of the trial, we designed criteria to stop part or all the trial. **Results:** There were no statistical differences among the three groups in baseline characteristics or in the incidence of major and or minor maternal complications. The interim analysis showed OM had statistically significant longer time to placental delivery compared with VM and IAPG. Therefore, we stopped recruitment in OM and completed recruitment in the other two groups in March 2001. At study completion, mean and standard deviation of the primary outcome in hours was 18.3±8.2 for VM, 21±10.2 for IAPG and 30.5±14.4 for OM. OM showed statistically significant difference in time to placental delivery compared with VM, $p < 0.001$ and IAPG, $p < 0.001$ with no statistically significant difference was found between VM and IAPG, $p < 0.33$. **Conclusion:** Results of this RCT suggest that VM is an acceptable method for second trimester pregnancy termination. However, oral misoprostol, as used in this study, is not an effective method. More research in oral misoprostol use may be warranted.

A simple and sensitive scoring system to identify fetal erythroblasts in maternal blood. *D.H. Cha, B. Hogan, R.M. Bohmer, D.W. Bianchi, K.L. Johnson.* Division of Genetics, Departments of Pediatrics and Obstetrics and Gynecology, Tufts-New England Medical Center, Boston, MA.

Background: Nucleated red blood cells (NRBCs) of fetal origin may have distinguishable characteristics from that of maternal NRBCs in both nuclear morphology and hemoglobin staining properties. However, these differences have yet to be quantified into a definable assay. Here, we present a scoring system using four parameters considered separately (nuclear roundness, nuclear morphology, gamma hemoglobin staining intensity, and peripheral brightness of the stained cytoplasm) to address this issue. **Methods:** NRBCs were isolated from four maternal blood samples by a density gradient, CD15/45 depletion, and a flow cytometry based anti-gamma hemoglobin positive selection after elective termination of a trisomy 21 male fetus (47,XY,+21). All cells were deposited onto microscope slides, and every NRBC was analyzed according to the scoring system. Each of the four individual parameters was given a value from 0 to 3 points and a combined score was obtained for each cell (range 0-12). FISH using X and Y specific probes was performed to determine whether the cell was maternal or fetal.

Results:

Combined score	5 or less	6	7	8	9	10	11 and 12
% fetal cells	5.7	19.2	37.5	63.6	71.4	91.7	100

Conclusions: Fetal NRBCs have a characteristic morphology and gamma hemoglobin staining appearance that makes them distinguishable from maternal NRBCs. The scoring system presented here is a sensitive and simple method to distinguish fetal NRBCs from adult cells in maternal blood and may have applications for both basic research into differences between fetal and adult cells as well as future clinical utility for noninvasive prenatal diagnosis. In addition, these defined parameters may also provide computational classifiers for the automated detection of fetal cells from maternal blood.

Fetal cells from maternal blood: High density gradient *versus* magnetic separation from whole blood. *R.M. Bohmer, H. Stroh, D.W. Bianchi.* Pediatrics, Tufts New England Medical Cent, Boston, MA.

Isolation of fetal cells from maternal blood using density gradient separation causes substantial loss of fetal nucleated red cells (NRBC), because of the similar densities of mature NRBC and erythrocytes. Using spikes of fetal into adult blood, we quantitated the recovery of HbF+ fetal NRBCs using flow sorting (FACS) and subsequent FISH to identify fetal cells by gender. We increased the Percoll gradient density to the maximum that would keep contaminating erythrocyte numbers small enough to allow subsequent flow sorting. At this density, up to 10 times more fetal nucleated red cells were recovered than with the standard Ficoll 1.077 or 1.083. Unfortunately, this optimal density varied with blood donor and blood storage history, and recovery was still only 40-60% of spiked fetal nucleated red cells. Therefore, we tested if we could avoid the density gradient altogether and isolate CD71+ cells from whole blood using magnetic beads. This was also followed by HbF+ fetal cell quantitation via FACS and FISH. Different commercially available magnetic bead systems were compared. The best fetal nucleated red cell recovery via whole-blood procedure was approximately equal to the recovery by maximum Percoll density. Further fine-tuning of both methods, as well as trials on maternal blood samples, may help decide which is the best approach to maximize fetal nucleated red cell isolation from maternal blood.

Prenatal diagnosis of mosaicism for structurally abnormal Y chromosomes: need for thorough cytogenetic and clinical evaluation. *L. Cartier, J-P. Capolicchio, A. Duncan, V. Desilets.* Prenatal Diagnosis Program, McGill Univ Health Ctr, Montreal, PQ, Canada.

Predicting the phenotypic consequences of different structural aberrations of chromosome Y is usually complicated by varying degrees of mosaicism (45,X cell lines). Few prenatally diagnosed cases have been reported.

We report on the outcomes of two cases of mosaicism for structurally abnormal Y chromosomes: mos 46,X,r(Y)(p11.3q12)[18]/45,X[5]/46,XY[5].ish r(Y)(p11.3q12)(SRY+) and mos 45,X[11]/46,X,idic(Y)(q11.2)[10].ish idic(Y)(wcpY+,DYZ3+,SRYx2) detected prenatally after amniocentesis done for advanced maternal age. High level resolution ultrasound at mid-trimester revealed well differentiated male external genitalia without anatomic features of Turner syndrome. Fetal echocardiogram was normal. Ultrasound at 32 weeks revealed testes in the scrotum without hypospadias. On postnatal examination, both babies had normal external genitalia and were not dysmorphic. Cord blood karyotype revealed the persistence of the 45,X cell line.

A wide spectrum of clinical manifestations including female phenotype with short stature and other characteristics of Turner syndrome, male phenotype with azoospermia, and ambiguous genitalia have been described in postnatally diagnosed patients. In studies of prenatally diagnosed 45,X/46XY mosaicism over 90% of cases have a grossly normal male phenotype, the remaining cases having ambiguous genitalia or female genitalia with Turner syndrome. There is a risk of about 15% for gonadoblastoma. This suggests that many patients with structural aberrations of chromosome Y go undetected. The 45,X cell line, regardless of the presence of Yp or a region including SRY carries an increased chance for that individual to be a phenotypic female with Turner features or to have ambiguous genitalia. The present cases illustrate the role of ultrasound in predicting the impact of a 45,X cell line and the role of genetic counselling in ensuring appropriate prenatal follow-up and postnatal management.

Simplifying Fetal Cell Analysis in Maternal Circulation. *P. Bayrak Toydemir*¹, *M.B. Fiddler*², *E. Pergament*^{1,3}. 1) Northwestern Reprogenetics Inc, Chicago, IL; 2) DePaul University, Chicago, IL; 3) Northwestern University School of Medicine, Chicago, IL.

Thirty samples of maternal blood, between 10 and 22 weeks gestation, were studied to determine the effectiveness of enriching fetal cells by a rapid and simple centrifugation procedure. **Material and Methods:** Five ml of heparinized blood was centrifuged at 1960 g-min to obtain a plasma fraction containing a low density cell population. Except in one case, all samples of blood were obtained prior to any invasive prenatal procedure (i.e., CVS or amniocentesis). Cells in this fraction were then re-centrifuged 2500 rpm and washed twice in PBS. The presence of fetal cells was determined by FISH analysis for Y-chromosome and/or chromosome abnormalities of the chromosome 18, 21, X, and/or Y. Blood samples were immediately processed and fixed in test tubes; samples from women carrying a cytogenetically abnormal fetus, as determined by 1-day FISH analysis, were given priority for analysis. Controls consisted of blood samples taken from non-pregnant women (2) and women carrying a female fetus (7). **Results:** Fetal cells, determined by the presence of a Y chromosome but no abnormalities, were detected in 77% of maternal samples (10 of 13 cases). When a chromosome abnormality was present, fetal cells were detected in 7 of 8 cases (87.5%). In one instance, a mosaic (47,XY,+20/46,XY) was not detected. In abnormal cases fetal cell frequency was 1 cell in 522 maternal cells; in normal male cases the frequency was 1 in 1838 maternal cells. Negative control cases did not have any Y-fluorescent cells. **Discussion:** These results demonstrate the potential for obtaining an enriched sample of fetal cells from maternal blood by a simple centrifugation; further studies to refine the conditions for centrifugation with the intent of improving yield are underway. In addition, these results affirm previous observations that cytogenetically abnormal fetal cells are found in maternal plasma with greater frequency than apparently normal fetal cells and that this frequency, with further improvement of enrichment techniques, may approach 100%.

Program Nr: 2312 from 2002 ASHG Annual Meeting

Molecular and Prenatal Diagnosis of Spinal Muscular Atrophy in families from North India. *A. Kesari, M. Mukherjee, S.R. Phadke, B. Mittal.* Medical Genetics, Sanjay Gandhi Postgraduate Ins, lucknow, UP, India.

Spinal muscular Atrophy (SMAs) forms a clinically and genetically heterogeneous group of autosomal recessive neuromuscular disorders leading to symmetrical muscle weakness and atrophy. The SMN gene responsible to cause SMA is present in two homologous copies, SMNt (telomeric) and SMNc (centromeric). In this report, we present the molecular analysis of exons 7 and 8 of SMN gene in patients (with suspected clinical diagnosis of SMA) from 42 North Indian families by using PCR-RFLP. Out of these, 18 have deletion of both exons 7 and 8 of SMNt, while two patients showed a deletion of only exon 8. Unlike in different populations where 90-95% SMA cases had SMNt deletion, our population showed SMNt deletion only in 43% patients. In the course of our study we also came across an unusual case, showing a homozygous deletion of SMNc gene. In addition to molecular analysis, prenatal diagnosis was performed in four families with previous history of SMA. One foetus was affected and the other was normal in the two families where mutation had been found in the surviving sibs. The families were counselled accordingly. The low frequency (43%) of the SMNt gene deletion in our population can be attributed to the presence of point mutations that might be more prevalent in North Indian patients. The results also add to the genetic heterogeneity suggesting that the patients may be SMA variants with gene deletion out side 5q13.

Normal Amniocentesis Hiding an Age Related Abnormality: Consider Adding UPD 15 Testing for Prader-Willi Syndrome to Prenatal Diagnosis for Advanced Maternal Age. *L. Medne, D. Stewart, E.H. Zackai.* The Children's Hospital of Philadelphia, University of Pennsylvania School of Medicine, Philadelphia, PA.

We diagnosed two infants in the newborn period with Prader-Willi syndrome (PWS) caused by maternal UPD 15. Both mothers had undergone an amniocentesis because of advanced maternal age (AMA) and in both cases karyotypes were normal. Case 1 was born to a 39 y/o G3 P1@2 (TAB for prior trisomy 21) mother by C-section due to a breech presentation. The infant had significant hypotonia and feeding difficulties requiring NG feeds. Case 2 was born to a 43 y/o G4 P0@1 (1 TAB, 2 SAB) mother by a C-section due to a breech presentation. The infant had IUGR, cryptorchidism, hypotonia and feeding difficulties. Maternal UPD 15 causes 25% cases of PWS cases, and the rate of maternal UPD 15 increases with age (Mascari et al, 1992). Under 35 years of age, the incidence of maternal UPD is 140 times less than that of trisomy 21, but the margin narrows with advancing maternal age. At age 40, the incidence of maternal UPD 14 is 1/3400 live births, only 68 times less than the incidence of trisomy 21 (Robinson et al., 1996). The mothers in our two families, who underwent amniocentesis to rule out maternal age related chromosomal abnormalities, would have terminated an affected pregnancy. They feel that their children should have been diagnosed prenatally because of the known associated age related factor in maternal UPD 15. We propose that routine screening for maternal UPD 15 in CVS and amniocentesis done for AMA be considered.

Analysis of Fetal Cells in Maternal Blood: Influence of Apoptotic Status and FISH Probes. *S. Mergenthaler, T. Babochkina, G. De Napoli, S. Hristoskova, W. Holzgreve, S. Hahn.* Obstetrics and Gynecology, University of Basel, Basel, Switzerland.

The use of fetal erythroblasts enriched from the maternal circulation provides a tantalising risk free alternative for prenatal diagnosis. The scarcity of these fetal cells, which even after enrichment may only be of the order of 0.001%, implies the tools used for their analysis have to be optimal; since if this method has small false positive rate, of the order of fetal erythroblast frequency, a significant number of the fetuses would be scored incorrectly. In our previous studies performed in the NIH funded NIFTY study, where we have mainly used FISH for the X and Y chromosomes as a model system, we have noted that the use of indirectly labelled FISH probes resulted in high false positive rates (over 23%). By switching to a commercial source of directly labelled FISH probes, we recently observed that the false positive rate could be lowered to less than 8% with a concomitant increase in sensitivity to over 72%. A further important aspect is the recent observation that almost half of these erythroblasts have an apoptotic phenotype, by having fragmented DNA in their nuclei (TUNEL positive). This raised the concern of whether these nuclei will be suitable for analysis by FISH, or whether they may be more suitable for analysis by single cell PCR. We have now determined that the efficiency of FISH analysis is not influenced by the apoptotic phenotype of the erythroblast interrogated. We did, however, note that the Y chromosome FISH probe was significantly less efficient in hybridising effectively to erythroblast nuclei in comparison with the X chromosome probe, in that on average only 73% of all male erythroblasts were identified correctly in contrast to almost 94% of all female erythroblasts. Our result, therefore, suggests that the current apparent lack of sensitivity for the identification of male fetal erythroblasts enriched from the maternal circulation may in part be attributable to the incorrect choice of a suitable FISH probe for the Y chromosome. We are, therefore, investigating which Y specific loci are most suitable.

Non detection of the fetal SRY sequence in healthy women who have had male offspring. *C. Le Marechal*^{1,2,3}, *C. Benech*¹, *C. Ferec*^{1, 2, 3}. 1) EFS Bretagne, Brest, France; 2) INSERM EMI 0115, Brest, France; 3) Universite de Bretagne Occidentale, Brest, France.

The discovery of fetal cells and free fetal DNA in the maternal bloodstream opened the field for performing non-invasive prenatal diagnosis (NIPD) using maternal venous blood. Risks for the fetus linked to invasive procedures (amniocentesis or CVS) could be eliminated, and with the recent advances in molecular biology techniques, the study of fetal DNA could be performed earlier in pregnancy. Previous studies have shown that fetal cells in the maternal circulation persist even decades after delivery (Bianchi 1996), whereas free fetal DNA disappears rapidly after birth (Lo 1999, Costa 2001). Until now, the rapid clearance of free fetal DNA from maternal serum and plasma allowed one to think that only a pregnancy in progress could be studied. Recent contradictory findings (Invernizzi 2002) have shown that fetal DNA (SRY sequence) is detectable in 20% of healthy women's serum up to 40 years after birth of their last male child. These findings modify the feasibility of an NIPD from maternal blood because of the possibility of false positive results linked to former pregnancies. In order to evaluate this approach, we extracted DNA from 1ml of serum (QIAamp ultraSens™ Virus kit- QIAGEN) from 33 healthy women with male offspring. The amount of time since the birth of their last male child ranged from 1.5 to 37 years (mean 13.9 years). TaqMan real time quantitative fluorescent PCR was performed to detect the SRY sequence. The final PCR volume was 50µl with 15µl of the extracted DNA. Pregnant women carrying male fetuses were chosen as positive controls and young healthy women who had never been pregnant were chosen as negative controls. Under these conditions we found no SRY sequence in the studied group. Thus, according to our conditions, we conclude that previous pregnancies do not interfere with serum free fetal DNA analysis performed for NIPD.

Program Nr: 2316 from 2002 ASHG Annual Meeting

Analysis of Cystic Fibrosis and Ashkenazi Jewish Disease Mutations by Multiplexed Elongation of Allele-Specific Oligonucleotides Displayed on Custom Bead Arrays. *G. Hashmi¹, Y. Song¹, M. Seul¹, L. Edelmann², R. Kornreich², R.J. Desnick².* 1) BioArray Solutions Ltd, Piscataway, NJ; 2) Mount Sinai School of Medicine, New York, NY.

A novel BeadChip assay system for the high throughput multiplexed analysis of mutations and polymorphisms has been evaluated for an augmented ACMG panel comprising the most common ~40 Cystic Fibrosis mutations. In addition, an Ashkenazi Jewish disease panel also has been developed using this system to detect common mutations known to cause Tay-Sachs, Canavan, Gaucher, Niemann Pick, Bloom Syndrome, Fanconi Anemia, Familial Dysautonomia and Mucopolysaccharidosis IV. In elongation-mediated multiplexed analysis of polymorphisms (eMAP), developed at BioArray Solutions, allele-specific oligonucleotides (ASO) containing variable 3'-terminal sequences are attached to color-coded beads which are in turn arrayed on silicon chips. Elongation products for mutated and normal sequences are simultaneously detected by instant imaging of fluorescence signals from the entire array using BioArray Solutions Array Imaging System (AIS). The design flexibility and convenience of implementing BeadChip assay system facilitates simultaneous screening for multiple alleles. Our results of a comparative study with an ASO dot blot method using patient samples demonstrates the sensitivity, specificity and reproducibility of the BeadChip assay system.

Factors affecting performance of prenatal genetic testing by Israeli Jewish women. *C. Sher*¹, *O. Romano*², *T. Shohat*². 1) Institute of Medical Genetics, Asaf Harofeh Medical Center, Israel; 2) ICDC, Ministry of Health, Israel.

The number of prenatal genetic tests that are being offered to women is constantly increasing. In Israel some of the prenatal tests are state subsidized (eg amniocentesis for women older than 35 years) or privately paid for (eg molecular genetic carrier testing). However, there is little national data as to who is performing the tests and the reasons for doing or not doing so. In a one day survey conducted in all the maternity departments in Israel we evaluated the proportion of Jewish women in Israel who perform the various prenatal genetic tests and the factors affecting the performance of these tests. Of the 377 women interviewed, 60.9% performed the Triple Test (TT), 50.8% women older than 35 years performed amniocentesis, while 63.3% and 24.3% performed Tay-Sachs (TS) and Fragile-X (FX) carrier testing respectively. In a stepwise regression analysis being secular was a significant factor associated with performing TT, amniocentesis, TS and FX testing. Higher income was significantly associated with performing all these tests. Having < 4 children was associated with performing amniocentesis, TS and FX testing. Women with a supplementary medical insurance performed significantly more FX tests. The main reason for the women not performing amniocentesis or the TT was for religious or moral grounds (53.3% and 67% respectively). The main reason for not performing TS or FX testing was that they were not referred for the tests (76% and 82% respectively). In view of the low performance rate of the recommended tests, consideration should be given to providing first trimester prenatal diagnosis to the religious groups, state subsidized FX testing and educating the primary care givers about the importance of prenatal genetic testing. The information from the present study is vital for the planning of equitable prenatal genetic services and provides guidelines for the implementation of such services in other countries.

Fetal DNA Diagnosis from Maternal Blood - PEP-TaqMan PCR Analysis of A Single Nucleated Erythrocyte (NRBC) -. *H. Takabayashi¹, M. Kita¹, K. Ikawa², k. Yamafuji³.* 1) Medical Research Institute, Kanazawa Medical University, Kahoku, Ishikawa, Japan; 2) Ishikawa Health Service Association, Kanazawa, Ishikawa, Japan; 3) Ukita Hospital, Kanazawa, Ishikawa, Japan.

The development of a real-time quantitative TaqMan PCR assay permits the high quality analysis of DNA or RNA. With the TaqMan PCR, Lo. et al. were successful in measuring the concentration of fetal DNA in maternal plasma and serum. Using ABI PRISM 7700 System (PE Applied Biosystems), we tried to detect the target DNA sequence of SRY and beta actin locus in the PEP (primer extension preamplification) products from a single cell. Single NRBCs (nucleated red blood cells) were retrieved from cord blood smear of male fetus using a micromanipulator. The detection rates of beta actin and SRY locus were 55% and 35%, respectively. Quantitative results of PEP products from single NRBCs were 0.5-59.5 (m=4.8) copies in beta actin and 2.4-278.4 (m=17.8) copies in SRY locus. Our quantitative data show the concentration of a single locus DNA amplified by PEP from a single NRBC. The advantages of PEP-TaqMan PCR system are high specificity and sensitivity. This system seems a powerful tool for fetal DNA diagnosis from maternal blood.

More cell-free fetal DNA from maternal plasma is recovered using vacuum pump preparation: A step toward more accurate fetal DNA analysis. *J.L. Simpson^{1,3}, D. Dang¹, D. Marquez-Do¹, C. Horne², A. Burke¹, D.E. Lewis², F.Z. Bischoff¹.* 1) Depts OB/GYN; 2) Immunology; 3) Molecular/Human Genetics, Baylor Col Medicine, Houston, TX.

Prenatal diagnosis of fetal chromosomal aneuploidies and single gene mutations is now feasible by analysis of cell-free DNA extracted from maternal blood. In particular, clinical diagnostic applications have been proposed using real-time PCR for quantitative analysis of cell-free fetal DNA in maternal plasma. Although cell-free fetal DNA is relatively abundant in maternal plasma, its admixture with maternal cell-free DNA can interfere with fetal DNA detection. Standardized protocols to combat this problem have not been developed, and methods for routine plasma DNA extraction have not been established. **OBJECTIVE:** To determine whether a vacuum manifold results in greater extraction of total and fetal DNA, as detected by real-time PCR. **METHODS:** Peripheral blood was obtained from women (n=28) prior to CVS or amniocentesis at 10.1 to 23.1 weeks gestation (mean 14.8 wks). Blood collected in vacutainers containing ACD was processed within 16 hrs. DNA extraction and purification was performed using the QIAamp DNA blood mini kit (Qiagen) with (n=19) or without (n=19) the vacuum manifold. Real-time PCR was performed using the TaqMan assay to detect the FCY (DYS1) and GAPDH (control) locus. Fetal DNA concentration (Geq/ml plasma) was determined using the Sequence Detection System software (PE Applied Biosystems). **RESULTS:** Mean concentration of total (GAPDH) and fetal (FCY) was significantly higher (P=0.03) among vacuum-processed samples (1,268 Geq/ml and 30.9 Geq/ml) than in samples processed without vacuum (417 Geq/ml and 17.6 Geq/ml). With vacuum, sensitivity for identifying fetal gender was 90% with 100% specificity in correctly identifying fetal gender; with no vacuum, sensitivity and specificity were 70% and 88%. **CONCLUSION:** Utilization of the vacuum manifold not only optimized recovery of total cell-free fetal DNA, but also resulted in greater sensitivity of detecting fetal DNA sequences. Vacuum manifold should be incorporated into protocols for optimal recovering cell-free DNA from maternal plasma.

Maternal serum cell-free fetal DNA levels are increased in cases of trisomy 13 but not trisomy 18. T.

Wataganara¹, E.S. LeShane¹, A. Farina², G.M. Messerlian³, T. Lee⁴, J.A. Canick³, D.W. Bianchi¹. 1) Division of Genetics, Department of Obstetrics and Gynecology, and Pediatrics, Tufts-New England Medical Center, Tufts University School of Medicine, Boston, MA; 2) Department of Obstetrics and Gynecology, University of Bologna, Italy; 3) Department of Pathology, Women and Infants Hospital, Brown Medical School, Providence, RI; 4) Department of Obstetrics and Gynecology, Brown Medical School, Providence, RI.

Cell-free fetal DNA in the maternal circulation is a potential noninvasive marker for fetal aneuploidies. In previous studies using Y DNA as a fetal-specific marker, circulating levels of fetal DNA were elevated in women carrying trisomy 21 fetuses. The goal of this study was to determine whether cell-free fetal DNA levels in the serum of pregnant women carrying male fetuses with trisomies 13 or 18 are also elevated. Serum from five cases of T13 and five cases of T18 were studied. Each case was matched for fetal gender, gestational age and duration of freezer storage to 5 control pregnancy samples presumed to be euploid after medical record review. Real-time quantitative PCR amplification of DYS1 was performed to measure the concentration of male fetal DNA present. Unadjusted median serum fetal DNA concentrations were 97.5 genome equivalents per milliliter [GE/mL] (29.2-187) for the trisomy 13 cases, 31.5 GE/mL (18.6-77.6) for the trisomy 18 cases and 40.3 GE/mL (3.7-127.4) for controls. Fetal DNA levels in trisomy 13 cases were significantly elevated ($p=0.016$), by analysis of variance of the ranks of values within each matched set. In contrast, fetal DNA levels in trisomy 18 cases were not different from controls. Second trimester maternal serum analytes currently used in screening do not identify fetuses at high risk for trisomy 13. Fetal DNA may facilitate noninvasive screening for trisomy 13 provided a gender-independent fetal DNA marker can be developed.

Subtelomeric rearrangement: low rate of spontaneous abortion in balanced carriers. *M.K. Tonnesen, L. Medne, K.L. Russell, J. Ganesh, I.D. Krantz, N.B. Spinner, E.H. Zackai.* Division of Human Genetics and Molecular Biology, The Children's Hospital of Philadelphia and University of Pennsylvania School of Medicine, Philadelphia, PA.

The rate of spontaneous abortions (SABs) in carriers of balanced translocations was found to be 25-50% (Neri et al., 1983). This led to multiple large scale studies of couples with recurrent SABs (>2), which revealed that in 3-5% (Tharaperl et al., 1985; Campana et al., 1986) there is one partner with a balanced chromosomal translocation. In the absence of a study for subtelomeric rearrangements in couples with recurrent SABs, we looked at the SAB rate in couples where one partner was identified to be a carrier of a balanced subtelomeric translocation ascertained because of an affected child. This study includes 5 couples identified at our center [t(15;19)(p13;q13.3); t(13;19)(p12;q13.3); t(13;18)(q34;q23); t(1;9)(p36.3;q34)] and 52 couples from the literature. Of the 139 total pregnancies of carriers, there were 11 SABs for a rate of 7.9% (6.9% (5/72) in female carriers and 8.9% (6/67) in male carriers). This SAB rate is significantly below the 25-50% SAB rate observed in carriers of cytogenetically detectable translocations and below the general population 10-15% SAB rate (US Department of Health and Human Services, 1982). We postulate that the observed low SAB rate in subtelomeric translocation carriers could be attributed to the high viability of unbalanced conceptions due to the very small chromosomal imbalance (Young, 1991). The data predict that testing for subtelomeric rearrangements in couples with recurrent SABs will have a low yield.

Prenatal diagnosis of Down syndrome - ten years' experience in the Israeli population. *M. Shohat*¹, *J. Zlotogora*², *Israeli consortium for Down syndrome prevention*³. 1) Dept Medical Genetics, Rabin Medical Ctr, Petah Tikva, Israel; 2) Dept Medical Genetics, Ministry of Health, Israel; 3) Medical Genetics Institutes of other Medical Centers, Israel.

Maternal serum biochemical markers, the major parameter introduced between 1990 and 1995, was supplemented with new promising modalities - nuchal translucency, soft signs on targeted ultrasound at 14-16 weeks, and first trimester biochemical markers - between 1995 and 2000. This study evaluated the effectiveness of a Down syndrome (DS) prevention program among the Israeli Jewish population between 1990 and 2000. We collected data on the total number of prenatal tests performed on Israeli Jewish women, DS cases detected prenatally and DS live births in Israel during these years. We also studied the use of the various newer screening tests for DS in 1990, 1992 and 2000. Between 1990 and 1995, the uptake of prenatal testing for DS in the Israeli Jewish population increased from 11.3% to 21.6% - this was accompanied by an improvement in the DS detection rate from 53% to 70%. However, between 1996 and 2000, even though new DS screening methods were introduced, the rate of uptake remained similar (20.7% to 19.8%) and the DS detection rate in the Jewish population decreased to 61% in 2000. The total cost per DS case detected increased from \$47,971 in 1990 to \$75,229 in 1992, and to \$190,171 in 2000. A significant improvement in the DS detection rate between 1990 and 1995 was associated with a significant increase in the amniocentesis rate - both are attributed to the introduction of the maternal serum biochemical marker tests. Unexpectedly, the introduction of new genetic modalities for the assessment of DS risk in Israel between 1995 and 2000 did not improve the overall detection rate or reduce the relatively high amniocentesis rate, but was accompanied by an increased cost per case detected.

The First Trimester Population Screening: Do We Need More Evidence? *G.L. Tsukerman^{1,2}, I.A. Kirillova^{1,2}, N.B. Gusina², H.A. Zinkevich², G.A. Krapiva², L.M. Lishtvan², O.V. Pribushenya², N.A. Venchikova², L.A. Savenko², H.I. Golovataya²*. 1) Joint Research Program, Reproductive Genetics Institute, Chicago, IL; 2) Institute for Hereditary Diseases, Minsk, Belarus.

During Joint Research Program 70,200 unselected pregnant women were screened in the first trimester by transabdominal or transvaginal ultrasound. The majority of them were screened between 10.5 and 13 weeks of gestation. There were 6.3% of women of 35 years and older. 1,504 empty sacs and non-viable fetuses, 680 multiple pregnancies and 182 cases of fetal malformations were revealed. 126 of them were neural tube defects. Practically, no cases of anencephaly were missed. Besides that, 16,000 serum samples from unaffected pregnancies and 42 Down syndrome cases were tested for AFP, Free b-hCG and partly for PAPP-A. The median level of AFP, Free b-hCG and PAPP-A in single unaffected pregnancies for each CRL was derived. The expected detection rate for different marker combinations was determined. A modelling exercise for screened population with maternal age, NTT, AFP, PAPP-A and Free b-hCG predicts a 92% detection rate for Down syndrome in FTS at 5% FPR. 10, 259 of unselected pregnant women were tested according to the protocol during the last two years. 93% of pregnant women were screened at CRL of the fetus between 38 and 70 mm. The risk of 1:360 at the expected date of delivery was chosen as the cut-off for an invasive procedure. 16 cases of trisomy 21 were detected with the expected number 14. In the last three month 2, 520 a sagittal views of the fetal face were obtained and the absence or presence of nasal bone was evaluated. The nasal bone was absent in three cases and one of them had trisomy 21. Taking into consideration the results of the other programs (Nicolaides K. et. al, 2002; Cicero S. et.al., 2001; Spencer K. et al., 2000; Krantz D. et al., 2000) it is beyond reasonable doubt that the first trimester population screening for various fetal abnormalities is not just desirable, but it should also become the standard of care in prenatal diagnosis.

Acellular fetal DNA in maternal plasma does not stem from the transplacental passage of fetal cells. X. Zhong, W. Holzgreve, S. Mergenthaler, S. Hristoskova, S. Hahn. Obstetrics & Gynecology, University of Basel, Basel, Switzerland.

A recent major advance in the non-invasive risk free determination of fetal genetic traits has been the discovery of acellular fetal DNA in the maternal circulation, by which means it has become possible to determine fetal genetic loci such as RhD with very high levels of accuracy. Currently the origin of this acellular fetal DNA in the maternal circulation is currently unclear and it has been speculated to result either from the shedding of apoptotic material from the placenta or from the apoptosis of fetal cells which have entered the maternal circulation. This latter supposition is largely based on the observation that numerous fetal erythroblasts exhibit an apoptotic phenotype, in that their nuclei contain fragmented DNA. This hypothesis is, furthermore, supported by reports indicating that elevated numbers of fetal erythroblast and acellular fetal DNA concentrations are present in pregnancies affected by certain pathologies, such as preeclampsia. In order to address this question we have examined fetal erythroblast numbers, following enrichment and acellular DNA concentrations, by real-time PCR, in the same maternal blood samples. Our data, obtained both from the analysis of both normal and pathologically affected pregnancies, indicates that no correlation exists between these two fetal cellular and molecular species. This result was most striking in pregnancies affected by onset of pre-term contractions, where we were able to detect significant elevations in acellular fetal DNA concentrations but not any concomitant increase in the trafficking of fetal erythroblasts. Consequently, our data suggest that an alternative cell type is the source of acellular fetal DNA, most probably of placental origin. It also appears that the release of cell acellular DNA from this cell type is affected by pathological placental conditions which are not associated with an increase in fetal cell trafficking.

Program Nr: 2325 from 2002 ASHG Annual Meeting

Cellfree fetal DNA in the maternal circulation after amniocentesis. *O. Samura, M. Hyodo, N. Miharu, K. Ohama.*
Dept OB/GYN, Hiroshima Univ Sch Medicine, Hiroshima, Hiroshima, Japan.

Our aim was to investigate whether amniocentesis increases the concentration of cell free fetal DNA in maternal serum. Twenty-four patients who had singleton male fetuses and were undergoing amniocentesis between 15 and 17 weeks of gestation were recruited. Five patients who had singleton female fetuses were recruited as controls. Maternal venous blood samples were taken before and within 10 minutes after amniocentesis. DNA was extracted from the serum samples. The amount of fetal DNA was quantified by calculating the concentration of the SRY gene sequence from the Y chromosome after amplification by polymerase chain reaction (PCR). The change in the concentration of the amplified SRY gene sequence before and after amniocentesis was compared by a paired sample t-test. There was a significant increase in the concentration of fetal DNA in maternal serum after amniocentesis (7.18±6.38copies per milliliter before amniocentesis ; 11.89±11.24 copies per milliliter after amniocentesis; p=0.011). Amniocentesis imposes a significant disturbance to the maternal- placental interface. Fetal DNA is a sensitive marker that is useful in the assessment of fetal-maternal hemorrhage.

Fetal Hepatic Calcifications: Prenatal Diagnosis and Outcome. *M.J. Simchen¹, A. Toi³, M. Bona¹, F. Alkazaleh², G. Ryan², D. Chitayat¹*. 1) The Prenatal Diagnosis and Medical Genetics Program; 2) Departments of Obstetrics and Gynecology; 3) Department of Medical Imaging.

Objective: To provide information on the etiologies and postnatal outcome of fetuses detected with liver calcifications on prenatal ultrasound. **Study design:** Cases with fetal liver calcifications seen between 1992-2001 were evaluated. A detailed fetal ultrasound for associated abnormalities, maternal TORCH analysis and parvovirus B19 serology, as well as parental CF mutation analysis were performed, and amniocentesis was offered in all cases. All cases born alive were examined and followed. **Results:** 61 pregnant women with fetal liver calcifications were identified. 40/61 cases had additional fetal abnormalities while 21/61 were isolated. 11/61 (18%) patients had abnormal karyotypes: 4-Trisomy 13; 2-Trisomy 21, 1 each Trisomy 18, 45,X 4p-22q+ and 8p+. 10/11 cases with abnormal karyotypes had other ultrasound abnormalities. 2 cases had intrauterine infection, one CMV and one parvovirus B19 infection. 18/40 patients underwent pregnancy termination, one fetus died in-utero, one newborn died postnatally and 2 suffered neurological sequelae. Of 21 cases with isolated liver calcifications, one fetus had parvovirus B19 infection and one infant had trisomy 21. Remaining infants had a good outcome. **Conclusions:** Fetal liver calcifications are relatively common. Isolated cases have a good prognosis after aneuploidy and infection have been ruled out. However, additional major abnormalities present a risk for chromosomal abnormalities, mainly trisomy 13.

Prenatal molecular diagnosis for infantile and late-infantile neuronal ceroid lipofuscinoses. *N. Zhong*^{1,2,3}, *W. Ju*^{1,2}, *D. Moroziewicz*^{1,2}, *W.T. Brown*². 1) SCL-Molecular Neurogenetic Diagnostic Laboratory; 2) Dept. Human Genetics, New York State Inst Basic Res, Staten Island, NY; 3) Dept. Neurology, SUNY-Downstate Health Science Center, Brooklyn, NY.

Infantile and late-infantile neuronal ceroid lipofuscinoses (NCL1 and NCL2) have been determined to result from genetic deficiency of gene CLN1 and CLN2, respectively. Applying molecular analyses may offer prenatal diagnosis for families affected by NCL1 or NCL2, in whose mutations have been identified. In this study, six pregnancies, three from NCL1 families and three from NCL2 families, were analyzed. In the NCL1 cases, two pregnancies were from the same family that both parents carry a mutation of 451C®T in CLN1 gene. DNA testing was done on CVS of both pregnancies and results showed that both fetuses were carrier for this mutation. In the second family, the father who had an affected NCL1 child from previous marriage was found to carry the 451C®T mutation. Prenatal diagnostic analyses of amniotic fluid cells showed the fetus does not carry this mutation, indicating a normal pregnancy. For NCL2 cases, testing R208X mutations were performed in two families. Both parents carrying R208X were found in one family. In the second family, R208X was found in the mother but the second mutation was not identified within CLN2 cDNA region from the father who had been determined to be a carrier by TPP1 enzymatic assay. Testing R208X mutation in this two cases showed both fetuses were carriers. In the third family, parents were identified to be carriers of either IVS5-1C or IVS5-1A mutation. However, the fetus carries neither mutation and is normal. All results obtained from prenatal tests were confirmed by postnatal tests. Our studies indicate that DNA testing may provide a definitive prenatal diagnosis for NCL disorders.

Increasing incidence of abdominal wall defects in the State of Illinois: trends and distribution suggests a common herbicide (2,4-dichlorophenyl-p-nitrophenylether) as a plausible candidate teratogen. *n.j. nadkarni¹, r.f. hume¹, t. egler², j. smith¹, p. prochnicki¹, h. kaufman¹, m. leonardi³, r. pearl³, p. Ittman¹, l.s. Martin¹.* 1) Medical Genetics, Neonatology and MFM, Rockford Health System, Rockford, IL; 2) Illinois Department of Public Health, Springfield, IL; 3) MFM and Pediatric Surgery, UIC.

Several centers have perceived an increased incidence of abdominal wall defects in agrarian communities in our region. An teratogen, 2,4-dichlorophenyl-p-nitrophenylether (DCNPE) is a congener of an herbicide in common use. Could the peculiar regional distribution be attributed to happenstance, or teratogen exposure? The purpose of this study is to examine the relationship between the development of congenital birth defects and a possible causal link to herbicide exposure in particular geographic regions of Illinois. We initiated a feasibility study to collect data from several disparate state sources to affirm the perceived increased incidence of congenital anomalies, review literature to ascertain credibility of biologic effect of putative agent, and compare distributions of anomalies and common use of herbicide. The Adverse Pregnancy Outcomes Reporting System (IDPH) has shown a statistical increase in the incidence of abdominal wall defects. In general rates for Chicago are lower than those for Illinois as a whole. This finding is consistent with the Regional Perinatal Centers perceived distribution of rural origin of abdominal wall defect cases. Congenital diaphragmatic hernia (CDH) cases are not significantly elevated in the state surveillance data, but do seem to be more common in the more rural regions. DCNPE has been reported to be a useful experimental teratogen in several animal models of CDH. Recent work from Europe suggests a teratogenic mechanism. Therefore, the initial work suggests the plausibility that a herbicide in common use may be a candidate teratogen and may explain the apparent rural distribution of an increasing trend of specific fetal anomalies in IL. A detailed case-control study and a correlation study of anomaly maps with state water quality are both justified, and required, to test the validity of our proposed hypothesis.

Program Nr: 2329 from 2002 ASHG Annual Meeting

First trimester ultrasound identification of severe congenital anomalies associated with Pallister-Hall syndrome.

V.A. Desilets^{1,2}, *J. Fitzpatrick*², *L. Rochon*³. 1) OB/GYN, McGill Univ, Montreal, PQ, Canada; 2) Human Genetics, McGill Univ, Montreal, PQ, Canada; 3) Pathology, McGill Univ, Montreal, PQ, Canada.

Introduction: First trimester ultrasound examination allows for early dysmorphic studies of fetuses, sometimes preceding invasive prenatal diagnosis.

Case report: This 23 yo mother previously had a 19 wk fetus with short-limb dwarfism, polydactyly and hypothalamic hamartoma. Short-limb polydactyly syndrome type II was suspected. Direct molecular testing was not available. In her second pregnancy, 12 week-ultrasound examination revealed significant shortening of all long bones. Fetopathologic exam confirmed these findings along with polydactyly and absent pituitary. Molecular testing for *GLI3* mutations is pending.

Conclusion: This severe form of Pallister-Hall syndrome has been described in neonates. This is the first documentation of first-trimester identification.

Non-random XCI and Second trimester RSA family maps to Xq28. *M.M. Thouin¹, C.A.G. Scacheri³, J.M. Giron¹, C. Romig², E.P. Hoffman^{1,2}.* 1) Children's National Medical Center, Washington, DC; 2) George Washington University, Washington, DC; 3) GeneDX, Rockville, MD.

Highly skewed X chromosome inactivation (XCI) occurs in 2% of women and involves greater than 90% of cells inactivating the same X. The etiology ranges from cancer and monozygotic twinning, to a carrier state for X-linked cell lethal trait. Pegoraro et al. (1997) demonstrated that highly skewed XCI patterns are heritable, and showed concordance of skewing between oral fibroblasts and lymphoblasts. In a recent case-control study (Lanasa et al, 2001), 14% of women experiencing recurrent first trimester pregnancy loss (RPL) displayed highly skewed XCI. Here we present a family ascertained with multiple second trimester known male losses, accompanied by polyhydramnios and ventriculomegaly. She and several maternal female relatives show highly skewed inactivation, preferentially activating their paternal X. Also of interest in this family is the non-concordance of skewing between blood lymphoblasts and oral fibroblasts, which show random XCI. Exclusion mapping was done using microsatellites throughout the X chromosome; this mapped the gene to a 50cM region in Xq28. This region includes several target genes of interest including arginine vasopressin receptor 2 (AVPR2), G6PD, and Factor 8. AVPR2 is expressed in the kidney tubule and helps maintain water homeostasis. Mutations are associated with nephrogenic diabetes insipidus (NDI), and polyhydramnios. Deficiencies in G6PD and Factor 8 both cause blood-related disorders and may explain the tissue-specific skewing in this family.

Program Nr: 2331 from 2002 ASHG Annual Meeting

A pairwise-splitting approximation to NPL linkage tests using the S_{pairs} scoring function and the linear model.

O.T. Atlason, D.F. Gudbjartsson, A. Kong. Statistics, deCODE genetics, Reykjavik, Iceland.

Working within the framework of nonparametric linkage as proposed by Kruglyak et al. (1996) we explore a method of approximating the NPL score in the special case of the scoring function S_{pairs} . We can approximate the contribution of each pair of affecteds, (**a**,**b**), by only regarding information contained in a sub-pedigree containing all paths between **a** and **b**. In the linear model introduced by Kong and Cox (1997), the NPL score is a sufficient statistic. We can thus approximate calibrated linkage tests for large pedigrees deterministically in the sense that there is no variation when the same data is analyzed more than once. Our approximation may also be used to do QTL analysis and is more accurate than the approximation proposed by Fulker et al. (1995).

Program Nr: 2332 from 2002 ASHG Annual Meeting

Test for Association in Family-based data. *X. Liu, D. Gordon.* Lab Statistical Genetics, Rockefeller Univ, New York, NY.

The transmission/disequilibrium test (TDT) (Spielman et al. 1993) can test for association between a genetic marker and disease susceptibility loci by using one affected child from affected sibships. Based on a TDT type linkage test developed by Spielman and Ewens (1996) for multiallelic markers, we propose a class of association tests for nuclear families with any number of affected children, for both diallelic and multiallelic markers. The association tests are constructed using the symmetry between the transmitted/nontransmitted alleles from heterozygous parents to affected children under linkage equilibrium. One of the proposed test statistics reduces to the TDT for nuclear families of single affected child, and to the association tests proposed by Martin et al. (1997) for affected sib pairs. The association test used in simulation and for real data (sitosterolemia) is the one which has the best overall power in detecting association. This association test is generally more powerful than the association test proposed by Martin et al.(1997). For the sitosterolemia data set, the association test has its most significant result (p -value=0.0012) for the marker locus on the same bacteria artificial chromosome as the disease locus.

Using Test of “Longest Run” to Estimate Region-Specific P-value in Gene Mapping Studies. *C.S.J. Fann¹, I.B. Lien², C.H.L. Chen¹, L.Y. Chen², C.J. Chang³.* 1) Epidemiology & Public Health, Inst Biomed Sci, Acad Sinica, Taipei, Taiwan; 2) Department of Mathematics, National Chang Hua University of Education, Taiwan; 3) Department of Medical Research, National Taiwan University Hospital, Taiwan.

In testing the association between a putative disease gene and genetic markers, one of the widely used study design is to focus on a pre-selected candidate region saturated with large number of single nucleotide polymorphisms (SNPs). In testing the significance, point-wise p-values need adjustment for multiple comparisons. Although it is known that problem of multiple comparison is less severe for tightly linked markers, it is essential to realize that improper correction inevitably lead to either increased false-positive rates or decreased statistical power. In this project, we studied the probability observing the longest run with fixed number of SNPs as the region-specific p-value. Longest run is defined as a consecutive string of positive signal from association tests. Previously, the asymptotic theory of “Longest Run” has been implied successfully in measuring the similarity between DNA sequences with sufficient length. In our case, however, the region might contain only a hundred SNPs; therefore we developed a method that calculates the exact distribution of the length of the longest run that also allows for a few random errors in the string. To account for the presence of linkage disequilibrium between tightly linked SNPs, Markov first order dependence was used to modify our method. The efficacy and validity of our methods are demonstrated by using simulated data.

Linkage disequilibrium error analysis via the application of bootstrap methods. *E.D. Kelly¹, R. McManus².* 1) Hitachi Dublin Laboratory, Hitachi Europe Limited, Dublin 2, Ireland; 2) Department of Clinical Medicine, Trinity College Dublin and Dublin Molecular Medicine Centre at St. James's Hospital, Dublin, Ireland.

In the hunt for the genes responsible for the more common, complex diseases such as cancer and heart disease, linkage disequilibrium testing has become a vital element. When the phase of sample data is known, Markov chain Monte Carlo (MCMC) methods may be used to estimate the level of disequilibrium between pairs of loci. However, if the haplotypic composition of patient data is unknown, MCMC methods are not applicable, and instead a likelihood ratio test is employed. Use of this method has become widespread, but despite this, there has been little investigation of the degree of error involved. This has been partially due to the significant extra computational demands that it places upon the resources of the investigator. We have developed an EM-based algorithm for the estimation of LD between locus pairs which incorporates an exact solver for SNP data and non-parametric bootstrapping for the calculation of accurate error bars. We present the results when LD is carried out on data derived from a population of cystic fibrosis patients. Initially the phase of the data is known and an MCMC method is used to calculate the level of LD between each locus pair. The phase of the data is then randomised and LD is recalculated using the EM-based likelihood ratio test. The technique of bootstrapping is then applied to generate error bars about the single point results. The accuracy of the EM method and the sensitivity of the bootstrap procedure to data sizes are assessed via a comparison between the results for the phase-known and the phase-unknown data. As expected, the accuracy of the estimation falls off as fewer individuals are included in the analysis. However, what is of particular note is the extent of the single standard deviation error bars. For statistically significant results (values of P less than 0.05), the error bars are small, with medians closely corresponding to the point estimates derived from the original data. In contrast, the error bars associated with non-significant point estimates ($P > 0.05$) are large, but importantly lie outside the 0.05 significance limit.

Path analysis of protein expression data in cancer-related metabolic pathways. *D.J. Kaufman, K. Buetow.* Lab of Population Genetics, NCI, Gaithersburg, MD.

Algorithms used to analyze gene expression data from microarray experiments often focus on differences between single genes, or group genes by patterns of expression rather than by known biological relationships between the gene products. To examine known biological relationships between gene products in well-studied metabolic pathways, we applied path analysis to cDNA microarray data. Path analysis is a statistical technique that identifies the correlation structure that best explains relationships of various proteins in a metabolic pathway, to determine which proteins in a stream most influence expression of downstream genes. Here, eight cancer-related pathways (including ones related to cell cycle regulation, growth and differentiation, apoptosis signaling, and immune/stress response), were examined in 60 cancer cell lines previously characterized by the NCI. The lineages were analyzed in aggregate to characterize correlations common to different tumor types. For example, in the G1/S checkpoint pathway, phosphorylated Rb permits transcription of S-phase genes. In the NCI cell lines proteins (cyclin D, cyclin E, cdk2, cdk4, cdk6) directly upstream of Rb did not influence Rb levels. The influence of contact inhibition and DNA damage (through p27, p21 and p53) remain intact but were only slightly correlated with Rb. In contrast, TGF β levels further upstream accounted for 25% of variation in Rb expression. Such analyses will become more powerful when they are used to compare the structure and magnitude of correlations in diseased and normal tissue. We will use similar path analysis to compare the best-fitting models of lung tumor and normal lung tissue. We are also developing public domain software for distribution to perform simple path analyses.

Program Nr: 2336 from 2002 ASHG Annual Meeting

Unbiased Quantitative Population Association Test. *J. Zhao, M. Xiong.* Human Genetics Ctr, Univ Texas, Houston, TX 77030.

In the past several years, there have been increasing interests in the genetic studies of common diseases. It is now recognized that linkage analyses which have been successfully applied to genetic studies of simple Mendelian diseases have been much less successful. Population association studies have been proving to be an alternative to linkage analyses for mapping complex disease genes when a dense map of SNP markers is available. However, population substructure creates spurious association, which increases type 1 error and compromises the performance of population association studies. To overcome this problem, various statistical methods for control of population stratification when analyzing case-control studies have been proposed. Although genomic control methods for association studies can alleviate spurious association, they need to genotype a large number of additional markers. In this report, we propose an unbiased population association test for identification of quantitative trait loci using unrelated individuals. We will show that in the presence of population substructure the proposed test is still valid and will not increase the type 1 error. Furthermore, the proposed test does not need to genotype additional markers. We evaluate the performance of the proposed test statistic through both asymptotic analytic analyses and simulations. Our preliminary results show that the proposed test has higher power than several genomic control methods.

Program Nr: 2337 from 2002 ASHG Annual Meeting

Assessing the Accuracy of Algorithmic Haplotype Inference. *A. Windemuth, B.A. Salisbury, R.S. Judson, J.C. Stephens.* Genaissance Pharmaceuticals, New Haven, CT.

Theoretical arguments and empirical data both justify the utilization of algorithmic approaches to inferring haplotypes from population-based genotypic data. First, under a simple but realistic model of molecular evolution, it can be shown that the pair of haplotypes that explains an individual's multi-site genotype will often be unique. Therefore, algorithms that deduce haplotypes from multi-site genotypic data are likely to be very accurate unless there are serious departures from the model. The model is one in which recombination and recurrent mutation are very limited. Second, considerable evidence is accumulating that recombination rate heterogeneity has produced long regions, 10s of kb if not longer, within which little or no evidence of recombination is seen, even from large population samples. SNPs within such regions can be used for inferring the haplotype structure relatively easily. Third, we have tested our own statistical method of haplotype inference on an empirical sample of over 2600 genes. The method achieved 97% agreement with haplotypes that were deduced strictly according to the rules of Mendelian inheritance in two families totaling 17 individuals; this high level of accuracy is comparable to what can be achieved by the best molecular methods.

Methods and software for association tests of uncertain haplotypes in case-parent trios. *F. Dudbridge*. UK HGMP Resource Centre, Cambridge, UK.

Association testing is used to fine map genes through linkage disequilibrium and to assess the trait association of candidate genes. Haplotype analysis can be useful when an ancestral chromosome is better marked by several closely linked markers than by any one marker, or when there are aetiological haplotype effects. Haplotype methods are also necessary for linear modelling methods which account for disequilibrium with primary linked loci. These methods are usually implemented by likelihood ratio tests. In the case-parents design, the likelihood consists of a parental component and an offspring component conditional on the parents. When the haplotypes are certain, the conditional part is independent of the population structure and yields the transmission/disequilibrium test. For diploid genotype data, some haplotypes are uncertain and standard theory does not apply to the conditional likelihood. The full likelihood can be used with an E-M algorithm which estimates parental haplotype frequencies under both null and alternative hypotheses. This approach is sensitive to population structure, association in the absence of linkage, ascertainment criteria, and patterns of missing genotypes; but these factors result in a misspecification of the parental frequency model and do not affect the matching of cases to controls. When the null is that no haplotypes are associated, a permutation test is possible by swapping the transmission status of haplotypes, retaining the same status for all possibilities in uncertain cases. The "unphased" software package implements association tests which include uncertain haplotypes and missing genotypes, includes a permutation test, and implements unbiased TDT for the certain haplotype cases. Main effects and full interaction tests are available to account for primary linked loci, and tests of individual haplotypes and pairwise comparisons are possible. The tests are also implemented for unrelated subjects and a graphical user interface is available on the world wide web.

Program Nr: 2339 from 2002 ASHG Annual Meeting

Software for Simulation Studies of Complex Traits: SIMLA. *M.P. Bass, E.R. Martin, E.R. Hauser.* Center for Human Genetics, Duke Univ Medical Ctr, Durham, NC.

We have developed a software package to assist with genetic analysis of complex traits. SIMLA is a general use simulation package that can simulate under specific linkage and association scenarios for dichotomous traits in nuclear and extended families. This package allows for simulation of variable levels of linkage and allelic association between the markers as well as between markers and one or more disease loci. We have used this software to examine correlation in linkage and family-based association statistics (Martin et al. 2001), to evaluate a new version of the PDT for genotypic association (Martin et al. 2002), and to examine the power of the Ordered Subset Analysis (OSA) to detect genetic heterogeneity (Hauser et al. 2001). We are in the process of generalizing SIMLA to simulate from observed family structures and from observed marker maps to allow for empirical p-value calculation for observed lod scores. We will describe how to obtain the software, show examples of the input and output and provide usage documentation.

Haplotype Analysis of Quantitative Phenotypes: Methods and Application to Adrenergic Receptor

Polymorphisms and Complex Cardiovascular Traits. *A. Chandra*¹, *B.K. Rana*¹, *A. Tahgva*², *D. Fallin*², *N.J. Schork*¹. 1) Polymorphism Resesarch Laboratory; Psychiatry, University of Calif, San Diego, La Jolla, CA; 2) Epidemiology, Bloomberg School of Public Health, Johns Hopkins University.

Recent developments in high-throughput genotyping technologies have enabled researchers to identify numerous polymorphic sites within candidate genes that may influence common complex disease and traits. Making use of these technologies is complicated, however. When two or more polymorphic sites are identified within a gene in unrelated individuals, tedious molecular techniques are necessary to determine the actual haplotype of each individual. Current statistical strategies are limited to estimating haplotype frequencies in the population or to only inferring individual haplotypes based on homozygosity. Since there may exist multiple haplotype combinations in a population sample, it is often difficult to assign individual haplotypes, especially in order to analyze haplotype effects on a quantitative phenotype. We have developed a mixture modeling method for analyzing haplotype effects on a quantitative phenotype using individuals sampled randomly from the population at large. We have applied this method to analyze SNP data on two highly polymorphic beta-adrenergic receptor loci, *ADRB1* and *ADRB2*, and to demonstrate haplotype effects on various complex cardiovascular traits including systolic and diastolic blood pressure, and adrenergic receptor cell surface density. Our methods will help facilitate mapping and sequencing efforts and allow genetic analysis of complex quantitative phenotypes that make use of this resource.

Comparing haplotyping program performance: Accuracy of haplotyping with polymorphic markers and SNPs.

E.M. Lindholm¹, M. Durner¹, D.A. Greenberg^{1,2}. 1) Div Stat Genet, Columbia Univ, New York, NY; 2) Div Clin Genet Epi, NY Psych Inst. New York, NY.

Genehunter (GH) and Simwalk (SW) are two programs commonly used to determine haplotypes. We tested the accuracy of these programs by investigating the frequency of haplotyping errors in tightly linked markers with varying informativeness. We generated marker data on 10 markers with no recombination. The number of alleles was 2-9 with equal allele frequency at each marker except for SNPs, in which we tested three allele frequencies (0.5, 0.25 and 0.1 for the minor allele). We generated 200 nuclear families of varying size following a population based distribution. The results are summarized in the table. Overall, the frequencies of haplotyping errors was low (1-2%) for markers of alleles greater than 3. In biallelic markers with 0.5 allele frequency, GH inferred wrong haplotypes in almost 10% of the families. Using SW the same estimate was 6%. In the wrong haplotypes, the average number of incorrect markers was about 1 for markers with 4-9 alleles; with 3 or 2 alleles/marker, about 2 markers were wrong. Among 2000 family analyses total, 78 had incorrect haplotypes. Of the 78, 34 errors were identical in GH and SW while 26 were wrong in GH only and 19 in SW only. [Support: NIH Grant DK31775, NS27941, MH48858]

Alleles	9	8	7	6	5	4	3	2	2	2
Freq.								0.5	0.25	0.1
SW errs	0.5	1	3	1.5	2	1.5	5.5	6	5.5	0
GH errs	1.5	2	3	1	1.5	2	6	9.5	4	1.5

Program Nr: 2342 from 2002 ASHG Annual Meeting

Haplotyping with respect to linkage disequilibrium on empirical data. *S. Lin, DJ. Cutler, A. Chakravarti.*
McKusick-Nathan Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD.

Contemporary sequencing and genotyping methods do not provide information on linkage phase in diploid organisms. The application of statistical methods to samples of diploid sequences is a potentially time and labor saving method by which to reconstruct the linkage phase of many polymorphic sites. Stephens et al. (2001) devised one such method, which incorporates concepts from population genetics theory, in a markov chain monte carlo algorithm.

We modified and improved the algorithm, accounting for missing data, and applied the resultant computer program to empirically derived, phase-known sequences. The sequences comprise eight X-linked regions from a sampling of forty males (Cutler et al. 2001) and range from 87 to 327 kb in length with 45 to 165 segregating sites. 100 random pairings of the set of forty haplotypes, to create diploid genotypes of known phase, for each region was run to determine the accuracy of the program. We find that phase reconstructions by the modified program are highly accurate over regions with high linkage disequilibrium (LD). If only high frequency polymorphisms ($q > 0.2$) are examined, reconstructions are 95.2% accurate over entire 100 kb stretches and 98.6% accurate within blocks of high LD (defined as relative LD > 80%).

With portions of the computer program coding the estimation of phase call certainties excluded, the program runs with remarkable speed. For, example, on standard 800 MHz PC machines, 10,000 iterations of the algorithm on a specific locus with 165 segregating sites takes no more than ten seconds.

PEDMST, A New Program for Identity Coefficients Calculation and IBD Patterns Enumeration. *C. Zhu¹, J. Graham²*. 1) Computing Science, Simon Fraser University, Burnaby, BC, Canada; 2) Statistica and Actuarial Science, Simon Fraser University, Burnaby, BC, Canada.

Since currently no specific model has been built to list all the possible IBD patterns between the genes from the individuals defined by a pedigree at certain autosomal locus, we design a labeled tree structure to enumerate those patterns, and also develop a recursive algorithm to construct the tree with one basic tree expanding rule and seven constraint rules. The final output patterns, excluding impossible ones given the relationship of the individuals in the pedigree, can be counted and listed using path searching on the constructed labeled tree. PEDMST (short name for Pedigree Master), written in Visual C++6.0, is the program where we implement this idea. Totally there are three major functionalities. First, the function of pedigree operation allows user to construct the pedigree or import the pedigree from the text file used by the other software such as PFIDDLER. A special graph drawing algorithm based on the generations of the individuals is designed and implemented for importation. Second, the function of kinship and identity coefficients calculation gives the user not only the numerical result but also the graphic result in terms of detailed or condensed identity states. Generalized kinship coefficients are used to compute the identity coefficients. Third, the function of IBD pattern enumeration allows the user to view all the possible IBD patterns between the input genes whose maternal or paternal source is specifiable. The maximal number of the genes currently is set to 10, but can be expanded easily later according to the large capacity of the tree model we use. PEDMST has received positive user feedback in functionality, usability, and visualization with its features such as the unique function of IBD pattern enumeration, the instant view of pedigree while editing, the graphic output of the calculation result, the capability of representing the pedigree and doing the computing on the same screen.

Program Nr: 2344 from 2002 ASHG Annual Meeting

Performance of Parallel Algorithms in Bioinformatics. *F. Sievers, E. Kelly.* Hitachi Dublin Laboratory, O'Reilly Institute, Trinity College, Dublin 2, Ireland.

Using a bootstrapped Haplotype Frequency Estimation Algorithm as an example we demonstrate the importance of parallel computing in Bioinformatics, as the calculation time for many problems in Bioinformatics scale exponentially with the number of loci and/or patients. This is particularly important when determining confidence intervals. We show that a naive equi-partition parallelisation scheme does not scale well, and better load-leveling of resources can be achieved using a Master/Slave approach. This is because of the long tail of the distribution of calculation times for different bootstrap-populations. These bootstrap times are the sum of individual calculation times for different initial conditions which in turn exhibit a great variability. We explain how performance can be enhanced by redundant parallel computation but that the accuracy of results could be degraded by this approach. We show how all those considerations are affected by Linkage- and Hardy-Weinberg Dis/Equilibrium. We address how marginal frequencies for different bootstrap-populations impact on the variability of the computation times.

PowerTrim: An Automated Decision Support Algorithm for Preprocessing Linkage Data. *T.A. Thornton^{1,2}, J.L. Haines²*. 1) Center for Integrative and Cognitive Neuroscience, Department of Biomedical Informatics, Vanderbilt University; 2) Program in Human Genetics, Vanderbilt University Medical Center, Nashville, TN.

Statistical genetics software packages for linkage analysis have unique pedigree size and structure constraints. As a result, analysts are often forced to exclude data from some individuals in a given family. The choice of which subjects to remove may involve consideration of numerous rules based on basic principles of inheritance. In addition, the task of locating transcriptional or data-entry errors, which can result in unsuccessful or erroneous analysis, is very time-consuming. We designed an algorithm called PowerTrim, coded in Perl, whose goals were to: 1) identify and report errors in pedigree data in a user-friendly manner; 2) trim from the pedigree those individuals who provide no information; 3) recommend how a pedigree might be further trimmed to maximize the power of the linkage analysis while conforming to the constraints of the target software; 4) automate the production of edited data and pedigree files. Toward the third goal, PowerTrim iteratively examines the relative contribution of each individual within each family to the power of the linkage analysis, using information on data-completeness and familial relation. For example, it reports the number and percentage of markers genotyped by individual and by family and allows batch-trimming of individuals within some or all families who fall below a user-specified threshold for data-completeness. PowerTrim also provides interactive decision support, offering recommendations based on known data constraints of the GENEHUNTER-Plus and Allegro programs. Each of these programs sets different limits on the number of bits the pedigree may contain, recognizing that the space and time complexity of the analysis increases exponentially with the size of the pedigree. Existing options in these programs are not interactive or user-directed and make arbitrary choices. PowerTrim calculates the pedigree bit size and then allows the user to choose which individuals to trim, while updating and reporting on which pedigrees continue to exceed the limits of either GENEHUNTER-Plus or Allegro.

Program Nr: 2346 from 2002 ASHG Annual Meeting

Population substructure effects on the extent of genotype sharing: A tool for detecting the presence of relatives in databases. *K.M. Teshima, H.S. Lee, R. Chakraborty.* Center for Genome Information, Department of Environmental Health, Univ. Cincinnati, Cincinnati, OH.

The random match probability in a substructured population is larger than that in a single homogeneous population. When each individual in a database is typed for the same set of loci, the distribution of the number of loci showing identical genotypes in pairwise comparison of profiles offers information as to the extent of population substructuring. Computations based on coalescence theory of mutation drift balance show that the mean number of loci exhibiting random match of genotypes increases with the coefficient of co-ancestry. However, the expected number of pairs with identical genotypes decreases with the number of loci at which identical genotypes are seen. Presence of relatives disturbs this monotonic relationship. Analytical results based on the Identity By Descent (IBD) theory, superimposed on the coalescence models of the sampling theory of allelic distribution, show that the distribution of loci showing genotype matches can be a tool for studying presence of relatives in databases, in addition to it being an indicator of population substructure effects. In the DNA forensic context, this implies that a substantial frequency of partial DNA profile matches may exist in databases, in spite of each specific multilocus DNA profile being rare, in particular when databases are large in size. This theory is also applicable for detecting cryptic relatedness differences of cases and controls in population-based disease-gene association studies. (Research supported by US Public Health Service Research grants from the US National Institutes of Health).

80% Posterior Probability of Linkage of Panic Disorder to Small Region on Chromosome 7. *M.W. Logue^{1,2}, V.J. Vieland^{1,2}, R.J. Goedken¹, R.R. Crowe²*. 1) Biostatistics, Division of Statistical Genetics University of Iowa, Iowa City, IA; 2) Psychiatry, University of Iowa, Iowa City, IA.

This work represents a re-analysis of 390 autosomal markers from the Crowe et al. (2001) genome screen for panic disorder. Increased computing capacity allows us to use a version of the 2-point posterior probability of linkage, or PPL, statistic (Vieland, 1998) which removes the need to fix the genetic model by integrating the parameters of the genetic model out of the likelihood. The result is a statistic which is "model-free" and yet uses the information from all of the individuals in large pedigrees. The model integrated PPL reaches 80% on chromosome 7, 24% on chromosome 16, and is less than 12% across the rest of the genome. One advantage of the PPL is that it can be directly interpreted as a measure of the probability that there is a disease gene linked to a given marker. Even so, null simulations were performed and model integrated PPLs were computed for 10,000 simulated, unlinked markers. Only one null replicate exceeded the PPL of 80% on chromosome 7, and only 9 were greater than the 24% on marker 16. The model integrated PPL analysis provides a much clearer indication of a gene for panic disorder on chromosome 7 than previously achieved, although the localization properties of this method are still under investigation.

Program Nr: 2348 from 2002 ASHG Annual Meeting

Efficient simulation of p-values for linkage analysis. *K.K. Song¹, D.E. Weeks¹, E. Sobel², E. Feingold¹*. 1) Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA; 2) Dept Human Genetics, UCLA, Los Angeles, CA.

In many linkage studies, p-values are obtained through simulation since the underlying distribution of the statistic is unknown. However, this can be very computationally intensive, in part because the linkage statistics are sums of contributions from the different pedigrees. A "bootstrap" approach has been suggested (Terwilliger and Ott 1992, Leal and Ott 1993) that generates p-values more efficiently by resampling from the simulated data for each pedigree. The bootstrap idea has been successfully applied, but has never been theoretically studied. An entirely different method for increasing the efficiency of p-value simulation is Besag and Cliffords sequential sampling method (1991), but this method has never been applied to linkage analysis. We propose an algorithm to combine Besag and Cliffords method with the bootstrap method. We also derive variance expressions for several different p-value estimators, and use these to make practical recommendations about what estimators are best and precisely how to implement them.

Score statistics for mapping quantitative trait loci with extended pedigrees. *K. Wang.* Dept Biostat Div Stat Genet, Univ Iowa, Iowa City, IA.

The method of variance components is the method of choice for mapping quantitative trait loci (QTLs) with general pedigrees. Using a likelihood ratio statistic, this method can be computation intensive even for nuclear families. Here two score statistics to detect QTLs are derived, one assumes the dominance effect of the trait at the candidate locus is negligible, and the other one does not make such assumption. One prominent feature of these two score statistics is that they are very easy to compute. The approach here is asymptotically equivalent to the method of variance components, but is different in two aspects: First, it is based on a different analysis model; Second, it is based on the concept of separation of the segregation parameters, the parameters that describe the distribution of the phenotypic values in the population, and the linkage parameters, the parameters that measure the effect of the candidate locus on the phenotypic values. The separation of the model parameters greatly reduces the number of parameters to be dealt with in the analysis of linkage. The asymptotic distributions of both score statistics are derived. Simulation studies indicate that, compared to the method of variance components, both score statistics have comparable or higher power and their false-positive rates are closer to the respective nominal significance levels.

Effect of Winsorization on Power and Type 1 Error of Variance Components and Related Methods of QTL

Detection. *S.S. Shete*¹, *T.M. Beasley*², *C.J. Etzel*¹, *J.R. Fernandez*^{2,3,4}, *J. Chen*¹, *D.B. Allison*^{2,3,4}, *C.I. Amos*¹. 1) Dept Epidemiology, Univ Texas MD Anderson CA Ctr, Houston, TX; 2) Dept Biostatistics, Section on Statistical Genetics, Univ of Alabama at Birmingham, Birmingham, AL; 3) Dept of Nutrition Sciences, Division of Physiology and Metabolism, Univ of Alabama at Birmingham, Birmingham, AL; 4) Clinical Nutrition Research Center, Univ of Alabama at Birmingham, Birmingham, AL.

Variance components analysis provides an efficient method for performing linkage analysis for quantitative traits. However, power and type 1 error of variance components based likelihood ratio testing may be affected when phenotypic data are non-normally distributed (especially with high values of kurtosis) and there is moderate to high correlation among the siblings. Winsorization can reduce the effect of outliers on statistical analyses. Herein, we considered the effect of winsorization on variance-components based tests. We considered the likelihood ratio test (LRT), the Wald test and some robust versions based on the variance components method and we compared these tests with Haseman-Elston least squares-based tests. We found that power to detect linkage is significantly increased after winsorization of the phenotypes. Winsorization does not greatly diminish the type 1 error for the variance components based tests for markedly non-normal data. The robust LRT showed the best power for non-normal data. Finally, phenotype winsorization reduces the bias in estimation of the major gene variance component.

Selecting Genetic Markers for Association Analyses Using LD and Haplotypes. *Z. Meng^{1,2}, D.V. Zaykin², M. Mosteller², C. Xu², M. Wagner², M.G. Ehm².* 1) Bioinformatics Research Center, North Carolina State University; 2) Discovery Genetics, GlaxoSmithKline.

Researchers are discovering that selecting and genotyping SNPs (single nucleotide polymorphisms) at densities less than 100 kb can result in a large number of highly correlated SNPs. High-density SNP data have been used to illustrate that large regions of the genome exist with extensive linkage disequilibrium (LD) and others with less LD. Furthermore, the extent of LD drives the number of possible frequent haplotypes observed in the region. Several studies have illustrated that it may be possible to select SNPs to maximize the information obtained about a genomic region reducing the genotyping cost and simplifying the analysis. Methods are needed to select a minimum subset of SNPs sufficient to retain most of the information provided by haplotypes observed in the region. We extend David Clayton's htSNP selection method, which utilizes haplotype information and propose another method. Both procedures require genotype information on a small number of samples to select SNPs that would be typed on larger numbers of samples. We have studied the properties of these methods using simulated data sets in linkage equilibrium and disequilibrium to assess performance as measured by the proportion of rejected SNPs, as well as by changes in haplotype numbers and diversity. In addition, we have applied the methods to data sets with 368 and 137 samples with SNPs typed at average densities of 20 and 50 kb, respectively. The amount of genotyping can be reduced while maintaining the genetic information content throughout the regions.

On detection of population growth based on SNP data. *A. Polanski, M. Kimmel.* Department of Statistics, Rice University, Houston, TX.

Single Nucleotide Polymorphisms (SNP) are promising genetic markers due to their high density in human genome. SNP data have already been used in association studies of complex diseases; it is believed that eventually they will enable creating fine genetic maps for complex traits analysis. Researches also started using SNP data in population genetics models, for inference on demographic parameters and history. These researches included estimation of the product parameter of effective population size and mutation rate in the population of constant size under hypotheses of spatial (chromosomal) distributions of SNPs, and estimation of parameters of exponential or stepwise models for populations growth.

In this study we address the following problem: How reliable and accurate are the estimates of population growth parameters, based on SNP data? This problem has not been fully explored in the existing literature. Using statistical simulations we estimate distributions and confidence regions of estimates of parameters of populations growth. In our simulations we used newly developed expressions for distributions of coalescence times in time - varying population size evolution, which greatly improved efficiency of numerical computations. Sample size ($n=20$) and number of SNP sites ($K=50$) which we used in our simulations, are comparable to those reported in observational studies.

The obtained distributions of maximum likelihood estimates of the parameter of the exponential growth scenario have atoms at zero and long right tails. For parameters of the stepwise growth scenario, loglikelihood functions have very long ridges (over many decades of the scale) of almost the same value of log likelihood. Therefore parameters of stepwise change cannot be obtained by maximization of the loglikelihood. Instead (like in other studies) we were only able to determine the shapes of regions, which correspond to high likelihoods of data. We have also analyzed observational data on SNP frequencies reported in the literature. When taking into account confidence regions for parameters obtained in our simulations, these data are not inconsistent with the hypothesis of population growth.

The impact of population stratification in case-control studies. *M.F. Freedman**^{1,2}, *D.E. Reich**¹, *S.B. Gabriel*¹, *P.M. Sklar*^{1,2}, *J.N. Hirschhorn*¹, *D. Altshuler*^{1,2}. 1) Whitehead Inst., Cambridge; 2) Mass. General Hospital, Boston.

*The first two authors contributed equally

Case-control studies are the most powerful method for identifying genes contributing to common human disease. There has been extensive debate, however, about the extent to which population stratification (systematic differences in ancestry between cases and controls) can cause false-positive associations.

To assess whether stratification occurs in real studies, we selected 81 unlinked SNPs, and genotyped them in >200 samples from each of 7 studies.

One study showed significant evidence for stratification according to a test developed by Pritchard & Rosenberg (1999). A computer program (Pritchard 2000) was then used to identify the samples contributing to the structure (a few African Americans in a study originally thought to include only Caucasians). Thus, Pritchard's suite of methods is highly reliable at dealing with stratification due to large differences in ancestry.

Finer degrees of stratification, however--which might arise due to individuals of both north and south European ancestry being included in the same study--cannot be practically addressed by these methods without genotyping thousands of SNPs. To set a maximum on the amount of 'cryptic' stratification consistent with our data, we therefore turned to Genomic Control methods (Reich & Goldstein 2001; Devlin & Roeder 1999). The analysis showed that 6 of 7 studies were consistent with stratification at a level that would produce many false-positive associations in a study involving thousands of samples.

Thus, while Pritchard's methods are adequate for correcting for gross stratification, they cannot rule out cryptic stratification. GC methods, however, provide a way of not only measuring, but also correcting for any stratification that exists. Application of GC allows investigators to be confident that any associations that are detected, and also pass the GC test, are real. We recommend that the GC test be used as a minimum criterion for publishing associations in all future case-control studies.

Sample sizes for detecting SNP variants in common diseases. *S.E. Hodge¹, S.L. Slager^{1,2}, R. Allikmets¹, T.C. Gilliam¹.* 1) Columbia U., New York, NY; 2) Mayo Clinic, Rochester, MN.

We examine a strategy to evaluate SNP variants within a gene, or across networks of interacting genes, that confer susceptibility for a complex trait, particularly in the presence of allelic or locus heterogeneity. The basic concept is to look for differences in total number of SNPs between cases and controls. Assuming Hardy-Weinberg equilibrium, and independence between SNP sites, we derive sample-size formulas as a function of desired type I (α) and type II ($\beta = 1 - \text{power}$) errors and of n = average no. of neutral polymorphisms/haplotype: $n = [Z(\alpha) + Z(\beta)]^2 (4n+1)$, where n = no. of controls = no. of cases, and $Z(x)$ = standard normal deviate with area of x in the right tail. If there is locus heterogeneity, with only a proportion p of cases having a variant in this particular gene, $(4n+1)$ is replaced by $(4n+p)/p^2$. The table shows values of n for selected values of n , p , and α , and for power=80%.

$\alpha=.05$	$p=1.0$	$p=0.5$		$\alpha=.10$	$p=1.0$	$p=0.5$
$n=0.5$	19	64		$n=0.5$	14	47
$n=1.33$	40	147		$n=1.33$	29	107

We also derive sample-size formulas for when an investigator desires unequal numbers of cases and controls; also how to *choose* unequal numbers so as to minimize cost and maximize power. Finally, we illustrate the method with ABCR gene data from 150 Stargardts (STGD) cases, 166 AMD (age-related macular degeneration) cases, and 220 controls. We observed 249 variants among 2,046,300 sites in STGD vs. 103 among 3,001,240 in controls, yielding a significant difference ($P < .00001$). For AMD, the difference was significant ($P < .00001$) or not, depending on whether certain common SNP variants were removed or included. This approach should prove helpful in detecting susceptibility SNP variants in complex diseases.

Program Nr: 2355 from 2002 ASHG Annual Meeting

Power computations with misclassified and missing genotype data in association studies of nuclear families. *R.W. Morris, N.L. Kaplan.* Biostatistics Branch, NIEHS, Res Triangle Park, NC.

We study power loss due to genotype errors and missing observations for a family-based likelihood ratio test for association. Under a general model of genotype misclassification or when some, but not all, parents are missing, we employ an EM algorithm to compute the noncentrality parameter under a specified alternative for a two-degree of freedom chi-square distributed test statistic. For power loss characterized by test efficiency, determined as the ratio of the noncentrality parameter for data with misclassified or missing observations to the noncentrality parameter for perfect or complete data, we find that high levels of genotype misclassification can result in substantial decline in test efficiency. With partial missing parental data, however, test efficiency does not decline greatly until most families are missing one or both parents. When both misclassification and missing genotype data occur together, we find the reduction in test efficiency can be substantial.

Two-stage design for tests of gene-environment interaction using haplotype. *X. Liu, D. Fallin.* Genetic Epidemiology, Johns Hopkins University, Bloomberg School of Public Health, Baltimore, MD.

Haplotype-based methods for association analyses have received increasing attention given the ability to capture LD patterns in a more informative way than single polymorphisms. With the advent of high-throughput SNP genotyping, it is now possible to gather genotype data on 100s-1000s of SNPs for large case-control or family-based projects, enabling haplotype analyses at hundreds of candidate genes and potentially across the genome. With this in mind, methods for data reduction and interpretation of such a large number of data points are needed. For projects with a primary interest in gene-environment interaction, such as pharmacogenetic studies, we propose a two-stage design based on haplotypes to provide a powerful and efficient strategy for such data reduction and interpretation: Case-only haplotype analysis followed by a full case-control or trio-based analysis. The first step involves a powerful case-only approach to prioritize regions for subsequent analysis. We show the improved power of this approach, but call attention to the potential bias when the gene region and environmental exposure are correlated in the general population, increasing the false positive rate. To maintain an appropriate overall type 1 error, we propose a subsequent step using a case-control or case-trio design, which is robust to the background GxE correlation bias. We suggest step 1 and step 2 threshold levels to achieve a desired overall type 1 error and show the utility of this triaged design versus a single step analysis requiring the genotyping of all samples on all candidates. This two-stage design using a highly sensitive (high power) GxE test followed by a more specific (correct type 1 error) case-control analyses could provide an efficient way to analyze genome-wide information to identify regions or candidate genes that modify exposure or treatment effects on disease outcomes.

Application of the False Discovery Rate to genome-wide significance thresholds in association analyses. *S.K. Service¹, N.B. Freimer¹, C. Sabatti²*. 1) Neurobehavioral Genetics, UCLA, Los Angeles, CA; 2) Statistics Department, UCLA, Los Angeles, CA.

The mapping of complex traits using association analyses in population samples will likely require the testing of thousands of microsatellite or SNP markers. Unlike linkage analyses, association analyses do not have clear guidelines for significance thresholds that appropriately deal with multiple testing issues. Deciding on an appropriate threshold is further complicated by dependence between marker loci, the level of which varies across the genome. We explore the conceptual and practical implications of the multiple testing procedure known as the False Discovery Rate (FDR) in the area of association mapping for complex traits. Using simulated data, with varying power to detect association and varying degrees of dependency between markers, we show that the FDR correction has consistently higher probability to detect true signals than does the traditional Bonferroni method. This increase in power is most pronounced when attempting to identify multiple loci, as might be expected in complex trait mapping, and we show FDR to be up to twice as powerful as the Bonferroni method when we stipulate that multiple loci are to be found. As might be expected, the trade-off is in the absolute number of false positives. The FDR is designed to control the ratio of false positive rejections to total rejections, therefore while the number of false rejections in our simulations using FDR was higher than that found using Bonferroni, the proportion of false rejections was controlled, and we show this to be true even in the case of strong dependency between markers. While FDR's power is higher than Bonferroni in all scenarios we have examined, both methods suffer from decreased power when markers are highly dependent, highlighting the need for developing resampling based rules to control the FDR.

Genetic analysis of ordinal traits. *H. Zhang*. Dept Epidemiology/Public Hlth, Yale Univ Sch Medicine, New Haven, CT.

Many health conditions including cancer and psychiatric disorders have a complex genetic basis, and genes and environmental factors are likely to interact one another in the presence and severity of these conditions. Assessing familial aggregation and inheritability of disease is a classic topic of genetic epidemiology, which is commonly referred to as segregation analysis. While it is routine now to conduct such analyses for quantitative and dichotomous traits, there do not exist methods and software that accommodate ordinal traits. To this end, I will present a latent variable model. The advantage of this latent variable model lies in its flexibility to include environmental factors (usually represented by covariates) and its potential to allow gene-environment interactions. The model building employs the EM algorithm for maximization and a peeling algorithm for computational efficiency. Asymptotic theory has been established for statistical inference and simulation studies have been conducted to confirm that the asymptotic theory is adequate in practical applications. This model is applied to examine the familial transmission of alcoholism, which is categorized into three ordinal levels: normal control, alcohol abuse, and alcohol dependence. Not only does our analysis confirm that alcoholism is familial, but also it suggests that the transmission may have a major gene component which was not revealed by previous analyses using dichotomous traits. Potential use of our latent variable for linkage analysis of ordinal traits will also be discussed.

Methods for testing familial aggregation of diseases in population-based samples: Application to lymphoproliferative cancers in Swedish registry data. *R.M. Pfeiffer¹, M. Gail¹, K. Hemminki², L.R. Goldin³*. 1) Biostatistics Branch, DCEG, National Cancer Institute, Bethesda, MD; 2) Dept. of Biosciences at Novum, Karolinska Institute, Huddinge, Sweden; 3) Genetic Epidemiology Branch, DCEG, National Cancer Institute, Bethesda, MD.

Familial aggregation of diseases can be tested in case-control or cohort studies. A unique cohort for conducting such tests is the Swedish Family Cancer Database (Hemminki et al. *Acta Oncol* 40:772, 2001) which includes 10.2 million individuals with defined familial relationships, over 1 million of whom have a confirmed cancer diagnosis. From this database, we have selected relatives of all cases diagnosed with a lymphoproliferative cancer along with relatives of matched controls. We propose a survival analysis method for testing familial aggregation comparing disease occurrence in families that were ascertained through a case proband with disease occurrence in families that were ascertained through a control proband. We outline the method that extends work presented by Liang (*Genet Epidemiol* 8:329,1991). Let t_{ij} denote the age or age at onset of disease for member j in family i . The parameter, t , is modeled by a marginal Cox model $l(t_{ij} | X_{ij}, Z_{ij}) = l_0(t_{ij}) \exp(b X_{ij} + g Z_{ij})$, where l_0 denotes the arbitrary baseline hazard function, X_{ij} stands for measured covariates for individual j in family i , for example gender and decade of birth, and Z_{ij} is an indicator of the proband's disease status, i.e. $Z_{ij} = 1$ if the proband of family i is a case and 0 otherwise. Testing for familial aggregation corresponds to testing $H_0: g = 0$. The parameters are estimated under a "working independence" assumption, accounting for truncation arising from the database design. We use the robust sandwich covariance matrix to account for the dependence of the family members. This can be compared to analysis of observed versus expected cancers in first-degree relatives of case-probands based on external population rates. Families of Hodgkin's disease cases and controls are used as an example to illustrate the method.

Haplotype Linkage Disequilibrium Mapping of Quantitative Trait Loci. *R. Fan*¹, *M. Xiong*². 1) Dept of Statistics, Texas A&M Univ, College Station, TX; 2) Human Genetics Center, University of Texas-Houston, Houston, Texas.

In this report, a mixture model is proposed for high resolution multipoint/haplotype linkage disequilibrium mapping of quantitative trait loci (QTL). Suppose that a quantitative trait locus is located in a chromosome region, in which several markers such as SNPs are typed. Since the trait locus is not necessarily at a typed marker locus, the genotype at the trait locus is unknown. By using information of markers/haplotypes in the chromosome region, the conditional probability of the genotypes at the trait locus given the marker/haplotype information can be calculated. Then a mixture model can be constructed under the normal assumption. The maximum likelihood method can be used to estimate the contribution of a putative QTL within the region. The point that yields the most significant result may be taken as the location of the putative QTL.

Program Nr: 2361 from 2002 ASHG Annual Meeting

Testing genotype-phenotype association in trisomic data. *E. Feingold*¹, *Z. Xu*¹, *K.F. Kerstann*², *S.L. Sherman*². 1) Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA; 2) Dept Human Genetics, Emory University, Atlanta, GA.

A number of congenital disorders are rare in the general population but more common in individuals with specific trisomies; examples include certain heart defects and leukemias in Down syndrome. With the completion of the genome sequence, it is timely to start searching for genetic variants that are associated with these disorders. We present a "trisomic TDT" - a statistical method for testing genotype-phenotype association using trios of trisomic individuals and their parents. Like the conventional TDT, our method conditions on parental genotypes and thus controls for population admixture and stratification. We also discuss methods for case-control association studies using trisomic data.

Sampling bias in the D' statistic and a bootstrap correction. *K.N. Conneely, G.R. Abecasis, M. Boehnke.* Dept Biostat, Univ Michigan, Ann Arbor, MI.

Lewontin's D' is a measure of linkage disequilibrium (LD) that is well suited for LD mapping and is consequently prevalent in the literature despite its unusually pervasive sampling bias. Although D' is asymptotically unbiased, its sampling bias is substantial and persists for large numbers of chromosomes. In contrast, other measures of LD are subject to smaller sampling biases that decay rapidly with increasing sample size. Nevertheless, D' has desirable properties not shared by the other measures of LD. Given some general assumptions, D' in large populations is independent of allele frequencies and is directly related to the recombination fraction and the number of generations since mutation. The advantages and the widespread use of D' suggest that it is a valuable tool despite its bias and that efforts to mitigate its bias are warranted. Through simulation, we examine the statistical properties of D' for biallelic marker pairs with the dual goals of documenting and reducing the sampling bias. We find that the bias varies with the level of LD and with marker allele frequencies. The bias is most pervasive when $D' \approx 0$ and is virtually non-existent when $D' \approx 1$. Estimates of D' are generally biased away from zero, so in the presence of positive LD they tend to be biased upward. The bias can be as great as 10% for samples of fewer than 100 chromosomes and 5% for samples of 500 chromosomes, and is even more severe in LD studies that use the absolute value of D' . When $D' = 0$, the expected value of estimated $|D'|$ ranges from 0.1 to 0.8 in a sample of 100 chromosomes. This type of bias will contaminate comparisons of LD across genomic regions and between samples of varying sizes, leading to the illusion that LD extends much further in smaller samples. To address this problem we propose a bootstrap estimator of D' which outperforms alternative estimators. Our simulations show that bootstrapping D' reduces its bias without increasing its mean squared error. Accordingly, bootstrapping should increase the validity of comparisons of LD across different populations and regions of the genome while fully utilizing the available information. To illustrate this, we use our methods to compare LD maps across populations with different sample sizes.

Simulation of LD block-structured SNP haplotype data and its use for the analysis of case-control data by supervised learning methods. *M. Nothnagel*. Dept. of Bioinformatics, Max Delbrück Center, Berlin, Germany.

Recent findings indicate that haplotypes of single nucleotide polymorphisms (SNPs) exhibit a block structure characterized by high degrees of linkage disequilibrium (LD) between SNPs from the same block and low degrees of LD between SNPs that are from different blocks. Also, only a small fraction of all possible block haplotypes occurs with notable frequencies. To find optimal approaches for analyzing these data, it is desirable to study various methods in well-defined settings. A software program, SNaP, was developed to simulate SNP haplotype data for an unlimited number of individuals, either using random sampling or sampling case-control data. Each individual can be assigned either an affection status or a quantitative trait, conditional on the genotype at one or more loci. Various parameters including penetrances, allele frequencies, and phenotypic effects can be specified. The haplotype is composed of LD blocks, each being defined by pre-set haplotypes and their frequencies. Additionally, SNaP allows for the incorporation of genotyping errors and the removal of causal SNPs from the sequence.

SNaP was used to carry out a simulation study where supervised learning methods (SLMs) were investigated for the analysis of SNP genotype data in a case-control design. One of SLMs' aims is to find the set of SNPs which can best discriminate between cases and controls, thus hopefully pinpoint differences that are causal of the disease status. For each model in a grid spanned by parameters like sample sizes, allele frequencies, and locus interaction and disease definition, data sets were repeatedly simulated using SNaP and various standard SLMs were applied to them. First results for single and two-locus models support the usefulness of classification trees whereas linear and quadratic discriminant analysis seem to be inappropriate. An essential requirement for reliable findings is sample sizes of at least 100 individuals per group. The better methods perform well in all models for penetrance values above 0.8 or susceptibility allele frequencies below 0.25. In general, recessive and multiplicative or heterogeneity models constitute advantageous settings.

Power and significance when screening SNPs in large case-control studies. *K.L. Lunetta, K.G. Ardlie.* Genomics Collaborative Inc, Cambridge, MA.

Under the scenario of candidate gene association studies (case-control, pharmacogenetic, etc.) that look at hundreds of SNPs in large numbers of genes, one preliminary analysis goal is to identify SNPs and more generally genes for follow-up analyses or further genotyping. In this context, one strategy is to consider any gene with at least one positively associated SNP a potential hit worth further study. The choice of test and significance level for declaring a hit depends on the goals of the study. Several strategies for screening large numbers of SNPs for individual associations in large case-control studies are possible. One is to use a 2df test that does not assume a genetic model, or alternatively, a 1df test assuming a specific model. Another possibility is to test more than one possible genetic model for an arbitrary allele (e.g., dominant, additive, and recessive) and compare the maximum statistic to the critical value. This latter strategy must overcome the problems inherent with multiple testing and correlated tests; the critical values used must be increased in order to avoid excessive false positives. We have computed the correlations among dominant, additive, and recessive codings of the Armitage trend test under the null hypothesis, and determined corrected critical values for the maximum Armitage trend test statistic (maximum trend test, MTT). We compare the power of Fishers exact (2df) test and the MTT and find that they are nearly identical under most situations, and that the MTT is marginally more powerful in some low-power situations. We next extend our study to multiple correlated SNPs in a gene. In the genome-wide candidate search context, where multiple SNPs are tested in each candidate gene, we may want to declare a gene a hit worth further study if any single SNP has a positive association, or if there is a positive haplotype association within the gene. We use simulation to determine reasonable criteria for acceptable levels of false positive and false negative hits.

A genotype-based association test for general pedigrees: The geno-PDT. *E.R. Martin, M.P. Bass, E.R. Hauser.*
Center for Human Genetics, Duke University Medical Center, Durham, NC.

Many family-based tests of linkage disequilibrium (LD), such as the pedigree disequilibrium test (PDT), are based on counts of alleles and are most powerful when the disease alleles at a locus act additively on disease risk. When alleles do not act additively, for example when the disease allele is dominant or recessive, tests based on genotype counts may be more powerful. We propose a test for association of genotypes with disease, the geno-PDT. The test is a simple modification of the PDT, and like the PDT, it is valid even in stratified populations. The geno-PDT is applicable to nuclear family or extended pedigree data. The statistic can be used to test any specific genotype or a global test can be used to test all genotypes simultaneously. The null hypothesis is that there is either no allelic association or no linkage between the disease and marker loci, thus the test will have power only when both association and linkage (i.e., LD) are present. The PDT and geno-PDT both test the same null hypothesis but can have different powers depending on the genetic model. We have conducted simulations to examine the false-positive rate and power for the geno-PDT and to compare the powers of the PDT and geno-PDT under different disease models. Genotypes for biallelic disease and marker loci were simulated in nuclear families allowing for variable levels of LD. Simulations show that individual tests and the global geno-PDT have the correct false-positive rates. Power for the global geno-PDT was somewhat higher than power for the PDT under dominant and recessive models, while the PDT tended to be more powerful for the additive model. Applying the geno-PDT to individual genotypes can lead to even more significant results when the model is dominant or recessive and can give important clues as to association at the genotypic level. The geno-PDT will be a useful tool for testing for LD in family data at SNPs. Furthermore, the extension of the geno-PDT to genotypes at multiple SNPs will allow one to test for multilocus effects without the ambiguities associated with haplotype analysis, and using markers in different genes will allow testing of gene-gene interaction.

Assuming independent male-female (m-f) recombination fraction (RF) can reveal imprinting. *D.A. Greenberg^{1,2}, B. Feenstra¹, S.E. Hodge^{1,2}*. 1) Div Stat Genetics, Columbia Univ.; 2) Div Clin Genet Epi, NY Psych Institute, NY NY.

In a linkage analysis of Juvenile Myoclonic Epilepsy [Greenberg et al AJHG 66:508], we noted a statistically significant difference between maximum lod scores (Z_{max}) calculated assuming equal m-f RF (the "restricted" Z_{max}) and Z_{max} allowing independent m-f RF ("global" Z_{max}). We also observed a surprising pattern in the distribution of independent m-f lod scores suggestive of heterogeneity. Because this occurred in a genomic region not known to have sex-based RF differences, we suggested this difference could arise from imprinting [Smalley, AJHG 52:210]. Or the observed difference might arise from ascertainment bias if study subjects are more likely to cooperate when family history exists on the paternal (or maternal) side. Here we answer three questions: 1) Can linkage analysis using differing m-f RFs reveal the existence of imprinting? 2) Can ascertainment bias lead to similar results? 3) How does heterogeneity affect the pattern of lod scores in imprinting? We simulated family linkage data with and without "imprinting" (defined as penetrance dependent on sex of the transmitting parent), but with no difference between m-f RFs. We then determined the difference between the global and restricted Z_{max} values. We found: 1) Restricted vs global differences were statistically significant in realistic samples. For ex., datasets of 20 nuclear families generated with complete imprinting yielded differences of approx. 1.5-2.5 lod score units - statistically significant at least at the $p < .05$ level after correcting for multiple tests. 2) Ascertainment bias based on parental sex does not lead to any differences in global vs restricted Z_{max} and thus does not mimic imprinting, no matter how great the bias. 3) When there is heterogeneity plus imprinting, using independent m-f RF can greatly increase the evidence for linkage as well as yield evidence of imprinting. [Support: NIH DK31775, NS27941, MH48858].

Allele-sharing linkage analysis on subsets of families stratified based on an associated allele. C. Li, L.J. Scott, M. Boehnke. Dept Biostatistics, Univ Michigan, Ann Arbor, MI.

To fine map genes we often test for disease-marker association in regions with previous evidence for linkage. Given an associated allele, we next ask if this allele, or one in linkage disequilibrium with it, could account for part of the observed linkage signal. We propose to address this question by determining if families selected based on an associated allele show stronger evidence of linkage. One possible subset is the set of families in which any affected member carries the allele; a second is the set of families in which all affected members are homozygous for the allele (Horikawa et al. 2000). Unfortunately, in the region of the marker, standard linkage analysis on the first subset is biased *against* linkage, reducing or even removing possible linkage signals, while that on the second subset is biased *for* linkage, artificially generating or amplifying linkage signals. Horikawa et al. proposed to correct this bias by simulations.

For affected sibships, one unbiased solution is to select families based on the genotype of one random sib. However, this subsetting scheme generates different subsets of families depending on the sib chosen, and introduces substantial variability. To make full use of the sibship information, we consider all possible resulting subsets, and observe that each family is selected into a fraction of the subsets, with the fraction being determined based on the genotypes of all affected sibs. This introduces a family weight variable and an unbiased weighted subsetting scheme. We define its corresponding NPL (Kruglyak et al. 1996) and LOD scores (Kong and Cox 1997).

To assess the significance of a result given evidence of linkage, we introduce a permutation test, in which we essentially test for association of a family weight variable with excess allele IBD sharing. Simulations show that this is a powerful test for moderate sample sizes. For example, for 500 ASPs and $I_s=1.1$ and significance level .01, if the disease allele frequency $p=.2$, the powers for additive, dominant, and recessive models are 93%, 94%, and 100%; if $p=.5$, the powers are 83%, 55%, and 98%.

Effects of prior screening for known mutations on power of sib-pair linkage studies. *R.A. Kerber¹, C.I. Amos², D.C. Thomas³, D.M. Finkelstein⁴, B.Y. Yeap⁴.* 1) Huntsman Cancer Institute, University of Utah, Salt Lake City, UT; 2) Department of Epidemiology, Box 189, 1515 Holcombe Blvd, M.D. Anderson Cancer Center, Houston, TX 77030; 3) Department of Preventive Medicine, University of Southern California, 1540 Alcazar Street, CHP-220, Los Angeles, CA 90089-9011, USA; 4) MGH Biostatistics, 50 Staniford St, Ste 560, Boston, MA 02114-2521.

If susceptibility to a disease can be caused by mutations of any of several unlinked genes, linkage analysis becomes more difficult because only a subset of families under study will be contributing to the linkage scores at any given locus, resulting in a loss of power. In designing a Cancer Genetics Network-Cooperative Family Registries for Colorectal Cancer Studies sib-pair study of colon cancer, we wondered whether the power of the study would be improved by excluding families segregating an already-identified predisposing mutation prior to genotyping marker data. To study this question, we performed a variety of simulations of a disease-susceptibility syndrome similar in its general characteristics to colorectal cancer (population rate = 2.2%), with two unlinked moderate-penetrance (27% risk to carriers) susceptibility syndromes present in the population with varying allele frequencies (.001 .005). We simulated a set of 500 families selected for analysis, each with two affected and two unaffected sibs sampled. We compared the power of a test for linkage at a recombination fraction of 0.05 from one disease locus employing all available families with a test for linkage after all families with a mutation at the other locus had been eliminated. We compared a test of mean allele sharing identical-by-descent (IBD) among affecteds only to a test of the mean IBD difference between affected pairs and discordant pairs of sibs. Our results show little difference in power between the designs if the proportion of disease attributable to the linked locus is larger than the proportion of disease attributable to the unlinked locus. However, if the linked locus accounts for a smaller proportion of the disease risk than the unlinked locus, experimentally eliminating families with mutations in the unlinked gene can result in increased power.

Program Nr: 2369 from 2002 ASHG Annual Meeting

Dissecting The Correlation Structure Of A Bivariate Phenotype For QTL Mapping. *S. Ghosh, T. Reich.* Dept Psychiatry, Washington Univ Sch Medicine, St Louis, MO.

One of the current challenges of genetic epidemiology is to unravel the genetic architecture of complex traits. Heritable quantitative characters, possibly correlated, generally underlie complex traits. Studies have revealed that a bivariate linkage analysis for two correlated traits is often more powerful than separate univariate analyses. However, a high correlation between two quantitative traits need not necessarily imply a common QTL controlling both the traits, but may be due to common environmental factors. The aim of this study is to develop statistical methods to extract the genetic contribution to the total correlation between the components of a bivariate phenotype. Using data on bivariate phenotypes and marker genotypes for sib-pairs, we derive an expression for the conditional cross-sib trait correlations (trait 1 of sib 1 - trait 2 of sib 2 and conversely) given the i.b.d. sharing at a marker locus. We show that, similar to the traditional Haseman-Elston regression (1972), the conditional correlation is a linear function of the marker i.b.d. sharing under low degrees of dominance at the traits. A test for linkage with a common QTL can be performed based on the coefficient associated with the marker i.b.d. sharing, which is zero under the null hypothesis of no linkage and positive in the presence of linkage. Monte-Carlo simulations are included to assess the performance of the proposed procedure. We also present an application of our method to two correlated alcohol related phenotypes in the COGA data. Univariate studies have obtained linkage in the ADH cluster on Chromosome 4 with maximum number of drinks in a 24 hour period as well as number of externalizing symptoms. Our correlation-based test yields a p-value < 0.001 with the ADH3 marker, suggesting a potential candidate gene.

Magnitude of Lod Score Differences from Unequal Male-Female Recombination Fractions. *B. Feenstra, S.E. Hodge, D.A. Greenberg.* Div. of Stat. Genet., Columbia University, New York, NY, and New York State Psychiatric Institute, New York, NY.

It is well-known that human recombination fraction (RF) can differ between males (m) and females (f). However, only recently have investigators begun to allow for or test this difference in linkage analyses. We quantified the effect of differential m-f RFs on linkage analysis for fully informative gametes (FIGs). (FIG = a gamete that is unambiguously either recombinant or nonrecombinant.) We calculated expected lod scores (ELODs) under two different conditions: 1) allowing sex-specific recombination fraction parameters (q_m, q_f) and 2) assuming $q_m = q_f$. We then examined the DELOD, defined as the difference between ELODs maximized as a function of (q_m, q_f) under condition 1) vs. 2). The magnitude of the DELOD depends on the true RFs (r_m and r_f), on sample size, and on the proportion (p) of paternally-derived (or $(1 - p)$ of maternally-derived) FIGs. We calculated minimum sample sizes required to achieve DELOD ³ 0.83, corresponding to a statistically significant c^2 at the 5% level.

(r_m, r_f)	(0.05,0.2)	(0.01,0.2)	(0.01,0.3)	(0.01,0.4)	(0.01,0.5)
# FIGs required	70	33	20	14	10

We also found that for any given sample size, DELOD is maximized for p between 0.36 and 0.64, depending on (r_m, r_f). Finally, we examined DELOD for sib pairs that are fully informative except for having phase-unknown parents, and found similar results. We note that other phenomena, such as imprinting, may also lead to lod score differences between analysis under conditions 1) vs. 2). This study shows the magnitude of differences that can be expected from differential m-f RF.

Fast evaluation of parametric models in pedigree analysis. *G.R. Abecasis.* Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor.

Parametric analyses allow explicit modeling of phenotype and genotype data. Traditionally, parametric models are specified for the trait locus and provide powerful linkage tests when the trait model is specified accurately. More recently, parametric analyses have become important in the modeling and detection of genotype errors and in the area of relationship inference. Although these applications are important in the mapping of complex traits, the evaluation of parametric models is very computationally demanding in many settings. For example, likelihood calculations that incorporate trait models with multiple alleles or allow for genotype error most often rely on approximate Monte-Carlo methods.

We describe an efficient computational approach for evaluating parametric likelihoods for individual inheritance vectors. Our approach has the following features: 1) binary trees are used to represent gene flow in pedigrees, allowing for gradual updates of likelihoods and reducing redundant calculations; 2) efficient orderings are used for evaluation of nested sums within each inheritance vector; 3) for suitable genotype error models, allele set recoding is applied to individual founder allele sets to simplify calculations and 4) optionally, greedy evaluation is used to skip unlikely inheritance vectors and founder allele sets implying large numbers of errors. Our model allows both for trait loci with multiple alleles and explicit modeling of genotyping error.

We show that our approach provides near instantaneous likelihood calculations for small pedigrees (such as sib-pairs) but can also handle larger pedigrees for either SNP or microsatellite data. Without explicit error modeling, undetected genotyping error greatly reduces power for linkage analyses. In the context of affected sib-pair linkage analysis, we use simulation to compare the efficacy of a) error detection and removal and b) explicit modeling of genotype error in recovering lost linkage information. We expect that results of this comparison will help investigators devise strategies for managing genotyping error.

Detecting low-quality markers using map expanders. *C.T. Ekstrøm*^{1,2}. 1) Department of Biostatistics, University of Copenhagen, Denmark; 2) Steno Diabetes Center, Denmark.

Genetic marker data play a crucial role in gene mapping and genotyping errors can therefore have substantial influence on the power to detect and the precision to locate disease loci. Statistical methods can be used to identify individuals, markers or pedigrees with high likelihood of containing genotyping errors. Putative erroneous genotypes can then be rechecked and either verified or corrected to reduce the loss of power introduced by the errors.

We present a method to detect genetic markers with high genotyping error rate. Genotyping errors are likely to appear as double recombinations, which will expand the genetic map around the marker. Markers flagged as map expanders (i.e., having an excessive number of double recombinations) can then be reread or regenotyped or a replacement marker of higher quality can be used instead. The method can be applied to any type of pedigree.

A simulation study of nuclear pedigrees and sib pairs shows that the proposed method generally has high power to identify map expanders when the set of markers is reasonably dense (e.g., an average marker distance of 5 cM) - even when the genotyping error rate is low (<2%). Not surprisingly, the power to detect map expanders increases with marker heterozygosity and genotyping error rate and is reduced with increasing inter-marker distance.

Linkage with multivariate summary measures of correlated phenotypes. *D.L. Koller, S.L. Hui, P.M. Conneally, C.C. Johnston, M.J. Econs, T. Foroud, M. Peacock.* Indiana Univ. Sch. of Medicine, Indianapolis, IN.

In the study of complex genetic disease, multivariate summary measures are often used to analyze the genetic contribution to related phenotypes. Inferences are often made from these analyses as to pleiotropic effects of the loci detected. We present the results of a linkage study in which a multivariate summary measure and a true composite phenotype were available for comparison. We ascertained a sample of 774 premenopausal sister pairs. Bone mineral density (BMD) at the hip was obtained for all sisters by DXA at femoral neck, trochanter, and Ward's triangle, as well as for total hip, which includes the three specific sites. A 10 cM genome scan was performed by CIDR. Principal component scores for BMD at the three hip sites were obtained using SAS. LOD scores were calculated with Mapmaker/SIBS. The three specific hip BMD measures and total hip BMD were highly correlated within individuals in our sample ($r=0.81-0.91$). Maximum LOD scores for chromosomes 14 and 15 for the 3 specific hip BMD measures, as well as for total hip and the first principal component (which explained 90% of total variation), are shown below. We conclude from these data that site-specific genetic effects may be detectable even among the highly-correlated phenotypes most amenable to multivariate analysis, and that genetic information may be lost in summary measures such as principal components. These data also show a substantial difference in linkage results using a true composite measure and a multivariate summary measure, implying that composite phenotypes may include non-redundant genetic information in addition to that contained in site-specific and summary measures.

Chromosome	Trochanter	Ward's tri.	Femoral neck	1st pr. comp.	Total hip
14	3.47	2.35	1.83	2.85	1.36
15	0.88	2.87	4.25	2.67	1.31

Linkage analysis of Alzheimer's Disease (AD) with latent class models. *R.J. Neuman¹, A. Myers¹, L. Sun¹, J. Williams², J.P. Rice¹, N.L. Saccone¹, A. Goate¹.* 1) Dept Psychiatry, Wash Univ, St. Louis, MO; 2) U. Wales, Cardiff U.K.

Although traditional allele-sharing (IBD) linkage methods play an important role in looking for disease loci, they have several limitations: eg., searching for only 1 trait locus at a time, or not utilizing unaffected individuals thus losing what may be important information. We applied latent class analysis (LCA) to IBD data in a late-onset AD dataset containing 429 ASP and 247 discordant pairs (DSP). LCA can be thought of as a parametric clustering method and, as such, does not have the restrictions of traditional linkage methods noted above. A recent ASP genome scan of these data [Myers et al., 2002] found 10 regions with LOD scores greater than 1. Their maximum MLS, 3.5, occurred at 82.2 cM on chr10. Our LC reanalysis of these data first analyzed markers on each chr separately. The strongest signal was on chr5 in a 9-cluster solution, the solution with the minimum Bayesian Information Criterion. The number of ASPs was greater than expected by chance ($p=0.005$) in a class in which over 97% of pairs shared IBD=2 at markers. This was in the same vicinity of chr5 where Myers et al. reported a LOD>1. Our next strongest signal was on chr10, again in a 9-cluster solution. A high proportion of ASPs ($p=0.07$) were assigned to a cluster in which over 90% shared IBD=2 in the vicinity of D10S1227 (75cM). To detect epistasis arising from non-syntenic regions, markers were analyzed jointly from chr5, 10, and 13 (where no signal was detected by Myers et al., nor by our LCA of chr13 markers). A cluster of sib pairs with an excess of ASPs and excess sharing at markers on chr5 and 10 in the regions detected by Myers et al. was singled out: cluster 8 contained 87.5% ASP versus 63.4% in the total sample ($p=0.002$). For comparison, over 90% of pairs shared at markers on chr13, but only 50% were ASPs, indicating no linkage evidence. AD presents a challenge for genetic analysis because of its uncertain etiology, inconclusive diagnosis before death, and other risk factors. Nevertheless, LCA was able to replicate some of the regions of interest found by Myers et al., and to detect a possible interaction among multiple susceptibility loci.

Evaluating results from genome-wide linkage scans of complex discrete traits by locus counting. *S. Wiltshire*^{1,2}, *M.I. McCarthy*¹, *L.R. Cardon*². 1) Imperial College Genetics and Genomics Research Institute, Imperial College, London, United Kingdom; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom.

Evaluating results from primary (~10cM) genome-wide linkage scans of complex human traits remains an area of considerable debate. In addition to measures of statistical significance, a complementary means of evaluation is possible, based on a comparison of the numbers of Independent Regions showing evidence for Linkage (IRLs) observed in a genome scan, at various LOD score thresholds, with those expected by chance. We have explored by simulation the characteristics of this locus counting method over a range of experimental conditions typically encountered during genome scans of discrete traits, using GENEHUNTER PLUS and treating loci as independent if their maxima are ³40cM apart. Under the null hypothesis of no linkage, factors impacting on data informativeness markedly influence the null IRL distribution. For instance, evidence for linkage with LOD=2.20 is expected <0.3 times by chance per primary scan, compared with once predicted under the assumption of complete information extraction. Our simulations suggest that in a typical primary scan we expect 8-11 IRLs with LOD³0.59 and 2-3 with LOD³1.18 by chance, depending on the precise data characteristics; IRLs with LOD³ are rare. Furthermore, we expect one region by chance with LOD=1.5-1.7. We have applied this method to the Warren 2 genome scan for type 2 diabetes susceptibility. We observe significantly more regions showing evidence for linkage with LOD scores of 1-2.5 in the primary scan than expected by chance (for example, 7 regions observed at LOD³1.18 vs 2 expected), even though no region achieved empirical genome-wide significance. Locus counting may be useful in assessing results from complex trait genome scans in general, especially from scans that fail to generate evidence for linkage reaching genome-wide significance. By accounting for the effects of reduced data informativeness on the expected numbers of IRLs, a more meaningful and less conservative evaluation of results from such studies is possible.

Comparison of methods for QTL mapping with selected sibships. *K. T. Cuenco*¹, *J. Szatkiewicz*², *E. Feingold*¹. 1) Dept of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Dept of Biostatistics, University of Pittsburgh, Pittsburgh, PA.

In the last few years, at least a dozen new methods for mapping quantitative trait loci (QTLs) using sibships have been published. Most of the papers describing the new methods have only considered population samples from normally-distributed traits. It is not at all clear which methods are most appropriate for selected samples, which are arguably more common than population samples in human genetics. We have written software to implement essentially all of the new methods for sib pairs, and have made both theoretical and analytical comparisons of their performance on samples that are selected on the basis of one sib with a high (or low) trait value. While most of the new statistics are asymptotically equivalent for population samples, there are important power differences for selected samples.

New statistical methods for QTL mapping with discordant sibling pairs. *J. Szatkiewicz*¹, *K. T. Cuenco*², *E. Feingold*². 1) Dept of Biostatistics, University of Pittsburgh, Pittsburgh, PA; 2) Dept of Human Genetics, University of Pittsburgh, Pittsburgh, PA.

Discordant sibling pairs can potentially be very powerful for mapping quantitative trait loci (QTLs). Statistical analysis for discordant sib pair studies has traditionally been based on the identity-by-descent (IBD) sharing statistic, though Forrest and Feingold (2000) also proposed a "composite" statistic that combines the IBD sharing statistic with an additional statistic such as Haseman-Elston. In the last few years, however, a number of new statistics for QTL mapping with sibling pairs have been published, and some of these are applicable to discordant pairs. We have reviewed the new statistics and compared their power for mapping using discordant pairs. We have also compared the power of the newer methods to that of the IBD sharing statistic and the composite statistic. We considered both extreme discordant pairs (one sib in the top 10% of the trait distribution and one in the bottom 10%) and moderately discordant pairs (one in the top 35% and one in the bottom 35%).

Power of a simplified multivariate test for genetic linkage. *O. Gorlova*¹, *C. Amos*¹, *D. Zhu*¹, *W. Wang*¹, *S. Turner*², *E. Boerwinkle*³. 1) Dept Epidemiology, Univ Texas MD Anderson CA Ctr, Houston, TX; 2) Division of Hypertension, Department of Internal Medicine, Mayo Clinic, Rochester, MN; 3) Human Genetics Center and Institute of Molecular Medicine, The University of Texas Health Science Center, Houston, TX.

We compare the power of the multivariate Haseman-Elston (MHE) test proposed earlier by Amos et al. (*Am J Hum Genet* 1990, 47:247-254) and a computationally rapid new version of the multivariate Haseman-Elston test (NMHE) (Elston et al., *Genet Epidemiol* 2000, 19:1-17). We show that the power of NMHE was, for different simulation setups, identical or higher than that of MHE. In the bivariate case, the power of the NMHE method was somewhat less than that of the computationally intensive maximum likelihood variance components method (Amos et al, *Hum Hered* 2001, 51:133-144). We present comparisons of the empirical distributions of the NMHE test to its limiting distributions for a range of numbers of traits. The distribution of NMHE test appeared to conform satisfactorily to its limiting asymptotic distribution in large samples. Otherwise, the test proposed by Elston et al. (2000) is non-conservative. The use of empirical critical values is therefore recommended for limited sample sizes (less than several hundred families). We also present the results of a linkage analysis performed by the NMHE method on a set of 4 body size-related traits. The method identified meaningful combinations of traits that showed significant linkage on chromosome 2 and suggestive linkages on chromosomes 16 and 17.

Program Nr: 2379 from 2002 ASHG Annual Meeting

Finding causal variants of complex diseases via haplotypes. *S. Bacanu*. Dept Psychiatry, 3811 O'Hara Street, E-1221, University of Pittsburgh, Pittsburgh, PA 15213.

The analysis of genetic polymorphisms as haplotypes is thought to be useful to detect causal polymorphisms affecting liability to complex disease. One of the methods transferred to statistical genetics from the data-mining field is the tree classifier. Tree-like classifiers have many good properties but, by themselves, they cannot take multilocus information into account. We propose a method that combines the desirable attributes of tree classifiers with the inherent multilocus information available in haplotypes. Our tree-like method aggregates the haplotypes based on their effect on the trait. It sequentially adds the haplotype with the highest effect on the trait that improves the cross validated log-likelihood significantly. The power and accuracy of the proposed method are assessed by use of simulated data. The performance of more traditional methods is also assessed on the same data for the purpose of comparison. We find the proposed method is excellent at detecting haplotypes bearing variants increasing liability and usually has at least as much power as other, commonly used methods.

Extensions of multipoint methods for localizing susceptibility genes. *D.V. Glidden¹, K.-Y. Liang², Y.-F. Chiu³, A.E. Pulver⁴.* 1) Epidemiology and Biostatistics, Univ. of Calif., San Francisco, San Francisco, CA; 2) Department of Biostatistics, Johns Hopkins Univ., Baltimore, MD; 3) Department of Biostatistics, Univ of N. Carolina, Chapel Hill, NC; 4) Department of Medicine, Johns Hopkins Univ., Baltimore, MD.

Recently, Liang et al. (2000) proposed a general multipoint method for estimating the chromosomal position of a putative susceptibility locus. Their technique is computationally simple and does not require specification of penetrance or a mode of inheritance. This paper considers various extensions including exploration and inference for covariates which may reflect etiologic heterogeneity. Here, we draw particular attention to incorporating age of onset information. The method can be extended, in a similar spirit, to include affected/unaffected sibling and general affected relative pairs. Through simulation studies and a data example, we demonstrate that these extensions allow for robust, precise localization of susceptibility genes for complex diseases.

Unraveling complex traits through the genetics of gene expression. *S.A. Monks^{1,2}, E.E. Schadt¹*. 1) Informatics, Rosetta Inpharmatics, Kirkland, WA; 2) Department of Biostatistics, University of Washington, Seattle, WA.

In 1980 Botstein et al. proposed that sequence differences be treated as markers in order to map genes involved in inherited traits. Since that time, the number of genes mapped to positions in the human genome has grown exponentially. Mapping these genes to inherited traits has been extremely successful for simple Mendelian diseases; however, finding such genes for diseases, and their associated risk traits, that are of public health interest has proven difficult. Reasons for this difficulty include disease heterogeneity (disease sub-types with some or no overlapping genetic causes), misclassification (from using discrete classifications of disease from thresholds and combinations of thresholds), and cumulative environmental influences. With the advent of technology to measure changes in gene expression, i.e., changes in mRNA transcript abundance, it should be possible to unravel some of the complexity existing for these common diseases. We will show that studying the genetic component of mRNA expression is possible through the use of a sample of CEPH (Centre d'Etude du Polymorphisme Humain) families. Discussion will include assessing differential expression of genes for the population, determining whether variation in expression is under genetic control and establishing loci that control variation in expression. Time permitting, it will be shown that combination of information across a number of genes can be used to establish, support and/or confirm a biological pathway.

Association meets haplotype sharing under allelic heterogeneity. *D. Qian*. Dept of Preventive Medicine, Univ of Southern California, Los Angeles, CA.

Despite the increasing evidence of allelic heterogeneity at loci predisposing to complex disease, most statistical methods have been developed and evaluated under a simplified assumption that complex disease is caused by multiple genes, each having minimal allelic heterogeneity. Allelic heterogeneity refers to multiple ancestral disease alleles at a single locus, and this phenomenon is expected to be the rule rather than the expectation for complex diseases in humans. We generate haplotype data with allelic heterogeneity by a forward population simulation procedure, where distinct ancestral alleles and linkage disequilibrium in population haplotypes can be monitored. When markers do not include the true disease locus, the haplotype sharing correlation (HSC) method has the capacity to map disease genes that are missed by transmission disequilibrium test method under allelic heterogeneity and weak LD. The HSC signals occur near the disease locus and show obvious drops at recombination hot spots, but the peaks may not pinpoint the true disease location. The false positive signals in HSC analyses are rare and weak in data sets we analyzed. For case-parent trios, the HSC significance on disease segment obtained using reconstructed haplotypes is much weaker than those obtained using true simulated haplotypes. On the other hand, when the true disease locus is a marker locus, association method is more powerful than HSC method under low frequency of disease alleles, but the two approaches have similar power under high frequency of disease alleles. These results suggested that haplotype sharing analysis is useful for finding genes under allelic heterogeneity and/or high frequency of disease alleles.

Efficiency and robustness of the set association approach for case-control studies with SNPs. *A. Wille*^{1,2}, *J. Ott*¹. 1) Statistical Genetics, Rockefeller University, New York, NY; 2) IMBIE, Bonn University, Germany.

In complex traits, multiple disease mutations with small marginal effects interact to produce the trait. For this reason, it has been difficult to map susceptibility loci by conventional locus-by-locus methods even with high resolution SNP marker maps. Novel fine mapping strategies are needed that focus on the simultaneous detection of interacting disease mutations and combine information over neighboring loci while handling large numbers of densely spaced markers.

Based on these requirements, a set association approach was proposed recently for case-control association studies with uncorrelated SNPs. In a stepwise selection process, markers are combined in a set whose overall association is evaluated by the sum of the single marker signals.

Here, the efficiency of the approach is examined depending on the underlying disease model, the sample size and the properties of the marker data. It is shown that the set association method performs particularly well when densely spaced markers with a homogeneous inter-marker correlation pattern are used in the study. However, when the correlation structure varies between susceptibility and non-susceptibility regions, the power to detect set association can be greatly reduced. An extension of the approach in which inter-marker linkage disequilibrium is taken into account proves to restore this loss of power.

Program Nr: 2384 from 2002 ASHG Annual Meeting

A multilocus association test for case control data with improved flexibility of the model assumptions. *D.V. Zaykin, M.G Ehm.* Dept Population Genetics, GlaxoSmithKline, Inc, Res Triangle Park, NC.

Allelic and genotypic chi-square tests are often used when testing for association on unrelated individuals. The extension to multiple loci results in haplotypic and multilocus genotypic tests. Although haplotypic tests assume (and can detect) only additive effects, the majority of biologically realistic genotype-driven models nevertheless marginally induce considerable additive effects of haplotypes. Haplotypic tests can be more powerful in these situations because the number of parameters involved is reduced. When gametic phase is unknown, the commonly used likelihood ratio test (LRT) incorporates an additional assumption of Hardy Weinberg equilibrium (HWE). We construct a new case-control test that involves the same number of parameters as the haplotypic LRT but does not assume HWE. The test can be considered as a genetically motivated way of reducing dimensionality of the data. We derive the asymptotic distribution of the test statistic and compare its properties with the LRT, the multilocus genotypic test, and the allelic tests on individual SNPs under variety of models. We report optimal properties of the new method and improved robustness with respect to the disease model and HWE.

The Importance of Model Validation in Determining the Clinical Utility of Genetic Interactions on Disease Risk.

*C.S. Coffey*¹, *P.R. Hebert*², *M.D. Ritchie*³, *H.M. Krumholz*², *J.M. Gaziano*⁴, *P.M. Ridker*⁴, *J.H. Moore*³. 1) UAB School of Public Hlth Birmingham, AL; 2) Yale Univ. School of Medicine New Haven, CT; 3) Vanderbilt Univ. School of Medicine Nashville, TN; 4) Brigham & Women's Hospital Harvard Medical School Boston, MA.

It is a well-known problem in statistics that models obtained using data-driven methods are prone to increased type 1 errors and, hence should always be examined for validation. Although there is general agreement regarding the importance of model validation, this problem is often ignored in published research possibly due to the fact that correction for overestimation often leads to less significant results. We illustrate the use of model validation for an analysis using data from the Physicians Health Study to examine a possible interaction among the angiotensin converting enzyme (ACE) insertion/deletion and plasminogen activator inhibitor-1 (PAI-1) 4G/5G gene polymorphisms on risk of myocardial infarction. Initially, the Multifactor Dimensionality Reduction Method (Ritchie et al. *AJHG* 69, 2001) found a significant interaction between these polymorphisms on risk of MI when applied to data obtained from 343 matched case-control pairs. However, using ten-fold cross-validation, the prediction error for the final models was only 46%, indicating that the model was only slightly better than that yielded by a coin toss (50% prediction error). After completion of the initial study, an additional 141 case-control pairs became available as a validation sample. The model developed in the initial study did not validate in this independent sample (52% prediction error). Furthermore, the interaction was no longer significant. This example reminds us that the purpose of research is not to obtain 'significant p-values', but rather to uncover relationships that can lead to improved treatments, therapies, or understanding of disease processes. As data-driven analytic methods continue to be developed and used to examine complex genetic interactions, it will become increasingly important to stress model validation in order to ensure that significant effects represent true relationships rather than chance findings.

Analytical methods for factors modifying disease risks in carriers of susceptibility alleles. *D.F. Easton¹, A. Antoniou¹, D.E. Goldgar²*. 1) Cancer Research U.K. Genetic Epidemiology Unit, University of Cambridge, Cambridge, U.K; 2) International Agency for Research on Cancer, Lyon, France.

There is currently great interest in identifying factors, either genetic or environmental, that modify the risk of disease in carriers of known susceptibility genes such as BRCA1 or BRCA2. In order to study large numbers of carriers, most such studies are based on retrospective analysis of affected and unaffected individuals, often ascertained through multiple case families. Analysis of such data is often performed using standard survival analysis techniques (e.g. Cox regression). Although this approach can give valid significance tests, it gives rise to biased relative risk estimates. We propose two alternative types of analysis. The first, a "full" likelihood analysis, is applicable to fixed covariates, e.g. genotypes. It can be conducted with unrelated individuals or with pedigree data, and we have implemented this in the program MENDEL. A full likelihood analysis is, however, not feasible for most lifestyle risk factors, which are time-dependent. As an alternative, we propose a method based on weighting observations so as to mimic a true cohort, and using these weighted observations in a standard survival analysis. Optimal choice of weights, and comparisons between these methods and a standard survival approach, will be discussed. We examine specifically examples from the IBCCS dataset on lifestyle risk factors in BRCA1/2 carriers.

The Maternal-Fetal Genotype Incompatibility Test to Detect Adverse Intrauterine Conditions. *S.L. Minassian*¹, *C.G.S. Palmer*^{2,6}, *J.A. Woodward*^{5,6}, *J.S. Sinsheimer*^{1,3,4}. 1) Departments of Biostatistics; 2) Psychiatry & Biobehavioral Sciences; 3) Human Genetics; 4) Biomathematics; 5) Psychology; 6) Statistics, University of California, Los Angeles.

Current research indicates that maternal-fetal genotype incompatibility may be a risk factor in a variety of diseases. We developed a maternal-fetal genotype incompatibility (MFG) test to examine hypotheses about incompatibility in the possible presence of linkage disequilibrium (LD) at a candidate gene. For a bi-allelic locus, the MFG test uses genotype information to delineate case-parent trios into 15 categories resulting from 6 mating types. This family-based design extends the case-parent log-linear model for trios. The expected number of each type of trio is modeled by a mating type parameter, an incompatibility relative risk parameter, and an LD relative risk parameter. The significance of incompatibility and LD effects can be tested using asymptotic test statistics such as the likelihood ratio test (LRT). The asymptotic chi-square LRT has adequate power with moderate effect size and sample size. As an example, for an incompatibility relative risk of 2.6, an allele frequency of 0.35 for the less common allele, and in the absence of LD effects, 150 trios will yield 88% power to detect the incompatibility effect, and 250 trios yield 98% power. The MFG test also has more power to detect incompatibility effects than the Gamete Competition model (which tests the incompatibility effect directly) or models that can indirectly test for the effect like the Transmission/Disequilibrium Test. In small samples, permutation p-values can be more accurate than asymptotic p-values. Thus, we have developed a permutation test to estimate p-values in small to moderately sized samples. The permutation scheme depends on the hypothesis to be tested. We always permute within trio categories that have the same expected number of counts under the null hypothesis, but different expected number of counts under the alternative hypothesis. We then compare the p-values obtained by the permutation test and asymptotic test. Finally, we give general guidelines for when to use each test.

Multifactor dimensionality reduction is an ideal discriminator of discrete clinical endpoints using multilocus SNP genotypes. *J.H. Moore, L.W. Hahn.* Program in Human Genetics, Vanderbilt Univ, Nashville, TN.

The identification and characterization of genes whose effects are primarily through interactions with other genes and environmental factors remains a statistical and computational challenge in the genetic epidemiology of common, complex multifactorial diseases. We have previously developed a multifactor dimensionality reduction (MDR) approach to identifying gene-gene and gene-environment interactions in case-control and discordant sib-pair study designs. MDR is nonparametric in that no parameters are estimated and is genetic-model free in that no particular genetic model is assumed. Using both simulated and real data, we have demonstrated that MDR has excellent power for identifying high-order gene-gene interactions in the absence of any detectable independent main effects of each gene. Further, we have demonstrated that the power of MDR to identify gene-gene interactions is robust in the presence of genotyping error and phenocopy. In the present study, we outline a mathematical proof that MDR ideally discriminates between discrete clinical endpoints using multilocus SNP genotypes. In this proof, we first define the context of the problem, the MDR decision rule, and the error evaluation on which the decision rule is optimized. We then prove that the MDR decision rule is optimal for the given error evaluation. This proof suggests that no analytical approach will classify discrete clinical endpoints using multilocus genotypes better than MDR. Based on this proof, we propose that MDR should be the "gold standard" with which other methods for identifying gene-gene interactions are compared.

Program Nr: 2389 from 2002 ASHG Annual Meeting

A novel strategy for selecting optimal subsets of SNPs for the analysis of gene-gene interactions. *B.C. White, L.W. Hahn, J.H. Moore.* Program in Human Genetics, Vanderbilt University, Nashville, TN.

A dense map of single nucleotide polymorphisms (SNPs) is expected to facilitate the identification of disease susceptibility genes. A complicating factor is the reality that the effects of some genes will only be detected when considered in the context of other genes (i.e. epistasis). The implication of this reality for using SNPs to identify disease susceptibility genes is that each SNP must be considered in the context of other SNPs. The evaluation of subsets of SNPs presents an enormous combinatorial problem when the total number of SNPs is large. Even with an accurate haplotype map, powerful computer systems and efficient search algorithms will be needed to facilitate the identification of optimal SNP subsets from an effectively infinite number of possibilities. We have implemented and evaluated a novel parallel search algorithm that is inspired by the problem solving abilities of ant colonies for food foraging. With this ant colony optimization (ACO) approach, each artificial ant initially carries out a random walk through multilocus SNP space. Each set of SNPs selected by an artificial ant is statistically evaluated and the probability of selecting those SNPs is increased or decreased based on how well the set of SNPs distinguishes affected from unaffected individuals (i.e. the statistical fitness). This is analogous to updating a pheromone trail. Many ants are evaluated and the process of updating the virtual pheromone trail is iterated until the artificial ant colony converges on a best SNP subset (i.e. a single pheromone trail to a food source). Using simulated data with 10,000 SNPs, we demonstrate the ACO approach is competitive with other search methods such as parallel genetic algorithms. The simplicity and efficiency of the ACO approach make this an attractive algorithm for the development of SNP subset selection software.

The multivariate Dale model and genetic associations. *K. Van Steen*¹, *G. Molenberghs*¹, *N. Tahri*^{2,3}. 1) Center for Statistics, Limburgs Universitair Centrum, Diepenbeek, Belgium; 2) INSERM U.525, C.H.U. Pitié Salpêtrière, Paris, France; 3) Genset Genomics Research Center, RN7 site snecma, Evry, France.

In a first attempt to investigate the potential merits of the multivariate Dale model (Molenberghs and Lesaffre 1994) when studying genetic associations, we assess the beneficial use of the model in a case-control setting, using unrelated individuals. In the multivariate Dale model joint probabilities are decomposed into main effects (described by marginal probabilities) and interactions (described by cross-ratios of second and higher orders).

Encouraged by promising results in the first stage described above, we then investigate the usefulness of the multivariate Dale model in modeling associations between genes, using family data or related individuals. In particular, we investigate how the model can be used as a means to relate the interplay between subsets of genes to different aspects (symptoms) of a disease.

Because of the extra complexity (elaborate familial inter-relationships), special attention is given to the choice of the estimation procedure. We recommend to adopt a pseudo-likelihood estimation technique (above GEE2) when both multivariate outcomes and (family) clustering are involved.

All research results (pros and cons) will be discussed in practical settings, such as data on late-onset Alzheimer's disease.

Study Design, Family History Measure, Confounding: Which cause discrepancy in effect estimates in Familial Aggregation Studies? R. Zimmerman, H. Ahsan, D. Greenberg. Department of Epidemiology and Division of Statistical Genetics, Columbia University, New York, NY.

Case control (CC) and reconstructed cohort (RC) study designs of familial aggregation of disease have been shown to result in discrepant effect estimates even when the exact same data set is being assessed (Khoury and Flanders, 1995). Researchers demonstrated that the effect estimate resulting from a CC design becomes more discrepant from the effect estimate derived from the RC with increasing disease prevalence and increasing rate ratio derived from the RC. They concluded that the discrepancy results from bias in the CC study. They also concluded that confounding by family size and age in the CC study may account for some of the discrepancy between effect estimates derived from each study. We do not agree with these findings. We provide a rationale for why we disagree and demonstrate the causes for discrepant effect estimates derived from the CC and RC. We also explain why neither number nor age of relatives *naturally* confounds the family history disease association in the CC study. Using simulated populations (Greenberg, MacCluer, et al. 1999) as the sampling frame for three epidemiologic familial aggregation study designs, Cohort, CC and RC, we compare effect estimates derived from identical populations and find that our hypotheses are correct. The discrepancy between effect estimates is due to the variation in family history measures (Hopper, 1996) not the study design. By distinguishing between family member(s) that define exposure and those that define disease, we also demonstrate that family size and number of relatives defining the exposure measure do not confound the family history - disease association. We conclude that the RC does not pose any benefit over the CC design in studies of familial aggregation and decisions on which to use depends on the particular specifications of the familial aggregation study.

Microsatellite Variation: Effects of Natural Selection, Population Structure, and Demographic Changes of Population Size. *H. Xu*¹, *Y.-X. Fu*¹, *M. Kimmel*², *A. Renwick*², *R. Chakraborty*³. 1) Human Genetics Ctr, Univ. Texas School of Public Health, Houston, TX; 2) Statistics Department, Rice University, Houston, TX; 3) Center for Genome Information, Department of Environmental Health, Univ. Cincinnati, Cincinnati, OH.

Statistical properties of all measures of genetic variation critically depend upon the composite parameter, $q = 4N_e m$, defined by the product of effective population size (N_e) and the rate of mutation (m) of the locus. Consequently, the differences of estimates of q based on alternative summary measures of variation have been used to develop test statistics to detect effects of natural selection, presence of population substructure, and signatures of past demographic history of populations. In this investigation, we show that these currently used test procedures cannot be uncritically used to analyze data on microsatellite loci. Based on analytical and simulation studies of coalescent theory, we show that for microsatellite loci evolving via a generalized stepwise mutation model, the number of segregating alleles (k) in a sample is not a sufficient statistic for the parameter q . Consequently, the relationship of expected homozygosity (F) and the number of segregating alleles (k) in a sample is different as q changes. Furthermore, the presence of population substructure differentially impacts the relationship of expectations of F and k , depending upon the value of q . For example, for small q (say, $q < 1$), substructuring generates an excess of F for a given k , while for large q (say, $q > 10$), the relationship is reversed (i.e., a deficiency of F is observed, like the effects of overdominant selection). As a consequence, the assertion that population substructure mimics the effect of overdominant selection appears to be true only for microsatellite loci with a comparatively higher mutation rate and/or in populations of large effective size. In contrast, exponential growth of populations always generates an excess of F for a given k compared with a population of constant size, and thus, it confounds the effect of directional selection on microsatellite variation irrespective of population size and the mutation rate.

Program Nr: 2393 from 2002 ASHG Annual Meeting

Bayesian Classification for Genome-Wide Control Using Multiple Unlinked Haplotype Blocks. *T. Niu*¹, *Z.S. Qin*², *J.S. Liu*². 1) Prog Population Genetics, Harvard Sch Public Health, Boston, MA; 2) Dept of Statistics, Harvard Univ, Cambridge, MA.

Case-control study is a power approach to identify susceptibility genes for complex traits. However, hidden population substructure can lead to spurious associations between the genetic marker and the disease. The recent advancement in biotechnology has allowed unprecedented speed and throughput in genotyping a voluminous number of SNPs. Thus, a standard set of unlinked SNPs that uniquely capture all possible common haplotype blocks in the human genome can be selected as genome-wide controls. We developed a Bayesian classification approach to utilize the unlinked haplotype data to assign subpopulation membership for each individual. We show that our method is robust and can reveal the underlying cryptic relations to correct for the population substructure in case-control analyses, which can effectively minimize the false-positive rates in discovering gene-disease association. This method can also be used for clustering haplotypes that will increase the power for linkage disequilibrium mapping.

Likelihood measures and methodology for distinguishing single vs. multiple DNAs using STRs in samples for epidemiologic studies. *S. Shrestha*^{1,2}, *S.A. Strathdee*¹, *T.H. Beaty*¹, *M.W. Smith*². 1) Genetic Epidemiology, Johns Hopkins University, Bloomberg School of Public Health, Baltimore, MD 21205; 2) Basic Research Program, SAIC-Frederick, National Cancer Institute, Frederick, MD 21702.

We developed a new likelihood measure of mixture discrimination to distinguish single from multiple genomes in biological samples. This likelihood approach uses short tandem repeats (STRs) as biomarkers and combines theoretical approaches in genetics, forensic science, epidemiology and bio-informatics. Exact probability estimates account for all possible combinations of STR alleles providing a uniquely informative approach to identifying mixtures. Theoretical frameworks have been developed for autosomal markers, plus X- and Ylinked STRs in all male/male, male/female and female/female mixtures. These analyses indicate that the cost of genetically determining the presence of male and female genetic material in an unknown sample outweighs the benefits of simpler interpretation of X and Y chromosome STRs. Thus, the laboratory methods focus on four autosomal STRs with heterozygosity >75% which provide a 99% probability of detecting mixtures of DNA. Pentanucleotide repeats are the STRs of choice since they have minimal slippage during PCR, resulting in simpler patterns of amplification and minimizing false positive alleles. Genetically determined mixture information can be used as surrogates for physical or behavioral characteristics in epidemiologic studies to examine molecular and infectious disease problems at both the individual and population level. One application of this method is being undertaken to determine and validate syringe-sharing behavior among injection drug users by analyzing the biological residues in the syringes. Funded in part by DHHS #NO1-CO-12400.

Inferring relationships between pairs of individuals from locus heterozygosities. *S. Presciuttini*^{1,2}, *C. Toni*¹, *E. Tempestini*¹, *S. Verdiani*³, *L. Casarino*³, *I. Spinetti*¹, *F. De Stefano*⁴, *R. Dominici*¹, *J.E. Bailey-Wilson*². 1) Dept. Biomedicine, Univ. of Pisa, Italy; 2) NHGRI, Baltimore, MD, USA; 3) Dept. Medicina legale, Univ. of Genoa, Italy; 4) Ist. Medicina Legale, Univ. of Cagliari, Italy.

The traditional exact method for inferring relationships between individuals from genetic data is not easily applicable to some situations that may be encountered both in forensic science and in other disciplines. This study describes an approach that gives affordable results and is easily applicable; it is based on the probabilities that two individuals share 0, 1 or both alleles at a locus identical by state. We show that these probabilities [z(i)] depend on locus heterozygosity (H), and are scarcely affected by variation of the distribution of allele frequencies. This allows us to obtain empirical curves relating z(i) values to H for a series of common relationships, so that the likelihood ratio of a pair of relationships between any two individuals, given their genotypes at a locus, is function of a single parameter, H. Application to large samples of mother-child and full-sib pairs shows that the statistical power of this method to infer the correct relationship is not much lower than the exact method. Analysis of a large database of STR data proves that locus heterozygosity does not vary significantly among Caucasian populations, apart for special cases, so that the likelihood ratio of the more common relationships between pairs of individual may be obtained by looking at tabulated z(i) values.

Program Nr: 2396 from 2002 ASHG Annual Meeting

Hearing Loss in Fabry Disease: The Effect of Agalsidase Alfa Replacement Therapy. *L. Richfield, D. Hajioff, Y. Enever, R. Quiney, A.B. Mehta and Royal Free Hospital, London, U.K.* Clinical Haematology, Royal Free Hospital, London, London, United Kingdom.

HEARING LOSS IN FABRY DISEASE: THE EFFECT OF AGALSIDASE ALFA THERAPY LINDA RICHFIELD, DANIEL HAJIOFF, YVANNE ENEVER, ROBERT QUINEY, ATUL MEHTA. Aims We aim to describe the nature and prevalence of sensorineural hearing loss (SNHL) in Fabry disease and its response to enzyme replacement. Methods Fifteen men aged 25 to 49 (median 37) were randomised to placebo or -Agalsidase alfa (Replagal A replacement for six months, Transkaryotic Therapies Protocol TKT005) and have received enzyme replacement (Protocol TKT007) for a further 24 months so far. Audiological assessments were performed at 0, 6, 18 and 30 months. These included pure tone audiometry, transient-evoked otoacoustic emissions and impedance audiometry. Results Four patients (27%) had bilateral and seven (47%) had unilateral middle ear effusions with conductive losses persisting beyond six months. Three (20%) had normal hearing. At baseline, the median high frequency hearing loss (pure tone average air conduction at 4 kHz and 8 kHz) was 25 dB ISO (interquartile range: 15 49.4). This high frequency SNHL deteriorated over the first six months in both placebo and treatment groups by a median 4.3 dB ($p=0.002$, Wilcoxon matched pairs): the greater decline in the placebo group was not significantly different from the treatment group. This hearing loss subsequently improved beyond baseline by 2.1 dB at 18 months ($p=0.02$) and 5 dB at 30 months ($p=0.003$). High frequency bone conduction changed similarly. Baseline hearing losses correlated strongly with age (Spearman's $R_s=0.64$, $p=0.0001$) and glomerular filtration rate ($R_s=0.45$, $p=0.014$) but changes in hearing loss did not. Conclusions Eighty percent of adults with Fabry disease have significant hearing loss, usually high frequency SNHL. -Alalsidase alfa therapy appears to reverse the natural decline but this improvement is slow and small: long term study is required.

Hematopoietic cell transplantation (HCT) is effective treatment for mucopolidosis II (MLII) and a-mannosidosis (MAN). C. Peters^{1,2}, S. Grewal^{1,2}, P. Orchard^{1,2}, W. Krivit^{1,2}, S. Davies¹, E. Shapiro^{1,2}, R. Ziegler^{1,2}, L. Charnas^{1,2}, L. Lockman^{1,2}, K. Dusenbery², E. Braunlin^{1,2}, C. Milla^{1,2}, W. Regelman^{1,2}, S. Christiansen^{1,2}, F. Rimell^{1,2}, A. Petryk^{1,2}, A. van Heest², J. Ogilvie², M. Ahrens², S. Berry^{1,2}. 1) Depart. of Pediatrics; 2) Comprehensive Genetic Dis. Evaluation & Treatment Prog., Univ. of Minnesota, Minneapolis, MN.

MLII, a lysosomal enzyme localization disorder, exhibits progressive severe psychomotor delay, dysostosis multiplex and early death from cardiopulmonary complications. MAN demonstrates progressive psychomotor delay, craniosynostosis, ENT infections/hearing loss, organomegaly and shortened lifespan. We present our complete HCT experience in 3 pts with each disease; all are alive, fully engrafted with NL heart function. Diagnosis was established clinically/biochemically by deficient phosphotransferase activity and/or increased plasma levels of lysosomal enzymes (MLII) or by deficient a-mannosidase activity (MAN). HCT in MLII and MAN can halt cardiopulmonary and cognitive decline and promote a favorable QOL.

Patient	Age @ HCT	Donor	Follow-up	Verbal IQ	Perform.IQ	Pulmonary	QOL
MLII-1	1.6y	Related	4.7y	mod. delay	mod. delay	NI	Very good
MLII-2	0.3y	Related	1.5y	mod. delay	mod. delay	NI	Good
MLII-3	1.1y	Unrelated	1.5y	mod. delay	mod. delay	Pulm HTN	Fair/good

Pamidronate use in infants with Osteogenesis Imperfecta (OI). *E.R. Elias*¹, *C.-H. Tsai*², *S. Zemel*³. 1) Special Care Clinic, Children's Hosp, Denver, CO; 2) Dept of Genetics, Children's Hosp, Denver, CO; 3) Dept of Endocrinology, Children's Hosp, Denver, CO.

The use of Pamidronate in OI has become common practice. However, its use in young infants, and the natural history of OI treated during infancy, is not well described. We report our experience treating infants with OI, two of whom developed severe neurologic complications.

Methods: Four infants with OI (2 girls and 1 boy with Type III-IV, and 1 girl with Type II-III) were treated with IV Pamidronate. A broviac catheter was placed prior to the first pamidronate course. Calcium metabolism was closely monitored pre and post-infusion. Urine calcium excretion and renal ultrasounds were assessed. Growth parameters and developmental course were monitored, and head imaging obtained.

Results: All four patients had early feeding difficulties and required neonatal oxygen. The child with Type II-III OI, now 26 months, is G-tube fed, with severe restrictive lung disease on O₂. Early nephrocalcinosis has resolved. Head MRI shows hydrocephalus, severe cervical stenosis, and basilar invagination. She is deaf, has moderate developmental delays, and has had line sepsis twice. She has occasional fractures. The male patient developed severe subdural hematomas and hydrocephalus 1 week after his first Pamidronate dose. Now 4 months, he has had no new fractures, but has continued feeding issues and needs O₂. The two other patients, now 8 and 9 months, are fracture-free, feed well, and have normal cognitive development.

Conclusions: Pamidronate can be safely used in young infants with OI. Broviac catheters ease blood draws and IV use, but line sepsis is a risk. Hydrocephalus was seen in 2/4 patients, with severe cervical stenosis and brainstem compression in 1, and subdural hemorrhage in the other. Clinical course is more helpful than biochemical results in defining prognosis in young infants with OI.

Bisphosphonate treatment for osteopenia associated with genetic disease in children. *S. Carter¹, R. Mendoza-Londono¹, V.R. Sutton¹, C.A. Bacino¹, K. Ellis², R. Shypailo², B. Lee¹.* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Dept. Pediatrics, CNRC, Baylor College of Medicine.

Osteoporosis is defined as low bone mass and bone fragility with increased susceptibility to fractures. It is also defined as bone mineral density (BMD) that is 2.5 SD below the mean peak value for age-matched controls. Until recently, treatment options for pediatric osteoporosis have been limited. Bisphosphonates inhibit osteoclast activity and have been shown to be safe in pediatric applications. Common genetic conditions associated with low BMD and susceptibility to fractures include osteogenesis imperfecta (OI), and secondary osteopenia due to lack of physical activity, as is seen in patients with neuromuscular disease. We present our experience treating 14 pediatric patients followed at the Texas Childrens Hospital Skeletal Dysplasia Clinic between 1999 and 2002. The diagnosis was OI type 3 or 4 in 11 patients and other neuromuscular disease in 3 patients. Ages ranged between newborn and 15 yrs. (Average 4.5 yrs). The diagnosis of OI was made in the first two months of life in 9 of the 11 patients. Bone mineral density of the lumbar spine, femoral head and total body was measured using dual-energy x-ray absorptiometry (DXA) before treatment and at regular intervals during treatment. The patients received Pamidronate at a dose of 13.5 mg/kg/year for children <2-3 years and 9 mg/kg/year for children >3 years. Bone metabolic parameters (alkaline phosphatase, urine collagen N-telopeptides) showed decrease in bone turnover. Average L-spine BMD values were Z= -3.86 (Range 6.78 to 2.92) before treatment and Z= -2.56 (range 3.72 to 1.4) after treatment. Physiologic response appeared more significant in younger children. Overall there was a subjective clinical improvement, with decrease in bone pain and frequency of fractures, resulting in better tolerance of daily activities and well being. Side effects were minor including transient febrile episodes and mild hypocalcemia which corrected with supplementation. This experience has demonstrated that bisphosphonates constitute an important adjuvant treatment for osteoporosis associated with genetic disease.

Precocious Puberty during Outpatient Pamidronate therapy in type I Osteogenesis Imperfecta. *T.C. Markello¹, B. Boston², R. Steiner³*. 1) Dept Pediatrics, Samaritan Health Services, Lebanon, OR; 2) Pediatrics, Oregon Health Sciences University, Portland, OR; 3) Molecular and Medical Genetics, Oregon Health Sciences University, Portland, OR.

Intermittent iv bisphosphonate therapy has decreased pain and reduced fractures in children with type I Osteogenesis Imperfecta (Glorieux et. al., NEJM 339:947-52,1998). We describe the clinical course, and one unique complication during the treatment of two sisters over 3 years. Methods: After informed consent and local IRB approval, treatment using bisphosphonate therapy was begun. The protocol followed published methods, modified to the outpatient environment of a rural pediatric practice. Results: Type I OI was confirmed by collagen fibroblast analysis in an affected first cousin. Prior to therapy both siblings had mild extremity fracture rates of 1 to 2 per year. Both had vertebral compression fractures by 2 years old, consistent with severe spinal involvement, a known variation in this familys OI expression. No fractures have occurred in either child since starting therapy. Growth in vertebral body height has improved in areas of previous compression fractures. One child began adrenarche 10months after beginning iv pamidronate, at age 7.0yr. By age 8.5yrs she showed an advanced bone age of 11years, elevated gonadotropins and breast development. At that time she was begun on dual therapy with pamidronate and leuprolide and has not had progression of precocious puberty. Her sister has not shown similar signs of precocious puberty after 30 months of therapy, but is currently only 5.5yr old. No other family member in the extended pedigree, with or without OI, has been documented to have precocious puberty. Conclusions: This is the first reported case of precocious puberty while receiving bisphosphonate therapy. It may be coincidental, or a rare complication. It did not require discontinuation of treatment nor has her sibling shown similar changes.

Controlled trial of pamidronate in children with Types III and IV OI. *J.C. Marini¹, A.D. Letocha¹, J. Reynolds³, C.M. Reing⁶, E. Chernoff¹, J. Troendle², S. Hill⁴, L. Gerber⁵, F.H. Glorieux⁷.* 1) SCTD/ NICHD/NIH, Bethesda, MD; 2) BMSB/NICHD/NIH, Bethesda, MD; 3) NMD/CC/NIH, Bethesda, MD; 4) DRD/CC/NIH, Bethesda, MD; 5) RMD/CC/NIH, Bethesda, MD; 6) Dept Ortho, INOVA, Fairfax, VA; 7) Shriners, Montreal, Quebec.

We are engaged in a randomized, non-blinded controlled trial of pamidronate (Aredia®, Novartis) in children with types III and IV OI. The purpose was to assess the effects of intermittent inhibition of bone resorption on vertebrae, long bones and serum markers of bone matrix and growth in children with abnormal matrix. Children over 2 years are randomized to receive pamidronate or not. Children are seen every 3 months; the pamidronate group receives 30 mg/m² over 3 days. Every visit includes physical rehabilitation and measurement of serum markers. AP and lateral x-rays of the spine and lower long bones and spine DEXA are obtained at 0, 6 and 12 months. QCT scan of the lumbar spine and femoral mid-shaft is obtained at 0 and 12 months. Dual-labeled iliac crest biopsies are taken at 0 and 12 months for histomorphometry. Fifteen patients completed 1 year; 2 completed 6 months. Repeated measures analysis examined 9 pamidronate vs 8 no-pamidronate patients. Baseline, 6 and 12-month vertebral data and baseline, 3, 6, 9, 12, 15 and 18-month data for serum markers were analyzed. Bowing, MOI, fracture rate and histomorphometry are pending. Pamidronate treatment resulted in significant differences for vertebral BMD, compression ratio and area. L1-L4 DEXA z-scores increased significantly for the pamidronate group vs controls (p=0.046). Vertebral compressions significantly improved in pamidronate vs no-pamidronate groups at T12, L1 and L2 (p=0.017, 0.038 and 0.006). Vertebral area significantly improved in treatment vs control groups at L1 and L2 (p=0.041 and 0.053) but not T12 (p=0.092). Analysis of serum markers of bone synthesis (PICP and OC) showed no significant difference between groups. These data support the claim that pamidronate enhances vertebral BMD and resistance to compression in children with OI. It remains unclear whether pamidronate is functionally beneficial or detrimental for cortical bone in the extremities.

Treatment of spinal muscular atrophy by hydroxyurea. *J.G. Chang¹, F.J. Tsai¹, W.Y. Wang², Y.J. Jong³.* 1) Dept Medical Res, Div Molec Med, China Medical Col Hosp, Taichung, Taiwan; 2) School of Rehabilitation Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 3) Departments of Pediatrics and Clinical Laboratory, Kaohsiung Medical University, Kaohsiung, Taiwan.

Background Proximal spinal muscular atrophy (SMA) is a degenerative motor neuron disease caused by a deficiency of the functional SMN protein. Effective treatment for this disorder is unavailable at present. We evaluated the effect of hydroxyurea treatment in patients with this disorder. **Methods** We treated different types of SMA cell lines with hydroxyurea to evaluate the effect on SMN (SMN2) expression, and then treated 2 of type I, 5 of type II and 2 of type III SMA patients with hydroxyurea at a dose of 35 mg per kilogram of body weight daily for 10 months. The patients were evaluated at baseline and every month for 10 months by detailed clinical examinations, muscle test, clinical laboratory evaluation, and measurements of expression of SMN gene. **Findings** The expression of full-length mRNA of the SMN2 gene increased significantly in all three types of SMA lymphoblastoid cell lines and in the blood mononuclear cells of SMA patients. Muscle power and clinical symptoms also improved. The effect began 2 months after treatment, and maximal effect was found within 4-6 months of treatment. No definite side effects were found in this study. **Interpretation** Hydroxyurea increases full-length mRNA expression of the SMN 2 gene both in vitro and in vivo, and ameliorate clinical manifestations of SMA patients. This drug offers a new approach in the treatment of SMA disease.

Performance IQ (PIQ) and MRI Severity Score (MRI-SS) Predict Survival and Disability after Hematopoietic Stem Cell Transplantation (HSCT) for Childhood Onset Cerebral Adrenoleukodystrophy (CALD). *L. Charnas, E. Shapiro, W. Krivit, L. Lockman, R. Ziegler, S. Abel, S. Grewal, P. Orchard, C. Peters.* Department of Pediatrics, University of Minnesota, Minneapolis, MN.

Introduction: Adrenoleukodystrophy (X-ALD) is an X-linked peroxisomal disorder characterized by impaired very long chain fatty acid (VLCFA) oxidation. 35% of boys with X-ALD will develop childhood onset cerebral disease (CALD) with cerebral demyelination, neurodegeneration and death 3-5 years after onset of symptoms. HSCT arrests disease progression in early CALD, but outcome in more advanced CALD is less well understood. The morbidity and mortality of HSCT are too great to offer to boys with biochemical X-ALD but no evidence of CALD. **Methods:** Between 1990 and 2001, 110 boys with XALD were evaluated at the University of Minnesota (UMN). 51 underwent HSCT at UMN, 10 were offered HSCT but were not treated at UMN, 18 had no cerebral disease, and 31 were too severe at presentation to be considered for HSCT. All had brain MRI, testing of verbal (VIQ) and PIQ and neurologic examination. An MRI-SS was assigned to each MRI. **Results:** Of the 51 boys undergoing HSCT, 23 boys had mild/moderate disease (PIQ>80, MRI-SS 0.5-14). 15 are alive, all can see and function independently. Only one death occurred due to ALD progression. 28 boys with severe disease (PIQ < 80, MRI-SS 5-20) had HSCT. 12 are alive, including 3 recent transplants. All are disabled, 5 are blind. ALD progression caused 11 deaths. A low MRI-SS was the best predictor of survival (P<0.001). PIQ and VIQ did not predict survival. Boys starting with a PIQ>80 had no significant functional deficits. Survivors with initial PIQ<80 had significant functional deficits, usually severe or profound. Initial MRI-SS and PIQ were inversely correlated, R = -.85. Both MRI-SS and PIQ were strongly correlated with the ALD Disability Rating Scale score, R = 0.65 and R = 0.85, respectively. **Conclusion:** MRI-SS identifies boys with early CALD and predicts survival from HSCT. PIQ predicts disability following HSCT. PIQ < 80 identifies boys at high risk for poor outcomes with current methods. HSCT is an effective therapy for boys with early, but not advanced, CALD.

Program Nr: 2404 from 2002 ASHG Annual Meeting

Pancreatic cancer therapy by intratumoral gene transfer of IL-13Ra2 chain followed by IL-13R-targeted bacterial cytotoxin administration in animal models. *K. Kawakami, M. Kawakami, S.R. Husain, R.K. Puri.*
Laboratory of Molecular Tumor Biology, Division of Cellular and Gene Therapies, CBER/FDA, Bethesda, MD.

Interleukin-13 receptor (IL-13R) $\alpha 2$ chain plays a key role in ligand binding and internalization. We have recently demonstrated that this cytokine receptor chain has unique characteristics in tumor biology: it inhibits tumorigenicity of breast and pancreatic cancer in animal models. In this study, we have utilized this chain and established a novel approach for aggressive pancreatic cancer therapy. For this, a plasmid containing IL-13Ra2 chain gene was mixed with liposome (a mixture of DOTAP and cholesterol) and injected into subcutaneously or orthotopically xenografted human pancreatic tumors in immunodeficient mice, followed by systemic or local therapy by IL-13 cytotoxin. IL-13 cytotoxin is a fusion protein comprised of human IL-13 and a truncated form of bacterial toxin (*Pseudomonas* exotoxin). Only tumors forced to express IL-13Ra2 chain acquired extreme susceptibility to the antitumor effect of IL-13 cytotoxin. There was a dominant infiltration of cells including macrophages and natural killer cells in the regressing tumors. Because macrophages were found to produce nitric oxide, IL-13Ra2 targeted cancer therapy involved not only a direct tumor cell killing by IL-13 cytotoxin but also activation of innate immune response at the tumor site. Therefore, this approach may be a new powerful tool for pancreatic cancer or other localized cancer therapy.

Enzyme Replacement Therapy (ERT) with agalsidase alfa leads to Regression of Left Ventricular Hypertrophy in Male and Female Patients with Anderson Fabry Disease (AFD). C. Kampmann¹, F.A. Baehner², C. Martin¹, C.M. Wiethoff¹, C. Whybra², E. Miebach², M. Ries², M. Beck². 1) Pediatric Cardiology, University Children's Hospital, Mainz, Germany; 2) Dpt. of Lysosomal Storage Diseases, University Children's Hospital, Mainz, Germany.

Background: In both genders, AFD is accompanied by a progressive hypertrophic cardiomyopathy (CM), which is related to accumulation of globotriaosylceramide (Gb3) in the myocardium. ERT is now available in Europe. Purpose of the study was to evaluate the effect of agalsidase alfa on the AFD-related CM in both males and females. **Methods and Results:** 40 genetically proven hemi- and heterozygotes (22 males, aged 34.5 ± 9.3 years and 18 females, aged 45.3 ± 12.8 years), older than 18 years, received biweekly 0.2 mg/kg BW infusions of agalsidase alfa (Replagal®). Echocardiographic and electrocardiographic examinations were performed at baseline and at three monthly intervals. 6 mo. data were available in 34 pts, 9 mo. data in 16, 12 mo. data in 9 and 18 mo. data in 2 pts. Overall, there was a progressive decrease in left ventricular wall thickness over time ($F=30.20$; $p=0.0001$) and also a progressive decrease in LV mass index (baseline: 172 ± 61.3 g/m², 3 mo: 160.5 ± 56.4 g/m², 6 mo: 145 ± 39.5 g/m², 9 mo: 122.5 ± 37.1 g/m², 12 mo: 121 ± 33 g/m²; $F=13.82$; $p=0.003$). QRS duration ($F=4.34$; $p=0.039$) and ECG signs of LV hypertrophy: Sokolow-Lyon voltage-duration product ($F=4.98$; $p=0.028$) also decreased progressively with ERT. No patient worsened during treatment. All patients in NYHA functional class III or IV (13 pts (6 males and 7 females) improved at least one class during therapy. **Interpretation:** ERT with agalsidase alfa in patients with hypertrophic CM related to AFD leads to significant reductions in LV wall thickness and mass, which are progressive with long term therapy, with associated improvement in NYHA clinical status in those patients with moderate to severe heart failure, presumed secondary to diastolic LV dysfunction. **Conclusion:** Agalsidase alfa (Replagal®) is effective in regressing AFD related hypertrophic CM in both male hemizygotes and female heterozygotes.

Vascular smooth muscle specific gene expression in vivo by the fiber-modified adenovirus vector. T.

HIRANUMA^{1,2}, *A. WATANABE*¹, *H. KINOSHITA*¹, *H. MIZUGUCHI*³, *T. HAYAKAWA*³, *M. MATSUKURA*², *T. MIIKE*², *T. SHIMADA*¹. 1) Dept Biochem and Molec Genet, Nippon Medical School, Tokyo, Japan; 2) Dept Child Development, Kumamoto Univ Sch Med, Kumamoto, Japan; 3) Div Biol Chem and Biol, Natl Inst Health Sci, Tokyo, Japan.

Vascular smooth muscle cells (SMCs) are an important target for gene therapy of atherosclerosis and restenosis. We are also interested in the possible involvement of vascular SMCs in progression of Duchenne muscle dystrophy (DMD). Specific gene expression in vascular SMCs may be important for elucidating the pathogenesis of DMD. In the present study, we attempted to establish the vascular SMC specific gene expression system which can be used for in vivo gene transfer. We constructed the hybrid promoter composed of the basic promoter of SM22alpha which is expressed exclusively in SMCs and the immunoglobulin heavy chain intron 1 enhancer. The hybrid promoter significantly increased the promoter activity with remaining the SMC specificity. Vascular SMCs express very low levels of the primary adenovirus receptor, coxsackie virus and adenovirus receptor (CAR). To increase the adenovirus mediated transduction, we generated a fiber-modified adenoviral vector containing the Arg-Gly-Asp (RGD) peptide that may infect the cells through the interaction of RGD and integrin avb5. The fiber modified adenovirus vector showed 10 times more efficient gene transfer into vascular SMCs in vitro. Finally, we directly administered this adenoviral vector to uninjured rat femoral arteries. The high expression of reporter gene was observed only in artery SMCs of the tunica media but not in endothelial or adventitial cells. Taken together, our results demonstrate that the fiber-modified adenoviral vector containing the SM22alpha based hybrid promoter may provide a highly effective tool for gene therapy of vascular disease.

Monitoring of Gene Stability Following Targeted Receptor-Mediated Endocytosis of the pAI-1 Insulin-Plasmid in HepG2 Cells. *L.R. Wing¹, H.S. Hamlin¹, M.A. Marino²*. 1) Dept Biopharmaceuticals, Transgenomic, Inc, San Diego, CA; 2) Transgenomic, Inc, Gaithersburg, MD.

Non-viral, receptor-mediated gene-delivery systems have been used to transfer genes into target cells followed by expression of the gene products of therapeutic importance. Targeted receptor-mediated pathways include the addition of targeting ligands to the DNA to induce specific binding, such as synthetic or naturally occurring carbohydrate ligands. Investigation of galactose-coupled plasmid DNA vectors following intracellular uptake and internalization includes the induction of mutations in the gene of interest. Depurination and other base pair alterations may occur due to the low pH and hydrolase activity in lysosomal storage vesicles, resulting in truncated, aberrant proteins with no activity or potential toxicity. Gene stability by mutation detection of the galactose-coupled pAI-1 plasmid (pBR322 containing the insulin gene) was evaluated following uptake, intracellular transport and lysosomal storage in HepG2 cells by denaturing HPLC using the WAVE® DNA Fragment Analysis System (Transgenomic, Inc.). Following the binding of pAI-1 to HepG2 cell surfaces (2h, 4⁰C) and endocytosis (0-2h, 37⁰C), pAI-1 was isolated from the culture media and cell lysate in the presence and absence of chloroquine (an inhibitor of endocytosis). A 240bp PCR product containing the insulin gene was isolated from the HepG2 media and lysate at various time points following the initiation of endocytosis (0,15,30,45,60,90,120 min). Samples were mixed with reference wild-type fragment to generate homoduplexes and/or heteroduplexes and subjected to dHPLC. The data indicated the formation of heteroduplexes in the lysates of the untreated HepG2 samples after 30 minutes post-endocytosis, whereas the chloroquine-treated HepG2 samples demonstrated only homoduplex peaks for each time point in the media and lysates. These results suggest that the process of receptor-mediated endocytosis may play a role in the generation of mutations in DNA-based therapeutics and intracellular gene stability monitoring of therapeutic genes is essential for evaluating the success of gene therapy delivery systems.

Mechanism of acid sphingomyelinase uptake by Niemann-Pick disease macrophages: Implications for enzyme replacement therapy. *R. Dhami*¹, *K. Kary*², *E.H. Schuchman*¹. 1) Dept Human Genetics, Mount Sinai Sch Medicine, New York, NY; 2) Genzyme Corporation, Cambridge, MA.

Types A and B Niemann-Pick disease (NPD) result from deficient acid sphingomyelinase (ASM) activity. Type A NPD is characterized by early onset neurodegeneration that leads to death by ~3 years of age, whereas patients with Type B NPD have little or no neurological involvement and may survive into adulthood. A mouse model of Types A and B NPD (ASMKO mice) has been constructed that develops many of the same biochemical, pathological, and clinical abnormalities as human NPD patients. To gain a better understanding of the mechanisms underlying ASM uptake by NPD macrophages, we obtained alveolar macrophages from normal and ASMKO mice and evaluated the uptake of recombinant human enzyme obtained from the media of overexpressing CHO cells. Two forms of recombinant enzyme were utilized: standard ASM containing complex oligosaccharides (cASM), and a modified form of ASM that contained high mannose type oligosaccharides (mASM). Surprisingly, both forms of recombinant ASM were taken up poorly by ASMKO macrophages as compared to normal macrophages, although the efficiency of uptake of mASM was ~10-fold greater than cASM. Inhibitor studies revealed that in both normal and mutant cells, mASM was primarily internalized by mannose receptors, while cASM was internalized by both mannose and mannose-6-phosphate receptors. To investigate why NPD macrophages internalized ASM poorly, receptor recycling studies were undertaken. These experiments revealed a general recycling defect in the NPD macrophages. Thus, a hypothesis is proposed to explain the therapeutic effectiveness of enzyme therapy in the lungs of NPD mice that suggests that the effects are largely due to a reduction in macrophage recruitment into the lungs, rather than direct enzyme uptake by lung macrophages.

Ambulatory enzyme replacement therapy and clinical evaluation in Fabry's disease. *F. Breunig¹, F. Weidemann¹, J. Strotmann¹, M. Beer², V. Krane¹, C. Wanner¹.* 1) Department of Nephrology, University Clinic, Wuerzburg, Germany; 2) Department of Radiology, University Clinic, Wuerzburg.

Fabry disease is X-linked lysosomal storage disorder due to α -galactosidase A (α -GAL A) deficiency with intracellular accumulation of the incomplete metabolised substrate, mainly globotriaosylceramide (Gb3). Affected organs are the vascular endothelium, heart, brain and the kidney with progressive renal insufficiency. We investigated feasibility, safety and side effects of ambulatory enzyme replacement therapy (ERT) in Fabry patients. Furthermore we established a clinical evaluation program to document baseline status and the course of the disease during ERT. Ongoing clinical evaluation includes cardiac testing, kidney and pulmonary function as well as dermatological evaluation. Recombinant α -GAL A (Agalsidase b, Fabrazyme®) was given i.v. to 16 male and 2 female patients every two weeks in a dosage of 1mg/kg/bw. Mean age was 42,4 years (range 29 to 57). Mean duration of treatment is 8,2 months (range 3-12). Infusion time was reduced within 8 applications from 240 to 150 min.. Patients were pretreated with paracetamol, clemastin and ranitidin to prevent infusion related reactions. So far about 300 infusions were administered. Documented side effects were fatigue after therapy (frequently), chills without fever (three patients), rigor (one patient), cramps of the calves (one patient, agalsidase b was administered during hemodialysis) and vertigo (one patient, during two non successive infusions). One patient had to start hemodialysis after two months of ERT (baseline creatinin clearance 7ml/min). In general treatment was well tolerated, no serious side effects occurred. All patients were treated as outpatients. No increased occurrence of side effects at a infusion time of 150 min compared to 240 min.. We conclude that ambulatory ERT of Fabry's disease with recombinant α -GAL A is feasible and safe. Side effects and clinical course at baseline and during therapy should be well documented. To reveal the clinical benefit of long term ERT on critical organs like kidney, heart and brain comprehensive clinical evaluation programs should be conducted on a regular basis.

The effect of enzyme replacement therapy with agalsidase alfa on cerebrovascular disease in a female heterozygote with Fabry disease. *J.T.R. Clarke*^{1, 2}, *C. Jaigobin*², *J.R. Wherrett*², *R.M. Iwanochko*³. 1) Clinical Genetics, Hosp Sick Children, Toronto, ON, Canada; 2) Neurology, University Health Network, Toronto, ON, Canada; 3) Nuclear Cardiology, University Health Network, Toronto, ON, Canada.

Neurological complications are common in both hemizygous males and heterozygous females with Fabry disease. Transient ischemic attacks (TIAs) and strokes (CVAs) are reported to occur in at least 25% of hemizygous males over 18 yrs of age and has also been reported in heterozygous females. Treatment of Fabry disease by enzyme replacement therapy (ERT) with agalsidase alfa has been reported to ameliorate the pain and reverse cerebral circulatory abnormalities, but clinical benefit in the treatment of TIAs has not been confirmed. Aim: We wish to report on our experience with ERT in a female Fabry heterozygote who presented with multiple TIAs at 19 yrs of age. Methods: The diagnosis of Fabry disease was established by demonstration of (1) typical intralysosomal inclusions in blood vessels in muscle, (2) elevation of ceramide trihexoside (CTH) levels in plasma, and (3) the presence of a missense mutation, 776C>T (P259L), in the *GLA* gene. Plasma a-galactosidase A levels were normal. After baseline clinical neurological investigation and cerebral MRI scanning, the patient underwent ERT by biweekly IV infusions of agalsidase alfa, 0.2 mg/kg. The effect of treatment was assessed by repeating the baseline studies after 15 months of ERT. Results: In the year prior to starting ERT, the patient suffered frequent recurrent headaches and had 3 transient episodes of dysarthria and left hemiparesis associated with the development of MRI lesions in the basal ganglia and the pons. Within 6 months of starting ERT, the headaches remitted and she had no further TIAs. Follow-up neurological examination showed no focal neurological deficits, though deep tendon reflexes were generally increased. Conclusions: Experience with this patient showed that (1) TIA is a potentially serious vascular complication of Fabry disease, even in young heterozygous females; and (2) the frequency and severity of TIAs is decreased by ERT with agalsidase alfa.

Biodistribution and cellular localization of recombinant α -galactosidase A: A comparison of Fabrazyme® and Replagal™. *T. Edmunds, P. Piepenhagen, L. Copertino, C. Nickerson, L. Andrews.* Genzyme Corporation, Framingham, MA.

Fabry disease is a lysosomal storage disease arising from deficiency of the enzyme α -galactosidase A. Two protein therapeutics, Fabrazyme (α -galactosidase beta) and Replagal (α -galactosidase alfa), have been approved as enzyme replacement therapies for Fabry disease in Europe and are undergoing further clinical testing in the United States. Both products contain the same protein, human α -galactosidase A. Fabrazyme is produced in a CHO cell line while Replagal is produced in a human cell line. Since these two production systems could lead to different post-translational modifications we have carried out biochemical comparisons of the two products. Biochemical analyses have demonstrated that the two products are structurally similar and functionally equivalent with the structural variations limited to the degree of sialylation and phosphorylation of oligomannose chains. Fabrazyme has a higher sialic acid to galactose ratio and a higher level of mannose-6-phosphate per mole of protein. While these variations in glycosylation do not significantly affect the in-vitro properties of the proteins they could impact biodistribution at either the organ or cellular level. To answer this question we conducted biodistribution and cellular localization studies in Fabry mice. Biodistribution studies were carried out in Fabry mice given equivalent (3mg/kg)i.v. bolus doses of each enzyme. Enzyme activities were measured in the kidney, heart, liver and spleen 1, 4, 8 and 24hr following injection. Cellular localization within these organs was determined using enzymes fluorescently labeled with either Oregon Green-488 or Alexa Fluor-546.

These studies demonstrated that similar amounts of each product are delivered to the tested organs with the majority of the injected dose (66% for Fabrazyme, 69% for Replagal) recovered in the liver 1hr following injection. Lower amounts of each enzyme were recovered from the kidney, heart and spleen. These results indicate that the variations in the glycosylation of the two products do not have a significant affect on organ distribution.

RhIDU enzyme replacement therapy for MPS I: 24-week extension study. *L.A. Clarke*¹, *J. Muenzer*², *E.H. Kolodny*³, *G.M. Pastores*³, *M. Beck*⁴, *J.E. Wraith*⁵. 1) UBC, Vancouver, BC, Canada; 2) UNC, Chapel Hill, NC; 3) NYU, NY, NY; 4) UMainz, Mainz, Germany; 5) UManchester, Manchester, UK.

Objective: To further evaluate the safety and efficacy of recombinant human α -L-iduronidase (rhIDU) for treatment of MPS I. **Methods:** All 45 patients from the 26-week Phase 3 randomized, double-blind, placebo-controlled study (Ph3DB) entered an open-label extension study (Ph3EXT) and received 100 U/kg (=0.58 mg/kg) rhIDU IV weekly. Efficacy endpoints were evaluated by within-group changes (rhIDU/rhIDU, n=22, 50 weeks rhIDU treatment; placebo/rhIDU, n=23, 24 weeks rhIDU treatment) from baseline (start of Ph3DB) and entry (start of Ph3EXT) to Week 24 of the Ph3EXT. **Results:** At baseline, the mean age was 15.5 years (range 6-43) and 82% had Hurler-Scheie syndrome (moderate phenotype). After 50 weeks of treatment, rhIDU/rhIDU patients maintained the improvement in percent of predicted normal FVC made in the Ph3DB (5.9 percentage points, p=0.003) and improved further in the 6MWT (42.9 meters, p=0.005). Placebo/rhIDU patients showed a slight decline in FVC in both the Ph3DB and PhEXT (-0.6 percentage points) but improved in the 6MWT by 23.8 meters (p=0.073), similar to rhIDU patients in both the Ph3DB and Ph3EXT. Placebo/rhIDU patients showed large reductions in liver volume (-12.6%) and urinary GAG level (-68.9%) comparable to those achieved and maintained by rhIDU/rhIDU patients. In patients with apnea-hypopnea index scores suggestive of sleep apnea, rhIDU/rhIDU patients maintained improvement seen in the Ph3DB, while placebo/rhIDU patients also improved. Increased joint range of motion and improved quality of life scores were observed in both groups. The safety profile was acceptable and similar to that of the Ph3DB. One patient death, unrelated to study drug, occurred. As with rhIDU-treated patients in the Ph3DB, nearly all patients (21/23) in the placebo/rhIDU group developed anti-rhIDU IgG antibodies; 2 patients in the rhIDU/rhIDU group tolerized. Antibody formation did not appear to impact safety or efficacy. **Conclusion:** rhIDU treatment continues to appear to be a promising treatment for the non-CNS components of MPS I disease. (Sponsored by Genzyme and BioMarin).

Enzyme replacement therapy improves cardiovascular control in Fabry patients during orthostatic stress. *M.J. Hilz*^{1, 2}, *H. Marthol*¹, *M. Brys*¹, *T. Haendl*², *G. Welsch*², *R. Franta*², *B. Stemper*^{1, 2}. 1) Neurology, New York University, New York, NY; 2) Neurology, University of Erlangen-Nuremberg, Erlangen, Germany.

Fabry disease, an X-linked α -galactosidase A deficiency, results in glycolipid accumulation in various organs including the nervous system. Loss or dysfunction of small nerve fibers may impair cardiovascular autonomic modulation. Although enzyme replacement therapy (ERT) with recombinant human α -galactosidase A has recently become available in many countries, the effects of ERT on autonomic cardiovascular control have not been analyzed. In this study, we evaluated whether ERT improves cardiovascular control during orthostatic stress in Fabry patients. In 11 Fabry patients (28.4 ± 7.9 years) undergoing ERT (1mg/kg recombinant human α -galactosidase A, Fabrazyme every two weeks) for 23 months and in 11 patients (28.8 ± 9.1 years) undergoing ERT for 18 months, we monitored electrocardiographic RR-interval (RRI) and blood pressure (BP) [Colin Pilot] at supine rest and during 5 minutes of active standing before and after ERT. As parameters of autonomic control, we analyzed spectral powers of RRI and BP in the low (LF: 0.04-0.15 Hz) and high (HF: 0.15-0.5 Hz) frequency range using autoregressive analysis. Differences between parameters measured in supine and standing position were expressed as percentage changes. After ERT, the orthostasis induced heart rate acceleration, i.e. decrease in RRI was more pronounced ($-28.4 \pm 13.2\%$) than before therapy ($-4.9 \pm 7.1\%$; $p < 0.05$). ERT had no influence on orthostasis induced changes of BP or RRI-LF-power ($p > 0.05$). In contrast, the orthostatic reduction of parasympathetic HF-power of RRI was more prominent after ERT ($-79.8 \pm 23.1\%$) than before therapy ($-46.7 \pm 58.1\%$; $p < 0.05$). After ERT, the orthostasis induced increase in sympathetic LF-power of BP was higher (357.9 ± 349.4) than before therapy ($112.7 \pm 177.1\%$; $p < 0.05$), while HF-power of BP remained unchanged. To conclude, ERT improves orthostatic cardiovascular control in Fabry patients as demonstrated by increased orthostatic heart rate acceleration due to cardiovascular withdrawal, sympathetic activation and sympathetic vasomotor control following therapy.

A phase I/II clinical study evaluating the safety and clinical activity of enzyme replacement therapy in Mucopolysaccharidosis II (Hunter syndrome). *J. Muenzer, D. Towle, M. Calikoglu, S. McCandless.* Department of Pediatrics, University of North Carolina, Chapel Hill, NC.

Mucopolysaccharidosis II (MPS II) is an X-linked recessive disorder caused by the deficiency of the lysosomal enzyme iduronate-2-sulfatase (I2S). MPS II is a progressive disorder with tissue and organ involvement due to storage of glycosaminoglycans (GAG). There is no effective therapy for MPS II. Exogenous enzyme replacement therapy offers the possibility of a safe and efficacious approach for the treatment of the somatic disease in MPS II. Human I2S was produced by genetic engineering technology in a human cell line by Transkaryotic Therapies (TKT), Cambridge, MA. Preclinical studies in an MPS II knock-out mouse model have demonstrated that treatment with human I2S results in decreased urinary GAG and reduction in tissue GAG. The phase I/II enzyme replacement clinical trial started in March 2001 with the primary goal of the trial to determine safety of the genetically engineered enzyme and the secondary goal to determine clinical activity. The clinical trial was a randomized, double-blind, placebo-controlled clinical study which enrolled twelve MPS II patients (6 to 20 years of age). Three dosages of I2S (0.15 mg/kg, 0.5 mg/kg and 1.5 mg/kg) were studied. Within each dose group, patients were randomized to receive either I2S (three patients) or placebo (one patient) by IV infusion biweekly for six months. All twelve patients have successfully completed the six-month study and all elected to enroll in an open-label extension study. Preliminary analyses of the data showed a 51% reduction in urinary GAG excretion in the MPS II patients receiving I2S. I2S treatment was also associated with significant reductions in liver and spleen volumes. Infusion-related reactions have occurred in four patients in the middle and high dose groups and have been successfully managed by slowing the infusion rate and using premedications. These initial results indicate that this I2S preparation is clinically active and is a promising treatment for patients with MPS II.

Replagal Treatment in Fabry Patients Following Renal Transplantation. *K. Nicholls, E. Centra, B. Lehmann, G. Becker.* Nephrology, Royal Melbourne Hospital, Parkville, Australia.

AIMS: To study the safety, tolerability and effects of Replagal on clinical findings, quality of life, renal function and exercise capacity in male Fabry patients with functioning renal transplants. **PATIENTS AND METHODS:** 4 patients aged 59, 59, 43 and 31 years received compassionate use Replagal fortnightly for 18 months. Patients had undergone successful renal transplantation 2.5-17 years previously, and had stable renal function. The two oldest patients were significantly disabled by advanced symptoms of Fabry disease, particularly muscle fatigue on minimal exertion. Patients kept daily diaries of exercise, bowel habit and all medication. Study visits at Weeks (W) 0-1, 9, 17, 24 and months (M) 9, 12 15 and 18 documented clinical findings, SF36 and EQ5D questionnaires, hematology and biochemistry (renal & liver function, lipids, albuminuria). Prophylactic analgesics were stopped prior to each study visit. Radionuclide glomerular filtration rate (GFR) was performed at baseline then 6-monthly. **RESULTS:** Tolerability: 3 patients tolerated infusions well, and 1 developed moderate infusion reactions from 12 months, requiring pre-infusion corticosteroid and antihistamine. Sweating: Patients reported definite increase in sweating at W9, 17, 17 and 37. Pain: One of the 3 patients on prophylactic carbamazepine was able to stop at M9, one decreased dose progressively at W9, M12 and M13, while the third maintained dose with decrease in pain score over M3-12. Exercise: Patients reported significantly increased daily exercise at 12 months compared with baseline (Scored as mean daily score over monthly intervals, ANOVA $p < .05$). Bowel habit: No change in bowel habit was seen. Renal Function: GFR, creatinine clearance and proteinuria remained stable. **CONCLUSIONS:** Over 72 patient months, Replagal was well tolerated, and was associated with increased sweating, decreased pain and increased physical activity.

Gastrointestinal symptoms in Fabry's disease respond to enzyme replacement therapy. *B.E. Hoffmann, B. Koletzko.* Div. of Metabolic Diseases & Nutrition, Dr. von Hauner Children's Hospital, Munich, Germany.

INTRODUCTION

M. Fabry is an X-linked metabolic disorder with autosomal recessive inheritance, deficiency of α -galaktosidase A and localisation of the defect at position Xq22.1. Globotriasylceramide (Gb3) accumulates in several tissues causing unlikely clinical findings (neuropathic pain, angiokeratoma, abnormal renal function, cardiomyopathy, gastrointestinal symptoms etc., 1,2). Reports about gastrointestinal symptoms in M. Fabry are few and no information has been published on possible response of gastrointestinal symptoms to enzyme replacement therapy (ERT).

CASE REPORT

Acroparaesthesia showed up at the age of 6 years and got worse with physical exercise and elevated temperature. From 10 years onwards symptoms became more severe and exacerbated by consumption of different foods. 18 years old determination of α -Galaktosidase-A (activity of 8 percent) confirmed the diagnosis of M. Fabry. Treatment was symptomatic. 34 years old gastrointestinal symptoms had become leading complaints (constipation and diarrhoea, dyspeptic symptoms and early feeling of fullness). Only small food portions within 10 meals/d were tolerated but body weight was only 51.2 kg, length 176.6 cm and BMI 16,4 kg/m.

ERT was initiated with a biweekly dose of 0.2 mg/kg of human recombinant α -galaktosidase (Agalsidase alfa). Medication was tolerated well except for a mild headache several times. Gastrointestinal complaints improved after a few infusions, the feeling of fullness waned, larger meal portions and a smaller meal frequency were tolerated. After 9 months of treatment BMI was increased to 17,4 kg/m.

CONCLUSIONS

Fabry's disease may present with severe gastrointestinal symptoms suggestive of a motility disorder that induce malnutrition. ERT with agalsidase alfa reduced these symptoms, made metoclopramide superfluous, increased body weight and BMI and enhanced life-quality. 1 Mac Dermot et al. 2001; 2 Argoff et al. 1998.

Treatment of Classical Infantile Pompe Disease(CIPD) with Recombinant Human Acid Alpha

Glucosidase(rhGAA): Preliminary 6 month data from a Phase 2 study. P. Kishnani¹, T. Voit², M. Nicolino³, A. Amalfitano¹, C.H. Tsai⁴, G. Herman⁵, J. Waterson⁶, R.C. Rogers⁷, H. Landy⁸, D. Corzo⁸, B. Thurberg⁸, S. Richards⁸, F.H. Yong⁸, Y.T Chen¹. 1) Dept of Medical Genetics, Duke University Medical Center, Durham, NC; 2) Univ Hosp, Essen, Ger; 3) Ped Hosp Brousse, Lyon, Fr; 4) Children's Hosp Denver, CO; 5) Children's Hosp Columbus, OH; 6) Children's Hosp Oakland, CA; 7) Greenwood Genet Cr, Greenville, SC; 8) Genzyme Corp, USA.

Purpose: To evaluate the safety and efficacy of rhGAA in patients with CIPD, an autosomal recessive disorder characterized by progressive cardiomyopathy, muscle weakness, respiratory insufficiency, and death usually by one year. **Methods:** This is a Phase 2 open-label, multinational, multicenter study of 8 patients with CIPD. Inclusion criteria are cardiomegaly by age 6 months, cardiomyopathy, CRIM(+) status and <1% GAA in fibroblasts. Chinese hamster ovary cell derived rhGAA is administered at 10 mg/kg IV weekly. Clinical efficacy assessments include ventilator-free survival, reduction in left ventricular mass (LVM), and motor development. **Results:** All patients have been enrolled (median age 4.7 months, range 2.7-14.6). rhGAA is generally well-tolerated. There have been 2 deaths, neither related to rhGAA. In 5/5 patients with 6 months of treatment data, there is reduction of LVM (mean LVM index difference from baseline to 6 months is $-157 \pm 66 \text{ gm/m}^2$, $p=0.006$; median LVM z-scores decreased from +7.4 to +2.9). After 3 months of treatment, histomorphometry of muscle glycogen content showed significant reduction in 2/7 patients evaluated so far. However, after 6 months of rhGAA therapy 6/6 surviving patients are ventilator-free and 4/6 patients have an Alberta Infant Motor score ³ 3rd percentile for age. All patients enrolled developed antibodies to rhGAA after 2 months of therapy. **Conclusions:** Preliminary data suggests that rhGAA is well tolerated and capable of improving cardiac status and skeletal muscle function in patients with CIPD. Additional data are needed to assess the long-term safety and efficacy of rhGAA, as well as the role of anti-rhGAA antibodies in clinical outcome.

A Phase I/II Study of Enzyme Replacement Therapy (ERT) for Mucopolysaccharidosis VI (MPS VI; Maroteaux-Lamy syndrome): 48 Week Progress Report. *P. Harmatz¹, C.B. Whitley², L. Waber³, R. Pais⁴, R. Steiner⁵, B. Plecko⁶, P. Kaplan⁷, J. Simon¹, J. Waterson¹, J. Hopwood⁸.* 1) Children's Hosp Oakland; 2) U Minn Med S; 3) U Tex SW Med; 4) E Tenn Children's Hosp; 5) Oregon H & S; 6) U Kinderklinik, Graz; 7) Children's Hosp Philadelphia; 8) Woman's & Children's H, Adelaide.

MPS VI is an LSD caused by a deficiency of N-acetylgalactosamine-4-sulfatase (ASB), leading to a progressive disorder with multiple organ and tissue involvement. Death usually occurs in the second decade. Currently there is no specific treatment other than symptomatic care and bone marrow transplant. A randomized, two-dose, double-blind study for 24 weeks to evaluate safety and efficacy of weekly treatment with human recombinant (rh) ASB in humans with MPS VI was recently completed. Patients were randomized to weekly infusions of either high (1.0 mg/kg) or low (0.2 mg/kg) doses of rhASB. Six patients completed at least 24 weeks of treatment (3M, 3F; age: 7-16 years); 5 patients have completed at least 48 weeks. The study blind was removed after the 24 weeks. One patient withdrew from the study for reasons unrelated to any adverse event. No study drug-related serious adverse events, significant laboratory abnormalities or allergic reactions have been observed. Complement studies were unremarkable. Patients on low or high dose rhASB had reductions in total urinary GAG excretion of 51 and 63%, respectively, at 48 weeks. Four of 5 patients had improvement in the 6 minute walk test, 3 were substantial. One of 3 patients without tracheostomy had improved forced vital capacity and two of these patients had a 4- to 7-fold decrease in Apnea-Hypopnea Index. Shoulder ROM improved in all 5 patients completing 48 week evaluations and joint pain improved in patients with significant pain. Patients on low dose enzyme were advanced to the 1 mg/kg dose after the 48 week evaluations. In conclusion, treatment was well-tolerated, urinary GAG decreased in a dose-related pattern, and clinical responses were present in all patients, but greatest in patients with advanced disease receiving high dose ERT. (Sponsored by BioMarin Pharmaceutical Inc., Novato, CA).

Program Nr: 2419 from 2002 ASHG Annual Meeting

Expression and Secretion of Alpha-galactosidase A by Primary Murine Myoblasts. *J. Wang, J.A Barranger.*
Human Genetics, University of Pittsburgh, Pittsburgh, PA.

Fabry disease is an X-linked inherited metabolic disorder due to a deficiency of lysosomal alpha-galactosidase A (AGA). The success of enzyme replacement for the lysosomal storage disorders, and recently Fabry disease, has stimulated consideration of alternative methods for the delivery of enzyme. One approach is a system that could supply AGA into the circulation continuously. We have previously reported that human genes coding lysosomal enzymes can efficiently transduce murine myoblasts. These cells express and secrete enzyme into the blood from which it is taken up and localized in the lysosome. We now demonstrate that primary murine myoblasts from a Fabry mouse can be transduced at high efficiency by MFG-AGA, where over 90% of MFG-AGA transduced Fabry mouse cells expressed AGA. The transduced primary murine myoblasts had intracellular enzyme activities of over 500 U/mg, while non-transduced controls had 0 activity. Furthermore, transduced primary myoblasts secrete AGA extracellularly for at least 21 weeks. Most importantly, secreted AGA was taken up by Fabry mouse cells. These data suggest that transduced primary myoblasts may be useful in supplying AGA as an alternative approach in the treatment of Fabry disease.

Enzyme replacement therapy improves sweat function and renal natural history in Fabry disease. *R. Schiffmann*¹, *K. Chen*¹, *S. Gupta*¹, *Y. Sharabi*², *R.O. Brady*¹. 1) Developmental and Metabolic Neurology Branch/NINDS/NIH, Bethesda, MD; 2) Clinical Neurocardiology Section/NINDS/NIH, Bethesda, MD.

Fabry disease is an X-linked disorder caused by a deficiency of lysosomal α -galactosidase A with accumulation of the glycosphingolipid globotriaosylceramide. Clinical manifestations include hypohydrosis with poor heat tolerance and progressive deterioration of renal function. We previously demonstrated the therapeutic safety and efficacy of enzyme replacement therapy (ERT) with agalsidase alfa for Fabry disease in a 6-month placebo-controlled trial (Schiffmann, et al, 2001). We subsequently evaluated the short, medium and long-range clinical efficacy of ERT. Patients (n=25, 19-52 yrs) received infusions of agalsidase alfa (Replagal, Transkaryotic Therapies, Inc., Cambridge, MA) at 0.2/kg/mg every two weeks for up to 3.5 years. Outcome measures were sweat function using acetylcholine iontophoresis, over 0.781 cm² of skin, for quantitative sudomotor axon reflex (QSART), renal function, and comparison with renal function data in the NIH natural history cohort (n=105, age range 11-60). When studied at the 2.5/3 year time point, pre-ERT sweat excretion in Fabry patients was 0.24 ± 0.33 mL vs. 1.05 ± 0.81 in concurrent controls (n=38, p<0.0001). Sweat function improved 24-72 hr post-enzyme infusion (0.57 ± 0.71 mL, p=0.04) and normalized in 4 anhydrotic patients. Renal function declined over 6 months in patients who initially received placebo consistent with the natural history of disease. Glomerular filtration rate significantly improved in these patients with ERT (p=0.025), and remained stable in the patient group as a whole for up to 2.5 years. No patient who has received ERT progressed to end-stage renal disease (ESRD). Time-to-event (ESRD) in treated patients was significantly better than in the NIH untreated cohort (p=0.02, log rank test). Over the last 2 years of the study, all patients have received agalsidase alfa infusions at home. Home therapy has been very well-tolerated. We conclude that ERT in Fabry disease is safe, corrects sweat malfunction, and likely beneficially alters the natural history of Fabry disease. QSART may be useful to further monitor ERT therapy.

Adenovirus-mediated transfer of huntingtin in neuronal and glial cells. *J. Shin*¹, *Z. Yu*², *S. Li*², *X. Li*². 1) Graduate Program in Genetics and Molecular Biology; 2) Dept Human Gen, Whitehead Bldg, Emory Univ, Atlanta, GA.

Despite its widespread expression, mutant huntingtin causes selective neurodegeneration in Huntington disease, an inherited disorder that results from polyglutamine expansion in the N-terminal region of huntingtin. N-terminal huntingtin containing expanded polyglutamine also forms aggregates in neurons and kills neurons in vitro. By examining HD transgenic mice expressing N-terminal mutant huntingtin, we also observed huntingtin aggregates in glial cells. Since glial cells support the survival of neuronal cells, it would be interesting to study how mutant huntingtin affects the function of glial cells and then neuronal viability. An efficient expression of mutant huntingtin in neuronal and glial cells will allow for better examining the neuropathological role of mutant huntingtin. As an initial step, we constructed adenovirus-mediated vectors that express the first 218 amino acid plus an additional 23 or 120 glutamine repeat. The expressed huntingtin is fused to the C-terminus of green fluorescence protein (GFP) to allow the visualization of transfected proteins in living cells. Western blots have confirmed that these transfected proteins are correctly expressed in HEK293 cells. Immunostaining also showed that mutant huntingtin forms aggregates or inclusions in transfected cells. We are currently preparing virus for infection of GFP-huntingtin into glial and neuronal cells and for examination of the effect of glial cells containing mutant huntingtin on the survival of neurons.

Fetal gene therapy via the cerebrospinal fluid using an HSV-1 amplicon cosmid based vector. *W. Patino¹, X.O. Breakefield², J.W. Larsen¹, A. Kwok³, C. Andry³, R.V. Lebo^{1,4}.* 1) Dept OB/GYN, George Washington Univ, Washington, DC; 2) Dept Neurology, Harvard Medical School, Charlestown, MA; 3) Dept Pathology, Boston Univ, MA; 4) Dept Pathology, Akron Childrens Hospital, Akron, OH.

Advantages of prenatal gene therapy include introducing genes to an immunologically privileged host with minimal rejection of non-self antigens, introducing normal gene function prior to progressive degeneration, and delivering genes to nerves prior to blood-brain barrier development. Advances in molecular biology and surgery make prenatal gene therapy more realistic. Proof of principle experiments tested reporter gene delivery into small laboratory animals with multiple fetuses and short gestation periods. Day 15.5 fetal mice were injected with a viral HSV-1 amplicon cosmid based vector carrying the bacterial LacZ reporter gene. During surgery, 1 microliter of packaged viral vectors carrying $>10^8$ reporter genes were delivered directly through the placenta to one of several locations including through a visible fetal fontanelle via a 50 micron I.D. glass tipped microinjection needle. The 14 dams whose injected fetuses survived for three days after surgery carried 142 fetuses for a total survival rate of 85%. Among these 142 fetuses, 81% of 47 injected fetuses survived while 86% of the uninjected littermates survived. This includes survival of 86% of fetuses injected with 1 microliter in the cerebrospinal fluid (CSF). All 18.5 day old fetuses that survived HSV-1ac injection had similar weights (1.41 0.19 grams, $P=0.13$) and crown-to-rump lengths (19.2 1.84mm, $P=0.96$) when compared to age-matched uninjected controls (1.47 0.24 grams, $P=0.16$; 19 2.79 mm, $P=0.15$) reflecting no significant adverse effect of the HSV-1ac injection in the fetal growth and development. Of the 30 fetuses screened for LacZ activity, 24 (80%) exhibited reporter gene activity in more than 3 consecutive sections. Genes introduced into the cerebrospinal fluid were expressed in multiple brain locations while fetuses injected in amniotic fluid typically expressed genes in the lung. These results suggest that gene injection into fetal cerebral spinal fluid is one approach to treat genetic neuropathies.

Metabolically biotinylated gene therapy vectors. *M.A. Barry, M.B. Parrott.* Molecular & Human Genetics, Immunology, Center for Cell and Gene Therapy, Baylor College of Medicine, Houston, TX.

Viral gene therapy vectors are often handicapped by their inability to transduce therapeutically-relevant cells while avoiding transduction of non-target cells. One method of altering adenoviral specificity is to genetically introduce cell-targeting ligands directly into the capsid proteins of the vector. While this approach can work, in many cases inserted ligands fail to function or destroy the function of the virus making targeting impossible. To avoid this problem, we have developed metabolically biotinylated vectors. In these vectors, the viruses are genetically engineered to display a biotin acceptor peptide (BAP) that is enzymatically biotinylated by the endogenous biotin ligase, holocarboxylase synthetase, of the mammalian cell, or that can be biotinylated by co-expression of the bacterial ligase BirA. BAP-modification of the adenovirus fiber protein generated biotinylated virus particles that could specifically target K562 cells using biotinylated antibodies against CD59 and CD71. Flow cytometry revealed that the biotinylated vector mediated up to 95% transduction of target cells versus 5% transduction by the wild type vector. When quantitated by luciferase gene delivery, the biotinylated virus showed a greater than 200-fold increase in transduction relative to wild type Ad5. This work demonstrates the ability to produce metabolically biotinylated adenoviral vectors for vector targeting. Similar approaches are being applied for retroviral envelopes and for AAV capsids to produce a repertoire of metabolically biotinylated viruses. Optimized biotinylated vectors will take advantage of the unique dual affinity aspects of avidin where vectors can be affinity purified on monomeric avidin ($K_d = 10^{-7}$) using only biotin for release, followed by re-targeting using high affinity tetrameric avidin ($K_d = 10^{-15}$) to bridge the virions to any biotinylated targeting ligand. This approach also avoids the necessity to genetically engineer a new viral vector for every new targeting ligand, since any biotinylated ligand can be combined with a single biotinylated vector to target multiple cell types.

Suppression of mRNA Nonsense Mediated Decay in Smith-Lemli-Opitz Syndrome. *L.S. Correa-Cerro, P.A. Krakoviak, C.A. Wassif, F.D. Porter.* Heritable Disorders Branch, NICHD/NIH, Bethesda, MD.

Nonsense-mediated mRNA decay (NMD) permits cells to recognize and degrade mRNA transcripts with nonsense mutations to prevent possible toxic effects of truncated peptides. In mammalian cells, there is no consensus whether NMD takes place in the nucleus or in the cytoplasm. It has been proposed that exon-exon junctions are tagged upon completion of splicing, producing an mRNA which undergoes NMD when a premature stop codon is present at a given distance from the tagged junction. Aminoglycoside suppression of NMD has been studied in several autosomal recessive diseases such as cystic fibrosis, Tay-Sachs, and Hurler syndrome. Smith Lemli-Opitz syndrome (SLOS) is an autosomal recessive, multiple malformation syndrome due to an inborn error of cholesterol biosynthesis. We have studied four fibroblast cell lines from patients with SLOS, in which one allele has a premature stop codon: T93M/W151X (2 patients), R450L/Q98X, and IVS8-1G>C/W151X. W151X occurs in about 8% of patients, while Q98X is a novel mutation in DHCR7. To test for aminoglycoside suppression of NMD in SLOS, we treated one control and four patient fibroblast cell lines with G418 and gentamicin. After 48 hrs of treatment we isolated total RNA, performed RT-PCR and sequenced these products directly. We observed two alleles in cell lines treated with antibiotics but only one in the untreated cells. We have also observed an increase in DHCR7 expression levels by Northern analysis in the cells that underwent treatment. We are now investigating the biochemical consequences of NMD-suppression in SLOS fibroblasts. If suppression of NMD can alter the sterol profile in fibroblasts with nonsense mutations, then it may represent a therapeutic approach in this subgroup of SLOS patients.

Adenoviral and AAV vectors for an efficient intracerebral gene transfer in the Sandhoff mouse model. C.

*Bourgoin*¹, *C. Emiliani*², *A. Gelot*³, *B. Tancini*², *L. Poenaru*¹, *C. Caillaud*¹. 1) Genetics, Cochin Institute, Paris, France; 2) Department of Cellular and Molecular Biology, Perugia, Italy; 3) Neuropathology Unit, Saint Vincent de Paul Hospital, Paris, France.

Sandhoff disease is an autosomal recessive neurodegenerative disease characterized by the intralysosomal accumulation of GM2 ganglioside. It is due to mutations in the HEXB gene encoding the hexosaminidases b-chain and results in a hexosaminidases A (ab) and B (bb) deficiency. In order to test the feasibility of gene transfer methods in this model, a recombinant adenoviral vector encoding the b subunit was injected intracerebrally into the murine model of Sandhoff disease. It led to a normal hexosaminidases total activity in the entire brain and a partial restoration of the Hex A specific activity. The injection of hyperosmotic concentrations of mannitol in combination with the adenoviral vector resulted in a drastic enhancement of the vector diffusion in the injected hemisphere. Although mannitol extended the inflammatory effects of the vector, the use of such a chemical agent significantly improved transduction efficiency into the CNS. AAV vectors containing the human HEXA and HEXB cDNAs under the control of the CAG promoter were also constructed. AAV-HEXB was first injected alone into the brain of hexb ^{-/-} neonates. Histological staining showed a high enzymatic activity in widely diffuse areas. Hexosaminidases activity was restored to the normal level in the whole brain, but Hex A only reached 20% of normal. The coadministration of both HEXA and HEXB vectors in the CNS permitted to reach therapeutic levels of hexosaminidases A and B, as demonstrated by the GM2 ganglioside degradation, confirming the necessity of supplying both subunits in the case of heterodimeric proteins, such as Hex A.

Towards successful gene therapy for OTC-deficiency: Evaluating *in vivo* efficacy of the Helper-Dependent

Adenoviral Vector in the OTC^{spf-ash} mouse. A. Mian¹, V. Mane¹, K. Oka², W. O'Brien¹, A. Beaudet¹, P. Ng¹, B. Lee¹.

1) Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Cell Biology, Baylor College of Medicine, Houston, TX.

Ornithine transcarbamylase (OTC) deficiency, an inborn error of hepatocyte metabolism, requires a high level of hepatocyte transduction and transgene expression for therapeutic correction. We hypothesized that the helper-dependent adenoviral vector (HDV) with a tissue-restricted promoter would be able to express OTC in the hepatocyte for a prolonged period with minimal chronic toxicity. We, therefore, generated a HDV construct containing human OTC cDNA driven by the tissue-restricted phosphoenolpyruvate carboxykinase (PEPCK) promoter. To test the therapeutic potential of the HDV *in vivo*, we utilized the OTC^{spf-ash} mouse, a hypomorphic mouse model for OTC-deficiency.

Affected mice treated with 1.5×10^{11} particles of HDV:PEPCK-hOTC showed no improvement in orotic aciduria, likely because of mitochondrial leader peptide sequence differences between the human and mouse OTC proteins (Ye *et al.* Hum. Gene Ther. 2001). However, no hepatotoxicity was associated with the HDV treatment, therefore warranting further studies. To determine whether higher hOTC expression might overcome leader peptide differences in the mouse model and at the same time increase the therapeutic index in human applications, we incorporated the woodchuck hepatitis virus posttranscriptional regulatory element (WPRE) into the adenoviral hOTC construct. Interestingly, 3×10^{11} viral particles of the HDV:PEPCK-hOTC-WPRE vector in the OTC^{spf-ash} mouse were sufficient to significantly reduce orotic aciduria for at least 6 weeks with ongoing measurements. At the same time, we generated HDV using the mouse OTC cDNA. Treatment of OTC^{spf-ash} mice with 3×10^{11} viral particles of HDV:PEPCK-mOTC corrected orotic aciduria comparable to a first generation adenoviral vector expressing the same mouse transgene. Further development of HDVs using the WPRE for *in vivo* gene replacement for diseases such as urea cycle disorders is warranted due to decreased long-term toxicity and prolonged transgene expression associated with these vectors.

TNF α signaling and its modulation in thrombocytopenia associated with adenovirus gene therapy. *V.P. Mane, G. Toietta, R. Cela, L. Pastore, A. Beaudet, B. Lee.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Intravenous administration of high doses of adenoviral vectors has been shown to be associated with thrombocytopenia leading to severe risk of disseminated intravascular coagulopathy and systemic inflammatory response. The molecular mechanism involved in the acute response leading to thrombocytopenia is not known. This early response is independent of viral gene expression, since helper-dependent Ad vectors devoid of all viral coding sequences cause a similar dose-dependent thrombocytopenia, albeit of lesser severity. To investigate a possible early response to adenoviral exposure mediated by tumor necrosis factor α (TNF α), we evaluated platelet levels following intra-tail vein administration of a first generation adenoviral vector in wild type and TNF α deficient mice on the same genetic background. The dose-dependent acute thrombocytopenia in wild type mice was more severe compared to that observed in TNF α deficient animals, indicating that TNF α plays a role in the acute toxicity associated with adenovirus. Moreover, wild type mice treated before Ad-vector injection with specific anti TNF α antibodies were partially protected from severe thrombocytopenia. Our data suggest the involvement of a host TNF α mediated response as one contributing factor leading to the dose-dependent thrombocytopenia associated with adenoviral vector administration. Moreover, a pretreatment with anti TNF α antibody may successfully decrease the acute toxicity without affecting the efficiency of transduction. The use of helper-dependent vectors in conjunction with pharmacologic modulation of TNF α signaling will increase the therapeutic index of adenovirus mediated gene therapy of genetic disease.

Gene Transfer by Receptor-Associated Protein/Polylysine Conjugates into Human Hepatoma Cells. *T. Kim¹, S. Kang¹, W. Yoo¹, S. Nam¹, J. Kang¹, M. Cho¹, H. Na¹, J. Kim¹, S. Jung², S. Kim¹.* 1) Department of Pharmacology, Korea FDA, Seoul, Seoul, Republic of Korea; 2) Korea National Institute of Health, Seoul, Korea.

The receptor-associated protein (RAP) is a ligand for all members of low density lipoprotein (LDL) receptor families and is also able to be internalized into cell via receptor-mediated endocytic trafficking, which is an attractive mechanism for efficient gene delivery. In this study, a gene delivery system using the RAP as a targeting ligand have been developed. The cDNA of RAP except C-terminal heparin binding domain was amplified by polymerase chain reaction (PCR) from human liver cDNA library and was re-amplified by primer that was added to a cysteine residue at the carboxyl end to facilitate its conjugation to polylysine (polyK), the DNA condensing non-viral gene carrier. The RAP was purified using a bacterial expression system and coupled to two kinds of polyK, poly-D-lysine (PDL) or poly-L-lysine (PLL) of average MW 50 kDa via the heterobifunctional cross-linker SPDP. Using fluorescence-labeled RAP ligand, cellular uptake of the transfection complexes into HepG2 cells was highly efficient and specific to RAP ligand conjugated with PDL. Plasmid DNA containing the luciferase reporter gene was condensed with either RAP-PDL or RAP-PLL. In vitro transfection into HepG2 cells with RAP-PDL conjugate resulted in significantly higher expression levels in comparison to non-conjugated PDL, RAP-PLL and LipofecAMINE/ DNA complexes in the presence of 10% fetal bovine serum. The maximum level of luciferase activity was detected 2 days after transfection, at which time the transfected cells were almost confluent. The degree of luciferase expression steeply declined after 3 days and persisted for at least 5 days. The transgene expression was inhibited by addition of excess RAP in the transfection medium, but augmented by treatment with Lovastatin, which inhibits cholesterol biosynthesis and increases expression of LDL receptor. These data indicates that the gene delivery is specifically mediated by LDL-receptor. Thus, this RAP-PDL conjugate could be useful as a non-viral gene delivery vector.

Phage fC31 Integrase Mediated Gene Therapy in a Mouse Model of Hereditary Tyrosinemia Type I. *P. Held¹, E. Olivares², E. Montini¹, M. Finegold³, M. Calos², M. Grompe¹*. 1) Dept Molec & Medical Gen, L103, Oregon Health & Sci Univ, Portland, OR; 2) Dept Genetics, Stanford University School of Medicine, Stanford, CA; 3) Dept Pathology, Baylor College of Medicine, Houston, TX.

Phage fC31 integrase is a site-specific integrase that mediates efficient integration of extrachromosomal DNA into the genome of the host cell using attB and attP phage attachment sites. It has been shown that phage attP sites inserted into human and mouse chromosomes at various locations can be targeted for site-specific integration by this system. In addition, "pseudo" attP sites found in human and mouse genomes can also mediate integration. These "pseudo" sites are similar, but not identical, in sequence to the native attP sites found in the bacterial genome. It has been proposed that phage integrase will be an efficient tool for non-viral gene therapy. In this study, we tested the ability of this system in the mouse model of Hereditary Tyrosinemia Type I (HTI), deficient in fumarylacetoacetate hydrolase (FAH). The full length cDNA human FAH sequence was cloned into two integrase vectors, one with an attB site (pBC-B FAH1) and one without an attB site (pBC-FAH1). Either construct was injected into FAH^{-/-} mice in a 1:1 ratio with the integrase (pCSI) or an empty vector control (pCS). The mice were removed from the protective drug, harvested, and histologically evaluated for FAH⁺ cells. Surprisingly, most FAH⁺ nodules of integrase treated liver consisted of abnormal, dysplastic cells (bizarre nuclei, enlarged cells). This phenomenon was not observed in controls (FAH plasmid without integrase) and therefore may be related to integrase overexpression. The nature of this early integrase toxicity is under investigation, but the cellular morphology suggests that integrase may be causing genomic instability. However, mice harvested after longer selection (90 days) had >75% repopulation with FAH⁺ hepatocytes that appeared healthy and of normal size. Therefore, long-term, stable correction of the FAH deficiency was possible with the integrase system despite the toxicity observed at early time-points. The copy number and structure of integrase mediated insertion events are currently under investigation.

Benefit of Cardiotrophin-1 adenoviral gene transfer in a mouse model of spinal muscular atrophy. J.C.

*Lesbordes*¹, *C. Cifuentes-Diaz*², *A. Miroglio*², *V. Joshi*², *T. Bordet*¹, *A. Kahn*¹, *J. Melki*². 1) GDPM, Institut Cochin, Paris, France; 2) Laboratoire de Neurogenetique Moleculaire , Inserm E9913, Genopole, Evry, France.

Mutations of the survival of motor neuron gene (SMN) are responsible for spinal muscular atrophy (SMA), a common genetic cause of death in childhood. Although its product, the SMN protein, is ubiquitously expressed, the pathological hallmark of SMA is degeneration and loss of spinal motor neurons resulting in paralysis and muscular atrophy. We have previously generated mice carrying homozygous deletion of *Smn* exon 7 directed to neurons. Mutant mice display a dramatic and progressive loss of motor axons resulting in skeletal muscle denervation process, a constant feature found in SMA. A symptomatic therapy approach using neurotrophic factors to prevent or reduce motor neuron loss was previously proved to be efficient in other mouse models of motor neuron diseases such as the progressive motor neuronopathy (pmn) and the Super Oxide Dismutase (SOD1G93A) mice. We therefore wondered if a cardiotrophin-1 adenoviral administration (AdCT-1) might represent a therapeutic strategy in SMA. We demonstrate here that neonate intramuscular injection of AdCT-1 delays the onset of the disease, prolongs mean life span and enhances motor performances of mutant mice: the AdCT-1 treated animals show better scores on functional test like Rotarod than untreated mutants. We show that denervation process assessed by an electromyographical recording on the couple sciatic nerve gastrocnemius is less pronounced after the AdCT-1 therapy. In addition, an increased number of myelinated axons of phrenic nerve was observed in treated mutant mice indicating a protection effect of CT-1 from proximal axonal degeneration. Finally, we show that cardiotrophin-1 greatly preserves neuro-muscular junctions from abnormal accumulation of neurofilament in terminal axons, a severe pathological feature occurring in this mutant. In conclusion, we demonstrate in this work that systemic delivery of neurotrophic factor has beneficial effects in the most relevant animal model of SMA, opening promising therapeutic perspectives in SMA patients.

The Coxsackie-Adenovirus Receptor (CAR) is Highly Expressed in Metastatic Prostate Carcinoma: Potential Impact for Adenoviral Gene Therapy. *K.A. Rauen^{1,5}, R. Rodriguez², A.M. De Marzo³, P. Carroll^{4,5}, V. Weinberg⁵, F. McCormick^{5,6}.* 1) Department of Pediatrics, University of California, San Francisco, San Francisco, CA; 2) Brady Urological Institute, Johns Hopkins Hospital, Baltimore, MD; 3) Johns Hopkins Oncology Center, Department of Surgical Pathology, Johns Hopkins Hospital, Baltimore, MD; 4) Department of Urology, University of California, San Francisco, CA; 5) Comprehensive Cancer Center, University of California, San Francisco, CA; 6) Department of Microbiology and Immunology, University of California, San Francisco, CA.

Adenovirus-based gene therapy may provide an alternative mode of treatment for prostate cancer, especially for late stage and androgen independent disease for which there is currently no effective treatment. Efficient adenovirus infection of target cells depends upon the presence of the coxsackie-adenovirus cell surface receptor, CAR, which is the primary receptor for Group C adenoviruses and is important for the attachment of adenovirus to the cell membrane. To evaluate the potential efficacy of adenoviral therapy for prostate cancer, we evaluated CAR expression in normal prostate tissue, prostate carcinoma of increasing Gleason grades and metastatic disease in paraffin-embedded, archival tissues using a polyclonal antibody raised against human CAR. Immunohistochemical analysis of benign prostate epithelia demonstrated intense luminal and lateral cell membrane staining. There was a statistically significant difference in CAR membrane expression with respect to Gleason score. Metastatic prostate specimens demonstrated strong membrane staining for CAR. Adenovirus therapy may, therefore, provide an alternate modality in the treatment of prostate cancer and may be especially efficacious in the treatment of metastatic disease.

Targeted exon skipping as a promising therapeutic tool for Duchenne muscular dystrophy. *J.C.T. Van Deutekom¹, A. Aartsma-Rus¹, M. Bremmer-Bout¹, J.A.M. Janson¹, W.E. Kaman¹, E.J De Meijer¹, F. Baas², J.T. Den Dunnen¹, G.J.B. Van Ommen¹.* 1) Dept Human Genetics, Leiden Univ Medical Ctr, Leiden, Netherlands; 2) Dept Neurology, Academic Medical Ctr, Amsterdam, Netherlands.

Duchenne muscular dystrophy (DMD) is a lethal muscle disease typically caused by frame-shifting mutations in the DMD gene that abort the synthesis of the dystrophin protein. In contrast to the gene therapy studies that are based on gene replacement, we are focusing on gene correction through the targeted modulation of the splicing of the patient-specific gene. Using antisense oligoribonucleotides (AONs) directed to exon-internal sequences, we aim to induce the specific skipping of a target exon in order to generate a shorter, but in-frame transcript similar to those found in the corresponding Becker muscular dystrophy (BMD) patients, having milder phenotypes and longer life expectancies. We have recently demonstrated the feasibility of AON-induced skipping of 15 different exons within the deletion hot spot regions. In this study we show the broad therapeutic applicability of skipping these exons in cultured muscle cells from DMD-patients affected by different mutations. In fact, through the AON-mediated production of novel, in-frame transcripts, we detected dystrophin synthesis in at least 70% of treated muscle cells. We here also show the in vivo feasibility of targeted exon skipping in mouse muscle tissue. Following intramuscular injections of mouse-specific exon 46 AONs, we were able to specifically induce exon 46 skipping in a dose-dependent manner. In a subsequent time-series experiment, the skipping effect was highest at 12 days post-injection with estimated efficiencies of 20% of total RT-PCR products, and, although gradually diminishing, continued for at least 29 days. Moreover, using DMD humanized transgenic mice carrying an integrated 2.7 Mb YAC-derived copy of the human DMD gene, we were able to test human sequence-specific AONs, and induce the skipping of human DMD exons, in an experimental mouse background. Our results confirm the therapeutic potential of AON-induced exon skipping, and contribute to its further development for DMD gene therapy.

Targeted transgene expression to the airway epithelia by helper-dependent adenovirus mediated gene transfer.

*G. Toietta*¹, *D.R. Koehler*², *M.J. Finegold*³, *B. Lee*¹, *J. Hu*², *A.L. Beaudet*¹. 1) Dept. of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Programme of Lung Biology Research, The Hospital of Sick Children, Toronto, Ontario, Canada; 3) Dept. of Pathology, Baylor College of Medicine, Houston, Texas, United States.

In this study we have evaluated the possibility of targeting transgene expression to the airway epithelium using helper-dependent adenoviral (HD-Ad) mediated gene transfer. We have taken advantage of an expression cassette developed for targeting transgene expression in airway epithelia and submucosal glands and used it to express transgenes in HD-Ad vectors. This expression cassette contains epithelium-specific control elements from the human cytokeratin 18 gene (K18). In order to evaluate the transduction efficiency and the level of transgene expression of HD-Ad vectors, we focused our attention on two reporter genes: one encoding a nuclear localized β -galactosidase and the other encoding the human α -fetoprotein (hAFP), a marker with potential to be used in human clinical trials due to its lack of immunogenicity. Therefore two HD-Ad vectors, one expressing NLS-LacZ and one expressing hAFP under the K18 regulatory elements were constructed (HD-Ad K18-NLSLacZ and HD-Ad K18-hAFP). Specific X-gal staining indicating expression in bronchiolar epithelium was observed three days after intranasal administration of HD-Ad K18-NLSLacZ at a dose of 5×10^{12} viral particles/kg in C56BL/6J mice. Specific epithelial expression was further confirmed by hAFP lung immunohistochemistry in mice treated with an equal dose of HD-Ad K18-hAFP. Moreover, strong hAFP expression was observed in both bronchioalveolar lavage (BAL) fluid and sera of treated mice for up to 15 weeks. Mice treated with both HD-Ad vectors did not show any severe airway inflammation as indicated by histological analysis of lung tissues. Moreover, the treatment was not associated with changes in liver function tests or thrombocytopenia. The encouraging results obtained with both the nuclear localized reporter and the secreted marker represent the basis for developing other vectors for expressing therapeutic transgenes.

Expressed multimeric hammerhead ribozymes self-cleave to monomers and abolish mutant collagen transcripts in an osteoblast model of osteogenesis imperfecta. *R. Wenstrup¹, J. Florer¹, G. Wu², I. Toudjarska³, Y. Smicum³, M.W. Kilpatrick³, P. Tsipouras³.* 1) Children's Hospital Research Foundation, Cincinnati OH; 2) Department of Medicine, University of Connecticut Health Sciences University, Farmington CT; 3) Department of Pediatrics, University of Connecticut Health Sciences University, Farmington CT.

Osteogenesis imperfecta (OI) is a heritable disorder of connective tissue whose cardinal manifestation is bone fragility. Severe variants of OI are due to dominant negative effects of mutations that do not exclude mutant chains from type I collagen molecules, a fact that must be taken into account in all strategies aimed at correcting the collagen defects in OI individuals. Antisense hammerhead ribozymes are small catalytic RNA molecules that can be targeted to any RNA molecule containing a putative cleavage site, and are thus applicable to the selective elimination of mutant gene products. RZ5-47 encodes a ribozyme designed to selectively target a truncated COL1A1 transcript stably expressed in MC3T3-E1 osteoblasts, a cellular model of OI. An expression gene containing a human COL1A1 promoter, RZ5-47 sequence, and a zeomycin resistance cassette was stably transfected into MC3T3-E1 cells; RZ5-47 was efficiently expressed and translocated to the cytoplasm. However, cleavage of mutant transcripts was equivocal, possibly due to relatively high rates of intracellular degradation of the ribozyme, as evidenced by ribonuclease protection assays (RPA) after incubations with and without cycloheximide. Subsequently, a multimeric ribozyme expression gene (M8RZ5-47) was constructed containing 8 tandemly arranged monomeric ribozyme coding sequences, with a 3' cis cleavage site. Stable transfection of M8RZ5-47 in MC3T3-E1 cells resulted in high titers of ribozyme. RPA using a multimeric ribozyme protection fragment showed self cleavage of octamers to derivative fragments. Transcripts from the mutant minigene, previously highly expressed, were completely abolished. These data demonstrates the intracellular capacity of hammerhead ribozymes to selectively cleave a target. It raises interesting possibilities for their use as therapeutic agents.

Targeted LacZ gene correction experiments in Chinese hamster ovary cells. *R.M.W. Hofstra¹, P.H.L. Schuilenga-Hut¹, M.F. Jonkman², J.P. de Boer¹, M. Nijenhuis², G. van der Steege², C.H.C.M. Buys¹, H. Scheffer¹.* 1) Medical Genetics, University of Groningen, Groningen, The Netherlands; 2) Dermatology, University Hospital of Groningen, Groningen, The Netherlands.

An increasing number of publications on gene correction has appeared in recent years. Most if not all describe the use of oligonucleotides. We have validated different methods by episomal correction of pCH110 LacZ 1651G>A in CHO-k1 cells. We failed to detect any repair of LacZ using RNA/DNA oligonucleotides, but could achieve episomal repair of at least one mutant pCH110 LacZ 1651G>A plasmid in 27% of the transfected CHO-k1 cells by using either a single-stranded or a double-stranded DNA fragment of 509 oligodeoxynucleotides. However, the percentage of corrected plasmids pooled from the corrected and uncorrected cells of the culture dish was only about 0.03%. Presence of a signature (a second silent mutation) in the corrected plasmids confirmed that the nucleotide correction was indeed achieved by means of the introduced 509 nucleotides DNA fragments. We could further optimise the repair efficiency using longer DNA fragments. With fragments of 2557 bp, 47% of the transfected CHO-k1 cells showed repair. With ODN, different kinds of mutations could be repaired, including substitutions, small insertions and small deletions. Making use of repair fragments containing five silent mutations, we showed that a region up to 165 bp can be involved in the repair process.

Inherited disorders in Amish & Mennonite Demes of Pennsylvania. *D.H. Morton¹, K.A. Strauss¹, E.G. Puffenberger¹, D.L. Robinson¹, R.I. Kelley^{1,2}.* 1) Clinic for Special Children, Strasburg, PA; 2) Kennedy Krieger Institute, Johns Hopkins, Baltimore, MD.

The Clinic for Special Children in Lancaster County PA is a non-profit medical clinic for Amish & Mennonite children who have genetic disorders. We see 38 Amish & 23 Mennonite disorders. Founder genes & drift: Most of the 61 disorders arise from mutations introduced by founders between 1700-1850 but present day disease expression rates vary. For 14 of 61 disorders, disease incidences are 1/400-500 births & carrier rates are 7-12%. More commonly disorders are clustered in a few families & disease incidence is lower. Diseases also have been excluded by drift e.g. cystic fibrosis is not seen in the Plain People of Lancaster Co. but is found in other demes. Because of different founders & a 400-year separation of the Amish & Mennonite churches, few disorders are common to both populations. Diagnosis: Most of these disorders are diagnosed by history, examination, & one laboratory test: By examination alone 13/61; Amino acid analysis 4; Organic acid analysis GC/MS 8; mutation analysis 18. Neonatal screens by tandem mass spectrometry are done routinely for 11/61 by Neo Gen, Pittsburgh. Genetic lesions are unknown for 18 disorders: 8 will be studied by candidate gene sequencing, 10 others will require linkage studies. Natural history, medical care & biology: Each disorder presents an array of clinical problems that influence disease severity. Diagnosis & management of such problems is medically important. 11/61 are lethal or invariably cause full disability. Identification of the underlying gene mutation has seldom provided insight into phenotypic diversity. Descriptions of mutations in branched chain keto acid dehydrogenase did not explain mental retardation, acute encephalopathy & brain edema of maple syrup disease. The biology of this disease can only be explained by the effects of abnormal leucine concentrations upon brain amino acid metabolism & cell volume regulation and by study of catabolic intoxication provoked by illnesses & fasts. Origins of phenotypic diversity will be most apparent to physicians who care for patients & are interested in pathophysiology & biology.

Generation of GFAP transgenic mice expressing lysosomal neuraminidase and protective protein/cathepsin A. G. Yogalingam, T. Walker, L. Mann, J. Raucci, G.C. Grosveld, A. d'Azzo. Dept Genetics, St Jude Children's Research Hospital, Memphis, TN.

Lysosomal N-acetyl-a-neuraminidase (NEU1) initiates the hydrolysis of oligosaccharides, gangliosides, glycolipids and glycoproteins by catalyzing the removal of their terminal sialic acid residues. NEU1 acquires its active and stable conformation in lysosomes by associating with the serine carboxypeptidase protective protein/cathepsin A (PPCA). Sialidosis is caused by mutations in the *Neu1* locus. The disease is systemic affecting both visceral organs and the nervous system. Knockout *Neu1*^{-/-} mice completely lack neuraminidase activity and manifest a phenotype similar to type II sialidosis. To design effective gene therapy strategies, particularly for the central nervous system (CNS) pathology, it is essential to identify the regions and cell types in the brain that have the greatest requirement for neuraminidase. We have generated transgenic mice that contain *NEU1* and *PPCA* gene sequences under the transcriptional control of an astrocyte-specific human glial fibrillary acidic protein (GFAP) promoter fragment (GNIP). In this study we describe one founder in which the GNIP transgene had integrated as head-to-tail concatamers in two independent sites; positions 7A3-BI and 14D2-3 respectively. The two transgenic alleles that were present in this original founder were segregated in subsequent matings and shown via Southern blot analysis to contain high and low copy numbers of the transgene (high TG and low TG, respectively). In low TG mice transgene expression was localized to the brain at normal levels. An unexpected and interesting finding in high TG mice was the high expression of NEU1 and PPCA transgene proteins in all tissues analyzed, including brain, liver, spleen, heart, kidney and lung. Enzyme activity measurements, Western blot analysis and immunohistochemical analysis of high TG and low TG mice will be presented. We are currently analyzing new GFAP transgenic lines. Appropriate transgenic lines are being crossed into the knockout *Neu1*^{-/-} background to determine the extent of correction of CNS pathology. (Supported in part by NIH grants DK-52025 and GM-60950).

Enzyme Replacement Therapy in Fabry Disease: Long Term Safety and Efficacy Update on a Phase 3 Study. W. Wilcox¹, D.P. Germain², M. Banikazemi³, P. Lee⁴ and Intl Fabry Study Group. 1) Cedars-Sinai Med Ctr; 2) Hôpital Européen Georges Pompidou; 3) Mt.Sinai Sch.of Med; 4) Natl Hosp. for Neurology/Neurosurg.

Fabry disease results from deficient activity of α -galactosidase A (α -GalA) and subsequent accumulation of neutral glycosphingolipids, predominantly globotriaosylceramide (GL-3). Based on results of a Phase 1/2 clinical trial (Eng et al. *Am.J.Hum.Genet.*, 68:711, 2001), a Phase 3 multicenter, multinational, randomized, double-blind, placebo-controlled trial was conducted with 58 classically affected patients receiving 1 mg/kg of recombinant human α -GalA (r-haGal, Fabrazyme®, Genzyme Corp.) every 2 weeks for 20 weeks. All 58 patients were subsequently treated with Fabrazyme in an ongoing open-label extension study for an additional 18 months. GFR has remained stable after 18-24 months of Fabrazyme treatment in the studies; average serum creatinine levels have remained stable and within the normal range during the same period of Fabrazyme treatment. Overall improvement in pain scores, assessed with the Short Form McGill Pain Questionnaire, was sustained throughout the period during which patients received Fabrazyme treatment. As expected, at the 18-month assessments, 52/58 patients (90%) IgG seroconverted; 44/52 (85%) seroconverted within 3 months of Fabrazyme treatment. This rate of early IgG seroconversion has not impacted efficacy: GL-3 reduction is maintained in multiple renal cell types examined by histopathology at up to 12 months of Fabrazyme treatment, plasma GL-3 clearance is sustained during the same period of time. Further, the majority of seroconverted patients demonstrated a four-fold or greater reduction in titer over the 18-month period. Importantly, the frequency of reactions during infusion has markedly decreased over time. This is in spite of progressive increases in the rate of administration. After 18 months of open-label treatment with Fabrazyme, 50/58 (86%) patients completed one or more complete infusions of Fabrazyme in \leq 2.5 hours, and 35/58 (60%) patients completed one or more complete infusions of Fabrazyme in \leq 2.0 hours. In summary, long-term therapy with Fabrazyme continues to demonstrate a favorable safety and efficacy profile.

Replagal in the home setting, Fabry Disease experience in the United Kingdom. *J. Stephenson, T. Hayward, G. Jones.* Healthcare at Home Ltd, Burton-upon-Trent, England.

Introduction Diagnosis of a lysosomal storage disorder can mean a lifetime of therapy. Due to lack of clinical specialists within this area, patients travel long distances for review and treatment. Difficulties of travel, associated time commitment, and limited hospital resources, impact on the quality of life of the patient and their family.

Aims The patient should be the primary manager of their chronic disease (Mellins et al 2000). Practitioners and patients should work as partners - developing strategies that give the patient the best chance to manage their disease, thereby reducing the physical, psychological, social and economic consequences of chronic illness (NIH Publication, 1997). By training patients to infuse at home, Healthcare at Home is working towards the restoration of an independent lifestyle, with an associated increase in quality of life for the patient and their family.

Methods Viewing the patient as an individual with specific needs and expectations, appreciating the uniqueness of personality, social background and experience of life (Charles-Edwards, 1983), the nurse devises a personalized training plan. The ultimate outcome being competency in the infusion process - confirmed by a pre-defined assessment tool, as approved by the multi-disciplinary team.

Results Of 145 patients diagnosed with a lysosomal storage disorder referred to Healthcare at Home over a four year period, 114, ie 79%, have been deemed competent in cannulation, reconstitution and infusion of medication at home.

Conclusions Home treatment is more convenient for the patient and their family, and can be integrated into normal daily routine. Self-administration of medication has been shown to increase self-esteem and independence (Edwards, 1995). Successful home infusion is only possible through teamwork. It is only by involving the whole team that we may afford the patient and their family the best possible care that we give (Fallowfield, 1995).

Rationale and Development of a Functional Disability Outcomes Measure for MPS I. *A.M. Skrinar, G.F. Cox.*
Genzyme Corporation, Cambridge, MA.

Mucopolysaccharidosis Type I (MPS I) is an autosomal recessive disorder caused by a deficiency of the lysosomal enzyme alpha-L-iduronidase, which is required for the breakdown of glycosaminoglycans. The progressive accumulation of glycoaminoglycans causes clinical symptoms in many organ systems, including neurologic, respiratory, cardiovascular, skeletal, gastrointestinal, ocular, and auditory. The spectrum of MPS I-related symptoms leads to functional impairment in activities of daily living, particularly in mobility and self-care domains. No single comprehensive instrument exists to assess functional disability in MPS I patients. Specific instruments have been developed to assess the various individual clinical manifestations that can occur in MPS I disease, e.g. sleep apnea, respiratory disease, and mobility impairment. However, most were developed for use as discriminative instruments to distinguish between patients at one point in time rather than as evaluative instruments to measure differences within patients over time. Consequently, these instruments lack the sensitivity to detect meaningful clinical changes in outcomes resulting from intervention. Ceiling and floor effects may further limit the responsiveness of these instruments when the content lacks sufficient breadth to capture the wide range of functional disabilities observed in a disease such as MPS I. To overcome these limitations, we seek to develop a functional disability outcomes measure for MPS I. Patients and medical experts have been interviewed to identify domains of functional disability and to characterize specific functional limitations associated with MPS I. This information will be used to generate an initial item pool to be presented to additional patients to ensure the relevance and responsiveness of the items to the broader MPS I population. Item responses will be analyzed and revised as part of an iterative process to establish the reliability and validity of the instrument. A scoring system will be developed to increase interpretability. The MPS I questionnaire will ultimately be used to establish the burden of illness in a patient registry setting and to assess the effect of future treatments on functional disability in a clinical trial setting.

Correction of fatty acid oxidation in CPT2-deficient fibroblasts by fibrates. *J. Bastin¹, J.P. Bonnefont¹, L. Thuillier², V. Droin², N. Khadom¹, A. Munnich¹, F. Djouadi¹.* 1) INSERM U393, Hopital Necker, Paris, France; 2) Service de Biochimie B, Hopital Necker, Paris, France.

Carnitine Palmitoyl Transferase 2 (CPT2) deficiency is among the most common inherited diseases of mitochondrial fatty acid β -oxidation (FAO). Clinical phenotypes range from mild adult forms with myalgia and rhabdomyolysis to severe neonatal forms with liver failure and cardiomyopathy. It has been suggested that the severity of the disease is related to the residual enzyme activity and FAO capacity. For this reason, we hypothesized that fibrates, which can stimulate mitochondrial β -oxidation, could have beneficial effects on FAO in CPT2-deficient cells. Bezafibrate, fenofibrate, ciprofibrate, or gemfibrozil were added for 3 days in culture medium of mild-type CPT2-deficient fibroblasts, at concentration ranging from 50 to 800mM, and the oxidation rate of 3H-Palmitate (3H-Pal) was measured. Bezafibrate (BZ) induced a dose-dependant increase in 3H-Pal oxidation, with maximal effects at 800mM (3.3 ± 0.3 nmol 3H-Pal/h/mg prot vs 1.8 ± 0.2 in untreated cells; $p < 0.001$), leading to restore normal values. Other fibrates tested had no significant effects. Antimycin added to BZ-treated cells completely blocked 3H-Pal oxidation, demonstrating that 3H-Pal was entirely oxidized through the mitochondrial β -oxidation pathway. Kinetic studies run from 2h to 72h using 800mM BZ demonstrated significant increases in 3H-Pal oxidation rate starting from 6h, with maximal effects reached at 24h. Finally, we showed that BZ treatment (800mM) resulted in a 48% increase in residual CPT2 enzyme activity in deficient fibroblasts. Correction of 3H-Pal oxidation by BZ was confirmed in fibroblasts of three other patients diagnosed with mild CPT2 deficiency. However, BZ failed to increase 3H-Pal oxidation in fibroblasts from patients with severe CPT2 deficiency. These data demonstrate that pharmacological approaches based on stimulation of residual capacities can in some cases successfully restore mitochondrial FAO in fibroblasts of CPT2-deficient patients. BZ is a ligand of the peroxisome proliferator activated receptor (PPAR), and probably acts by stimulating cellular CPT2 gene expression.

a- and b-sarcoglycan delivery by recombinant adeno-associated virus: efficient rescue of muscle, but differential toxicity. *D. Dressman*^{1,2}, *K. Araishi*³, *M. Imamura*³, *T. Sasaoka*³, *L.A. Liu*⁴, *E. Engvall*⁴, *E.P. Hoffman*^{1,2}. 1) Center for Genetic Medicine, CNMC, Washington, DC; 2) University of Pittsburgh, Department of Molecular Genetics & Biochemistry, Pittsburgh, PA; 3) National Institute of Neuroscience, NCNP, Tokyo, Japan; 4) Burnham Institute, La Jolla, CA.

The sarcoglycanopathies are a group of four autosomal recessive muscular dystrophies (LGMD 2D, 2E, 2C, and 2F), caused by mutations of the a, b, g, or d sarcoglycan genes. The d-sarcoglycan deficient hamster has been the most utilized model for gene delivery to muscle by recombinant adeno-associated virus (AAV) vectors, however human patients with d-sarcoglycan deficiency are exceedingly rare with only two patients described in the United States. Here, we report construction and use of AAV vectors expressing either a- or b- sarcoglycan, the genes responsible for the most common forms of the human sarcoglycanopathies. Both vectors showed successful short-term genetic, biochemical and histological rescue of both a- and b-sarcoglycan deficient mouse muscle. However, comparison of persistence of expression in 51 injected mice showed substantial differences between AAV a-sarcoglycan (a-SG) and b-sarcoglycan (b-SG) vectors. AAV b-SG showed long-term expression with no decrease in expression for over 21 months after injection, while AAV a-SG showed a dramatic loss of positive fibers between 28 days and 41 days post-injection ($p=0.006$). Loss of immuno-positive myofibers was correlated with significant inflammatory cell infiltrate, primarily macrophages. To determine if the loss of a-sarcoglycan positive fibers was due to an immune response or cytotoxic effect of a-sarcoglycan over-expression, SCID mouse muscle was assayed for cytotoxicity after injection with AAV a- SG, AAV b- SG, or PBS. The results were consistent with over-expression of a-sarcoglycan causing significant cytotoxicity. The cytotoxicity of a-sarcoglycan, and not b- or d-sarcoglycan over-expression, was consistent with biochemical studies of the hierarchical order of assembly of the sarcoglycan complex. Our data suggests that even closely related proteins might require different levels of expression to avoid toxicity and achieve long-term tissue rescue.

Immunostimulatory Properties of Dystrophic Muscle Alter Persistence of Transgenes. *E.P. Hoffman*^{1,2}, *H. Gordish*³, *K. Araishi*⁴, *M. Imamura*⁴, *T. Sasaoka*⁴, *D. Dressman*^{1,2}. 1) Research Center for Genetic Medicine, Children's National Medical Center, Washington, DC; 2) University of Pittsburgh, School of Medicine, Department of Molecular Genetics & Biochemistry, Pittsburgh, PA; 3) University of Pittsburgh, Graduate School of Public Health, Department of Environmental and Occupational Health, Pittsburgh, PA; 4) National Institute of Neuroscience, NCNP, Tokyo, Japan.

Inherited biochemical deficits in patients with muscular dystrophy result in cycles of degeneration and regeneration of myofibers. Complementation of the biochemical deficiency in myofibers has been the major focus of experimental gene delivery in animal models of dystrophin and sarcoglycan deficiency. Recombinant adeno-associated virus (AAV) has been shown to deliver genes to mature normal muscle with long-term persistence, although persistence in dystrophic muscle has been more variable. We hypothesized that the degeneration/regeneration cycles and immune cell infiltrate in dystrophic muscle could be immunostimulatory, leading to increased immune response to a transgene relative to normal muscle. To test this hypothesis, we delivered both marker (b-galactosidase) and therapeutic genes (b-sarcoglycan) to dystrophic muscle and to normal muscle using identical AAV vectors. We show that dystrophic muscle does indeed elicit a stronger immune response to b-galactosidase, than normal muscle, showing both greater circulating antibodies ($p < 0.05$) and greater loss of transduced fibers ($p < 0.05$). Co-delivery of marker and therapeutic AAV attenuated the immune response ($p < 0.05$), despite the use of twice as much AAV. Our results show that pathological muscle is immunostimulatory towards transgene-delivered proteins, leading to decreased persistence after AAV delivery. However, biochemical rescue of myofibers by a therapeutic transgene can attenuate this immune response, and in most cases leads to immunotolerance and long-term survival of transduced fibers.

Valproic acid increases SMN levels in spinal muscular atrophy fibroblasts. *J.A. Markowitz¹, D.D. Coover², K. Schussler², A.H.M. Burghes^{2,3}, K.H. Fischbeck¹, J.P. Taylor¹.* 1) National Institute of Neurologic Diseases and Stroke, Neurogenetics Branch, Bethesda, MD; 2) Dept. of Molecular Genetics, College of Biological Sciences, Ohio State University, Columbus, OH; 3) Dept. of Medical Biochemistry, Dept. of Neurology, College of Medicine, Ohio State University, Columbus, OH.

Spinal muscular atrophy (SMA) is a severe autosomal recessive form of motor neuron disease caused by mutations leading to inadequate levels of survival motor neuron (SMN) protein. The SMN gene is normally duplicated on chromosome 5, with a telomeric copy (SMN1) that produces most functional SMN, and a centromeric copy (SMN2) that produces mainly mRNA lacking the penultimate exon. Most SMA patients harbor homozygous deletions in SMN1, limiting them to the small amount of full-length SMN produced by SMN2. Decreased SMN is associated with a decrease in the number of structures called gems formed by SMN in cell nuclei. Since the level of SMN protein is inversely correlated with phenotypic severity, agents that upregulate SMN2 expression might mitigate the severity of disease. We investigated the effects of histone deacetylase (HDAC) inhibitors on SMN transcription. Valproic acid, an approved anticonvulsant and mood stabilizer, has recently been identified as an HDAC inhibitor. We studied the effects of treatment with valproic acid on fibroblast lines from patients with SMA. Cells treated with 0.5 to 2 mM valproic acid showed increased SMN protein relative to untreated fibroblasts by Western blot. The same doses of valproate were associated with increased full-length SMN mRNA, ranging from 1.5 to 4 times untreated levels. Fibroblasts treated with 2 to 20 mM valproic acid for five days showed an increased number of intranuclear gems to several times the untreated gem number. We are currently exploring the effects of valproate in an SMA mouse model and planning in vivo studies of the effect of valproic acid on SMN expression in SMA patients. Since the doses we used overlap the range of clinically achievable serum levels, valproic acid may have therapeutic potential in SMA.

Upregulation of SMN2 gene expression by 4-phenylbutyrate: relevance for a therapeutic approach to spinal muscular atrophy. *F.D. Tiziano¹, C. Andreassi¹, C. Angelozzi¹, T. Vitali¹, E. De Vincenzi¹, A. Boninsegna², M. Villanova³, G. Neri¹, C. Brahe¹.* 1) Institute of Medical Genetics, Catholic University, Rome, Italy; 2) Institute of General Pathology, Catholic University, Rome, Italy; 3) Casa di Cura Nigrisoli, Bologna, Italy.

Spinal muscular atrophy (SMA) is an autosomal recessive neurodegenerative disorder caused by the absence of the survival motor neuron gene (SMN1) resulting in an insufficient level of the SMN protein. All patients retain at least one, usually more, copies of the SMN2 gene which produces only small amounts of functional SMN protein due to alternative splicing. Recently, data obtained in a SMA mouse model and our own independent preliminary studies have suggested that sodium butyrate could increase the synthesis of the SMN protein. We have performed a preclinical study on primary fibroblast cultures from SMA patients aimed at determining optimal conditions for stimulating SMN2 gene expression. We used 2mM 4-phenylbutyrate (4PBA) which, in contrast to sodium butyrate, showed no apparent toxic effect on cell cycle progression. Using real time PCR technology, we found that treatment with 4PBA resulted in an increase in full length SMN2 transcripts in all cell cultures except one. The maximum extent of increase in SMN2 expression varied among the different cultures and incubation times (4-16 hrs), ranging from 71% up to 350% (average: 180%) compared to untreated cultures. SMN protein expression, evaluated as number of SMN positive dot-like nuclear structures (gems), was also increased up to 2-3 fold by 4PBA treatment. Furthermore, we found that the increase in full length transcripts was not due to a reduction of the alternatively spliced form (lacking exon 7), indicating that 4PBA induces upregulation of the SMN2 gene(s) probably through its hyperacetylating activity. These results suggest that 4PBA, which is FDA approved, could be beneficial for SMA patients and will be useful for designing a therapeutic protocol.

Identification of hnRNP-G as a novel trans-factor that promotes inclusion of the alternatively spliced exon 7 of SMN2 as a basis for therapy in patients with spinal muscular atrophy. *B. Wirth, Y. Hofmann.* Dept Molecular Genetics, Inst Human Genetics, Bonn, Germany.

Proximal spinal muscular atrophy (SMA) is a common motorneuron disease caused by homozygous loss of the survival motor neuron gene (SMN1). A nearly identical copy of the gene, SMN2, fails to provide protection from SMA due to the disruption of an exonic splicing enhancer (ESE) by a single silent nucleotide exchange, which causes alternative splicing of SMN2 exon 7. Identification of splicing factors that stimulate exon 7 inclusion and thereby produce sufficient amounts of full-length SMN2 from the remained copy gene is of great importance for somatic gene therapy approaches. Here, we identify the protein hnRNP-G as a novel trans-acting splicing factor that directly binds to SMN RNA regardless of a particular RNA binding motif, and promotes the inclusion of SMN2 exon 7 in a dose-dependant manner. Moreover, hnRNP-G interacts in vivo with Htra2-b1, an SR-like splicing factor which we have previously identified to stimulate inclusion of exon 7 through a direct interaction with the AG-rich ESE in SMN2 exon 7 pre-mRNA. By use of deletion mutants of hnRNP-G we show that the interaction of hnRNP-G with Htra2-b1 rather than that of hnRNP-G with SMN pre-mRNA mediates the ESE-dependant inclusion of SMN2 exon 7. Through this assembly of hnRNP-G and Htra2-b1 on SMN pre-mRNA to a functional complex, the hnRNP protein stabilizes the SR-like protein and enhances/modulates SMN2 exon 7 inclusion. Thus, beside the overall involvement of hnRNP proteins during pre-mRNA processing, a specific function of hnRNP-G during pre-mRNA splicing can be described here for the first time. Additionally, we show for the first time that the influence of recombinant trans-acting splicing factors such as hnRNP-G and Htra2-b1 is also effective on endogenous SMN2 transcripts and increases the endogenous SMN protein to high levels.

Molecular mechanisms in chronic rejection of renal allografts. *J. Chen*¹, *M. Yang*¹, *B. Zerlanko*¹, *J.A. Tischfield*¹, *R.M. Jindal*², *A. Sahota*¹. 1) Genetics, Rutgers University, Piscataway, NJ; 2) Surgery, University of Glasgow, United Kingdom.

Advances in immunosuppressive therapy and surgical techniques have made kidney transplantation a routine procedure in most countries. One-year allograft survival rates range from 80% for cadaveric and up to 95% for living related donors (LRD). However, these advances have had little impact on chronic rejection (CR), which remains the major cause of graft loss. A wide variety of cytokines, chemokines, and growth factors have been implicated in CR but the cascades of events that eventually result in graft dysfunction are not fully understood. We used Affymetrix HG-U95A v.2 GeneChips to identify genes that are differentially expressed in CR. Data analysis tools (GeneSpring 4.2.1) were then used to organize the identified genes into functional clusters. In this preliminary study, we investigated gene expression changes in samples from transplanted kidneys that were removed from three patients because of CR. One was a cadaver transplant and the other two were LRD. The control samples were from unrelated donor kidneys pre-transplant (two cadaveric and two LRD). Experimental clustering demonstrated that gene expression profiles in the two pre-transplant LRD kidneys were remarkably similar, but markedly different from the two cadaveric donor kidneys. This may be due to the trauma associated with handling cadaveric organs and it may partly explain the lower long-term survival rates for these organs. The three kidneys removed because of CR were closely grouped with the cadaver kidneys. Fas was consistently expressed at high levels in CR. Fas, upon binding to Fas ligand, induces apoptosis, suggesting the involvement of the Fas/FasL pathway in CR. Another 201 genes functionally clustered with Fas with a correlation coefficient of 0.95. On the other hand, 128 genes (including PDGF and TGFb) were down regulated in CR. Further analyses of gene expression changes in renal biopsies or blood samples from transplant patients may identify subsets of genes that may serve as surrogate markers for the early diagnosis of CR.

Adenoviral Rescue of Mice Deficient for Succinate Semialdehyde Dehydrogenase (SSADH; ALDh5a1^{-/-}). *M. Gupta¹, M. Callan¹, H. Senephansiri¹, B.M. Hogema^{1,2}, C. Jakobs², M. Grompe¹, K.M. Gibson¹.* 1) Molecular and Medical Genetics, Oregon Health & Science University, Portland, OR, USA; 2) Metabolic Unit, Dept Clin Chem, VU Med Ctr, Amsterdam, Netherlands.

SSADH deficiency (OMIM 271980), presenting as gamma-hydroxybutyric (GHB) aciduria, is a rare autosomal recessive defect of GABA degradation featuring non-specific neurological manifestations including psychomotor and language delays, and epilepsy. Aldh5a1^{-/-} knockout mice manifest a similar phenotype but die in the first month of life from repetitive tonic-clonic seizures. Previous work demonstrated that mutant mice could be pharmacologically rescued with the antiepileptic vigabatrin, CGP 35348 (a GABA_B receptor antagonist), NCS-382 (a GHB receptor antagonist), and the non-protein amino acid taurine. Aldh5a1 is highly expressed in liver; thus, we hypothesized that adenovirus administration (i.p.) directed towards liver could rescue mice from premature death. Plasmid pAd:RSV (kindly provided by Dr. B. Fang) was derived from pCX1 and substituted with Aldh5a1 E1 sequences, driven by an RSV promoter with BGH poly A tail. Following co-transfection into 293 cells with adenovirus plasmid pJM17, an E1 defective recombinant Adv-pAd:RSV:Aldh5a1 was generated via homologous recombination. Aldh5a1^{-/-} mice were injected i.p. with 10⁸ pfu at day 0 or 10 post-natal. Survival to day of life 30 was scored as significant. Seven of 18 injected mice survived (39%; p<0.001). Limited analysis of mice injected at day 0 revealed similar results (1/3 survivors; 33%). Despite lowered body weight, treated mice appeared healthy. Aldh5a1 enzyme activity from liver (harvested at day of life 35-50; day 10 injected animals only) was undetectable, most likely related to temporal loss of expression. Hepatic correction of Aldh5a1 deficiency may represent a new approach for treatment of inherited SSADH deficiency, historically considered a predominantly neurometabolic disorder. Supported by NIH NS40270 and March of Dimes #1-FY00-352.
