

Cytogenetic and molecular aberration data for oncogenetic data analysis projects. *M. Baudis*. Pediatrics, University of Florida, Gainesville, FL.

Main targets in the analysis of cytogenetic abnormalities in human malignancies are 1. identification of "hot spots" as presumptive loci of genes involved in neoplastic transformation and growth, and 2. identification of genomic markers aiding in differential diagnosis and prognostic prediction. Whereas banding analysis of tumor metaphase spreads has led to groundbreaking insights in oncogenetic mechanisms, metaphase and interphase based DNA hybridization techniques (FISH, CGH, mFISH, SKY) have increasingly been applied over the last decade. Currently, genomic array technologies gain in popularity due to the combination of high spatial resolution, independence from fresh tumor tissue, possible complete genome coverage and supposedly high automatization potential. For combining different types of genomic screening data, experimental readouts have to be reduced to information atoms, representing the status of a given interval (chromosomal band or genomic map). For the Progenetix database project (www.progenetix.net), evaluation software for ISCN 1995 conform karyotype and CGH annotations has been developed. As example for the integration of available data sources, 715 breast adenocarcinomas from the Mitelman database and 350 cases analyzed by CGH from Progenetix were compared using two-sided Kolmogorov-Smirnov test and correlation analysis, showing unequivocal similarity in the chromosomal deletion patterns.

Initially developed as a collection of data from published CGH projects, the Progenetix database has become a general repository for supervised genomic aberration data. Besides chromosomal band based annotations, the current evolution of array based CGH variants from proof of concept status to reference screening methods has warranted the development of a general data exchange format based on genomic intervals. Here, the draft version of an XML based data exchange format will be presented. A unified format for genomic aberration data will support data mining efforts aimed at the identification of genomic hot spots and disease specific aberration patterns, and simplify the integration with results from expression array experiments for the identification of relevant target genes.

Small upstream deletions of *ABL1* are rare in Chronic Myelogenous Leukemia. *A.M. Marion*¹, *P.K. Rogan*¹, *W. Flejter*², *D. Persons*³, *J. Cowan*⁴, *J.H.M. Knoll*¹. 1) Children's Mercy Hospital, University of Missouri-Kansas City; 2) Esoterix Oncology, Brentwood, TN; 3) Kansas University Medical Center, Kansas City; 4) Tufts-New England Medical Center, Boston, MA.

Many chronic myelogenous leukemia (CML) patients with poor prognoses have large chromosome 9 deletions upstream of *ABL1* that extend at least 450 kb and encompass at least 4 genes (*ASS*, *FBP3*, *PRDM12*, *RRP4*). We hypothesized that some other CML patients might exhibit smaller deletions which are not detectable with the commercial FISH probe that spans all of these loci. A dense array of short single copy (sc) FISH probes (1272 - 3965 bp in length) was developed directly from the genome reference sequence for each of these genes. We validated 15 sc probes in the interval upstream of *ABL1*, an average density of 1 probe per 28 kb; and 15 probes within *ABL1*, a density of 1 per 14 kb. Probe subsets were hybridized to diagnostic cytogenetic preparations from 71 unselected CML patients harboring t[9;22]. Six patients with large deletions were detected. FISH with sc probes from 5' *ABL1* (a 2207 bp probe that includes exon 1 of *ABL1* and 119 bp of IVS1b; and 1552 bp and 1272 bp probes derived from the middle of IVS1b) did not reveal smaller deletions in the remaining samples. We also excluded noncontiguous deletions with a 3005 bp probe from *FBP3*. Thus, we cannot attribute adverse outcomes in deletion patients to hemizyosity of particular genes in this interval. This study also localized various translocation breakage intervals within IVS1b (position 124,604,542-124,725,532; <http://genome.ucsc.edu: hg12>) of *ABL1* in non-deletion patients. Forty-five patients had a translocation breakpoint distal of coordinate 124,685,740; at least 6 patients distal of 124,604,661; 12 patients within a 26 kb region (124,604,661-124,630,536); and single individuals between 124,632,735-124,670,404 and 124,592,531-124,602,455. From these data, there appears to be preference for breakage in the COOH-terminal half of IVS1B, a finding that contrasts with published data. The *ABL1* breakage interval distributions in patients with der(9) deletions were similar to those seen in non-deletion samples, consistent with common initiation sites.

Are Meningiomas Benign Tumors: A Cytogenetics Approach. *C. Isaza¹, M.I. Escobar¹, A. Montoya², J. Sanchez³.*

1) Departamento de Morfología, Facultad de Salud, Centro de Estudios Cerebrales, Universidad del Valle; 2) Departamento de Neurocirugía, Hospital Universitario del Valle, Universidad del Valle. Instituto de los Seguros Sociales, Clínica Rafael Uribe Uribe, Cali; 3) Instituto de los Seguros Sociales, Clínica Rafael Uribe Uribe, Cali.

Objective: To demonstrate that in vitro culture of meningiomas is useful to determine cellular behavior, growth rate and karyotype; this data added to histopathology may be used to better determine prognosis and recurrence. **Materials and Methods:** Cells from 54 tumor samples taken from surgery of meningiomas in any location of the brain were cultured in vitro. The cellular growth rate was determined and karyotypes were prepared to assay for chromosomal alterations. **Results:** 52% of the meningiomas cultured successfully were not benign and were in progression having a rate of recurrence higher than 10%. **Conclusions:** Study of the cytogenetics and in vitro behavior of tumor cells may be an excellent complement to the surgical result and the pathological study, helping establish the risk of recurrence and the prognosis of the patient. **Financial Support:** Colciencias and Universidad del Valle.

Identification of genetic alterations in pediatric ependymal and embryonal central nervous system tumors by metaphase and arrays-based CGH. *M. Yoshimoto*¹, *N.S. Silva*², *J. Bayani*¹, *P.A.S. Nuin*³, *S. Cavalleiro*⁴, *J.A.D. Andrade*⁵, *M. Zielenska*⁶, *J.A. Squire*¹, *S.R.C. Toledo*^{2,5}. 1) Ontario Cancer Institute, Toronto, Ontario, Canada; 2) Instituto de Oncologia Pediátrica, São Paulo, Brazil; 3) Department of Biology, McMaster University, Hamilton, Ontario, Canada; 4) Divison of Neurosurgery, Universidade Federal de São Paulo, Brazil; 5) Division of Genetics, Universidade Federal de São Paulo, Brazil; 6) Department of Pediatric Laboratory Medicine, Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada.

Genetic investigations, primarily in medulloblastomas, have contributed significantly to our overall understanding of embryonal tumor development of central nervous system (CNS). In contrast, there is little information concerning the genetic changes in ependymomas. The main purpose of this study was to characterize genomic imbalances in pediatric embryonal and ependymal tumors by conventional metaphase-based comparative genomic hybridization (CGH). In all ependymomas CGH copy number profiles indicated that no imbalance was present. The finding of normal profiles suggests that the development of ependymomas at younger age is independent of the acquisition of copy number imbalance per se. In contrast, observed abnormal CGH profiles including gains of 16p and amplification of 5p in medulloblastomas from patients presenting with a progressive and fatal disease course. The amplified genomic region mapped to cytoband 5p15.33 with concurrent non-syntenic amplification at cytoband 2p24. This study illustrates the value of understanding the genomic mechanisms underlying pediatric CNS tumors drawn from Brazilian populations to identify novel biological markers to provide a molecular basis for future prognostic assessment. (Research supported by CAPES, Projeto Crianca e Vida and GRAACC).

Dual color break apart FISH probes: applications and limitations. *S. Adhvaryu*. Dept Pathology, Univ Texas Health Sci Ctr, San Antonio, TX.

Due to their ability to pick up variant translocations involving important loci involved in leukemia-lymphoma, the interest in use of dual color split-apart FISH probes has increased. We encountered two cases of AML that highlight limitation of using these probes on interphase nuclei. This point will be emphasized with help of following two cases:(I) A bone marrow, with a history of possible Acute Myeloid Leukemia was provisionally diagnosed as del(16)(q22). The FISH probe LSI CBF β Dual Color, Break Apart Rearrangement was used. The interphase nuclei showed normal pattern of two fusion (2F) signals. The metaphases showed one fusion signal on one chromosome 16 and the other F-signal on 3q. The abnormality was identified as 46,XX,t(3;16)(q28;q21). (II) A peripheral blood specimen was received with a diagnosis of possible Acute Pro-myelocytic Leukemia. The analysis showed a t(3;17) and a der(15), with no evidence for the typical t(15;17). FISH analysis using LSI RARA Dual Color, Break Apart Rearrangement probe was used. The analysis showed fusion signal on one 17q, whereas, the other chromosome 17 showed red and green signals separated from each other. The interphase nuclei showed abnormal pattern of one orange, one green and one fusion (1O1G1F) signals. Use of only interphase FISH could have missed detection of exact rearrangement in both the cases. Details of both the cases, including the clinical outcomes will be presented emphasizing the limitation of interphase FISH as a stand alone technique.

Genetic Instability on Benign Prostatic Hyperplasia(BPH). A. Amiel¹, I. Leibowitch^{2,3}, T. Sivan^{1,3}, M.D. Fejgin^{1,3}. 1) Genetic Institute, Meir Hospital, Kfar-Saba, Israel; 2) Department of Urology; 3) Tel Aviv University Medical School.

Genetic instability parameters like aneuploidy and replication pattern are known to be associated with pre-malignant and malignant conditions. Aneuploidy is known to be involved in prostate cancer and less in BPH. In order to assess replication and aneuploidy we applied FISH technique to BPH tissues taken from 34 men aged 51-91 (mean 72). For gene replication assay the RB-1 and 21q22 loci were used. Monosomy of chromosome Y (which has already been reported in BPH) was found in 35% of the samples. Other abnormalities found were monosomy of chromosome 7 (in 26% of the samples) and excess of chromosome X (in 6% of the samples). These last two abnormalities have been reported in prostate cancer but not in BPH. As to the gene replication assay, in both loci there was a shift from synchronized bi-allelic replication to asynchronized monoallelic replication compared to control cells ($p < 0.001$), as previously described in pre-malignant and malignant conditions. The two loci replicate earlier in the BPH tissue compared to control cells ($p < 0.05$). To conclude- Molecular cytogenetic parameters like aneuploidy and replication pattern which are known to reflect chromosomal instability, may be part of the tumor genesis process. It is possible that in BPH, the presence of genetic instability may represent the proliferative hyperplastic process and not necessarily a malignant potential.

An isolated tetrasomy 11 in a case of acute myeloid leukemia. *R. Ben Abdelali¹, H. Sennana¹, S. Ayari², H. El Ghezal¹, A. Hafsia², A. Saad¹.* 1) Laboratory of Cytogenetics, Farhat Hached Hospital, Sousse, Tunisia; 2) Hematology Department Aziza Othmana Hospital, Tunis, Tunisia.

Tetrasomy 11 as a sole chromosomal abnormality is very rare in AML and its clinical and prognosis significance remain largely unknown. In the current study we present clinical and laboratory characteristics and outcome data of de novo AML-M5 patient with tetrasomy 11 at diagnosis. Case report: A 43 year old woman was admitted because of fever and asthenia associated with cervical lymphadenopathies. Physical examination on admission revealed a pallor, signs of acute bronchitis and cervical lymphadenopathies. No hepato- or splenomegaly was noticed. Her peripheral blood count showed white blood cells 70,000/mL; hemoglobin 6.9 g/dL; and a platelet count of 110,000/mL. All of the bone marrow cells were myeloblasts of M5 morphology (FAB). At diagnosis, conventional cytogenetic analysis showed: 48,XX, +11, +11[9] / 46,XX[13]. FISH study using LSI MLL (11q23) dual color DNA probe revealed four separate fused signals in most of interphase cells, but not in any metaphase cells. The patient was treated with chemotherapy (aracytine and idarubicin). She did not respond to chemotherapy and died of sepsis occurred with pseudomonas perineal cellulite 13 days after first presentation. In a review of the literature 2 cases of tetrasomy 11 as sole cytogenetic abnormality have been reported. One of them was diagnosed with chronic myelomonocytic leukemia and the other with acute myelomonocytic leukemia. For both there is no description of clinical and hematological features. More cases are recommended for making the assessment of molecular and clinical characteristics of this chromosomal abnormality.

Co-amplification of 12q14-q21.3 and 5p14-pter in a Liposarcoma with atypical cytogenetic results. *M. Bertoni*¹, *M.J. Macera*^{2,3}, *V. Mizhiritskaya*^{2,3}, *W. Thelmo*¹, *P. Chandra*³, *A. Babu*^{2,3}. 1) Dept of Pathology; 2) Div of Molecular Medicine & Genetics; 3) Dept of Medicine, Wyckoff Heights Medical Ctr, Brooklyn, NY.

A 55 year old white male with a ten year history of sciatic pain first noticed a bump in his right flank in November 2003. He lost 40 lbs within three months, and the very rapidly growing mass caused increasingly severe pain that eventually incapacitated him. His past medical history was unremarkable. A CAT scan and MRI detected a large mass posterior from heart level to sacrum showing evidence of vertebral involvement with bone destruction. The mass could not be completely removed due to extensive involvement of the fascia. The histological diagnosis of the 21 cm x 14 cm x 6 cm mass was a liposarcoma, myxoid and spindle cell type. Clinically, however, the mass behaved very aggressively. Cytogenetic analysis showed a hyper variable chromosome complement ranging from 64 to 83 chromosomes. Most cells consistently showed several clonal abnormalities consisting of five large marker chromosomes and two ring chromosomes. CGH analysis identified high amplification of chromosome segments 12q14-q21.3(2.5 s.d.) and 5p14-pter (2.0 s.d.), and loss of segments 13q13.2-q22.2 and q31.2-qter. Metaphase FISH using whole chromosome paints of 5 and 12 (wcp5 and wcp12) showed positive labeling for both 5 and 12 paints adjacent to each other on several markers. These findings on FISH signal patterns in view of segmental amplification seen by CGH indicate that the regions 5p14-pter and 12q14-q21.3 were not only present in multiple copies but were co-amplified. One of the oncogenes, MDM2 located at 12q14-15, encodes a protein that inhibits p53 by binding and is implicated in soft tissue sarcomas. Thus the amplification of the chromosome segment 12q14-q21.3 is likely to contribute to increased MDM2 protein that overwhelms p53 regulation. The significance of co-amplification seen between 5 and 12 remains to be seen, whether it is a contributing factor or a coincident. Further molecular studies to investigate the role of chromosome 5p14-ter in this disease are under way. These results emphasize the importance of molecular cytogenetic analysis for all liposarcomas.

Multicolor karyotyping in 50 patients with acute myeloid leukemia. *G. Calabrese^{1,2}, D. Fantasia^{1,2}, P. Guanciali Franchi^{1,2}, M. De Cinque², R. Di Gianfilippo², E. Morizio², G. Perla³, G. Gentile⁴, A. Zatterale⁴, M. Marino¹, A. Spadano⁵, L. Stuppia¹, G. Palka^{1,2}, B. Dallapiccola⁶.* 1) Scienze Biomed/Genetica Medica, Univ G D'Annunzio, Chieti, Italy; 2) Genetica Umana, Ospedale Civile, Pescara, Italy; 3) Ematologia, CSS S. Giovanni Rotondo, Italy; 4) Genetica Medica, ASL 01, Naples, Italy; 5) Dip. Ematologia, Ospedale Civile, Pescara, Italy; 6) CSS-Ist.Mendel, Rome, Italy.

In acute myeloid leukaemia (AML) conventional cytogenetics is unable to establish a karyotype in 20-40% of patients. We analysed by spectral karyotyping (SKY) 40 patients suffering with AML who had a highly rearranged karyotype, i.e. over two breakpoints or at least three rearranged chromosomes, as by conventional cytogenetics. Ten more AML patients with normal karyotype by G-banding were also included in this study. In patients with highly rearranged karyotypes SKY analysis allowed to classify all undefined, or partially defined abnormal chromosomes. Using SKY approach karyotype was refined in 92,5% of patients (37/40). SKY analysis confirmed normal karyotype in the ten patients without apparent abnormalities at G-banding. We classified 41 marker chromosomes (mar), 33 partially identified chromosomes (add), four dicentric chromosomes, and eight cryptic translocations. Chromosomes 5, 7, and 17 were the most frequently rearranged being involved in 70% of cases. We redefined 83 non-specific translocations. Among these a t(5;17)(p10;p10) was observed in two patients. Moreover multicolour chromosome banding (MCB) analysis for chromosomes 5 and 11 disclosed very complex intrachromosomal rearrangements supporting known variability of chromosome-specific breakpoint location and contributing to hunt genes involved in those rearrangements. FISH analysis carried out to confirm SKY/MCB results disclosed involvement of different genes such as AML1 (11 cases), TEL (six cases), MLL (six cases), and deletion of TP53 (13 cases). In conclusion SKY and MCB analyses in AML patients provided a relevant contribute for characterisation of highly rearranged karyotypes unravelling cryptic specific translocations and biological mechanisms of disease.

Breakpoint localization for der(16)t(1;16) in pediatric Wilms tumor using chromosomal and array CGH analyses. *S. Chan, C. Harvard, C. Fawcett, G.P. Jevon, E. Rajcan-Separovic.* Department of Pathology and Laboratory Medicine, Children's and Women's Health Centre of British Columbia, University of British Columbia, Vancouver, Canada.

Background: Wilms tumor is the most common pediatric renal neoplasm and displays various cytogenetic abnormalities. Der(16)t(1;16) is a recurrent rearrangement in Wilms tumor, the breakpoints of which have not been well-defined. We examined the breakpoint (bp) regions of chr 1 and 16 in der(16) using chromosomal and array CGH and correlated the results with the original cytogenetic findings.

Materials and Methods: Three cases of Wilms tumor with der(16) were studied. DNA was extracted from frozen tissue and chromosomal and array CGH were performed. The chromosomal and array CGH analyses were undertaken independently and without the knowledge of the previous cytogenetic findings other than the presence of der(16). The results were then compared and correlated with one another.

Results: Comparison of the conventional cytogenetic findings with the chromosomal and array CGH results showed good correlation of gains and losses in all cases. The results suggested that the chr 1 bp was either in the 1q heterochromatic region (HR) or within the proximal 3.8 Mb of 1q21.1 in all 3 cases. For chr 16, the bp was either in the HR of 16q or within the proximal 0.3 Mb of 16q12.1 in 2 cases. For the remaining case, the bp appeared to be within a 0.6 Mb segment in 16q12.1, located 2.1 Mb from the heterochromatic/euchromatic boundary.

Conclusions: The bp's of chr 1 and 16 in der(16) appear to be within the HR or in the 1st euchromatic band of the q arm a short distance from the heterochromatic/euchromatic boundary. Although the extent of heterochromatic involvement could not be determined in most cases due to the lack of clones in those regions on the array, we demonstrated the extent of euchromatic involvement by using array CGH, and in 1 case, the chr 16 bp was localized to a 0.6 Mb segment in a euchromatic band. Array CGH allows better definition of the bp's and the chromosomal regions involved, facilitating future studies for identifying potential genes involved in Wilms tumor development.

Cytogenetic changes in a L3 lymphoblastic leukemia/Burkitts lymphoma associated with HIV infection. *L. Chen¹, L. Cao¹, Q. Tao¹, F. Haque¹, M. Zhuang¹, HO. Shah^{1,2}, JH. Lin^{1,2}.* 1) Department of Pathology, Nassau University Medical Cent, East Meadow, NY; 2) SUNY Stony Brook, NY.

A 44-year-old man with a history of HIV infection was admitted to hospital with complaints of gum bleeding and generalized weakness. Physical examination revealed petechiae all over skin and splenomegaly without lymphadenopathy. The positive HIV infection was diagnosed six months ago. CD4 count was 772/mm³. The blood count showed RBC of 2.15 x 10⁶/mm³, Hb 6.6 g/dl, Hct 19.5%, platelets of less than 10,000/mm³ and WBC of 23.2 x 10³/mm³ with 28% lymphoblasts. The lymphoblasts exhibited scanty to moderate basophilic cytoplasm containing multiple vacuoles, and nuclei with fine chromatin and conspicuous nucleoli. Cytogenetic study of peripheral blood revealed 46,XY [13]/45,Y,der(X)t(X;18)(p22.1;q12),add(6)(q23),t(8;14)(q24.1;q32),der(13)t(1;13)(q25;q34),add(16)(p11.2),add(17)(q23),18,del(20)(p11.2)[13]. Burkitts lymphoma is most common lymphoma in the patients with HIV infection and often occurs as the initial manifestation of the acquired immunodeficiency syndrome (AIDS). In contrast to other lymphomas associated with HIV infection, Burkitt lymphoma is usually identified in patients commonly having a higher CD4+ T-cell counts (more than 200/mm³), with a short interval between the diagnosis of positive HIV infection and occurrence of lymphoma. Except classic t(8;14)(q24.1;q32), which results in over-expressing MYC gene by juxtaposing the MYC gene adjacent to the promoter of the Immunoglobulin (Ig) heavy chain gene, the possible role of tumorigenesis of other translocations identified in this case, such as t(X;18)(p22.1;q12) and t(1;13)(q25;q34), is not known. Interestingly, the regions of 6q23 and 16p11.2 are the loci of Myb and TLS genes, respectively. Both Myb and TLS have been found to enhance hematopoietic/lymphoid cell proliferation. Additional 6q23 and 16p11.2 in this case likely indicate a positive effect of tumor cell proliferation due to increased gene dosage, which may contribute to the development and progression of Burkitts lymphoma in this AIDS patient.

Oncogene identification in the 1q31 minimal region of genomic gain in retinoblastoma. *T.W. Corson*^{1,2}, *B.L. Gallie*^{1,2,3,4}. 1) Cancer Informatics, Ontario Cancer Institute, Toronto, ON; 2) Molecular & Medical Genetics, University of Toronto, Toronto, ON; 3) Medical Biophysics, University of Toronto, Toronto, ON; 4) Ophthalmology, University of Toronto, Toronto, ON.

The pediatric ocular cancer retinoblastoma is initiated by loss of function of both alleles (M1 & M2) of the prototypic tumor suppressor gene, *RBI*. However, additional genetic alterations (M3 to Mn) are necessary for malignancy. Using comparative genomic hybridization, we and others have previously shown common chromosomal aberrations in retinoblastoma tumors, which may reflect M3 to Mn events. Prominent among these is a region of gain spanning chromosome 1q31, seen in 50% of tumors and likely to harbor oncogene(s) important in retinoblastoma development. To define the minimal common region of gain at 1q31 in retinoblastoma, we used quantitative multiplex (QM)-PCR to screen tumor DNA for gain of 14 sequence tagged sites (STSs) spanning 1q25.2 to 1q32.3. STS marker SHGC-154194 at 1q31.3 showed the most frequent gain in retinoblastoma tumor samples (70%; 39/55). We have thus narrowed the region of 1q31 gain from initially more than 27 Mb, to only 1.2 Mb between markers flanking SHGC-154194. This STS lies within predicted gene *LOC400800*, the mRNA of which is highly expressed in retinoblastoma compared to healthy adult retina by RT-PCR. A slightly expanded 3 Mb region flanking SHGC-154194 contains 16 other known and predicted genes. Of these, only two are highly expressed at the mRNA level in retinoblastoma tumors: *ZNF281* (ZBP99), a zinc-finger transcription factor; and *KIF14*, a kinesin. Moreover, ZBP99 protein is also highly expressed in retinoblastoma. One or more of these highly expressed genes in the minimal region of gain at 1q31.3 may be important in the pathogenesis of retinoblastoma, and may thus be a potential target for novel therapeutics.

Early secondary cytogenetic changes in t(14;18) positive follicular lymphoma. *B.J. Dave, W.C. Chan, D.D. Weisenburger, M.M. Hess, W.G. Sanger.* University of Nebraska Medical Center, Omaha, NE.

The t(14;18)(q32;q21) is the most common recurrent cytogenetic abnormality observed in non Hodgkin lymphomas and is observed in 80-90% of follicular lymphomas (FL). Although the t(14;18) is considered to be the primary abnormality, it is speculated by some that additional genetic alterations are essential to generate a fully malignant phenotype of FL. Complex karyotypes with numerous cytogenetically indefinable changes at diagnosis hampers the delineation of the sequence of alterations which lead to progressive FL. In an attempt to define some of the initial and early secondary changes, we examined the karyotypes of 275 consecutive, histologically confirmed FL containing the t(14;18). Sixty-two cases (23%; 62/275) contained karyotypes that revealed either a t(14;18) alone or had only one other structural or numeric abnormality in the stemline clone. Of these, 16 cases (26%; 16/62) contained the t(14;18) alone and 36 (58%; 36/62) revealed karyotypes with one additional abnormality in a single abnormal clone. Ten cases (16%; 10/62) contained two related abnormal clones where the stemline clone contained only one additional abnormality. Among the 46 cases with one additional abnormality, nine (20%; 9/46) involved chromosome 18, either as a +der(18)t(14;18) or as a +18. Eight cases (17%; 8/46) involved the structural rearrangements of chromosome 1 with 1p36 and 1q44 as recurrent breakpoints. Eight cases (17%; 8/46) contained numeric (+7) or structural changes of chromosome 7, with 7q36 as a recurrent breakpoint; and four cases (9%; 4/46) presented with a structural alteration of chromosome 3 with 3p25 and 3q29 as recurrent breakpoints. Thus, the earliest secondary alterations, as detected by clonal evolution of the karyotypic changes, involved the chromosomes 18, 1, 7, and 3 in descending order, with the recurrent breakpoints being 18q21, 1p36, 1q44, 7q36, 3p25, and 3q29. DNA microarray investigations to determine the possible presence of subtle genomic alterations in the cases with t(14;18) as a sole abnormality, and to delineate the genetic alterations in the recurrent breakpoint regions, will better elucidate the pathogenesis and progression of FL.

Structural alterations of c-MYC, Her-2/neu and CCND1 oncogenes in Langerhans cell histiocytosis. *J. Gogusev*¹, *L. Telvi*², *I. Murakami*¹, *A. Stojkoski*¹, *C. Glorion*³, *F. Jaubert*⁴. 1) INSERM U507, Hosp Necker,; 2) Cytogenetics Laboratory, Hosp St Vincent de Paul,; 3) Orthopedic Surgery Department, Hosp Necker; 4) Pathology Department, Hosp Necker, Paris.

Langerhans cell histiocytosis (LCH) is characterized by the presence of destructive granulomas containing CD1a + Langerhans-like cells, lymphocytes and eosinophils. LOH at several loci as well as DNA copy number changes on chromosomes 1, 5, 7, 9, 13, 16 and 18 were described in LCH lesions of bone. To identify additional changes of pathogenetic importance, we determined the copy number in situ and possible rearrangement of the c-myc, CCND1(cyclin D1), Her-2/neu and p53 proto-oncogenes in LCH of bone. LCH cell suspension was obtained after collagenase treatment of the granulomas (n=7) and smears on slides were prepared. LCH derived stromal cell lines, DOR-1 and Prud-1 were used for comparison. Peripheral blood lymphocytes from a healthy donor were used as an internal control. FISH analysis was performed with centromeric probes for chromosomes, 1, 5, 7, 8, 11, 17 and 22 and locus identifying probes for c-myc, CCND1, Her-2/neu and p53 proto-oncogenes. Expression of mRNAs and proteins was studied by immunocytochemistry and Northern blot. By FISH analysis, amplification of c-myc and Her-2/neu (between 5 and 14 copies per nucleus) was found in 3/7 cases, corrected for aneusomies 8 and 17. Low level of amplification of Her-2/neu was revealed in 2 samples. The fraction of nuclei with c-myc and Her-2/neu amplification ranged between 16 and 23 % and was associated with large bone lytic lesions. In two samples, an increased number of CCND1 copies was revealed in more than 28 % of nuclei. None of the lesions exhibited amplifications of p53 gene. The LCH derived cell lines DOR-1 and Prud-1 showed strong amplification of c-myc (7-23 copies) in 21% of the nuclei, Her-2/neu (9-15 copies) and CCND1(4 to 9 copies) in 21% and 12% of the nuclei respectively. The presented results demonstrate an alteration of c-myc, Her-2/ neu and CCND1 genes copy number in LCH lesions of bone. Structural changes of cell cycle related protooncogenes support the neoplastic origin of a distinct subtypes of histiocytic lesions of bone.

Characterizing complexity: CGH, SKY, and targeted FISH analysis of 15 pancreatic cancer cell lines. A.

Hawkins^{1,4}, *L. Morsberger*^{1,4}, *M. Haddadin*¹, *A. Patel*¹, *E.J. Perlman*¹, *E. Jaffee*², *E. Schrock*³, *T. Ried*³, *C.A. Griffin*^{1,2}. 1) Dept Pathology JHU, Baltimore, MD; 2) Kimmel Cancer Center, JHU, Baltimore, MD; 3) Genetics Branch, NCI, Rockville, MD; 4) both authors contributed equally to this work.

Karyotype analysis can provide clues to significant genes involved in the genesis and growth of pancreas cancer. The genome of pancreas cancer is complex, and G-band analysis cannot resolve many of the karyotypic abnormalities seen. We studied the karyotypes of 15 recently established cell lines using molecular cytogenetic tools. G-banded karyotypes of 10 of these cell lines were previously reported (*Cancer J Sci Am* 4:194). Comparative genomic hybridization (CGH) analysis of all 15 lines identified genomic gains of 3q, 8q, 11q, 17q, and chromosome 20 in 9 or more cell lines. CGH confirmed frequent loss of chromosome 18, 17p, 6q, and 8p. 14/15 cell lines demonstrated loss of chromosome 18q, either by loss of a copy of chromosome 18 (n=5), all of 18q (n=7) or portions of 18q (n=2). Multicolor FISH (Spectral Karyotyping, or SKY) of 11 lines identified many complex structural chromosomal aberrations. 93 structurally abnormal chromosomes were evaluated, to which SKY added new information to 67. Several apparently site-specific recurrent rearrangements were observed. Chromosome region 18q11.2 was recurrently involved in 9 cell lines, including formation of derivative chromosomes 18 from a t(18;22) translocation (3 cell lines), t(17;18) (2 cell lines), and t(12;18), t(15;18), t(18;20), and ins(6;18) (1 cell line each). To further define the breakpoints involved on chromosome 18, YACS from the 18q11.2 region, spanning approximately 8 MB, were used to perform targeted FISH analyses of these lines. We found significant heterogeneity in the breakpoints despite their G-band similarity, including multiple independent regions of loss in a region far proximal to the already identified loss of DPC4 at 18q21. (supported in part by NCI P50CA62924).

Clonal evolution mechanism of Ph negative acute lymphoblastic leukemia involving placement of BCR-ABL fusion gene on other sites than 22q11. *S. Hazourli¹, R. Fetni^{2, 3}, L. Busque², J. Hébert^{1, 2}.* 1) Leukemia Cell Bank of Quebec, Guy Bernier Research center, Maisonneuve-Rosemont Hospital; 2) Department of Hematology, Maisonneuve-Rosemont Hospital; 3) Department of Pathology, MontrealChildren's Hospital.

Amplification of BCR-ABL gene is suggested as one of the mechanism of progression and drug resistance to Imatinib Mesylate in chronic myeloid leukemia (CML) and acute lymphoblastic leukemia (ALL). We have investigated a patient with Philadelphia chromosome (Ph) negative but BCR-ABL fusion gene positive ALL by molecular cytogenetics and Quantitative reverse transcriptase polymerase chain reaction. Fluorescence in situ hybridization (FISH) analysis demonstrated the presence of multiple subclones with one to five copies of BCR-ABL fusion genes located on chromosome 9 and on one to four marker chromosomes. Spectral karyotyping (SKY) identified the marker chromosomes as originating from chromosome 8. The amplification of BCR-ABL fusion was confirmed at the mRNA level by Quantitative RT-PCR. We simultaneously, used centromeric probe for chromosome 8 and the BCR-ABL extra signal dual color probe to detect the intermediate clones of the complex karyotype. This allowed us to identify the mechanism of clonal evolution by successive non-disjunction of the derivative chromosome harbouring the fusion gene. This is the first illustration, to our knowledge, of intermediate clones involving placement of BCR-ABL fusion gene on other sites than 22q11 and successive non-disjunction, leading to amplification of BCR-ABL fusion gene.

CGH-array analysis of primary and metastatic ovarian tumors. *O. Israeli*^{1,2}, *A. Aviram-Goldring*², *E. Friedman*², *J. Korach*³, *G. Ben-Baruch*³, *B. Goldman*¹, *S. Rienstein*¹. 1) Danek Gertner Institute of Human Genetics ; 2) The Susanne Levy Gertner Oncogenetics Unit; 3) Gynecology-Oncology Department, Chaim Sheba Medical Center, Tel Hashomer, Ramat-Gan, Israel.

Invasive epithelial ovarian cancer is the most lethal gynecologic malignancy in the western world. In the majority of patients (~75%) peritoneal metastases are found at the time of primary surgery. Understanding the molecular mechanisms involved in tumor initiation and progression offers hope for developing early detection tools and novel therapeutic approaches. By comparing the genetic alterations in primary ovarian tumors with those in their respective metastases, using Comparative genomic hybridization (CGH) and FISH, we previously showed that genomic alterations in the primary tumors are mimicked in the metastases. In the present study somatic genetic alterations were sought in the same set of tumor-metastases pairs (n=3 primary and 3 metastases) at the gene level by applying the array-CGH method. The results show that most (69%-82%) of the primary tumor alterations can also be detected in the respective metastases, yet the metastases demonstrate additional alterations. One cluster of alterations that was exclusively altered in the metastases, but not in the primary tumors is clustered to 17p12-p11.12. This genomic region was described as an area with a high LOH rate and contains the tumor suppressor gene *LLGL1* and the anti-proliferative gene *PMT1*, which might have a role in ovarian cancer progression. We conclude that there are additional genes that are associated with progression of ovarian cancer that may be detected using the array-CGH technique.

Variant APL t(15;17) originating from two subsequent balanced translocations involving the same chromosomes 15 and 17 and preserving the PML/RARA fusion. *J.A. Jahn¹, J. Scheerle¹, R.J. Meister², R.J. Christie², C.D. Croft¹, S. Wallingford¹, D.W. Heritage¹, P.N. Mowrey¹, A. Meloni-Ehrig¹.* 1) Cytogenetics, Quest Diagnostics Nichols Inst, Chantilly, VA; 2) Arlington-Fairfax Hematology-Oncology, P.C., Arlington, VA.

Acute promyelocytic leukemia (APL) is a myeloid disorder characterized by the t(15;17)(q22;q21). Variants of this translocation have been described. We report a 24-year-old male with APL, who presented with pancytopenia and severe headaches. A fluorescence in situ hybridization (FISH) analysis on bone marrow revealed a variant fusion pattern. The typical t(15;17) FISH pattern for the Vysis dual-color, dual-fusion probe is 1 PML signal, 1 RARA signal, and 2 fusion signals. However, the FISH in this patient showed 2 PML signals, 2 RARA signals, and 1 PML/RARA fusion signal. In order to better understand the origin of this variant pattern, a G-banded chromosome study was performed. The karyotype was: 46,XY,del(15)(q15q22),der(17)t(15;17)(q22;q21)t(15;17)(q15;q21). The combined FISH and chromosome analyses suggested that 2 subsequent translocations had occurred involving the same chromosomes 15 and 17. The first gave origin to the typical t(15;17)(q22;q21) and the second caused the separation of the RARA/PML fusion, which typically occurs on the derivative chromosome 17, while preserving the PML/RARA fusion on the derivative chromosome 15. Although by conventional cytogenetics, we did not see any cells with the typical t(15;17), FISH detected a typical fusion pattern in 5% of nuclei, supporting the occurrence of 2 subsequent events. According to previous reports, the prognostic course of complex and variant t(15;17), in which the PML/RARA fusion on the derivative chromosome 15 is intact, such as in the present case, does not differ from the one in the typical t(15;17). In fact, our patient is presently in remission and doing well after chemotherapy with daunorubicin and treatment with all trans-retinoic acid (ATRA). As the prognostic outcome in APL is associated with the presence of a PML/RARA fusion, it is useful and important to perform both cytogenetic and FISH to better characterize a variant and complex t(15;17).

FISH analysis in a woman without Turner stigmata who has unilateral gonadoblastoma and a 45,X/46,X, idic(Y)(q11.2) karyotype. *S. Kaneko*¹, *S. Tsukishiro*¹, *H. Nishikawa*¹, *A. Arakawa*¹, *K. Suzumori*¹, *S. Young*². 1) OB/GYN, Nagoya City Univ, Nagoya, Aichi, Nagoya, Japan; 2) Cancer and Research Genetics, Univ. of South Carolina School of Medicine.

Gonadoblastoma is a rare ovarian lesion composed of germ cells resembling those of dysgerminoma and gonadal stroma cells resembling those of a granulosa or Sertoli tumor. The presence of Y chromosome material in phenotypic females is associated with a risk of up to 30% of developing a gonadoblastoma in the dysgenetic gonads. We report on a 20-year-old woman with no Turner stigmata, completely female external genitalia with no virilization, who had a gonadoblastoma. At the age of 18 years, she was referred for amenorrhea. Chromosome analysis showed mos 45, X[15]46, X, idic(Y)(q11.2). ish idic(Y)(q11.2)(DYZ3++, SRY++) [15] in lymphocytes. After chromosome analysis and laboratory investigations, she started taking hormone therapy and had menstrual cycles. The follow-up MRI revealed that she had developed a 5cm tumor on her right gonad. Subsequently, r-gonadectomy and a biopsy of l- streak ovary were carried out. Histological investigation revealed a gonadoblastoma in the right gonad and only fibrous tissue in the left gonad. Molecular study by Fluorescence in situ hybridization (FISH) showed that all the tumor cells contained Y chromosome material. Most of the tumor cells had two copies of centromere probes of X and Y chromosomes (DXZ1 and DYZ3) and two copies of SRY. Since gonadoblastoma develops only in patients who have Y-chromosome material and dysgenic gonads, it has been hypothesized and indicated that there is a GBY gene (gonadoblastoma locus on Y chromosome) near the centromere of the Y chromosome. In this case, our finding that all the tumor cells had Y chromosome material also support the possible existence of a GBY.

Genomic imbalances in Korean Brain Tumors By Comparative Genomic Hybridization. *H. Kim¹, Y. Suh², H. Kim¹, Y. Chun¹, S. Park¹.* 1) Institute of Human Genetics, Department of Anatomy, Brain Korea 21 Biomedical Sciences, Korea University College of Medicine, Seoul, Korea; 2) Department of Pathology, Samsung Medical Center, Sungkyunwan University School of Medicine.

Twenty-eight of brain tumors were investigated for chromosomal aberrations by comparative genomic hybridization (CGH). The most frequently detected chromosomal gains involved chromosome 9p21-pter (36%), 7p15-pter (32%), 13q21-q23 (29%), 1q42-qter (25%), 4p15-p15.3 (25%), 4q33-qter (25%), 5p13-pter (25%), 8p21-pter (25%), Yq11.2-12 (25%), Xq25-qter (25%), 4q33-qter (21%), 7q21-q31 (21%), and 18q21-q22 (21%). The frequent sites of copy number decreases were detected at 1p36-pter (18%) and 19q (11%). The recurrent gain and loss of chromosomal regions identified in this study provide candidate regions that may contain oncogenes or tumor suppressor genes respectively involved in the tumorigenesis of brain tumor.

Trisomy 22 as a sole primary abnormality in a patient with unusual acute myeloid leukemia. *M.M. Li^{1,2}, K.C. Kim¹, J. Krause³, M. Rozans^{1,2}*. 1) Hayward Genetics Ctr;; 2) Dept of Pediatrics;; 3) Dept of Pathology Tulane Univ School Med, New Orleans, LA.

It has long been debated whether trisomy 22 is invariably secondary to inversion 16 in AML, or whether it could be a primary aberration in AML. We report trisomy 22 as the sole primary chromosomal abnormality in a patient with an unusual presentation of AML. The patient, a 13-year-old boy, initially presented with fever, weight loss, hepatosplenomegaly, adenopathy, and pancytopenia; his bone marrow was hypercellular with trilineage maturation and mild increase in histiocytes. Lymph node biopsy demonstrated effacement of the normal architecture with T-cells. Cytogenetic studies revealed trisomy 22 as the only abnormality in both the bone marrow and lymph node. FISH study with the CBFβ/MYH11 probe was negative. Skin biopsy showed a normal male karyotype. A maternally inherited, previously undescribed perforin gene mutation was also detected. The tentative diagnoses were LPD, HLH, or lymphoma. Although the patient responded to chemotherapies based on above diagnoses, he continued to show hepatosplenomegaly, pancytopenia, and trisomy 22 in his bone marrow. After 1.5 months treatment, the patients bone marrow showed a striking change: it was now extensively infiltrated by immature myeloid cells, indicating AML. AML-specific chemotherapy was administered and a complete remission was achieved. The trisomy 22 disappeared at remission, but reappeared at AML relapse a few months later with an additional der(17)t(11;17)(q13;p11.2). FISH study with the CBFβ/MYH11 probe at relapse was normal. Trisomy 22 as a sole chromosomal abnormality in leukemia is rare; and, if present, is often associated with AML. AML-M4, in which cryptic inv(16) may be present, accounts for nearly 45% of all trisomy 22-associated AML. However, our case as well as others demonstrate that trisomy 22 can be a sole primary abnormality in AML without a cryptic inv(16). The unusual presentation in said patient could be the result of a possible underlying infection that initially mimicked a lymphoproliferative disorder; or may be associated with the mutated perforin, prompting an initial lymphohistiocytic response.

Molecular Detection of 11p Involvement in 5q- Leukemia Cases. *L. Li¹, J. O'Malley¹, B. Wang¹, L. Guo¹, J. Defeo¹, R. Felgar¹, G. Segel², N. Wang¹.* 1) Pathology, University of Rochester, Rochester, NY; 2) Pediatrics, University of Rochester, Rochester, NY.

The 5q- is a non-random chromosomal aberration associated with MDS and AML. The regions most consistently deleted is 5q31.1. To rule out the involvement of other chromosome(s) in the 5q- formation, chromosome microdissection was applied to the 5q- in a case of myeloproliferative disease. To identify the component chromosomes involved in the 5q- and to confirm the specificity of the probe generated to the 5q-, 10-15 copies of the 5q- were dissected and collected, the DNA was isolated, amplified by DOP-PCR, fluorescent labeled and reversely hybridized to normal metaphase spreads as well as the spreads containing the 5q-. When the 5q- probe was hybridized to normal metaphase spreads, it painted the chromosome segments 5pter->5q13 and 11pter->p13 which indicates that the 5q- involves a translocated segment of chromosome 11pter->11p13. FISH with WCP5 and WCP11 confirmed the reverse FISH results. In a second case of leukemia with an apparently 5q-, FISH with the EGR1 probe(5q31) demonstrated the insertion of EGR1 from chromosome 5q31 to 11p15 instead of a deletion.. The insertion of EGR1 from 5q31 to 11p15 was further confirmed by FISH with the probes specific for the subtelomeric regions of 5p, 5q, 11p, and 11q. In conclusion, our data suggests that gene(s) on 11p may play an important role in some of the 5q- cases and that molecular analysis is crucial for defining structural aberration within this heterogeneous subgroup.

Complex Chromosomal Abnormalities in an Acute Lymphocytic Leukemia. *JH. Lin^{1,2}, N. Motiwala¹, Y. Li¹, E. Seguer¹, L. Chen¹, HO. Shah^{1,2}.* 1) Department of Pathology, Nassau University Medical Center, East Meadow, NY; 2) State University of New York at Stony Brook, NY.

A 64 year-old man revealed leucocytosis and numerous blasts in the peripheral blood on follow-up visit for the treated rectal adenocarcinoma in remission. Eight months prior, a rectal adenocarcinoma was discovered and was managed with combined radiotherapy and chemotherapy with 5 Fluorouracil for three months, followed immediately by an abdominoperineal resection with no evidence of residual carcinoma or regional lymph node metastasis. Peripheral blood flow-cytometry and marrow study confirmed the diagnosis of acute B precursor lymphocytic leukemia FAB L2 (ALL) with positive markers for CD19, CD20, kappa sIg and HLA-DR and negative markers for tdT, CD10, CD13, CD14, CD33 and other T cell markers. Marrow chromosomal studies showed 47,XY,del(3)(q23q25),t(4;7)(q35;q32),t(6;14)(q27;q22),t(11;12)(p13;q13),del(16)(q22),+18,add(19)(q13.3),add(21)(q21). Majority of ALL is primarily present in children under the age of 6 years. Most of ALL seen in adults are of B precursor ALL. ALL is commonly associated with chromosomal abnormalities. The most frequently seen and recently characterized is that of t(12;21)(p13;q22). In this particular case, the chromosomal changes were multiple and complex. There was no specific chromosomal modification, which had been previously elucidated; yet there were individual chromosomes or its segments known to involve in ALL chromosomal alteration, i.e., chromosomes 4, 11, 12, 19, 21. The findings of add(21)(q21) conceivably influences the transactivation of genes by normal AML1 protein triggering some regulatory function of cellular proliferation. The presence of transforming gene, BCL3 in aberrant add(19)(q13) might have set in motion a deregulated expression. It is plausible structural and functional alteration in AML1 protein and BCL3 gene in an intricate interaction with several other chromosomal transfigurations, might have generated disease process resulted in B-ALL in this case.

High-resolution mapping of genomic imbalances in osteosarcoma DNA by use of CGH analysis of microarrays.

P. Marrano^{1,2}, *M. Zielenska*^{1,3}, *P. Pei*^{1,3}, *J. Bayani*^{1,2}, *B. Beheshti*^{1,2}, *P. Thorner*^{1,3}, *J. Squire*^{1,2}. 1) Department of Laboratory Medicine and Pathobiology, University of Toronto, Toronto, Canada; 2) Medical Biophysics, University of Toronto, Princess Margaret Hospital and The Ontario Cancer Institute, Toronto, Canada; 3) Department of Pediatric Laboratory Medicine, Hospital for Sick Children and University of Toronto, Toronto, Canada.

Conventional cytogenetic studies have shown that osteosarcomas (OS) are characterized by complex structural and numerical chromosomal alterations. The application of comparative genomic hybridization (CGH) has led to the rapid accumulation of cytogenetic information on osteosarcoma (OS), however, the limited resolving power of metaphase CGH does not permit precise mapping of imbalances. Array CGH allows quantitative detection and more precise delineation of copy number aberrations in tumors. Unfortunately the high cost and lower density of BACs on available commercial arrays has limited the ability to comprehensively profile copy number changes in tumors such as OS that are recurrently subject to genomic imbalance. In this study, we used high-resolution CGH to investigate recurrent patterns of genomic imbalance by use of DNA derived from eleven fresh and eight formalin-fixed paraffin embedded tumors hybridized to a 19,200-clone cDNA microarray. Chromosomes 1, 6, 8, 17, and X harbored the most imbalances. Ten OSs showed copy number gain or amplification of 17p between the loci bounded by 17p11.2-17p12, and five of these tumors were accompanied by a distal deletion in the region of the p53 gene. Gain/amplification of the X chromosome was verified using interphase FISH using a subset of OS FFPE sections and an OS tissue array. In summary, microarray CGH analysis of the chromosomal imbalances of OS confirm the overall pattern observed by use of metaphase CGH and provides a more precise refinement of the boundaries of genomic gains and losses that characterize this tumor.

Molecular Cytogenetic Characterization of a New Human Papillomavirus Positive Cell Line 16-MT. *E.M. McGhee, P.D. Cotter, J.W. Weier, J.F. Berline, M. Gormley, J.M. Palefsky.* University of California San Francisco, CA.

Anogenital cancers are closely associated with human papillomavirus (HPV). HPV-infected individuals, particularly those with high-grade dysplasias, are at increased risk for cervical and anal cancers. Although genomic instability has been documented in HPV-infected keratinocytes, the full spectrum of genetic changes in HPV-associated lesions has not been fully defined. Only a few karyotypes based on chromosome banding techniques have been reported. We examined four HPV-positive epithelial cell lines, Caski, SiHa, HeLa, and 16-MT, by G-banding and spectral karyotyping (SKY) which revealed multiple numerical, complex and cryptic chromosome rearrangements. Newly analyzed 16-MT cells revealed a complex hypertriploid karyotype with multiple structural and numerical abnormalities. The 16-MT karyotype was interpreted as 78 - 83,XXY,+add(1)(p36.3), +3,+4,+5,+5,+7,+8,+i(8)(q10)x2,+10,der(12),der(13;14)(q10;q10),+15,+16,add(19)(q13.3), +21,+21,-22[cp20]. Multicolor analysis by SKY confirmed and further characterized the anomalies identified by GTG banding. The add(1) was identified as a der(1)(1qter-1q25::1p36.1-1qter), the add(19) as a dup(19) and the der(12) interpreted as a der(11) involving a duplication of chromosome 11 material and rearrangement with chromosome 19. In addition, previously unidentified der(9)t(9;22), der(3)t(3;19) and der(4)t(4;9) were noted. All four cell lines showed losses and gains of DNA due to unbalanced translocations and complex rearrangements of regions containing known tumor suppressor genes. Chromosomal damage in these regions might explain the increased risk of cancer associated with HPV. Furthermore, these data represent the first full characterization of the HPV-positive cell line 16-MT.

Deletion (14)(q21) in a case of precursor B-cell acute lymphoblastic leukemia. *A. Meloni-Ehrig¹, K. Chen¹, J. Jahn¹, S. Suchan¹, J. Scheerle¹, G. Crosby¹, N. Seibel², D. Leitenberg², P. Mowrey¹.* 1) Laboratory of Cytogenetics, Quest Diagnostics Nichols Institute, Chantilly, VA; 2) Department of Hematology and Oncology, Childrens National Medical Center, Washington, DC.

The detection of chromosome abnormalities in precursor B-cell acute lymphoblastic leukemia (pre-B ALL) is a powerful tool for disease management. In fact, some abnormalities are associated with particular prognostic outcomes, such as t(12;21), which correlates with good prognosis, and t(9;22), which is associated with poor prognosis. It is understandable why new abnormalities may be challenging to both cytogenetists and clinicians. We present a case of del(14)(q21) as a sole abnormality in a 5-year-old boy with pre-B ALL. To our knowledge, this has not been reported in pre-B ALL. The G-banded karyotype showed a del(14)(q21) as the only abnormality. FISH using the probes TEL/AML1 and immunoglobulin heavy chain (IGH) showed no rearrangement of TEL/AML1 and a single IGH signal in 20% of interphase cells. Search of the literature yielded one report with a del(14)(q22q24). Lymphoid disorders with del(14q) include B-cell non-Hodgkin lymphomas and chronic lymphocytic leukemia, usually with additional abnormalities. Despite the scarcity of cytogenetic reports on del(14q) in pre-B ALL, several molecular/immunology studies have revealed rearrangements and deletions of the IGH locus in approximately 30% of pre-B ALL, leading to oligoclonality. Although pre-B ALL is thought to arise from the monoclonal expansion of committed B-lymphocyte precursors that are arrested at an immature stage of differentiation, the finding of oligoclonal populations suggests that deletions or rearrangements of the IGH locus are an important factor in this transformation. It is surprising that there are so few cytogenetic reports of del(14q) in this disorder. It is safe to assume that the majority of rearrangements and deletions of the IGH locus may not be detected by routine cytogenetics. Reasons may include low level of abnormal cells or deletions may be too small to be detected. Studies similar to this are warranted to understand the relationship between del(14q) and pre-B ALL and to determine its role in the prognostic outcome.

Cytogenetic Follow-Up of Iranian Breast Cancer Patients. *R. Mirfakhraie*¹, *M. Atri*², *P. Mehdipour*³. 1) National Institute of Genetic Engineering & Biotechnology, Tehran, Iran; 2) Department of Surgery, Cancer Institute, Faculty of Medicine, Tehran, Iran; 3) Department of Medical Genetics, Faculty of Medicine, Tehran University of Medical Sciences.

Breast cancer is the most common malignancy among women. Several factors are involved in initiation and development of breast carcinoma, but epidemiologic evidence point to two areas: Environment and Genetics. Cytogenetic studies in breast have revealed chromosomal alterations in tumor cells. Most breast tumor cytogenetics studies thus far reveal complex chromosomal alterations, and hence it has not been possible yet to associate breast cancer with specific chromosome aberrations, although some specific anomalies are beginning to emerge. Blood cultures from breast cancer patients also have revealed chromosomal changes which are similar to those of tumor cells. Such similarities may be very interesting, since it indicates that factors causing alterations in tumor cells may also operate in human lymphocytes. In the present study we have observed such similarities.

Tumor Genome Anatomy Project (TGAP): Gene Discovery in Tumors in the Genome Era. *S.D.P. Moore*^{1,2}, *P. Dal Cin*^{1,2}, *B.J. Quade*^{1,2}, *S. Herrick*¹, *T. Ince*^{1,3}, *M. Parisi*⁴, *M. Mealiffe*⁴, *D.J. Harris*^{2,5}, *H.L. Ferguson*¹, *S. Strehl*⁶, *A.H. Ligon*^{1,2}, *M. Kleinman*¹, *R. Kucherlapati*^{1,2}, *C.C. Morton*^{1,2}. 1) Brigham & Women's Hosp., Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Massachusetts Inst. of Technology, Cambridge, MA; 4) University of Washington, Children's Hosp. and Regional Center, Seattle, WA; 5) Children's Hosp. of Boston, Boston, MA; 6) Children's Cancer Research Institute, Vienna, Austria.

TGAP is a new initiative to identify genes involved in neoplasia in a high throughput manner taking advantage of naturally occurring human genomic and genetic changes resulting from chromosome rearrangements in individuals with a wide spectrum of neoplasms. The completion of the Human Genome Project is redefining the rapidity of genetic discoveries with potential clinical applications. TGAP will exploit these growing biological resources, and will coordinate an integrated group of researchers with expertise in cytogenetics, molecular biology and oncology. This gene discovery initiative is a natural extension in the application and translation of the complete human DNA sequence.

The strategy of TGAP is first to identify a tumor with novel primary or secondary rearrangement(s) primarily from tumor samples submitted for analysis to the Cytogenetics Laboratory at the Brigham & Women's Hospital. Chromosomal breakpoints are mapped by FISH to discover candidate genes or regions of conserved non-genic sequence. Molecular analysis ensues to pinpoint potential disruption or position effects on gene function.

Preliminary work has uncovered new roles for genes in uterine leiomyomata (UL), acute myelocytic leukemia (AML) and lipomas. A UL with a t(10;17) rearrangement disrupted the histone acetyl transferase (HAT) *MORF* on chromo 10, representing the first HAT to be associated with UL. In addition, an AML patient with a t(11;17)(q23;q12-21) involves a *MLL* and *AF17* fusion where the chromo 17 breakpoint was proximal to *RARA*. Another patient with multiple lipomas was found to have a constitutional rearrangement disrupting *HMGA2* representing the first reported constitutional disruption of *HMGA2*.

Modulation and the Fate of the Cytogenetically Abnormal Myelodysplastic Clone by Azacitidine (AZA C). V.

Najfeld¹, A. Scalise¹, R. Odchimer-Reissig², L.R. Silverman². 1) Path and Med, Tumor Cytogen, Box 1079, Mount Sinai School of Medicine, New York, NY 10029; 2) Medicine, The Mount Sinai School of Medicine, New York, NY 10029.

Myelodysplastic syndrome (MDS) is a clonal hematopoietic stem cell disorder characterized by progressive bone marrow failure leading to death. Transformation to acute leukemia occurs in 50%. Progression of the disease is associated with accumulation of genomic changes with consequential poor outcome. Aza C has anti-tumor activity through modulation of gene expression and changes in DNA methylation. Treatment with Aza C resulted in significant (60%) improvement in bone marrow function and reduction in transformation to AML (Silverman et al JCO 2002). The aim of this study was to determine whether karyotype changes reflect hematological response and if so, what is the fate of the MDS clone. The Aza C modulation of the karyotype was examined in 159 pts with multiple sequential follow up. Three different cytogenetic/FISH patterns emerged. Group I consisted of 98 pts who had no change in karyotype irrespective whether they presented with normal or abnormal karyotype. They were on Ara C for a mean of 17 months (mo) and hematological response was noted in 70%. Group II consisted of 26 pts who had normalization of the karyotype and achieved a full cytogenetic/FISH reversal within a mean of 15 mo. Hematological improvement was seen in 83%. Group III consisted of 35 pts who either progressed from normal to an abnormal karyotype or presented with an abnormal karyotype and had a clonal evolution. Hematological improvement was noted in 33%. These findings suggest that AZA C can modulate the function of MDS clone in one of three ways: full cytogenetic/FISH remission (21%), lack of cytogenetic progression (54%), and persistence of the cytogenetically abnormal clone with improved bone marrow function (16%). Therefore, patients with a poor or intermediate prognostic score may substantially benefit from AZA C treatment. These chromosomal changes suggest that AZA C may function as a biologic response modifier which alters the malignant phenotype in the absence of cytotoxic effect.

Deletion in the derivative chromosome 9 in a variant Philadelphia (Ph¹) translocation, t(3;9;22). *P. Narasimhan*¹, *A. Babu*^{2,3}, *R. Zeng*^{2,3}, *V. Mizhiritskaya*^{2,3}, *P. Chandra*³, *M.J. Macera*^{2,3}. 1) Forest Hills Medical Center, Forest Hills, NY; 2) Div of Molecular Medicine and Genetics; 3) Dept of Medicine, Wyckoff Heights Medical Ctr, Brooklyn, NY.

A 57 year old female was seen for an elevated white cell count, (WBC 78000 mm³, HB 9.3g/dl, hematocrit 29.0, MCV 80, platelets 486,000 mm³). Differential counts showed promyelocytes, myelocytes, blasts 5%;, eosinophils and basophils all suggestive of CML. The spleen was palpable to about 7 cm below the left cortical margin. Cytogenetic analysis with GTG banding on a bone marrow specimen, revealed a variant Ph¹ translocation, 46,XX,t(3;9;22) (q29;q34;q11.2), in all metaphase cells. FISH analysis for BCR/ABL was performed using a dual color probe set with extra signal (ES) (Vysis). The ES probe is approximately 650 kb on 9q that includes an area well centromeric (upstream) to the argininosuccinate synthetase gene (ASS) to an area well telomeric (downstream) beyond the last ABL exon. Hybridization with this probe in typical BCR/ABL rearrangement produces an extra signal on the derivative chromosome 9, der(9), in addition to the BCR/ABL fusion signal. In this patient, the fusion signal of BCR/ABL on der(22) and corresponding signals on both normal chromosomes 9 and 22 were consistently seen in all metaphase cells. However, the extra signal was consistently absent, indicating a deletion 5' of the ABL breakpoint including the ASS gene on the der(9) chromosome. It has recently been shown that 10 to 15 %; of typical t(9;22) Ph¹ positive CMLs have genomic deletions flanking the breakpoints on the der(9) chromosome. It was also shown that deletions are approximately 3 times more frequent in those cases with variant Ph¹ translocations. The survival rate of patients with a deletion is shorter than that of the patients without a deletion. Therefore, deletions in der(9) is considered to be of prognostic value. The patient has responded remarkably well to Gleevec treatment. She had a normalization of cells with no immature cells present and the spleen returned to normal size. Additional studies are in progress to further delineate the extent of the deletion in the der(9).

Analysis of candidate tumor suppressor genes in prostate cancer pathogenesis. *H. Ostrer¹, M. Salman¹, A. Pearlman¹, A. Grossberg¹, A. Goldsweig¹, J. Melamed¹, M. Zeegers²*. 1) New York Univ School of Medicine, New York, NY; 2) University of Birmingham, UK.

Both germline mutations as well as gross somatic genomic alterations, including allelic loss and gene amplification, contribute to the development of prostate cancer. Genes that are identified within the smallest region of deletion overlap may represent tumor suppressors. To evaluate the status of positional cloning studies for candidate tumor suppressor genes, we performed meta analyses on articles for linkage and allelic imbalances that were published from 1992 to January, 2004. For linkage studies, we identified and mapped the critical breakpoints of recombination for HPC1 between markers, D1S215 and D1S158, a region that contained approximately 33 known and 30 assembly genes, including RNASEL. For HPC2, the critical breakpoints of recombination were between markers D17S974 and D17S953, a region that contained approximately 11 known and 19 assembly genes, including ELAC2. For loss of heterozygosity (LOH) studies, we measured the frequency of events and created smoothed density plots, by estimating marker specific summary LOH together with their corresponding 95% confidence intervals for chromosomes 1, 8, and 17. These LOH intervals were concentrated around RNASEL and MSR1 loci, but not around ELAC2. To further examine whether RNASEL and ELAC2 demonstrate LOH, we used Pyrosequencing to genotype and quantify SNPs within the coding regions. When applied to 20 matched tumor and normal samples, we did not detect any LOH events for either gene, suggesting that such events are rare. To examine for loss of expression of RNASEL, MSR1 and ELAC2 at the protein level, we performed immunocytochemical analysis using peptide-specific polyclonal antibodies against fixed sections of normal prostate and prostate cancer. The resulting analyses showed that RNASEL, MSR1 and ELAC2 were expressed at moderate to high levels in prostate epithelium and had no reduction of expression in 75 prostate cancers. Based on these findings, we exclude these tumors as tumor suppressors and propose other candidates within the critical regions on chromosomes 1, 8 and 17.

Formation of der(19)t(1;19)(q23;p13) in acute lymphoblastic leukemia. *K. Paulsson, A. Horvat, T. Fioretos, F. Mitelman, B. Johansson.* Dept. of Clinical Genetics, Lund University Hospital, Lund, Sweden.

The t(1;19)(q23;p13), which results in a fusion of *TCF3* (previously *E2A*) at 19p13 with *PBX1* at 1q23, is one of the most common translocations in acute lymphoblastic leukemia (ALL). It is seen either as a balanced t(1;19) or as an unbalanced der(19)t(1;19); occasional cases with co-existing t(1;19)- and der(19)-positive clones have also been described. Although it has generally been assumed that the unbalanced form arises from the balanced t(1;19) through loss of the derivative chromosome 1 followed by duplication of the normal homologue, this has never been proven. At least two other mechanisms are possible for the formation of the der(19): an initial trisomy 1 followed by translocation and subsequent loss of the der(1), or a rearrangement taking place in the G2 phase of the cell cycle, with the derivative chromosomes 1 and 19 ending up in separate daughter cells. The different alternatives may be distinguished by investigating markers proximal to the breakpoint in 1q23, because they would be expected to lead to different allelic patterns. Thus, loss of heterozygosity due to the presence of uniparental disomy (UPD) - i.e., both copies of a chromosome being derived from only one of the parents - for chromosome 1 would be present in all der(19)-harboring cases arising via the duplication pathway and in one third of the cases arising via the trisomy pathway, but in none of the der(19) formed via the G2 pathway. In this study, we have used quantitative fluorescent PCR with polymorphic microsatellite markers to investigate chromosomes 1 and 19 in two t(1;19)- and four der(19)-positive ALLs. None of the der(19) cases displayed UPD1, excluding that this aberration arises through the duplication pathway. Because previous findings of cases with co-existing t(1;19) and der(19) clones are difficult to explain if the translocation originated in G2, the present results suggest that unbalanced der(19) may arise from an initial trisomy 1 followed by t(1;19) translocation and loss of the derivative chromosome 1.

Breakage at *FRA11F* may be associated with 11q13 gene amplification. *S.C. Reshmi*¹, *D.W. Schoppy*^{2,3,4}, *R.C. Black*², *X. Huang*¹, *W.S. Saunders*^{2,3,4}, *S.M. Gollin*^{2,3,4}. 1) Dept Human Genetics, GSPH, Univ Pittsburgh, Pittsburgh, PA; 2) Dept. of Biological Sciences, University of Pittsburgh, Pittsburgh, PA; 3) The Oral Cancer Center at the University of Pittsburgh, Pittsburgh, PA; 4) University of Pittsburgh Cancer Institute, Pittsburgh, PA.

Inefficient repair of double strand breaks has been observed in the form of stalled replication forks within areas of the genome exhibiting higher strand flexibility, namely, chromosomal fragile sites. Recent studies have demonstrated that gene amplification in the form of a homogeneously staining region (hsr) may result from breakage at a common fragile site. We previously demonstrated that the 11q13 hsr present in 45% of oral squamous cell carcinomas (OSCC) contains an inverted repeat pattern of amplified *CCND1* flanked by *RINI*. Furthermore, we have evidence supporting a breakage-fusion-bridge (BFB) cycle mechanism for 11q13 gene amplification. Thus, we propose that breakage at the distal, *FRA11F* common fragile site may promote gene amplification of 11q13 in OSCC. In order to characterize the physical map of the *FRA11F* region, we hybridized BACs mapping to 11q13 to normal peripheral blood treated to enhance breakage at common fragile sites. Our data suggest that the *FRA11F* region falls within a 7.7 Mb region. Further studies are underway to determine the precise size of *FRA11F*. However, preliminary results from hybridization of BACs spanning the 7.7 Mb *FRA11F* region to OSCC cell lines with 11q13 gene amplification suggest that breakage at *FRA11F* may be an important step for initiating 11q13 gene amplification in OSCC.

Karyotypic complexity and heterogeneity as potential targets for cancer therapy. *A.V. Roschke¹, S. Lababidi², G. Tonon¹, K.S. Gehlhaus¹, J.N. Weinstein², I.R. Kirsch¹.* 1) Genetics Branch, Ctr Cancer Res, National Cancer Inst, Bethesda, MD; 2) Laboratory of Molecular Pharmacology, Ctr Cancer Res, National Cancer Inst, Bethesda, MD.

We have recently completed a detailed analysis of the chromosomal aberrations present in the drug-discovery panel of 60 human cancer cell lines (the NCI-60) used by the Developmental Therapeutic Program of the National Cancer Institute to screen compounds for anticancer activity, and identified a set of general chromosomal states based on the complexity and heterogeneity of their karyotypes. For the first snapshot of relations between these markers of chromosomal state and drug resistance or sensitivity, we used a 1429-drug subset of the more than 100,000 compounds tested against the cell lines. We have identified groups of chemical compounds that are more cytotoxic toward cancer cell lines with more complex and/or unstable karyotypes. This suggests a novel and complementary approach to current anti-cancer drug discovery. It is a plausible hope that the assessment of chromosomal state of a cancer cell population may provide a future guide for the selection of drugs active against aggressive and intractable cancers.

A Case of a del(21)(q22q22), Trisomy 21 and Rearranged AML1 Gene. *P. Scott*^{1,2}, *S. Hazourli*⁴, *J. Hébert*⁴, *A.M.V. Duncan*^{1,2,3}, *R. Fetni*³. 1) Departments of Human Genetics; 2) Pediatrics; 3) Pathology, McGill University and Montreal Childrens Hospital; 4) Centre de recherche Guy-Bernier, Hôpital Maisonneuve-Rosemont, Montréal, Québec.

Trisomy 21 is the second most frequent trisomy associated with malignant hematopathological disease after trisomy 8. Recent studies associate the deletion del(21)(q22q22) and point mutations of the AML1 gene in hematological malignancies with trisomy 21. We present here a patient with trisomy 21 and thrombocytopenia in transformation. Standard bone marrow cytogenetic analysis revealed trisomy 21 in all cells analyzed with a del(21)(q22q22) in two of the three chromosome 21. Interphase in situ hybridization with the probe AML1/ETO, which covers a 1.3MB region of the sub-band 21q22.1, confirmed the interstitial deletion of band 21q22.1 on one of two chromosome 21 in one of two clones, and on two of three chromosome 21 in the other. Further FISH analysis with probe TEL/AML1, which covers the gene AML1 at the sub-band level of 21q22.1, revealed a single copy of the gene AML1. We analyzed the proliferative activity of the different clones using simultaneous detection of in vitro bromodeoxyuridine incorporation and FISH and showed that the trisomic cell line had a growth advantage over the disomic cell line. We will discuss the relationship between del(21)(q22q22), trisomy 21 and rearrangements of the AML1 gene and their implications in leukemic evolution.

Minimal interval defined on chromosome 7q in uterine leiomyoma. *S.M. Sell, C. Tullis, D. Stracner, C. Song, J. Gewin.* Department of Nutrition Sci, 346 WEBB, University of Alabama at Birmingham, Birmingham, AL.

Uterine leiomyoma are benign, smooth muscle tumors of the female reproductive tract. The tumors are very common and affect approximately 10-15 million women in the United States annually. Uterine leiomyomata are often asymptomatic but they may cause symptoms that range in severity from mild abdominal discomfort to uterine prolapse. Several different chromosomal aberrations are found in the tumor tissue. Because of the common occurrence of this tumor and the potential severity of associated sequelae, research delineating the different molecular subtypes is necessary. Deletions on the long arm of chromosome 7 are thought to be the most common genetic anomaly in uterine leiomyoma. The size of the deletion is variable. This makes it difficult to identify the genes that, upon deletion, contribute to tumor growth. The smallest previously defined interval was greater than 12,000 kb. Using a set of intercalating microsatellite markers we have narrowed a minimal region to an interval of less than 500 kb. The single known gene in this interval is *ORC5L*, a member of the human origin recognition complex. Loss of this gene has previously been described for tumor samples involving larger deletions. It has been hypothesized that loss of this gene might prevent progression to malignancy by retarding the cell cycle. This gene has also been shown to play a role in regulating transcription. Carefully controlled microarray analyses may shed light on this latter possibility.

Genomic analysis of bridge-breakage-fusion events and fragile sites associated with gene amplification in the osteosarcoma cell line MG63. *S. Selvarajah*^{1,3}, *G. Lim*³, *B. Beheshti*⁵, *B. Vukovic*^{2,4}, *J. Squire*^{1,2,4}, *M. Zielenska*^{1,3}. 1) Dept of Pediatric Lab Medicine, Hospital For Sick Children, Toronto, ON, Canada; 2) Department of Cellular & Molecular Biology, Ontario Cancer Institute, Toronto, ON, Canada; 3) Hospital for Sick Children, University of Toronto, Toronto, Ontario (Canada); 4) Department of Medical Biophysics, University of Toronto, Toronto, Ontario (Canada); 5) Faculty of Medicine, University of Toronto, Toronto, Ontario (Canada).

The bridge-fusion-breakage (BFB) cycle is a well-established mechanism for the generation of gene amplification in tumors and model systems. Osteosarcoma (OS) is distinguished by chromosomal instability and high copy number gene amplification, thus the BFB cycle is an attractive mechanism to explain the origins of genomic instability and the evolution of complex abnormal chromosomes carrying amplified DNA (complicons). MG63 is a representative human osteosarcoma cell line that was shown to have acquired complicon structures, comprising equally-spaced intrachromosomal amplifications arising from chromosomes 6, 8 and 9. Detailed analysis of this cell line showed that dicentric chromosomes and inverted duplications were present at a high frequency. In addition, FISH analysis using mBAND subregional cytoband paint probes of the complicon, showed a pattern of interspersed amplification of regions 6p21, 8q24 and 9p22. Moreover, inverted duplications were found within amplicon subunits suggesting that BFB was associated with the generation of gene amplification from these three regions in this cell line. Known intermediates of the BFB cycle, such as dicentrics, anaphase bridges and chromatin strings were also quantified and observed to occur at high frequency. The precise regions of co-amplification were then mapped by high-resolution array CGH and FISH. Interestingly, the amplicon boundaries were found to be flanked by regions containing fragile sites, suggesting they may have been involved in generating precursor amplicon structures. In summary, this study provides further support for the role of BFB mechanism and fragile sites in gene amplification and chromosomal instability in OS.

Retinoblastoma in a newborn baby with a heterozygous Rb gene deletion. *HO. Shah^{1,2}, P. Koduru³, A. Karnik¹, B. Miller¹, V. Diaz-Barrios¹, Y. Zhang¹, M. Zhuang¹, J. Sherman^{1,2}, JH. Lin^{1,2}.* 1) Pathology & Lab Cytogenetics, Nassau Univ Medical Ctr, East Meadow, NY; 2) State Univ. of Stony Brook; 3) Cell Genetics, Northshore University Hospital, Manhasset, NY.

A full-term baby boy was born to a gravida 1, para 1, 20-year-old woman. Shortly after pulmonary hypertension was diagnosed and treated accordingly. The baby exhibited facial asymmetry, swollen right sternocleidomastoid muscle and dysmorphic bulging eyes. Funduscopic findings and a well-defined soft mass along the posterior aspect of right globe by CT scan and MRI established the clinical diagnosis of retinoblastoma in the right eye. Peripheral blood chromosomal analysis revealed 46,XY,del(13)(q12.3q21.2). Parental blood samples for chromosomal studies showed a structurally unremarkable normal chromosomal makeup in both parents. Fluorescence in-situ hybridization study with LSI-13 (RB1, Vysis) was performed on metaphase spreads of the child and of both parents. Normal signal pattern was detected in both parents. In the child, the target region (RB1 region) was deleted in the abnormal 13 only. These findings suggest that a de-novo deletion in one 13 retinoblastoma region leading hemizyosity for this region in the child. At the age of one and one half months, the right eye was enucleated which was followed by chemotherapy. Patient is doing well at the age of 5 months. Retinoblastoma (RB) is the most common intraocular tumor of children and usually diagnosed between the ages of 16 months and two years. About 60% of RB is sporadic and the other 40% are inherited. The retinoblastoma gene (Rb) locates in chromosome 13q14. Persons who carry one of mutant alleles in association with predispositional factors have a risk of 80-90% chances to develop RB. The Rb protein produced in this gene is inactivated when both alleles are mutated rendering cellular proliferation and thus formation of neoplasms. Since this case displays de-novo deletion of one single retinoblastoma gene in chromosome 13, this must have been followed by a mutation in the other allele triggering the development of retinoblastoma in the child.

Program Nr: 325 from the 2004 ASHG Annual Meeting

Inferring the location of tumor suppressor genes and oncogenes by modeling array CGH data. *A. Sterrett, F.A. Wright.* Biostatistics, University of North Carolina, Chapel Hill, NC.

Comparative genomic hybridization (CGH) can detect partial chromosomal deletions and amplifications, which may contain genes associated with the development of tumors. The use of array CGH in the literature has increased dramatically in the past year, yet many of these studies do not use a statistical approach to search for genes associated with tumorigenesis. Statistical modeling of array CGH data can improve genomic searches by accounting for sporadic background loss and correlations between neighboring markers. We use Hidden Markov Models to calculate likelihoods from array CGH data, from which we can infer the location of tumor suppressor genes and oncogenes. Specifically, we define three hidden states (decreased copy number, normal copy number, and increased copy number) underlying the raw intensity ratios or a discretized transformation of the intensity ratios. Our model accommodates unequally spaced markers and missing observations. Additionally, it is possible to allow the model parameters to depend on covariates, such as tumor stage, in order to increase precision. We demonstrate the use of this statistical methodology through a recent array CGH study.

Cell death by chromosome elimination: Characterization of drug induced chromosomal fragmentation. J.B.

*Stevens*¹, *S. Savasan*², *G. Liu*¹, *S.W. Bremer*¹, *M. Atanasovski*¹, *W. Xu*¹, *T. Trivedi*¹, *C. Ye*⁵, *H.H. Heng*^{1, 3, 4}. 1) CMMG, Wayne State University, Detroit, MI; 2) Hematology/Oncology, Childrens Hospital of Michigan, Detroit, MI; 3) Karmanos Cancer Insititute, Detroit, MI; 4) Department of Pathology, Wayne State University, Detroit, MI; 5) SeeDNA Biotech Inc, Windsor, ON.

The subject of cellular death is of great importance in the regulation of development and the process of carcinogenesis. Here we describe a novel form of mitotic cell death in which chromosomes are eliminated through fragmentation into many small pieces. Chromosome fragmentation refers to a phenomenon in which chromosomes are cut into progressively smaller pieces. This can result in mitotic figures where cut and uncut chromosomes coexist within the same figure. Under drug treatment, the degree of chromosomal fragmentation increases until all chromosome morphology is lost and the cell dies. Occasionally, some fragmented chromosomes can form micronuclei if the cell can complete telophase. Even though there are some morphological similarities between chromosomal fragmentation and S-phase PCC (Premature Chromosome Condensation), the key difference is that fragmentation takes place only in mitotic cells. Unlike classical apoptosis, chromosomal fragmentation does not depend on p53 status and does not require caspase activation. Fragmentation is TUNEL negative, however there are DNA strand breaks present as indicated by -H2AX staining. Additionally multiple color SKY has shown that certain chromosomes are more frequently found to be fragmented, indicating that chromosome fragmentation is an orderly event. Treating cells with clinically significant drugs such as doxorubicin and methotrexate can consistently induce chromosome fragmentation. It is therefore possible that the process of chromosomal fragmentation could provide a potentially important biomarker to document levels of cell death in tumors and determine drug toxicity.

Chromosomal aberrations in Korean cervical squamous cell carcinoma cell lines by CGH and array-CGH. K.

Uhm¹, K.Y. Oh², S. Chun³, S.C. Kim³, K. Jeong³, J.I. Kim³, S. Park⁴, S. Park¹. 1) Institute of Human Genetics, Department of Anatomy, Brain Korea 21 Biomedical Sciences, Korea University College of Medicine, Seoul, Korea; 2) Department of Obstetrics and Gynecology, Eulji Medical College, Daejeon, Korea; 3) Department of Obstetrics and Gynecology, College of Medicine, Ewha Womans University, Seoul, Korea; 4) Department of Anatomy, College of Medicine, Ewha Womans University, Seoul, Korea.

The array-comparative genomic hybridization (CGH) provides a method to measure the DNA copy-number changes quantitatively at an extremely high resolution and to map them directly onto the complete linear genome sequences. The non-random chromosomal DNA aberrations were analyzed in cervical squamous cell carcinoma cell lines from Korean women, SNU-17, SNU-682, and SNU-902 using CGH and array-CGH. Gains of 5p, 5q22-q23, 8q11.2-q12, 14q21-qter, and 20q were found in all three cell lines. Gains on chromosome 3q, 7p13-pter, 9p22-pter, 9q21-qter, 15q21-q22, 17q22-qter, 18p11.3-pter, 18q11.2-q21, 19p13.3-pter, and 19q13.2-q13.3, with losses on 4p14-pter, 10p11.2-p13, 10q24, and 21q were observed in two of three cell lines. The results of CGH in cervical squamous cell carcinoma cell lines were similar to array-CGH analysis. Data about chromosomal aberrations of Korean squamous cell carcinoma cell lines in this study could afford very useful basic information for the development of diagnostic and therapeutic modalities targeting the abnormal genes associated with uterine cervical cancer in Korea.

The use of culture mitogens in B-cell disorders. *D. Van Dyke*^{1,2}, *A. Wiktor*^{1,2}. 1) Dept Lab Medicine & Pathology, Mayo Clinic, Rochester, MN; 2) Henry Ford Hospital, Detroit, MI.

A low mitotic rate and a poor response to mitogens have hampered cytogenetic analysis of B-cell disorders. By identifying optimal cell culture conditions, the likelihood of detecting cytogenetic abnormalities may be increased. From a series of 1885 samples with a known or suspected B-cell disorder, we compared the detection rate of abnormalities in unstimulated and mitogen stimulated cultures (B-cell lipopolysaccharide plus pokeweed). We excluded 30/1436 (2%) bone marrow, 25/94 (27%) peripheral blood, and 79/355 (22%) lymph node samples that failed to produce metaphases. We also excluded cases with fewer than analyzable 5 cells from a culture (68 marrow, 9 blood, and 40 lymph node samples). A clonal abnormality was identified in 168/1338 (13%) marrow, 6/60 (10%) blood, and 38/236 (16%) lymph node samples. Analysis of cells from B-cell mitogen cultures increased the yield of abnormalities in marrow aspirate samples by 13%, from 146/1338 (11%) to 168/1338 (13%). For lymph node samples, B-cell mitogenized cell cultures were of no significant added value in detecting chromosome abnormalities. The sample size of abnormal peripheral blood samples was too small to be informative. Of the 213 abnormal cases, at least 24 (11%) were identified solely in B-cell mitogenized culture, and in another 15 cases (7%) the B-cell cultures served to confirm a non-clonal abnormality seen in the unstimulated culture. Of the 24 cases that only had an abnormality in the B-cell cultures, 21 had the abnormal cell population in fewer than 30% of cells; additional studies may help determine whether B-cell mitogens are useful to reveal an emerging population. Of these 24 cases, 6 would have exhibited a normal FISH pattern using our current B-cell FISH probe panels, five had simple +12 or 11q+, and 13 had additional aberrations that would not have been observed by interphase FISH alone. Although interphase FISH is useful to identify common abnormalities associated with B-cell disorders (Wiktor & Van Dyke, 2003 ASHG abstract and in press), a B-cell mitogenized culture does provide a modest improvement in the chromosome aberration detection rate when a B-cell disorder is suspected.

Cytogenetic Analysis and FISH of terminal deletion of the long arm of Chromosome 9 in one patient with Acute Promyelocytic Leukemia. *G. Vasquez-Palacio¹, O. Botero-Galeano¹, A. Posada-Sanchez², T. Teknirat³, M. Sierra-Sanchez², N.E. Durango-Calle¹, C.M. Cristancho-Salgado¹, J.C. Herrera-Patino¹, F. Quintero-Rivera^{1,4}, J.L. Ramirez-Castro¹.* 1) Medical Genetic Unit, School of Medicine, University of Antioquia, Medellin, Colombia; 2) Children's Hospital, Hospital Universitario San Vicente de Paul, Medellin, Colombia; 3) Department of Genetics and Development, Columbia University, New York, NY; 4) Center for Human Genetic Research, Massachusetts General Hospital, Harvard Medical School, Boston, MA.

Deletions of the long arm of 9 del (9q22-ter) are rare aberrations specifically found in acute myeloid leukemia (AML). Yamamoto et al 1999, reported the first case of acute promyelocytic leukemia (APL) with a terminal 9q deletion as sole abnormality. Here we describe the second case with the same aberration. The patient, an eleven-years-old girl with APL. The laboratory studies (Hb) of 88 g/L, 12x10⁹/L, count neutrophils 12%, lymphocytes 15%, blasts 71%. Cell suspension immunophenotypic studies were performed using the following antibodies: CD3, CD 13, CD19, CD33 and myeloperoxidase (MPO) positive. Chromosomal analysis by the Giemsa R banding technique and FISH using LSI BCR/ABL Vysis probe was performed on short-term cell cultures from bone marrow. Average of 50 metaphases per patient. Normal chromosome 9, and del (9)(q22) were detected. Deletions of 9q are described to be about 3 to 4% in AML, especially in Myeloid Leukemia M1 and M2. Sole 9q terminal deletions, are less common than interstitial ones and predominant involve q21~q22 band. The ABL proto-oncogen has been localized in this region on chromosome 9, this gene is important for understanding the genetic mechanisms involved in leukemogenesis of LMC. However, a recent study suggests that patients with APL and del deletion (9)(q22) shows a relatively good prognosis.

Bridge-fusion-breakage (BFB) as a driving force for karyotypic evolution of prostate cancer (CaP). *B. Vukovic*^{1,2}, *B. Beheshti*², *G. Lim*², *J. Bayani*², *S. Watson*³, *W. Lam*³, *J. Squire*^{1,2}. 1) Medical Biophysics, Ontario Cancer Institute, Toronto, Ontario, Canada; 2) University Health Network, Toronto, Ontario, Canada; 3) BC Cancer Research Centre, Vancouver, British Columbia, Canada.

BACKGROUND: Telomere erosion and ploidy changes were found to be early events in prostate cancer progression, but there is no evidence of a BFB mechanism generating the observed genetic changes. An ongoing chromosomal instability (CIN) was observed in DU-145 cell line with generation of novel numerical and structural aberrations upon cell division. To investigate BFB as a mechanism underlying the observed CIN process, molecular cytogenetic methods were used to study the karyotypic evolution in prostate cell lines. **METHODS:** Anaphase bridge frequency was determined using immunocytochemistry (ICC) with CREST antibodies for kinetochore identification. Dicentrics were analyzed using FISH and their functionality evaluated through examination of CENPA/B status. Progression of structural rearrangements concordant with BFB was examined using spectral karyotyping (SKY) and multicolor banding (mBAND) methods. Comparison of mBAND to aCGH profiles allowed more precise mapping of regions highly prone to BFB induced breakage. **RESULTS:** DU145 and PC3 were found to have high frequency of anaphase bridges with involvement of dicentrics seen at much higher frequency in comparison to control lines (PrEC-T). Stabilization of clonal dicentrics was concordant with inactivation of one of the centromeres. Detailed examination of karyotypic rearrangements has shown complex structures and resulting derivatives concordant with repeated fusion and breakage of chromosomes. The breakage was found to be non-random and clustered at specific points along the chromosomes. The breakpoints often mapped to amplicon boundaries and regions of high fragility in the genome. **DISCUSSION:** BFB was found to be one of the mechanisms that contributed to CIN previously documented in prostate cancer cell lines although there were indications of other mechanisms at play. Analysis of telomere length in these lines suggested further telomere dysfunction as a source of observed BFB. Implications of these findings in CaP progression will be discussed.

Trisomy 22 is an important secondary change associated with AML M4 (AML-M4) with inv(16)(p13q22). D. Wei¹, K.H. Ramesh¹, V.R. Pulijaal¹, M. Zohouri¹, D.T. Walsh¹, R.A. Conte¹, A.R. Deshikar¹, T. Zhou¹, H. Ratech², X.Y. Yang², C. Sands², M. Ramirez², L.A. Cannizzaro¹. 1) Department of Pathology, Montefiore Medical Center, Albert Einstein College of Medicine, Bronx, NY.10461; 2) Hematology-Oncology, Montefiore Medical Center, Albert Einstein College of Medicine, Bronx, NY.10461.

A 36-year-old female with anemia and elevated white blood count was diagnosed with AML-M4 in June 2001. Flow cytometry showed CD2+, CD11b+, CD11c+, CD13+, CD14+, CD15+, CD33+, CD34+, CD38+, HLA-DR+. Cytogenetic analysis of bone marrow (BM) at this time showed a 46,XX,inv(16)(p13q22)[20] karyotype. She achieved complete remission in May 2002. In Jan. 2004, BM morphology showed normocellular marrow (40-60%) with relative erythroid hyperplasia and maturation arrest in the myeloid series. Flow cytometry was 14-19% CD13+, CD33+, CD34+, CD38+, CD117+ myeloblasts. Cytogenetic and FISH analyses in Jan 2004 revealed a karyotype of 47,XX, inv(16)(p13q22),+22 [16]/46,XX[4]. ish inv(16)(p13q22)(pcp16q sp)(wcp22+). These results were consistent with AML in relapse. She achieved clinical and cytogenetic remission in Apr. 2004. Inversion 16 (p13q22) has been reported in about 2% of AML and is specifically associated with the M4E0 subtype and a favorable prognosis. In about 40% of AML cases with inv (16), trisomy 22 can be found as an additional abnormality. It has been suggested that trisomy 22 occurs as a secondary change during clonal evolution of AML with inv(16). It has been shown that about one third of the patients with molecular evidence of CBF/MYH11 fusion do not have cytogenetic changes of inv (16). The literature and our observations suggest that trisomy 22 is an important secondary change in AMML or AML with a monocytic component and inv (16). Inv (16) can be difficult to recognize, particularly in poor cytogenetic preparations. Therefore, the presence of trisomy 22 should alert the hematologists, cytogeneticists and molecular biologists to perform appropriate tests such as FISH or other molecular tests to confirm the evidence of inv (16), which has an important prognostic impact in the clinical management of AML.

Concurrent presence of t(10;11)(p12;q23) and t(11;19)(q23;p13.3) in an infantile AML case. *S. Wu^{1,2}, G. Lu¹, J. Dang¹, XR. Chen¹, J. Quinn².* 1) Dept of Pathology and Lab Medicine; 2) Dept of Pediatrics, Children's Hospital Los Angeles, Keck Med School, University Southern California, Los Angeles, CA, USA.

The translocations t(10;11)(p12;q23) and t(11;19)(q23;p13.3) are closely associated with human acute leukemia with the former predominantly presented in de novo AML(m5a) and the latter occurred in both acute myeloid and lymphoid infantile leukemia. To the best of our knowledge, these two translocations have yet to be reported in the same patient. We report here an infantile leukemia case with concurrent presence of two translocations: t(10;11)(p12;q23) and t(11;19)(q23;p13.3). This is a 3.5-month old Latino infant who initially was presented with leukemic skin involvement and hepatosplenomegaly with the bone marrow showing 31% myeloblasts. The bone marrow cytogenetic analysis showed concurrent presence of t(10;11) and t(11;19) which were confirmed by FISH studies. The patient was treated with Idarubicin, Fludarabine, Ara-C, and L-asparaginase and received a short period of remission following a recurrent leukemia cutis and involvement of testis. He was then administered reinduction therapy with mitoxantrone and Ara-C and awaits recovery. The correlation between the unique leukemia cutis and testis and the concurrent presence of t(10;11) and t(11;19) in this patient is worth further investigation.

Direct visualization of hybrid tumor cells in human cancer by FISH: Donor Y chromosome in renal carcinoma cells of a female BMT recipient. *Y. Yilmaz*^{1,4}, *R. Lazova*^{2,4}, *M. Qumsiyeh*^{1,4}, *D. Cooper*^{3,4}, *J. Pawelek*^{2,4}. 1) Dept Genetics, Yale Univ Sch Medicine, New Haven, CT; 2) Dept Dermatology, Yale Univ Sch Medicine, New Haven, CT; 3) Section Medical Oncology, Yale Univ Sch Medicine, New Haven, CT; 4) Yale Cancer Center, Yale Univ Sch Medicine, New Haven, CT.

There are more than 25 reports of spontaneous tumor hybridization in animals, and several link hybridization with metastasis. To investigate this in humans, we probed a primary renal cell carcinoma from a female patient who, 2 years prior to detection of the tumor, received a bone marrow transplant (BMT) from her 15 year old son. Karyotype/G-banding analyses revealed that some of the tumor cells contained a chromosome 17 trisomy (T17). This provided an opportunity to use FISH to visualize cells in fixed tumor sections containing both the T17 tumor marker, and the Y chromosome BMT donor marker. Combining H&E staining with dual-label FISH, these markers were detected together in individual nuclei of carcinoma cells, providing direct genetic and morphological evidence that such cells were BMT-tumor hybrids. In a single tumor section nearly 50 cells contained both the Y chromosome and a T17. Further, when a sequential section was stained for beta 1,6-branched oligosaccharides (a metastasis-associated trait, associated with poor outcome in breast, lung, and colon carcinomas) in combination with FISH, 80% of the carcinoma cells staining for these sugars also contained the Y chromosome, indicating that BMT-tumor hybrids were the predominant source of the sugars in this tumor. To our knowledge, this is the first direct visualization of hybrid tumor cells in human cancer. That these cells produced beta 1,6-branched oligosaccharides indicates they may have had increased metastatic potential. The results suggest that tumor hybridization merits renewed consideration as an underlying factor in human metastasis. Continued analyses of malignancies in BMT recipients should be a fruitful approach to this important question.

Chronic Lymphocytic Leukemia: A Prospective Study Using FISH, CD38, and ZAP-70. *E. Zafer, S. Abbasi, B. Cheson, M. Ozdemirli, D. Hartmann, J. Meck.* Georgetown U Hosp, Washington, DC.

CLL shows a highly heterogeneous clinical course with some patients not requiring therapy for years, while others progress rapidly. Thus, alternate molecular, cytogenetic and clinical factors have been sought as possible prognostic factors. Cytogenetic findings are a strong predictor of outcome. Deletions of ATM, p53, and perhaps trisomy 12, are associated with an unfavorable outcome, whereas deletion 13q14 is associated with a better outcome. ZAP70 and CD38 expression have been shown to predict response to therapy and survival, and correlate with a more aggressive clinical course and shorter median survival. Georgetown U. Hospital is conducting a prospective study of CLL patients in whom chromosomal aberrations by FISH, CD38 and ZAP70 status are being examined. Since Jan 2003, a total of 44 B-CLL patients have been studied. Metaphase chromosome analysis is difficult and unreliable, making FISH an important tool in CLL. Probes to p53, ATM, 13q14, 13q34, and 12 centromere were used. FISH results were abnormal in 27/44 (61%) cases: 17 with del13q14 (63%), and 7 trisomy 12 (26%). Deletions of ATM and/or p53 were infrequent (11%), and never seen as sole events. Our results show a clear correlation between two good prognostic factors: deletion 13q and absence of CD38. Thirty-two cases were CD38- (73%), and 12 were CD38+ (27%). Absence of CD38 was associated with a higher incidence of chromosomal abnormality: 20 (63%) CD38- cases had abnormal and 12 (37%) CD38- cases had normal FISH results. Among the 20 CD38 negative patients with abnormal FISH results, 15 (75%) had loss of 13q, 3 (15%) had +12 and 2 (10%) had multiple abnormalities. ZAP70 expression was evaluated in 26 cases by immunohistochemistry (IHC) and/or flow cytometry: 16 were positive (62%) and 7 (27%) negative, and 3 discrepancies between IHC and flow data. Among the 16 ZAP70+ cases, 7 were normal (43%), 6 were del13q (38%) and 3 were +12 (19%). Among the 16 ZAP70+ cases, 11 of them were CD38- (69%), 5 of them were CD38+ (31%). The prognostic importance of various combinations of FISH, ZAP70 and CD38 will be monitored in larger numbers of patients with respect to patient survival.

Nonrandom duplication of the active and inactive X chromosomes in non-Hodgkin lymphoma (NHL). P.

Zeitlhofer¹, A. Weinhäusel¹, M. Pfeilstöcker², H. Grüner², S. Strehl¹, M. König¹, O.A. Haas¹. 1) CCRI, Vienna, Austria; 2) Ludwig Boltzmann Institute for Leukemia Research and Hematology, Hanusch Hospital, Vienna, Austria.

The gain of one or more X chromosomes is one of the most common acquired numerical chromosome aberrations in NHL and occurs in both male and female patients. In female patients either the active or inactive X may be gained in a random or nonrandom fashion, whereas the only active homologue must be duplicated in male patients. However, a supernumerary active X could subsequently also become de novo inactivated in both sexes. Previous molecular genetic evidence that derives from the semi-quantitative analysis of differentially methylated polymorphic X chromosome sequences suggested that the acquired X chromosomes are and remain always active in male patients, whereas both the active and inactive X may be randomly duplicated in females (McDonald et al, *Genes, Chromosomes & Cancer* 28:246;2000). However, reliable quantification is difficult, particularly in cases with multiple copies of X chromosomes. In addition, de novo hypermethylation of particular regions that are commonly used for such analyses may also impede the interpretation of the respective results. To overcome these problems, we have developed a dual-color DNA/RNA FISH assay that enables the simultaneous enumeration of active and inactive X chromosomes on a single cell level (see abstract by Haas et al). We used this assay to study 29 methanol/acetic acid-fixed NHL cell samples. They comprised 18 male (9 in the hypo- to hyperdiploid and 9 in the pseudotri- to pseudotetraploid range) and 11 female patients (7 with three X and 4 with four X chromosomes). Except for one case, which most likely was a Klinefelter syndrome with a constitutional XXY, all X chromosomes were active in male patients. This was also the case in all females with three X, whereas those with four X had duplicated both the active and inactive X chromosome. These results concur with those obtained in hyperdiploid childhood ALL and imply that in all instances a single nondiscjunction event leads to the maldistribution of chromosomes irrespective of the ploidy range.

Characterization of breakpoints by fluorescent in-situ hybridization (FISH) analysis in a patient with t(14;18) (q32;q21) and CD- lymphoplasmacytic lymphoma. *M. Zohouri¹, L.A. Cannizzaro¹, V.R. Pulijaal¹, R.A. Conte¹, D.T. Walsh¹, D. Wei¹, A.R. Deshikar¹, T. Zhou¹, T. Hebert¹, X.Y. Yang¹, H. Ratech¹, E.W. Friedman², K.H. Ramesh¹.* 1) Pathology, Montefiore Medical Center, Albert Einstein Col. Med., Bronx, NY; 2) Hematology-Oncology, Montefiore Medical Center, Bronx, NY. 10467.

A 71 year old female with a 10 year history of CLL presented with confusion, headache, and epistaxis. CBC showed Hct of 26%, WBC of 16,200, total protein of 11.8g/dl, IgM of 8160mg/dl, viscosity 5cp, and a thrombin time of 27/2s. CAT scan showed adenopathy but no splenomegaly. Bone marrow (BM) was hypercellular (80%-90%) and was infiltrated in a diffuse and infiltrative pattern by small lymphocytes with plasmacytoid features (70%). Normal trilineage hematopoiesis was reduced. Megakaryocytes were decreased and hypolobated. There were no granulomas. Rare lymphoid cells containing globules that stained focally positive with PAS-D were present. Flow cytometry interpretation was: abnormal cells comprising 23% of the total population, CD5-, CD10-, CD19+, CD20 (moderately bright)+, CD22+, CD23-, FMC7 (partial)+, CD56-, CD138-, monoclonal IgM+, IgD+, KAPPA (bright)+, aberrant mature B-cell phenotype. Based on BM morphology and flow cytometry, a diagnosis of lymphoplasmacytic lymphoma was established. Cytogenetic analysis of BM revealed a 46,XX,t(14;18)(q32;q21) [6]/46,XX [14] karyotype. The t(14;18) is usually seen in follicular lymphoma and diffuse large B-cell lymphoma (DLBCL). FISH analysis with the IGH/BCL2 DNA probe showed an unusual signal pattern; the breakpoint in 18q21 was found to be proximal to the expected BCL2 breakpoint, which resulted in the transpositioning of the entire BCL2 locus to the 14q32 chromosome region. Whereas the breakpoint on IGH occurred at the IGH J segments breaking apart the IGH probe, thereby resulting in partial transpositioning of IGH sequences on to 18q21. The FISH results showed that BCL2 was intact, and does not support follicular or DLBCL in this patient. This case shows the importance of performing FISH analysis where t(14;18) (q32;q21) has been reported by cytogenetics analysis.

Genomic Evolution in Chronic Lymphocytic Leukemia. *L. Zou, L. Li, M. Shaver, J. Lian, J. O'Malley, L. Defeo, N. Wang.* Pathology, University of Rochester, Rochester, NY.

To identify the sequential genetic alterations associated with the onset and progression of CLL, 48 cases were analyzed using both G-banding and Fluorescence In situ Hybridization (FISH) analyses with a panel of probes specific for the regions of 11q22.3(ATM), 12cen, 13q14.3(D13S319), and 17p13.1(p53). Fourteen cases were normal by both G-banding and FISH analyses. A single genomic aberration was identified by FISH in 12 cases: 8 cases (66.7%) with a del(13)(q14.3) and 2 cases (16.7%) with a +12. In contrast, G-banding detected only two cases with an aberration. Twenty cases were detected with more than one genetic alteration by combined G-banding and FISH analyses. Four cases were found to have multiple karyotypic aberrations by G-banding but with no aberrations detected by FISH. Out of 16 cases with aberrations detected by FISH, del(13)(q14.3) was identified in 13 cases, del(11)(q22.3) in 8 cases, +12 in 6 cases, and del(17)(p13.1) in 2 cases. Out of the 13 cases with del(13)(q14.3), 7 cases with an additional aberration of del(11)(q22.3), 3 with an additional aberration of +12, 2 with del(17)(p13.1), and 1 with +11. With the exception of one, all of the 8 cases with del(11)(q22.3) are associated with del(13)(q14.3). Out of the 6 cases with +12, 3 cases are associated with del(13)(q14.3), 2 with del(17)(p13.1), and 1 with a +11. In one case, initially, only del(13)(14.3) was detected, while 6 months later del(11)(q22.3) was detected in 74% of the cell population. In summary our data suggests that del(13)(q14.3) is an initial genetic aberration associated with CLL onset while del(11)(q22.3), +12, and del(17)(p13.1) may take place sequentially afterward during the progression of the disease. Furthermore, FISH analysis with CLL panel probes can highly facilitate the detection of genetic aberrations associated with CLL and increase the sensitivity by extending the analysis to the nondividing cell population. However, G-banding should be applied as well for the detection of other chromosomal aberrations.

Lower Cancer Risks in Amsterdam-I Criteria Families Without Mismatch Repair Deficiency. *K. Rabe¹, G. Petersen¹, R. Haile², G. Casey², M. Aronson³, B. Bapat³, J. Hopper⁴, J. Jass⁴, L. LeMarchand⁵, J. Grove⁵, J. Terdimann⁶, P. Conrad⁶, J. Potter⁷, P. Newcomb⁷, G. Moslein⁸, S. Thibodeau¹, L. Boardman¹, D. Seminara⁹, N. Lindor¹.* 1) Mayo Clinic,Rochester,MN; 2) USC,LA,CA; 3) U of Toronto,Ontario; 4) U of Melbourne,Aust; 5) U of H,Honolulu,HI; 6) UCSF,CA; 7) FHCRC,Seattle,WA; 8) Dusseldorf,Germany; 9) NCI,Bethesda,MD.

Background: The Amsterdam I Criteria (AC-I) helps identify families with Hereditary Non Polyposis Colorectal Cancer(HNPCC). 60% of ACI families have a hereditary defect in a mismatch repair gene, resulting in tumor microsatellite instability (MSI). Cancer risks in these HNPCC families are very high and well defined. Other AC-I families have no evidence of a mismatch repair defect (microsatellite instability low or stable, MSI-L/MSS). Risks in such families are unknown. We compared cancer risks in AC-I families with MSI versus MSI-L/MSS. **Methods:** We identified 161 AC-I pedigrees that could be assigned to Group A: due to hereditary mismatch repair defects (MSI) or to Group B: AC-I families not due to defective mismatch repair (MSI-L/MSS) as determined by tumor testing. We analyzed cancer risks compared to SEER data in the 1st and 2d degree relatives of the triad. **Results:** 3,422 relatives (excluding triad members) were included in analyses. Cancer risks in Group A (MSI) showed the expected increased risk for cancers consistent with HNPCC. Group B (MSI-L/MSS) showed only moderate increased risk for colorectal cancer. In Group A, (n=1855) relative risks(CI) were: colorectum:6.1(5.3-7.1); uterus:4.1(2.9-5.6); small bowel:7.6(2.9-16.5); small bowel:7.6(2.9-16.5); kidney/ureter: 3.1(1.9-4.8); ovary:2.0(1.0-3.5). In Group B (n=1567), colorectal RR=2.3(1.8-3.0). No other cancers were significantly increased. **Conclusion:** Families fulfilling the AC-I criteria can be divided into true HNPCC/Lynch syndrome and those that do not have true HNPCC. ACI families without DNA mismatch repair deficiency should be counseled that it is very unlikely they have HNPCC; screening recommendations can be customized, based on these data and an individual's family history. Supported by NCI, National Institutes of Health RFA #CA-95-011.

Matching patterns of genomic imbalances point to common pathways of disease progression in hereditary and non-hereditary retinoblastomas. *S. Schneider*¹, *D.R. Lohmann*², *L. Hehn*¹, *E. Lieth*¹, *S. Herzog*¹, *H. Rieder*¹. 1) Clinical Genetics, Philipps-University, Marburg, Hessen, Germany; 2) Institute of Human Genetics, University Hospital, Essen, Nordrhein-Westfalen, Germany.

Genomic imbalances have been demonstrated in 65-95% of Retinoblastomas (Rb) and are more frequent in Rb of older than in those of younger patients. Because patients with hereditary Rb are younger than patients with non-hereditary Rb, we investigated if both groups differ from each other by the patterns of copy number changes (CNC) as revealed by comparative genomic hybridization (CGH). Tumors of 100 patients with unilateral isolated non-hereditary Rb (nhRb) and of 65 patients with bilateral hereditary Rb (hRb) were studied. In all tumors biallelic RB1 inactivation was verified. Both tumor groups showed an increase of genomic imbalances with age. The fractions of abnormal tumors in patients with ages ≤ 12 months was 43.5% in hRb and 40% in nhRb. In children with ages > 12 months 73.7% of hRb and 91.4% of nhRb showed abnormal tumors. In hRb and nhRb gains of 6p (55% and 32.3% of abnormal tumors) and 1q (41% and 15.4%), as well as losses of 16/16q (37% and 9.2%) were most frequent. Moreover, gains at 1q and losses at 16/16q were restricted to patients with ages > 12 months in both groups. Retinal development and retinoblast differentiation progress from central (macula) to peripheral (ora serrata). Thus, in children of younger ages the proportions of retinoblasts and of differentiated retinal cells is different from that in older children. The observed increase of CNCs in nhRb and hRb with age may, therefore, reflect differences in the genetic pathways of tumor progression depending on different differentiation stages and/or locations of the transformed retinal cells. Funded by the DFG, Ri-1123/1-1.

Identification of genes associated with ovarian cancer metastasis using microarray expression analysis. *J.M. Lancaster¹, H.K. Dressman⁴, J.L. Pittman⁵, A.H. Henriott³, R.A. Sayer¹, J. Gray², R.S. Whitaker³, M. West⁵, J.R. Marks⁶, J.R. Nevins⁴, A. Berchuck³.* 1) Interdisciplinary Oncology, H. Lee Moffitt Cancer Center, Tampa, FL; 2) Institute of Medical Genetics, University Hospital of Wales, Cardiff, CF14 4XN, UK; 3) Departments of Obstetrics and Gynecology/Division of Gynecologic Oncology, Duke University Medical Center, Durham, NC 27710; 4) Molecular Genetics and Microbiology, Duke University Medical Center, Durham, NC 27710; 5) Howard Hughes Medical Institute, Institute for Genome Sciences and Policy, Institute of Statistics and Decision Sciences, Duke University Medical Center, Durham, NC 27710; 6) Surgery, Duke University Medical Center, Durham, NC 27710.

The transition from early to advanced stage ovarian cancer is a critical determinant of survival, but little is known about the molecular underpinnings of ovarian metastasis. We applied Affymetrix U95Av2 microarrays to characterize the molecular alterations that underlie the development of omental metastasis from 47 epithelial ovarian cancer samples collected from multiple sites in 20 patients undergoing primary surgery for advanced stage serous ovarian cancer. Fifty-six genes demonstrated differential expression between ovarian and omental samples ($p < 0.01$), and 20/56 (36%) differentially expressed genes have previously been implicated in metastasis, cell motility or cytoskeletal function. Ten of 56 genes (18%) are involved in p53 pathways. Bayesian statistical tree analysis was applied to validate the significance of the gene expression patterns, and identified 27 genes that could accurately predict tumor site (ovary vs. omentum) in 87% of cases in cross-validation studies. Nine of the 27 genes (GRP135, FHL-2, GA, LAMC2, MAGE-A10, CDK5, RPS6KB1, AIM2, SLIT3) have previously been shown to be involved in oncogenesis, and 10/27 genes (LAMC2, APOBEC2, FHL, STAR, PARD6B, ELAVL1, ANGPT1, CDK5, RPS6KB1, RFXAP) have been implicated in p53 pathways. Using genome-wide expression technology and novel statistical and gene pathway analyses we have identified a distinct genetic profile that underlies omental metastasis from epithelial ovarian cancer.

Contribution of Fluorescent In Situ Hybridization analysis to detect *BCR-ABL* complex in patients with Philadelphia negative chronic myelogenous leukemia. *M. Soto Quintana, A. Rojas-Atencio, F. Álvarez Nava, K. Urdaneta.* Unidad Genética Médica, Universidad del Zulia, Maracaibo Zulia, Venezuela.

Chronic myelogenous leukemia (CML) is genetically characterized by the presence of the Philadelphia (Ph) chromosome that arises from t(9;22)(q34;q11). About 95% of patients with CML have the translocation or a variant of this. The remaining 5% has a submicroscopic translocation that is not evidenced by conventional cytogenetics methods (Ph negative). Fluorescent In Situ Hybridization (FISH) analysis, however, reveals the t(9;22) and formation of the *BCR-ABL* fusion gene. The translocation fuses the *ABL* and *BCR* genes by inserting the *ABL* proto-oncogen located at 9q34.1 to the *BCR* region at 22q11.2. This chimerical gene codes for an abnormal protein which has tyrosine kinase activity and significant leukemogenic potential. The objective of this study was to detect of the *BCR-ABL* complex in patients with Ph negative chromosome CML. Bone marrow samples from 15 patients with CML were analyzed. To determine the *BCR-ABL* rearrangement by FISH we used the probe LSI *BCR-ABL* and hybridization protocol that were supplied by VYSIS. FISH analysis showed that all patients presented the fusion *BCR-ABL*. Our study demonstrates the significance of this assay in the detection of the *BCR-ABL* complex in patients with Philadelphia negative CML. Thus, FISH is a crucial to the accurate diagnosis and correct medical management of this patients.éé.

Statistical Analysis of cDNA Array CGH Data in Breast Cancer Cell Lines and Tumors. *S. Colby¹, S.B. Bull^{1,2}, A. Bane¹, L. Bosnoyan-Collins¹, N. Gokgoz¹, S. Minaker¹, I.L. Andrulis^{1,3}.* 1) Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, ON; 2) Department of Public Health Sciences, University of Toronto, Toronto, ON; 3) Department of Molecular and Medical Genetics, University of Toronto, Toronto, ON.

The identification of genes involved in cancer has benefited from detection of changes that occur in tumor cells. Array-based comparative genomic hybridization (*a*-CGH) provides a measure of DNA copy number variation across the entire genome an alternative to identifying novel genetic targets by studying multi-case families using linkage methods. We have completed *a*-CGH on 5 breast cancer cell lines (BT474, MDA-MB231, SKBR3, T47D and UACC) and on over 50 tumor DNAs from a cohort of axillary node-negative cases from the Toronto area. In the first stage of the analysis, we delineated regions of chromosomal loss or gain for each patient using the Bioconductor package DNACopy (Olshen and Venkatraman, 2004). Each region was assigned an alteration type (i.e., normal, loss/deletion, gain/amplification) based on the log copy number ratios of the clones within the region. In the second stage of the analysis, the alterations were tabulated yielding a ranking according to alteration frequency of the top regions for further examination.

Analysis of the BT474 cell line detected known amplifications on 17q11.2-22 and 20q12-13.3. We detected gains in 80% of the tumors, losses in 47% of the tumors, and found no detectable alteration in only 5 tumors. Many of the the regions of alteration detected in the tumors have been implicated in breast cancer through conventional CGH.

Gonadal tumors at an early age in patients with mixed gonadal dysgenesis. *I. Palma¹, Y.R. Pena², K. Nieto¹, R. Alvarez¹, L. Erana², L.M. Dorantes², S. Kofman-Alfaro¹, G. Queipo¹.* 1) Dept Genetics, Hosp General de Mexico, Mexico City, Mexico; 2) Intersex Clinic. Hospital Infantil de Mexico-Federico Gomez, Mexico City, Mexico.

Gonadoblastoma is an unusual mixed germ cell-sex cord stromal tumor that occurs mostly in individuals with abnormal gonadal development and a karyotype with Y chromosome or Y-derived sequences. Half of the gonadoblastomas show germ cell overgrowth leading to a typical dysgerminoma transformation. The age at diagnosis is variable but they are very rare at early ages. We present 5 patients with different types of gonadal dysgenesis, in 4 of them (cases 1-4) the tumor was recognized in early childhood while in case 5 a dysgerminoma was observed at age 15. In these patients we found different types of tumors: juvenile granulosa cell tumor beside a gonadoblastoma, bilateral gonadoblastoma and dysgerminoma. FISH analyses performed to evaluate the X and Y cell distribution between the tumor and the dysgenetic gonadal tissue, showed that Y cells were more frequent in the tumor than in the gonad. We discuss these findings and the genesis of these tumors in young children and recommend early surgical management of the dysgenetic gonads.

Urovysion assay on fresh urine samples: needs to find a general consensus. *D. Bettio*¹, *A. Venci*¹, *M. Corinti*², *P. Graziotti*². 1) Cytogenetic Laboratory, Humanitas Clinical Institute, Rozzano, Milan, Italy; 2) Urology Operative Unit, Humanitas Clinical Institute, Rozzano, Milan, Italy.

The study was performed in order to introduce FISH on urine as a powerful tool for the detection, follow-up and prediction of bladder tumors. Some interesting observations led us to correlate the FISH results with the tumors' biological behaviour. FISH was performed on fresh urine from 35 patients without prior knowledge of biopsy, cystoscopy and cytology results. Patients were selected following several criteria: all except 3, presenting with hematuria, had a history of transitional cell carcinoma. We used the two more common criteria for FISH positivity: one recommended by the manufacturer (Vysis) that we call maximum criteria (MC) and the other by Bubendorf et al. (2001). The latter sets the cutoff for positivity at more than 2 cells with an abnormal signal copy number of at least 1 of the 4 probes, that we call minimum criteria (mc). In 13 MC+ cases the presence of the tumor was confirmed, while the 11 negative ones had TUR and/or therapy before FISH was performed. Of the 3 cases with hematuria, 2 were MC+ and 1 mc+. Twelve out of 35 cases turned out to be MC- but mc+. So far, after 1 year average follow-up, 4 turned MC+ and 1 remained MC-. Three MC+ patients had tumor recurrence within 6 to 18 months following the positive FISH result. The predictivity of FISH led us to choose a strict follow-up in some patients. So far we have 9 false positive cases with several MC+ results without evidence of the disease. Since we defined a negative at 24-month follow-up we consider these cases still in progress. In 3 MC+ and 2 mc+ cases we observed 9p21 deletion associated with monosomy 17 as the sole anomalies. Because of this finding we screened the 35 cases looking for monosomy 17 in at least in 1 cell. For 6 out of the 20 found we had a follow-up after at least 6 months demonstrating an increased number of aneuploidy cells and so far 3 patients had tumor recurrence. This observation indicates that monosomy 17 might be the second genetic alteration after loss of P16 and is suggestive of recurrence risk. Based on this result we suggest that monosomy 17 should be included in the criteria for positivity.

Program Nr: 345 from the 2004 ASHG Annual Meeting

The effects of trichostatin A on adenovirus-mediated p16 gene transfer in Balb/c nude mouse. *M. Park, O. Kim, S. Lim, J. Kim, C. Song, H. Jung, H. Kang.* Toxicological Research Dept., NITR, KFDA, Seoul, Korea.

To enhance therapeutic effects of gene therapy, the combinational strategy with chemotherapeutic agent is rapidly increased for cancer treatment. But there is limited information about efficacy and safety of combinational gene therapy. We investigated the effects of trichostatin A, a antitumor agent, on Ad5CMV-p16 (p16-expressing adenoviral vector) in non-small cell lung cancer. We confirmed that replication competent adenovirus and contaminations of microorganism were not detected in our adenoviral vectors (Ad5CMV-p16, Ad5CMV-LacZ) by PCR and mycoplasma test. Trichostatin A increased the inhibition effect of Ad5CMV-p16 on A549 cell-induced lung tumor formation and A549 xenograft tumor growth in Balb/c nude mice. As a safety concern, we investigated biodistribution changes after combinational treatment of Ad5CMV-LacZ and trichostatin A. We found that -galactosidase activities were detected in liver, kidney, spleen, and lung after tail vein injection of Ad5CMV-LacZ. Trichostatin A enhanced the transduction of Ad5CMV-LacZ into lung and changed biodistribution pattern in kidney. Taken together, we suggest that combinational gene therapy with trichostatin A could enhance the transfection efficiency of Ad5CMV-p16, and it will be helpful to reduce the titer of adenoviral vector. Further studies will be needed to investigate whether CAR and integrin expression would be changed or not by trichostatin A in vivo.

Multiplex PCR / Liquid Chromatography assay for detection of gene rearrangements: Application to the RB1 gene. *C. Dehainault¹, A. Laugé¹, V. Caux Moncoutier¹, S. Pagès Berhouet¹, F. Doz², L. Desjardins³, J. Couturier^{1, 4}, M. Gauthier Villars¹, D. Stoppa Lyonnet^{1, 4}, C. Houdayer¹.* 1) Genetics; 2) Pediatric Oncology; 3) Ophthalmology; 4) Inserm U509, Institut Curie, Paris, France.

Screening for large gene rearrangements is established as an important part of molecular medicine but is also challenging. A variety of robust methods can detect whole-gene deletions but will fail to detect more subtle rearrangements that may involve a single exon. Here we describe a new versatile and robust method to assess exon copy number, termed Multiplex PCR/Liquid Chromatography assay (MP/LC). Multiple exons are amplified using unlabelled primers, then separated by ion-pair reversed-phase high performance liquid chromatography, and quantitated by fluorescent detection using a post-column intercalation dye. The relative peak intensities for each target directly reflect exon copy number. This novel technique was used to screen a panel of 121 unrelated retinoblastoma patients, previously tested using a reference strategy i.e. a combination of FISH, QMPSF and RT PCR analyses. MP/LC correctly scored all deletions and evidenced a previously undetected RB1 duplication, the first to be described. MP/LC appears as an easy, versatile, and cost-effective method, which is particularly relevant to DHPLC users since it broadens the spectrum of available applications on a DHPLC system.

A Tiling Resolution Bacterial Artificial Chromosome Array Delineates Distinct Regions of Genetic Alteration in Breast Cancer Genomes. *T.P.H. Buys, A. Shadoo, S. Yip, K.A. Gelmon, T.O. Nielsen, W.L. Lam.* British Columbia Cancer Agency, Vancouver, BC, Canada.

Breast cancer is the most commonly diagnosed malignancy in Canadian women. Genetic alterations that drive disease progression may differ between disease subtypes. The newly developed whole genome Sub-Megabase Resolution Tiling-set (SMRT) array has moved genomic profiling beyond marker-based analysis, comprehensively identifying copy number alterations. We have identified known and novel recurrent genetic alterations by comparing whole genome profiles of ten cases of the postulated basal subtype of disease, which has the ER-, Her2-, KRT5/6+, PR-immunohistochemical (IHC) staining pattern. These cases were identified from archived breast cancer samples at the Vancouver General Hospital. DNA was extracted from microdissected malignant cells for SMRT array comparative genomic hybridization (CGH) analysis. Genome profile comparison revealed multiple recurrent gains and losses of DNA segments. Amongst the numerous alterations identified, recurrent novel alterations were found, including copy number gains at 1p32.1-p32.2, 5p15.2, 6p22.3, 10p14 and losses at 8p11.2 and at multiple segments between 19q13.2-q13.3. Array-based results will be verified by fluorescence in situ hybridization analysis. This work represents the highest resolution analysis of breast cancer genomes to date. SMRT array CGH profiles revealed multiple recurrent genetic alterations, including sub-megabase regions which harbor candidate tumor suppressors or oncogenes potentially crucial to the development of BC.

This work was supported by grants from Genome British Columbia and an educational grant from Aventis Inc.

High resolution mapping of genomic imbalance and gene expression profiles associated with differential chemotherapy response in serous epithelial ovarian cancer. *M. Bernadini¹, P. Shaw¹, C-H. Lee¹, B. Beheshti¹, H. Bagley¹, M. Prasad¹, S. Minkin¹, J. Murphy¹, B. Rosen¹, W. Lam², S. Watson², P. Macgregor¹, J.A. Squire¹.* 1) University Health Network, Toronto, Ontario, Canada; 2) British Columbia Cancer Agency, Vancouver, British Columbia, Canada.

This study is applying whole genome analytical methods at the DNA and RNA levels in serous epithelial ovarian cancer (SEOC) in the context of clinical parameters such as tumor stage, CA125 levels, treatment response and survival. In the first phase of this study high- resolution microarray comparative genomic hybridization (CGH) was used to identify genomic regions associated with chemotherapy resistance in epithelial ovarian cancer. The analysis has confirmed the presence of copy number alterations at specific chromosomal regions in 26 tumors. Gains at 1q, 3q, 8q, 12p and 20q as well as losses at 1p, 4q, 6q, 8p, 9q, 13q, 16q, 17p, 18q, were consistent with previously reported recurrent genomic imbalance detected by metaphase CGH. A systematic bioinformatics analysis using the high resolution CGH array datasets has further allowed us to identify small sub-genomic regions that discriminate drug resistance as determined by the kinetics of serum CA125 levels following chemotherapy. These regions include recurrent losses at 1p36.33 (2.2Mb) and 6q24.3-25.2 (18.4Mb) with gains being detected at 1q42-44 (25.6Mb) and 13q12.2-13.1 (6.3Mb). Expression profiles were obtained in a companion parallel study and findings concerning novel pathways previously implicated in cis-platinum adduct repair will be reported. The information gained in this study provides the first step to identifying discriminating regions of genomic imbalance that may potentially play a role in predetermining patients for specific chemotherapeutic regimens.

RNA Expression Changes and Concordance with DNA Copy Number Alterations in Serous Epithelial Ovarian Carcinoma Associated with Resistance to Chemotherapy. *C-H. Lee¹, M. Prasad¹, M. Bernadini^{2,3}, B. Beheshti², P. Marrano², H. Begley³, P. Shaw³, A. Covens⁵, J. Murphy⁴, B. Rosen⁴, S. Minkin², J.A. Squire^{2,3}, P.F. Macgregor¹.* 1) Microarray Centre, Clinical Genomics Center, University Health Network, Toronto, Ontario, Canada; 2) Ontario Cancer Institute, Princess Margaret Hospital, University Health Network, Toronto, Ontario, Canada; 3) Department of Laboratory Medicine and Pathobiology, University of Toronto, Ontario, Canada; 4) Department of Gynecological Oncology, University of Toronto, Ontario, Canada; 5) Toronto Regional Cancer Centre, Sunnybrook and Women's College Hospital, Toronto, Ontario, Canada.

To improve our knowledge of resistance to chemotherapy in Serous Epithelial Ovarian Cancer (SEOC) patients, we used RNA profiling by cDNA microarrays on a cohort of tumors obtained from patients sensitive and resistant to carboplatin/taxol treatment. Based on their CA 125 levels before, during, and after treatment, ten SEOC samples were selected from patients who exemplified extreme cases of differential response to the drug regimen. We identified RNA signatures distinct to ovarian tumors resistant or sensitive to chemotherapy. Within these signatures five genes (GAPD, HMGB2, HSP70, GRP58 and HMGB1), previously shown to form a nuclear complex associated with resistance to DNA-conformation altering chemotherapeutic drugs in in vitro systems, may represent a novel class of genes associated with in vivo drug response in ovarian cancer patients. A concordance analysis of overall genomic imbalance (presented by Squire et al) and RNA expression change indicated only weak DNA copy number dependence. Thus, the goals of this study were to identify RNA profiles that are predictive of treatment failure and to determine whether gene copy number differences are reflected at the RNA level.

P16 hypermethylation, a possible epigenetic risk factor in a familial esophageal squamous cell carcinoma as compared to CEA tumor marker. *H.R. Raziee^{1,2}, S. Afsharnezhad¹, H. Khallaghi¹, K. Ghaffarzagdegan³, M.R. ghavamnasiri², M.R. Abbaszadegan¹.* 1) Division of Human Genetics, Immunology Research Center, Bu- Ali Research Institute, Mashhad University of Medical Science (MUMS); 2) Department of Radiation Oncology, Omid Cancer Hospital, MUMS; 3) Department of Pathology, Omid Cancer Hospital, MUMS, Mashhad, Iran.

New tumor markers for early detection in esophageal squamous cell carcinoma (ESCC) may improve the life expectancy for this disease. Methylation of P16 may be detected in serum DNA of cancer patients as a tumor marker. DNA from serum and blood of ESCC patients for p16 hypermethylation in Northeastern Iran showed a family with clustering of ESCC. Three histological proven cases of ESCC in two consecutive generation and other deceased cases with history of ESCC in this pedigree provoked a p16 hypermethylation study. DNA from blood of 28 family members in 3 generations and 30 healthy volunteers was examined for methylation status of p16 promoter using methylation specific PCR (MSP). The results revealed aberrant p16 promoter methylation in blood from 64.3% (n=28) of ESCC family members and none 0% (n=30) in normal volunteers. The proband with ESCC had p16 hypermethylation in DNA extracted from tumor, blood and serum. Seventeen asymptomatic family members also had p16 hypermethylation in their blood. Five of 28 family members had negative endoscopy results for ESCC, but 4 of these members had p16 hypermethylation in their blood. The family members with negative endoscopy but positive p16 promoter methylation are being followed for any signs of ESCC development using chromoendoscopies. In sporadic ESCC in northeastern Iran, 73.3% (n=30) of tumor tissue samples had p16 hypermethylation. Serum and blood samples from these patients showed p16 hypermethylation in 26.6% and 43.3% respectively. Results were compared with the serum Carcinoembryonic antigen (CEA), a tumor marker with elevations in tumors of gastrointestinal tract. Only one serum sample presented elevated CEA. Results indicated that aberrant p16 methylation may be a valuable epigenetic tumor marker for identification of individuals in high risk ESCC families.

GDNF INDEPENDENT ACTIVATION OF A Src/JAK/STAT3 PATHWAY BY RET-FMTC MUTANTS Y791F

AND S891A. *R.M.W. Hofstra¹, I. Plaza Menacho¹, R. Koster¹, A. van der Sloot², W.J. Quax², T. van der Sluis³, H. Hollema³, O. Gimm⁴, G. Burzynski¹, C.H.C.M. Buys¹, B.J.L. Eggen⁵.* 1) Dept. Pharmaceutical Biology, Univ Groningen Groningen, The Netherlands; 3) Dept. Phatholgy, Univ Hospital Groningen, Groningen, The Netherlands; 4) Dept. Surgery, Martin-Luther-Universitat Halle-Wittenberg, Germany; 5) Dept. Developmental Genetics, Univ Groningen, Groningen, Netherlands.

The RET proto-oncogene encodes a receptor tyrosine kinase whose dysfunction plays a crucial role in the development of several neural crest disorders. Distinct activating RET mutations are found associated with Multiple Endocrine Neoplasia types 2A (MEN2A), 2B (MEN2B) and Familial Medullary Thyroid Carcinoma (FMTC). Despite clear correlations between the mutations found in these cancer syndromes and their phenotypes, the molecular mechanisms connecting the mutant receptor to the different disease phenotypes are far from completely understood. Luciferase reporter assays in combination with immunoprecipitations, western and immunohistochemical analyses were performed in order to characterize the signaling properties of two FMTC-associated RET mutations, Y791F and S891A, respectively, both affecting the tyrosine kinase domain of the receptor. We show that these FMTC mutations lead to dominantly activating monomeric receptors which are autophosphorylated and activated independently of GDNF. Moreover, we demonstrate that the dysfunctional signaling properties of these mutations, when compared to wild type RET, involve the constitutive activation of STAT3. This STAT3 activation is mediated by a signaling pathway involving Src and JAK1-2. Three-dimensional modeling of the RET catalytic domain suggests that the structural changes promoted by the respective amino acid substitutions lead to a more accessible substrate binding conformation. The in vitro data are supported by the results of immunohistochemical analysis of FMTC tumor samples support that show nuclear localization of Y705-phosphorylated STAT3 as well as a high degree of RET expression at the plasma membrane.

Identification of tumor associated SNPs based on EST analysis. *W. Ding¹, M. Kostich¹, P. Qiu¹, L.Q. Wang², J.R. Greene¹, M. Hernandez¹.* 1) Bioinformatics Group, Discovery Technology Department, Schering-Plough Research Institute, Kenilworth, New Jersey 07033; 2) GenScript Corporate, 120 Centennial Avenue, Piscataway, New Jersey 08854.

Carcinogenesis occurs, at least in part, due to the accumulation of mutations in critical genes that control the mechanisms of cell proliferation, differentiation and death. Expressed Sequence Tags (ESTs) are derived from cDNA libraries generated from a vast number of normal and disease tissues. By statistical analysis of human ESTs, we detected 176,207 candidate Single Nucleotide Polymorphisms (SNPs). We manually curated and catalogued EST cDNA tissue libraries into non-tumor libraries and tumor libraries and examined the association between individual SNPs and tumor tissues. A total of 5152 SNPs were identified which were present at higher allele frequencies in tumor compared to normal tissues. A subset of 1955 (37.9%) SNPs induce amino acid changes to the protein coding sequences. This approach identified many SNPs which have been previously associated with carcinogenesis, as well as a number of SNPs that now warrant further investigation. This genome-wide in silico approach can assist in detection of tumor associated SNPs and help to elucidate the genetic mechanisms underlying the development of cancer.

UMD-BRCA1 and BRCA2 mutation databases. *D. Hamroun*^{1, 2}, *S. Bezieau*², *I. Biché*³, *B. Bressac-de Paillerets*³, *F. Coulet*³, *M.C. Gorisse*³, *A. Hardouin*³, *M. Longy*³, *S. Olschwang*³, *J.P. Peyrat*³, *C. Philippe*³, *P. Rostagno*³, *T. Noguchi*³, *O. Sinilnikova-Evrard*³, *D. Stoppa Lyonnet*³, *C. Toulas*³, *N. Uhrhammer*³, *M. Claustres*², *C. Beroud*², *R. Lidereau*¹. 1) Rene Huguenin Center, Saint Cloud, France; 2) Dept of Molecular Genetics, CHU de Montpellier, Montpellier, France; 3) Sub group of laboratories of cancer genetic's group of FNCLCC (GGC).

BRCA1 and BRCA2 are the major genes responsible for ovary and/or breast cancers. Germline mutations are mainly small size mutations and are distributed throughout both genes. If the deleterious character of truncating mutations is generally assumed, only few data are available for missense mutations biological significance. The development of databases collecting mutations of both BRCA1 and BRCA2 genes characterized from French families was performed with the UMD "Universal Mutation Database" generic software. In addition to the full molecular description of each mutation (consequence at the DNA, RNA and protein levels), we collected clinical information from genetic counseling of the GGC.

So far we have collected data from 1207 families for BRCA1 gene and 842 families for BRCA2 gene among those 736 and 377 families respectively have deleterious mutations. Among the BRCA1 deleterious mutations, 48.9% are out of frame deletions, 0.8% in frame deletions, 18.2% out of frame insertions, 6% missense mutations, 22.1% nonsense mutations and 11.6% intronic mutations. For BRCA2 64.7% are out of frame deletions, 10.9% out of frame insertions, 0.3% missense mutations, 21.2% nonsense mutations and 2.9% intronic mutations.

Mutations of either gene can be found in various familial situations (numbers are given for BRCA1 and BRCA2, respectively): breast cancer (43%; 63%); breast and ovary cancers (47%; 25%); ovary cancer (5%; 4%); young isolated breast or ovary cancer (4%; 3%); man breast cancer (0%; 5%); other (2%; 1%).

The computation of these data should help in the identification of deleterious mutations among variations of unknown biological significance. This should prove particularly useful for families with missense mutations to better design patients follow-up.

Bone marrow engraftment chimerism monitoring by short tandem repeat (STR) analysis. *L.M. Hire, P. Labrousse, J. Garces, B.A. Allitto.* Genzyme Genetics, Westborough, MA.

Objective: Monitoring of hematopoietic cell chimerism is important for establishing graft rejection and disease relapse. We evaluated a method for monitoring chimerism using fluorescent multiplex PCR of STRs and compared the limit of detection and heterogeneity of various STR loci available in the AmpFLSTR kits from Applied Biosystems. **Methods:** Blood and bone marrow mixtures were made based on cell counts or spectrophotometric DNA measurements. Straight and mixed samples were subjected to multiplex PCR using the ProFiler Plus and COfiler kits followed by capillary electrophoresis with fluorescent detection. Percent chimerism was calculated as a ratio of allele peak heights measured in RFUs between donor (D) and recipient (R) alleles using the formula: $[(R1+R2)/(R1+R2+D1+D2)] \times 100$. **Results:** The sensitivity of allele detection and the total number of informative alleles were comparable between pre and post extraction mixtures for both blood and bone marrow specimens. A 5% detection limit was consistently measured for a subset of the markers tested, although 1% detection was observed for a number of allelic combinations. Preliminary data suggest that on average 1 in 4 markers should be detected as informative in 5% mixtures using these STR panels. To ensure accurate calculation of percent chimerism, samples should be analyzed in duplicate with averaging of peak intensities. **Conclusions:** The ratio of allele peak heights following PCR amplification and fluorescent detection of STR markers serves as an adequate and reproducible semi-quantitative measure of the relative amounts of both the major and minor component in cell mixtures such as those observed following bone marrow engraftments. We developed several criteria around RFUs and genotype combinations to ensure detection of at least 5% chimerism in a clinical assay. While both the ProFiler Plus and COfiler panels are adequate for chimerism detection, the COfiler panel produced more informative markers on average at a 5% detection limit than the ProFiler Plus panel. In our sample set, D8S1179, D16S539, and D3S1358 were the most informative markers in mixtures where the minor component was present at 5%.

High-Risk Breast Cancer and a 5'UTR Triplet Repeat Polymorphism in the Glutamate-Cysteine Ligase Catalytic Subunit (GLCLC) Gene. *A.R. Kallianpur^{1,4,5}, A.S. Willis^{3,4}, B.W. Christman^{1,4,5}, M.L. Summar^{2,3,4}.* 1) Departments of Medicine; 2) Pediatrics; 3) Molecular Physiology & Biophysics; 4) Vanderbilt University Medical Center, Nashville, TN, USA; 5) TN Valley Health Services VA Medical Center, Nashville, TN, USA.

Oxidant stress, the increased production of free radicals that damage cellular lipids, proteins and DNA, is implicated in the pathogenesis of many diseases, including cancer. The tripeptide glutathione is an important scavenger of free radicals in vivo, and the enzyme glutamate L-cysteine ligase (GLCL) catalyzes the first and rate-limiting step in glutathione synthesis. We investigated polymorphisms of a previously described GAG trinucleotide repeat in the 5'UTR of the gene (GLCLC) that encodes the catalytic subunit of this enzyme in 132 patients undergoing bone marrow transplantation for high-risk cancers. The mean age of this transplant cohort was 43.710.6 years, gender composition was 60% female, and the underlying diagnosis was breast cancer in 35 women and hematological cancer in 97 patients. Patients with varying GAG repeat alleles were similar with respect to age, race, and gender. The observed GAG repeat allele frequencies in this cohort were also not significantly different from frequencies previously described by our group in a population representative of middle Tennessee. However, the frequency of the GLCLC GAG 8/9 genotype in breast cancers was higher (14.3%) than frequencies in all other cancer patients in this cohort (1.0%, $P=0.005$), women without breast cancer (0%, Fisher's exact $P=0.014$), and in the general TN population (6.5%, $P=ns$). This strong association with breast cancer was unchanged by adjustment for age and the hemochromatosis C282Y mutation (also on chromosome 6p), previously associated with breast cancer in this cohort (adjusted OR 14.1, $P=0.023$). Our findings in this cancer cohort suggest that polymorphisms in the 5'UTR GAG repeat of GLCLC may be important determinants of the clinical behavior of breast cancer in vivo and may play a role in the pathogenesis of this disease. Studies of GLCLC GAG polymorphisms in larger numbers of women with breast cancer and in normal controls are needed.

Cellular responses to genotoxic stress induced by temozolomide in an astrocytic cell line (U343 MG-a). *M.O. Bahia*^{1,2}, *C.L. Bassi*¹, *S.S. Mello*¹, *R.S. Cardoso*¹, *A.L. Fachin*¹, *G.A.S. Passos*⁵, *E.A. Donadi*³, *C.G. Carlotti Jr*⁴, *E.T. Sakamoto-Hojo*^{1,6}. 1) Depto. de Genética, FMRP, USP, SP, Brazil; 2) Depto. de Patologia, UFPA, PA, Brazil; 3) Clínica Médica, FMRP, USP, SP, Brazil; 4) Depto. de Cirurgia e Anatomia do Hospital das Clínicas, FMRP, USP, SP, Brazil; 5) Faculdade de Odontologia de Ribeirão Preto, USP, SP, Brazil; 6) Depto. de Biologia, FFCLRP, USP, SP, Brazil.

Alkylating agents, such as temozolomide (TMZ), have been widely included in the chemotherapeutic regimens for patients with gliomas. However, there is still a relative lack of understanding of the action of TMZ in glioma cells. In the present study, we analyzed the cellular responses to TMZ, in terms of clonogenic efficiency, alterations in cell cycle kinetics and apoptosis in an astrocytoma cell line (U343MG-a). In addition, the profiles of gene expression were studied by cDNA microarrays. Clonogenic efficiency was also assessed in an U343MG-a cell line transfected with a tetracycline repressor system harboring the p16 gene. Cell treatment with TMZ concentrations ranging from 10 to 360M induced a significant reduction in the reproductive capacity of U343 MG-a cells. However, an increased resistance to TMZ was observed in the transfected cell line after induction of the p16 gene. Cell cycle kinetics changes were also observed after treatment with 5 and 10M TMZ, while the induction of apoptosis was not evident until 72h after drug treatment. The analysis of gene expression by cDNA microarrays indicated many up-regulated genes observed at 48h after TMZ (10M) treatment. Among them, many genes known to participate in MAPK/JNK/c-jun pathways and genes controlling the cell cycle. Genes participating in DNA repair processes (BER, NHEJ and HRR) were also activated, indicating the signaling response mechanism towards the base-alkylation caused by TMZ, as well as against the secondary-damage, both of them being susceptible to the DNA repair machinery. Further experiments are under course with the trasfected U343 MG-a cell line in order to evaluate the effects of TMZ treatment after induction of the p16 gene on the cell cycle kinetics, apoptosis and gene expression.

Localization and protein interaction of Tsga10 and developmental changes of the gene/protein expression in mice embryo, testis, brain and some malignancies in relation to cellular division and brain development. *B. Behnam*¹, *MH. Modarressi*², *S. Manistre*¹, *S. Povey*¹, *F. Van der Hoorn*², *J. Wolfe*¹. 1) Dept Biol/Galton Lab, University College London, London, NW1 2HE United Kingdom; 2) Department of Biochemistry & Molecular Biology, University of Calgary, Canada T2N 4N1.

Tsga10-encoded protein contains a putative myosin/Ezrin/radixin/moesin (ERM) domain and has a 27-KD fibrous sheath component of sperm tail after modification. High level of TSGA10 expression is reported in some cancers. In this study we attempted to determine putative functions for Tsga10 during every active dividing cell process including spermatogenesis, neurogenesis, embryogenesis and carcinogenesis. To address this, we analysed the pattern of expression and localisation of this protein in mouse testicular cells during postnatal development and adulthood, in developmental stages of mouse embryos, in adult mice brain and in two types of malignancies including human germ cell tumour and acute myeloid leukemia. Also a testis cDNA library is screened to study Tsga10 protein interaction to other proteins by yeast two hybrid assays. Using Northern blotting, in situ hybridisation and immunostaining of testis sections we showed Tsga10 mRNA and Tsga10 protein expression in spermatogonia at pachytene to mature elongated sperms. We also found that Tsga10 localises around the nucleus, which indicates a potential porin activity of this protein. By RT-PCR and immunoreactivity study, we show Tsga10 expression mouse embryogenesis as well as brain development, germ cell tumour and acute promyelocytic leukemia. This pattern of Tsga10 gene/protein expression suggests that Tsga10 involved in spermatogenesis, neurogenesis, differentiation, tumorigenesis and embryo development. It is highly expressed with two transcripts in testis and whole embryo but with only one transcript in brain embryo. Three proteins are found as interacting proteins with Tsga10 in sperm tail. We localized a novel one among them in principal piece of sperm tail exactly where Tsga10 FS protein was localized. We hypothesize a scenario in spermatozoa, axonal transport in the brain and synaptogenesis and all actively dividing cells for Tsga10 as a structural protein.

GERMLINE AND SOMATIC MUTATIONAL ANALYSIS, GENOTYPE/ PHENOTYPE IMPLICATIONS IN A COHORT OF 46 UNRELATED TUBEROUS SCLEROSIS COMPLEX (TSC) PATIENTS. *R. Giugliani¹, A. Puga^{1, 2}, M. Logrip², R. Beauchamp², N. Smith², M. Bowser², M. McQueen², V. Ramesh².* 1) Medical Genetics Serv, Hosp Clin P Alegre, Porto Alegre, RS, Brazil; 2) Molecular Neurogenetics Unit, Department of Neurology, Massachusetts General Hospital- East, Harvard University, Charlestown, MA, USA.

Introduction: Tuberous Sclerosis Complex (TSC), an autosomal dominant disease caused by mutations in either TSC1 or TSC2 tumor suppressor genes, is characterized by development of hamartomas, preferentially in kidneys, heart and in the central nervous system (CNS). There are various cutaneous manifestations, including multiple hypomelanotic macules, facial angiofibromas and periungual fibromas. TSC occurs in both familial and sporadic patterns. Among the familial cases, causative mutations in TSC1 and TSC2 are equally distributed. In sporadic cases, however, TSC2 can account for up to 2/3 of the diagnosed patients. Review of specific literature reveals an ongoing controversy regarding causative gene and its association with phenotypic severity in TSC, with a suggestion of TSC2 patients being more severely affected, presenting higher frequencies of seizures, mental retardation and autism. **Methods:** We screened 46 patients clinically diagnosed with TSC, using SSCP, direct sequencing, and long range PCR in order to identify their germline mutations. Additionally, five cortical tubers were analyzed via LOH and long range PCR in an effort to identify their second hit mutation (somatic mutation). **Results:** We found a statistically significant under-representation of TSC1 germline mutations among sporadic cases of Tuberous Sclerosis Complex ($P= 0,03$; Fishers exact test), but an equivalent distribution of TSC1 and TSC2 in familial cases ($P>0,05$). There were no statistically significant differences between phenotypes developed by patients with TSC1 or TSC2 mutations. **Conclusions:** In contrast to kidney angiomyolipomas and cardiac rhabdomyomas caused by TSC, the five cortical tubers analyzed here showed no loss of heterozygosity (LOH), for a panel of 8 microsatellite markers scanning TSC1 and TSC2, supporting the hypothesis of haplo-insufficiency being enough for TSC lesion development in the CNS.

Gene trapping and cDNA microarray coupled analyses of a p21-Ras mouse model for astrocytomas. *V. Lee¹, A. Guha^{1,2}, D. Kamnasaran^{1,2}*. 1) Surgery (Pediatric Neurosurgery), Hospital For Sick Children, Toronto, Ontario, Canada; 2) Surgery (Neurosurgery), Western Hospital, University of Toronto, Toronto, Ontario, Canada.

We have developed an astrocytoma mouse model with GFAP regulated expression of 12V-Ha-Ras, using embryonic stem cell transgenesis. In one line (RasD7), death occurred within ~3-4 weeks, another line (RasB8) line developed multi-focal low & high-grade astrocytomas with death over a period of ~3-6 months. The RasB8 mice are not born with astrocytomas, but progressively develop increased number of them and of higher grade. We therefore hypothesize that embryonic activated Ras creates genomic instability in the astrocytes, inducing genetic alterations leading to transformation. Taking advantage of this susceptibility, we are undertaking random mutagenesis by Gene Trapping and cDNA microarray analysis to identify early onset genes that contribute to astrocytoma development and progression in this mouse model. Astrocyte cultures were developed from P0-RasB8 (prior to development of astrocytomas), 3 months-RasB8 (harboring low- & high-grade astrocytomas), 2 week-RasD7 (harboring multiple high-grade astrocytomas) and wild-type (wt) mice. The P0-RasB8 and P0-wt astrocytes did not grow colonies in soft-agar assays, while 5-10% of the 3 months-RasB8 and > 90% of 2 week-RasD7 astrocytes did. Retroviruses were engineered encoding a Splice-acceptor type of gene trap vector, to infect ~1.2 million of the P0-RasB8 and P0-wt astrocytes, at an MOI of 1.5. Of the gene-trapped P0-RasB8 astrocytes, 0.002% became transformed as per growth in soft-agar, compared to none of the retroviral infected P0-wt astrocytes. This is consistent with our hypothesis that early expression of activated Ras makes astrocytes susceptible to transformation. We have used the Retroviral gene trap tag to identify a novel tumor suppressor genes thus far. Furthermore, to investigate additional susceptibility genes, cDNA microarray expression experiments on 15,000 murine genes were undertaken on all of the astrocyte lines. Several genes were found to be differentially expressed, results of which will be discussed in detail.

Comprehensive *NF1* screening on the selected tumorigenic cell population of dermal neurofibromas: towards an extensive study of the somatic mutation spectrum in neurofibromatosis type 1. *O. Maertens*¹, *H. Brems*², *S. De Schepper*³, *E. Legius*², *F. Speleman*¹, *L. Messiaen*^{1, 4}. 1) Center for Medical Genetics, Ghent University, Ghent, Belgium; 2) Center of Human Genetics, KULeuven, Louvain, Belgium; 3) Department of Dermatology, Ghent University, Ghent, Belgium; 4) Department of Genetics, University of Alabama at Birmingham, Birmingham, USA.

A typical hallmark of neurofibromatosis type 1 (NF1), a common autosomal dominant disorder caused by mutations in the *NF1* gene, is the occurrence of benign peripheral nerve sheath tumors or neurofibromas. These tumors comprise a mixture of cell types and the somatic *NF1* inactivation appears to occur in a subpopulation of the Schwann cells. This implicates that the somatic mutational spectrum can only be established without bias when pure cell populations harbouring the somatic mutation are analyzed. This prerequisite together with the large size of the *NF1* gene has thusfar hampered thorough investigations of the spectrum of somatic mutations in neurofibromas. The study of the somatic mutational spectrum in NF1 may provide important clues about different aspects of tumorigenesis in the disease. In order to obtain further insight into these mechanisms, we developed an improved strategy for somatic mutation detection and performed extensive *NF1* mutation screening specifically on the tumorigenic cell population of dermal neurofibromas. We detected 21 somatic mutations in 26 tumors derived from 5 NF1 patients. Of these 21 somatic mutations, 19 represented subtle mutations of different types (9 small deletions (1-19bp), 5 nonsense and 5 splicing mutations), whereas only 2 samples showed loss of heterozygosity. In conclusion, our results represent the highest somatic mutation detection rate (81%) described so far in neurofibromas illustrating that this sensitive mutation detection technique is an important tool to screen for somatic mutations in neurofibromas. Our data together with additional analysis of an extended series of tumors might help elucidate the molecular basis underlying tumorigenesis which is a major challenge in NF1 research as this might facilitate patient risk prediction and open new venues for therapeutic interventions.

BRAIN LESIONS OF TUBEROUS SCLEROSIS COMPLEX (TSC) RETAIN EXPRESSION OF HAMARTIN

AND TUBERIN. A. Puga^{1, 2}, A. Stemmer-Rachamimov³, J. Roy³, N. Smith², S. Yeul Han², V. Ramesh², R. Giugliani¹.

1) Dept Genetics, Hospital Clinicas Porto Alegre, Porto Alegre, RS, Brazil; 2) Molecular Neurogenetics Unit, Department of Neurology, Massachusetts General Hospital- East, Harvard University, Charlestown, MA, USA; 3) Molecular Neuro-Oncology Laboratory, Department of Pathology and Neurosurgery, Massachusetts General Hospital- East, Harvard University, Charlestown, MA, USA.

Introduction: Tuberous Sclerosis Complex (TSC) a degenerative neurocutaneous disease, of autosomal dominant inheritance, affecting 1:6000 births, caused by mutation in one of two tumor suppressor genes, TSC1 or TSC2; resulting in the development of hamartomas and low-grade neoplasms in multiple organs, such as brain, heart, kidneys, and skin. **Methods:** We used specific antibodies against hamartin (HF6) and tuberin (TDSF), the gene products of TSC1 and TSC2, respectively, to analyze protein expression in kidney angiomyolipomas (AMLs), cardiac rhabdomyomas, cortical tubers, and subependymal giant-cell astrocytoma (SEGA). Samples were obtained through autopsy or surgery, from six unrelated TSC patients, with ages between 33 weeks of gestation and 61 years old, and equivalent tissues from normal controls. **Results:** Hamartin and tuberin co-localized on the cytoplasm of normal control cells. Cardiac rhabdomyomas and kidney angiomyolipomas were immunonegative for both proteins. Dymorphic neurons and balloon-cells, in cortical tubers and SEGA, were strongly immunopositive for both hamartin and tuberin, corroborating previous findings of Tuberous Sclerosis Complex CNS lesions behaving distinctly from lesions in other organs. The new polyclonal anti-tuberin antibody (TDSF), proved to be as specific as the standard polyclonal antibody (C20), in recognizing tuberin cell expression. **Conclusions:** Retention of both hamartin and tuberin expression in brain lesions of Tuberous Sclerosis Complex, suggests allelic haplo-insufficiency or disruption of phosphorylative inhibition over the TSC1/TSC2 complex, caused by changes in various modulating proteins involved in cell growth and cell division control, as sufficient conditions to cause hamartomatous development in CNS structures.

NF1 pathogenesis: Four types of neurofibromas defined by components of the nerve sheath. *V. Riccardi.* The Neurofibromatosis Inst., La Crescenta, CA.

While clinical and natural history delineations of 4 types of neurofibromas (nfs) of NF1 are widely accepted, a pathogenetic substantiation of them has been lacking. Based on histopathology and ultrastructural studies of developing and mature peripheral nerves, in vitro reconstruction experiments and strategic utilization of knockout mice models, the importance of the nerve sheath in determining the nature of each nf can now be specified, providing a cogent underpinning of the 4 types of NF1 nfs, which in turn will be critical for further natural history and treatment protocols. The schema respects that there are 4 major elements to the nerve sheath, namely, the epineurium (EP), perineurium (PN), endoneurium (EN) and the Schwann cell (SC). Cutaneous nfs are **Endoneurial nfs**: no elements of the PN or EP contribute to the nf. Subcutaneous nfs are **Perineurial Simplex nfs**: single fascicles of a nerve give rise to a nf encapsulated by a well-defined PN. Nodular Plexiform nfs are **Perineurial Multiplex nfs**: multiple nerve fascicles in close proximity within a nerve form dense clusterings of PN-encapsulated nfs. Diffuse Plexiform nfs are **Epineurial nfs**: the EN breaches the PN and is only partially contained by the EP, the ultimate lack of EP containment allowing for encroachment on and replacement of surrounding normal tissue. The SC contributes to all four nfs, although endoneurial (cutaneous) nf SCs generally do not manifest loss of heterozygosity for *Nf1*. Thus, NF1 nfs are not accounted for simply in terms of a tumor suppressor gene model. Rather, a histogenesis control gene model is most likely to be informative about pathogenesis and potential treatments.

Interphase FISH screening for the LCR-mediated common rearrangement of isochromosome 17q in primary myelofibrosis. *G.A. Bien-Willner¹, P. Stankiewicz¹, J.R. Lupski^{1,2,3}, J.K. Northup⁴, G.V.N. Velagaleti⁵.* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Department of Pediatrics, Baylor College of Medicine, Houston, Texas; 3) Texas Childrens Hospital, Houston, Texas; 4) Department of Pathology University of Texas Medical Branch, Galveston, Texas; 5) Department of Pediatrics, University of Texas Medical Branch, Galveston, Texas.

Non-allelic homologous recombination (NAHR) between low copy repeats (LCRs) has been implicated recently in somatic rearrangements including isochromosome i(17q), which is associated with hematologic malignancies as well as solid tumors. In hematological malignancies, the most common i(17q) breakpoint results from LCR-mediated NAHR that creates a dicentric chromosome, idic(17)(p11.2). We report an elderly patient who presented with primary myelofibrosis (MF) with myeloid metaplasia (MMM), associated with idic(17)(p11.2) as the sole chromosomal abnormality. The rearrangement breakpoint maps to the previously defined LCR cluster, further suggesting that the genomic architecture of proximal 17p may be responsible for the formation of the majority of i(17q) cases. We developed a rapid screening test using interphase FISH to detect idic(17)(p11.2), discuss the potential prognostic value of this molecular diagnostic test, and examine the relevance of LCR-mediated NAHR to common rearrangements in neoplasms.

Characterization of a Population Polymorphism within cytoband 14q12 using high resolution BAC microarray CGH analysis. *I. Braude¹, B. Vukovic¹, S.K. Watson², W.L. Lam², J.A. Squire¹.* 1) Ontario Cancer Institute, Toronto, Ontario, Canada; 2) BC Cancer Agency, Vancouver, BC, Canada.

Array comparative genomic hybridization (aCGH), allows for a vastly improved resolution (as low as 80kb) compared to conventional CGH (5-10 MB), by using a series of contiguous BAC clones in a region of interest or across the entire human genome. Segmental duplications (duplicons), which account for ~5% of the genome, have been implicated in genomic alterations such as duplications, deletions, and inversions and are thought to be facilitating chromosomal translocations leading to cancer. Furthermore, duplicons that have been studied on detail have been shown to be highly polymorphic in copy number distributions in human populations. aCGH profiling of 4 CML cancer patients using a 1-2MB resolution BAC array identified a BAC clone within cytoband 14q12 that exhibited allelic gain on one homologue in 3 of 4 individuals. This genomic imbalance was confirmed using quantitative PCR (QPCR). To further characterize this observation, we analyzed a series of 14 normal individuals and 66 hematologic and pediatric neoplasms. Normal individuals, as well as 2 Chronic Myeloid Leukemia (CML) patients on whom both aCGH and QPCR were performed, were analyzed using quantitative FISH (QFISH). QFISH analysis identified the gain to be the result of a duplication of the signal on a single chromosome in both CML patients. Additionally, 3 of 14 normal individuals showed duplication of this 14q12 specific BAC. QPCR analysis of 18 of 64 neoplasms had allelic copy number imbalance. No statistically significant difference between the incidences of gain in normal individuals and cancer patients was seen. Locke et al. recently reported on the presence of duplicons in BAC clones used for aCGH. They suggest that duplicons may mimic events occurring elsewhere in the genome thereby yielding erroneous results. The results of our experiments suggest that duplicons may affect aCGH analysis and thus must be taken into account when designing the microarray as well as for accurate interpretation of aCGH results.

Chromosomal instability and cancer predisposition in Bub1 haploinsufficient mice. *D.V. Carrion¹, W. Zhang¹, P. McDonald¹, M. Lia², J. Heyer³, R. Kucherlapati¹*. 1) Harvard-Partners Center for Genetics and Genomics, Harvard Medical School, Boston, MA; 2) Institute for Cancer Genetics, Columbia University, New York, NY; 3) GenPath Pharmaceuticals, Cambridge, MA.

Genomic instability is the most common hallmark of human cancer. The loss of the mitotic checkpoint control has been thought to be responsible for genomic instability. Bub1 is a gene involved in the mitotic checkpoint control and mutated in some cancers. To study the role of this gene in cancer and genome instability we generated mice that carry a null mutation in Bub1. Homozygous mutant mouse embryos were detected at E3.5 but not at E8.5. We examined chromosome segregation in Bub1^{+/-} and wild type (WT) ES cell lines. At different passages the Bub1^{+/-} line showed a higher percentage of aneuploid cells. To confirm this observation FISH analysis was performed in blood lymphocytes of WT and Bub1^{+/-} mice using probes for chromosomes 9 and 17. Bub1^{+/-} mice showed a higher percentage of aneuploid cells ($P < 0.0001$). Bub1 heterozygous mice are fertile and show a tumor susceptibility phenotype late in their lives. Analysis of Bub1^{+/-} liver tumors by microarray-based comparative genome hybridization (aCGH) showed high chromosomal instability. These findings show that Bub1 haploinsufficiency leads to chromosomal instability in vivo and that this degree of instability predisposes the mice to develop tumors. Our results suggest that the Bub1 gene is essential for normal survival, chromosomal stability and tumor suppression.

Program Nr: 366 from the 2004 ASHG Annual Meeting

Novel Genetic Alterations in Early Stage Lung Cancer. *C. Garnis, J. Davies, E. Vucic, C. MacAulay, S. Lam, W. Lam.* Cancer Genetics, BC Cancer Research Center, Vancouver, British Columbia, Canada.

Lung cancer is the leading cause of cancer deaths in the United States. Despite advances in lung cancer treatment the overall 5 year survival rate for those diagnosed with lung cancer is bleak. In order to provide new clinical strategies that will ultimately result in increase survival rate we must determine the genetic alterations that drive this disease. The objective of this study is to identify novel genetic alterations in the progression of squamous cell carcinoma. Using a bacterial artificial (BAC) array comprised of 32,433 near over-lapping BAC clones that span the entire human genome we profiled microdissected CIS and invasive squamous cell lung cancer samples. Detailed comparison of a panel of pre-invasive and invasive samples revealed numerous recurrent sub-megabase alterations that are likely causally involved in lung neoplastic development. These include regions containing known oncogenes/tumor suppressor genes such as c-myc and cyclinD1 as well as novel sub-megabase regions containing only one or two genes. Coupling pre-invasive lesions with arrayCGH technology provides the most comprehensive and informative analysis from which candidate genes can be selected. This work was supported by funds from the Genome Canada/BC and the NCIC Terry Fox New Frontiers Program.

eIF-5A2 functions as an oncogene in the development of ovarian cancer. *X-Y. Guan¹, J.M. Fung¹, N-F. Ma¹, S.H. Lau¹, D. Xie¹, C.H. Tzang², M. Yang², J.S.T. Sham¹.* 1) Dept Clinical Oncology, Univ Hong Kong, Hong Kong, Hong Kong; 2) Department of Biology and Chemistry, The City University of Hong Kong, Hong Kong, China.

Ovarian cancer is the leading cause of death from female gynecological malignancies in developed countries and its incidence has been increasing in Asian Countries such as China and Singapore recently. Recurrent chromosomal changes in ovarian cancer have been well studied by comparative genomic hybridization (CGH) and amplification of 3q26 is one of the most frequent alterations. Recently, we have isolated a candidate oncogene eIF-5A2 from 3q26.2 using chromosome microdissection and hybrid selection. Sequencing analysis showed that eIF-5A2 shares a significant sequence homology (126/153, 82% amino acid identity) to eukaryotic initiation factor 5A (eIF-5A), including the domain needed for hypusine modification and the lysine-50 residue where the hypusine residue can be formed by posttranslational modification. The proliferation-related function of eIF-5A supports that eIF-5A2 is a candidate oncogene related to the development of ovarian cancer. In this work, the tumorigenic ability of eIF-5A2 was demonstrated by anchorage-independent growth in soft agar and tumor formation in nude mice. Furthermore, antisense DNA against eIF-5A2 could inhibit cell growth in ovarian cancer cell line UACC-1598 with amplification of eIF-5A2 in form of double minutes (DMs). Cell growth rate in UACC-1598 was also inhibited when the expression level of EIF-5A2 was decreased by the reduction of the copy-number of DMs. cDNA microarray study revealed that the oncogenic role of eIF-5A2 could be through WNT signal pathway. The correlation of EIF-5A2 overexpression and clinical features of ovarian cancer was investigated using tissue microarray and the result showed that eIF-5A2 overexpression was significantly associated with the advanced stage of ovarian cancer. These findings suggest that eIF-5A2 plays important roles in ovarian pathogenesis.

Amplification of the Steroidogenic Factor 1 (SF-1) Gene in Childhood Adrenocortical Tumors. *B. Haddad*¹, *L. Cavalli*¹, *M. Pianovski*², *I. Lalli*³, *R. Sandrini*², *R. Ribeiro*^{4, 5}, *G. Zambetti*⁴, *L. DeLacerda*², *G. Rodrigues*², *B. de Figueiredo*². 1) Georgetown Univ., Washington, DC; 2) Federal Univ. of Parana, Curitiba PR, Brazil; 3) Univ. Louis Pasteur, Illkirch, France; 4) St. Jude Children's Res. Hospital, Memphis TN; 5) Univ. of Tennessee, College of Medicine, Memphis, TN.

The incidence of childhood adrenocortical tumors (ACT) is 10-15 times greater in Southern Brazil than worldwide. The reasons for this increase and the genetic basis of this disease remain elusive. To further characterize the genetic changes in childhood ACT, we recently showed that gain/amplification of the 9q34 chromosomal region detected by CGH, is common in these tumors. Other subsequent studies involving both childhood and adult ACT have corroborated our findings. To follow up on these results, we have examined whether the Steroidogenic factor 1 (SF-1) gene located in this chromosomal region, is amplified in childhood ACT. SF1 is an orphan member of the nuclear receptor family of transcription factors. It plays an important role in the development and function of the adrenal cortex. We designed a FISH probe consisting of a BAC clone containing sequences of the SF-1 gene and used FISH to detect SF-1 copy number changes in a cohort of nine pediatric ACT cases where we had previously detected a consistent gain of 9q34 in 8 of them using CGH. Our FISH analysis was in full agreement with our CGH findings. Specifically, all 8 patients who showed copy number gain of 9q34 by CGH, showed increased copy number of the SF-1 gene by FISH. This is the first study showing an association between an increased copy number of SF-1 and ACT. The significance of this observation needs to be further investigated in both pediatric and adult ACT. Because this gene is detected at the earliest stages of development of the urogenital ridge, where both the gonads and the adrenal cortex are derived, and because this expression is maintained throughout development up till adult life, further studies examining the mechanisms and consequences of the amplification of this gene in ACT are critical to a better understanding of the onset and progression of this disease.

The somatic QMPSF : an efficient tool to detect genomic rearrangements in cancer. *A. Killian¹, F. Blanchard², A. Lamy², F. Le Pessot², J. Mtayer², T. Frebourg¹, J-M. Flaman¹, R. Sesboüé¹.* 1) Inserm U614, Faculty of Medicine, 76183 Rouen, France; 2) Department of Pathology, Rouen University Hospital, 76031 Rouen.

The majority of the malignant tumors exhibit a strong chromosome instability (CIN) that contributes to the malignant transformation, through the loss of tumor suppressor genes and activation of oncogenes. It is therefore essential to identify genes whose alterations are responsible for this genetic instability. Using an original biological screen in yeast based on a CIN indicator strain, we identified candidate genes whose inactivation or activation disturbs the correct segregation of the chromosomes. These genes encode mainly cell cycle regulators, phosphatases and proteins involved in ribosome biogenesis. In order to look for genomic rearrangements (loss of heterozygosity (LOH), or gain of gene copy numbers) of these candidate genes in primary aneuploid tumors, we developed a simple molecular assay based on the QMPSF (Quantitative Multiplex PCR of Short fluorescent Fragments), a method initially designed to detect germline genomic rearrangements. The QMPSF is based on the simultaneous amplification of multiple target sequences, using dye labeled primers in conditions that allow rapid and reliable quantitative comparison of the fluorescence of each amplicon. For each patient, the somatic QMPSF profile generated from the tumor is superimposed to that generated from the non tumoral tissue. The somatic QMPSF allows the simultaneous analysis of 10 different genes. The somatic QMPSF, performed on 30 primary tumours, revealed recurrent somatic rearrangements of genes involved in ribosome biogenesis. The somatic QMPSF is a simple, cheap and sensitive method to detect loss or gain of genetic material in cancer. Furthermore, its flexibility should facilitate the mapping of recurrent somatic genomic rearrangements observed in malignant tumours.

The effects of low dose gamma radiation in Trp53 heterozygous cancer prone mice: Genomic instability and Loss of Heterozygosity. *J. Lavoie¹, J-A. Dolling², R.E. Mitchel³, R. Carter⁴, D.R. Boreham¹.* 1) Medical Physics, McMaster University, Hamilton, ON, Canada; 2) The Credit Valley Hospital, Mississauga, ON, Canada; 3) Atomic Energy of Canada Limited, Chalk River, ON, Canada; 4) Health Sciences Center, McMaster University, Hamilton, ON, Canada.

The Trp53 gene is clearly associated with increased cancer risk. This, coupled with the broad understanding of its mode of action at the molecular level, makes this gene a good candidate to study the relationship between genetic risk factors and spontaneous cancer occurring in mice exposed to low dose radiation. We have shown that adaptive responses to low dose could increase cancer latency, as well as lifespan. These end points were used to assess changes in the risk in Trp53 heterozygous mice. To understand the molecular processes that influence cellular risk, spectral karyotyping (SKY) was used to detect chromosomal stability, and the loss of heterozygosity (LOH) at the Trp53 locus was evaluated using Rolling Circle Amplification (RCA). Mice were gamma-irradiated with daily doses of 0.33 mGy for 73, 143, 217, 295, 331 or 366 days, corresponding to total body doses of approximately 2, 5, 7, 10, 11 or 12 cGy. For each mouse exposed to 11 and 12 cGy and their unexposed littermates, 100 metaphases were analyzed using SKY and virtually no structural anomalies were observed in any group. This indicates that the presence of a defective copy of Trp53 does not appear to affect either spontaneous or chronic low dose induced chromosomal instability in cancer prone mice. To evaluate LOH, detection of the NEO and the Trp53 alleles using the dual color RCA was utilized. In our hands, this protocol did not give the required sensitivity. Therefore, a quantitative real-time PCR experiment using the LightCycler instrument was designed to target both alleles. More than 800 QRT-PCR reactions were conducted on DNA extracted from tissues of the irradiated and unexposed mice. A statistical analysis of the data is in progress to confirm any changes in the original number of DNA copies. This research will provide information regarding the health effects and cancer risk of low doses of radiation in genetically susceptible individuals.

Immunohistochemical analysis of P53, CYCLIN D1, RB, C-FOS and N-RAS genes _expression in hepatocellular carcinoma in Iran. *E. NOBAKHT HAGHIGHI¹, M.R. Zali¹, S.J. Mirhassani Moghaddam², S. Dadgar⁴, S. Samiee¹, N. Shahid¹, A.R. Keramati¹, H. Najmabadi³.* 1) RCGLD, Taleghani Hospital, Evin Ave, TEHRAN, Iran; 2) The University of Texas MD Anderson Cancer Center Pulmonary Research Lab, 2121 Holcombe Blvd, Houston, TX Email: smoghadd@mdanderson.org; 3) The Socail Welfare and Rehabilitation Sciences University; 4) Banting And Best Department of Medical Research, University of Toronto, Canada.

Purpose: The effects of some genes have been shown in development of hepatocellular carcinoma in several studies but there are some controversies about them yet. This study was undertaken to analyze simultaneous status of p53, cyclin D1, Rb, C-fos and N-ras genes in Iranian patients. **Methods:** The paraffin-embedded tissue samples of 25 patients (18 male and 7 female) with documented hepatocellular carcinoma were collected from 22 pathology centers in Tehran one year (2001). Using immunohistochemistry method (Avidin-Biotin-Peroxidase), they were stained for detection of p53, cyclin D1, Rb, C-fos and N-ras proteins accumulation. **Results:** All of 25 tumors were in grade I (well differentiated). Six (24%), 5(20%), 13(52%) and 2(8%) were positive for p53, cyclin D1, C-fos and N-ras, respectively. Besides, 22(88%) cases showed complete loss of Rb protein _expression. Comparing p53 positive cases with the negative ones, the former group showed a higher (9 times) risk of being positive for Rb gene. This figure was 2.66, 2.75 and 3.6 for cyclin D1, C-fos and N-ras, respectively. Rb loss of _expression in association with p53 over-_expression has been observed in 4(16%) of samples. This figure was 5(20%) for Rb and cyclin D1, 2(8%) for Rb and N-ras and 11(44%) for Rb and C-fos. Comparing cyclin D1 positive cases with the negative ones, the former group showed a higher (2.85 and 4.75 times) risk of being positive for C-fos and N-ras genes. **Conclusion:** Like previous studies, the development of mutation in some of these genes especially C-fos, Rb and p53 appears to have a key role in the carcinopathogenesis of hepatocellular carcinoma in Iran. Also a significant association between the simultaneous mutations of some of these genes during development of this cancer is likely.

The Role of *FANCD2* in the DNA Damage Response of Oral Cancer Cell Lines. *E.M. O'Leary*¹, *K. Mitchell*², *R.A. Parikh*², *J.S. White*^{2,3}, *S.M. Gollin*^{2,3}. 1) Genetic Counseling Program, University of Pittsburgh Graduate School of Public Health, Pittsburgh, PA; 2) Human Genetics, University of Pittsburgh, Pittsburgh, PA; 3) University of Pittsburgh Cancer Institute, Pittsburgh, PA.

The genetic mechanisms that contribute to Head and Neck Squamous Cell Carcinoma (HNSCC) and Oral and Oropharyngeal Squamous Cell Carcinomas (OSCC) are incompletely understood. Cancer predisposition is associated with chromosome instability and hypersensitivity to DNA damaging agents. Fanconis Anemia patients are extremely sensitive to cross-linking agents and are at increased risk to develop several cancers including leukemias, gynecological and oral cancers. The Fanconis Anemia proteins (FANCs) are thought to be involved in pathways necessary for repairing cross-linked DNA. Six FANC proteins (A, B, C, E, F and G) assemble in a nuclear core complex and two other identified proteins, *FANCD1/BRCA1* and *FANCD2* act downstream of the complex. This core complex is required for the monoubiquitination of the *FANCD2* protein to the *FANCD2-L* isoform in response to DNA damage. To determine if mutations in FANC genes may contribute to head and neck cancer, cell lines were treated with the clastogenic cross-linking agent, DEB, to quantify the number of double strand breaks induced. Based on the association of Fanconis Anemia and OSCC, we expected to see similarities among the treated oral cancer cell lines and the cell lines from FA patients when treated with DEB. *FANCA*^{-/-} (GM06914) and *FANCD2*^{-/-} (GM16633) cell lines were analyzed as positive controls and normal fibroblasts were used as negative controls in demonstrating the inability of HNSCC cells to repair DNA damage. The tumor cell lines treated with DEB have a increased number of double strand breaks, leading to the formation of tri- and quadrads, which is indicative of defects in the DNA damage response. Immunoblots with a *FANCD2* antibody show differential activation of *FANCD2-L* in the presence of this particular DNA cross-linking agent.

***ATR* gene abnormalities in squamous cell carcinoma of the head and neck.** R. Parikh¹, J. White^{1,4}, D. Schoppy^{1,3}, R. Bhaskaran², S. Gollin^{1,4}. 1) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Molecular Genetics and Biochemistry, University of Pittsburgh, Pittsburgh, PA; 3) Department of Biological Sciences, University of Pittsburgh, Pittsburgh, PA; 4) University of Pittsburgh Cancer Institute, Pittsburgh, PA.

Squamous cell carcinoma of the head and neck (SCCHN) at oral and oropharyngeal sites is the sixth most common cancer worldwide. A wide variety of genetic and epigenetic defects are seen in the tumor cells. Amplification of *CCND1* gene located in 11q13 as a homogenously staining region (hsr) and a gain of distal 3q are seen in nearly 45% of SCCHN. The *ATR* gene maps to chromosomal band 3q22-24 which is frequently gained in different types of cancers. *ATR* is a serine threonine kinase and a critical regulator of cellular responses to DNA damage. It phosphorylates and activates different substrates like c-Abl, p53, Nbs1, Smc1 and Chek1 in response to UV radiation and cross-linking agents. *ATR* also plays an important role in maintenance of integrity of fragile sites. We performed dual color FISH using probes for *ATR* and chromosome 3 centromere (CEP3) on eight SCCHN cell lines. We found copy number gain or structural rearrangement of *ATR* gene in five out of the eight SCCHN cell lines. Three cell lines showed a gain (*ATR*/CEP3 ratio >2.0) associated with isochromosome 3q formation. This correlates with over expression of the *ATR* protein and loss of p53 expression in these cell lines detected by immunoblotting. We hypothesize that *ATR* overexpression (caused by an increase in copy number or chromosomal rearrangements) is an important event which may contribute to the development and progression of carcinoma. Our studies also show loss that of p53 expression is associated with overexpression of *ATR* though the exact relationship between the two needs to be elucidated.

ABERRATIONS AT 8P12 IN BREAST CANCER. *A.A. Shadoo^{1,2}, R.J. deLeeuw^{1,2}, V.S. Lestou^{2,3}, D.G. Huntsman^{2,3}, W.L. Lam^{1,2}.* 1) Cancer Genetics, British Columbia Cancer Research Centre, Vancouver; 2) Pathology and Laboratory Medicine, University of British Columbia, Vancouver; 3) Genetic Pathology Evaluation Centre, Vancouver Hospital and Health Sciences Centre and British Columbia Cancer Agency.

Background: Breast carcinoma is the most frequently diagnosed cancer and is one of the leading causes of cancer related deaths in women. Recurrent chromosomal translocations involving the *NRG1* gene located at 8p12 have been observed in multiple breast cancer cell lines. However, the relevance of this translocation in clinical breast cancers remains unclear. Fluorescence in situ hybridization (FISH) has identified amplified *NRG1* in a number of invasive clinical breast cancer specimens, raising the possibility that *NRG1* disruption is more complex than a simple translocation event. **Hypothesis:** 1) Alterations at 8p12 will be present in clinical specimens. 2) The increase in *NRG1* copy number observed in breast cancer specimens is related to a translocation event with the breakpoints at 8p12 potentially disrupting the gene. **Experimental Design and Results:** Five archival specimens with amplification of the *NRG1* locus identified through FISH using Tissue MicroArray (TMA) were selected for this study. Isolated sample and pooled female genomic reference DNA were differentially labelled and hybridized to SMRT arrays containing approximately 32,000 BACs. These arrays provide overlapping coverage of the human genome while using 600ng of specimen DNA. CGH imaging and analysis was done using a charge coupled device (CCD) based scanner and associated analysis software. Visualization was accomplished using custom software called SeeGH. FISH results were confirmed in all cases and boundaries of amplification were identified. **Conclusion:** Using the newly developed Sub-megabase Resolution Tiling Set (SMRT) array for comparative genomic hybridization (CGH), we have identified the specific boundaries of amplification at the *NRG1* gene region on chromosome 8p.

Analysis of prostate cell lines and microdissected tumors using tiling resolution whole genome analysis. *S.K. Watson¹, J.A. Squire², B. Beheshti², W.L. Lam¹*. 1) Cancer genetics, BC Cancer, Vancouver, BC, Canada; 2) Cellular and Molecular Biology, Ontario Cancer Institute, Toronto, Ontario, Canada.

The advent of a tiling resolution BAC CGH array has increased the resolution of DNA amplification or deletion analysis allowing copy number analysis of the entire genome in a single experiment. In this study we looked at well identified cell lines such as DU 145, PC3 and LnCaP as well as Gleason 3 or 4 grade laser capture micro-dissected tumor samples. This high resolution technique allows rapid identification of DNA irregularities that can be easily linked to prostate cancer profiling. Through array CGH analysis it is possible to detect single copy alterations within the genome when compared to a diploid reference sample. Using this technique, common prostate cancer cell lines showed unique patterns allowing potential trend recognition of prostate cancer progression. The array consisted of 32,433 BAC clones spotted in triplicate on two slides. As conventional CGH allows only 10-20MB resolution this array represents a 100-200 fold increase over traditional methods. Six cell lines commonly used to model prostate cancer were individually comparatively hybridized against normal male reference DNA to determine alterations in the genome. 200ng of sample and reference DNA were random primed with Cy3-dCTP or Cy5-dCTP fluorochromes and hybridized to the slides in the presence of COT-1 DNA. The whole genome array allowed identification of numerous novel and previously reported regions not described in these prostate cancer cell lines. Single copy deletions and amplifications were detectable and identifiable as confirmed by FISH and SKY karyotyping. Comparison of the sub-megabase tiling path resolution tiling (SMRT) whole genome array CGH profiles for commonly used prostate cell lines will allow rapid recognition of putative genes involved in prostate pathogenesis. This combined with the clinical sample data may offer a better understanding of prostate cancer progression globally within the genome. This work was supported by funds from Genome Canada/Genome BC.

Phosphorylation of Histone Variant H2AX as a Marker for DNA Damage Pathway Competency in Oral Cancer Cells. *J.S. White*^{1,2}, *R.A. Parikh*², *D.S. Schoppy*^{2,3}, *S.M. Gollin*^{1,2}. 1) University of Pittsburgh Cancer Institute, Pittsburgh, PA; 2) Department of Human Genetics, University of Pittsburgh Graduate School of Public Health, Pittsburgh, PA; 3) Department of Biological Sciences, University of Pittsburgh, Pittsburgh, PA.

A subset of head and neck squamous cell carcinomas (HNSCC) and Oral and Oropharyngeal Squamous Cell Carcinomas (OSCC) are characterized by amplification of chromosomal band 11q13, which is thought to be driven by cyclin D1 (*CCND1*) overexpression. As a result of this process, the genes distal to 11q13 are often lost, a number of which are involved in the DNA damage response. One of these genes, *H2AFX*, is a histone variant thought to be critically important to the recognition of DNA strand breaks. Other genes distal to the amplicon include *ATM*, *CHEK1*, and *MRE11A*, all of which are involved in the damage repair response. We hypothesize that haploinsufficiency, or partial insufficiency, of the DNA repair genes distal to 11q13 would lead to increased susceptibility of the cell lines to DNA damage. Fluorescence *in situ* hybridization (FISH) was used to confirm the presence of the 11q13 amplicon, and the copy number of the chromosome 11 centromere (CEP11) and the *H2AFX* gene at 11q23.2-23.3. FISH results indicate that four cell lines have amplification of 11q13, and loss of genes distal to that region. Five cell lines show distal loss on the long arm of chromosome 11, and the remaining two cell lines have no alterations on chromosome 11. Using phosphorylation of H2AX as a surrogate marker of a proficient DNA damage response, we evaluated the competency of DNA repair in eleven OSCC cell lines after treatment with (10Gy) ionizing radiation (IR) or (20 J/m²) ultraviolet (UV) exposure by formation of -H2AX foci. Preliminary foci data indicate an incomplete response to IR and UV. Immunoblots of the damage response genes showed differential expression between cell lines. Inadequate response to either IR or UV is expected to be critical to the phenotype of these cells. Using these cell lines as models for the original tumor, these studies may indicate patient response to treatment, environmental or other exogenous exposures.

Breast and ovarian cancer screening practices and prophylactic surgery in at risk women: an Australian multicenter study. *Y.C. Antill¹, T. Dudding², T. Hall³, J. Kirk⁴, J. Reynolds¹, K. Tucker⁵, S. Wong⁶, MA. Young¹, KA. Phillips¹.* 1) Peter MacCallum Cancer Centre, VIC; 2) Hunter Genetics, NSW; 3) Monash Medical Centre, VIC; 4) Westmead Hospital, NSW; 5) Prince of Wales Hospital, NSW; 6) Royal Melbourne Hospital, VIC, Australia.

This study examined screening for breast and ovarian cancer, and prophylactic surgery (PS) undertaken by women at moderate or high risk for hereditary breast and ovarian cancer following risk management consultation at a Family Cancer Center (FCC). A self-report questionnaire was mailed to 396 women with no personal history of cancer. They had attended one of six FCCs, a median of 3.63 years prior. Questions included; screening or PS undertaken, risk perception and cancer specific anxiety. Family history, level of risk and screening recommendations given were abstracted from subjects medical record. Fishers exact test or the exact form of the Mantel-Haensel test was used to investigate associations between adherence and each factor. Ordinal logistic regression was used to investigate associations between continuous-scale covariates and adherence. 182/266 (68.4%) responded. 130 were lost to follow-up. Screening adherence was: breast self exam 39%, clinical breast exam 44%, mammogram 65%, transvaginal ultrasound 37%, CA125 64%, (no difference between risk groups). Predictors of adherence included; older age, BRCA1/2 positive, having an affected first degree relative (FDR), higher risk perception, and greater income (all $p < 0.05$), but these associations were not consistent across all screening strategies. Predictors of over-screening were; higher cancer specific anxiety and/or a mutation. Low levels of cancer anxiety predicted for under-screening. 16/182 (9%) respondents had undergone PS: mastectomy (7), oophorectomy(10). Predictors of PS were; at least one affected FDR, or cancer death of a FDR. Despite specific advice, women at risk for breast and ovarian cancer were mostly nonadherent to the recommendations for screening with low and high levels of anxiety having a negative influence on compliance. Further studies are needed to evaluate interventions that might improve screening adherence.

Defective splicing is not a major consequence of missense mutation in HNPCC. *J. Auclair¹, M-P. Buisine², C. Lasset³, F. Desseigne⁴, V. Bonadona³, J-C. Saurin⁵, A. Puisieux¹, Q. Wang¹.* 1) Unit d'Oncologie Molculaire, Unit INSERM 590, Centre Lon Brard, Lyon, France; 2) Laboratoire de biochimie et biologie molculaire, CHU Lille, France; 3) Unit de prvention et d'pidemiologie gntique, Centre Lon Brard, Lyon, France; 4) Dpartement de mdecine, Centre Lon Brard, Lyon, France; 5) Service de Hpathogastroenterologie, Centre Hospitalier Lyon Sud, France.

HNPCC is a common cancer syndrome with the predisposition to colorectal cancer and some extracolonic cancers and is caused by germline mutation of one of DNA mismatch repair genes. Up to 30% of the mutations identified so far affect only one nucleotide, making the pathogenic effect determination difficult. Recent studies have shown that nucleotide substitutions can alter pre-mRNA splicing when they affect elements essential to exon recognition called ESE (Exonic Splicing Enhancers). Recently, Gorlov et al (2003) reported that an excess of presumed deleterious missense mutations of hMLH1 and hMSH2 genes in HNPCC families were located in predicted ESE sites (ESEfinder), suggesting that the disruption of ESE sites was the cause of their deleterious effect. For evaluating the role of ESE, we screened 20 hMLH1 and 16 hMSH2 variants for aberrant splicing. 60% were located at sequences predicted as the target of at least one of the SR proteins with a threshold value higher than 2.5 (ESEfinder). Five additional variants affecting consensus exon-intron splicing sites were used as controls. RT-PCR were performed using the RNA isolated from lymphoblastoid cell lines after puromycin treatment. Our results revealed that all variants affecting exon-intron consensus sites generated aberrant splicing, whereas none but one ESE-unrelated variant gave rise to abnormal splicing. Our results suggest that although a number of sequences are recognizable by one of the SR proteins, their role in splicing control seems to be limited when individually affected. Location at such predicted ESE sites should not be considered determinant for interpreting pathogenic effect of missense mutations in genetic consultation, before confirmation at the RNA level.

A 25 year perspective of the DEB test for Fanconi anemia: correlation of mosaicism with clinical outcome. A.D. Auerbach¹, Y. Flit¹, S.D. Batish¹, J. Morales¹, M. Berwick². 1) Lab. Human Genetics & Hematology, The Rockefeller Univ., New York, NY; 2) Dept. Medical Epidemiology, Univ. of New Mexico, Albuquerque, NM.

Fanconi anemia (FA) patients are characterized by a cellular hypersensitivity to DNA cross-linking agents and cancer predisposition. Diepoxybutane (DEB) test results were analyzed for validation with 523 subjects diagnosed as affected and 2097 diagnosed as unaffected. Subjects were tested if they had bone marrow failure (BMF), congenital malformations (CM), BMF + CM or were siblings of FA patients. Peripheral blood lymphocytes were cultured with 0.1g/ml DEB according to a protocol previously described (Auerbach et al., Blood 73:391-396, 1989). Affected and unaffected groups had 8.5 (SD=4.6) and 0.01 mean breaks/cell (SD=0.03) respectively. 98.9% of patients diagnosed as FA and none of the patients diagnosed as non-FA had greater than 0.65 mean breaks/cell. 96.6% of non-FA subjects and 0% of FA patients had less than 0.09 mean breaks/cell. Thus only a small number of affected individuals could not be discriminated on the basis of mean breaks/cell. These mosaic patients have two populations of lymphocytes: (i) aberrant cells with breaks and exchanges typical of DEB-treated FA cells and (ii) non-aberrant cells with no breaks. For FA and non-FA subjects, the mean % aberrant cells was 92 and <0.01 respectively. Most FA patients (98%) had >18% aberrant cells; 2% had between 1-18%. Among non-FA subjects, 74% had 0 aberrant cells, while 26% had between 1-18% aberrant cells. About 10% of FA patients have 50% or less aberrant cells. We next analyzed data for 673 non-mosaics (>50% aberrant cells) and 77 mosaics for clinical outcome. There are 246 deaths among non-mosaics and 22 deaths among mosaics. Using Kaplan-Meier estimates, the median age at death for non-mosaics is 22.8 years and the median age at death for mosaics is 32.1 years (log-rank $p < 0.01$). There are 133 non-mosaics with malignancy (including MDS) and 18 mosaics. By Kaplan-Meier estimates, the median age at cancer for non-mosaics is 33.4 years and for mosaics 37.7 years ($p = 0.37$). Thus, mosaics live significantly longer than non-mosaics but there is no evidence of a difference in cancer incidence between the two groups.

Direct mutation detection in breast and ovarian cancer susceptibility genes using Meta/PCR. *B. Azimifar*^{1,2}, *M. Eram*^{1,2}, *V. Lotfi*², *M. Masrouri*², *P. Folady*², *S. Zeinali*^{1,2}. 1) Biotechnology Research Center, Biotechnology Research Center, Pasteur Institute of Iran, Pasteur St., Tehran, Iran; 2) Medical Genetic Lab of Dr Zeinali.Fatemi Square, bisetoon St, Leon Building, Tehran, Iran.

Approximately 5-10% of breast cancer and ovarian cancer cases are thought to be associated with an autosomal dominant pattern of inheritance, usually relates to mutations in the BRCA1 and BRCA2 genes. The lifetime risk of eventually developing breast cancer accumulates to 55-90% and 44-80% by age 70 for carriers of BRCA1 and BRCA2 mutations, respectively. Moreover, it is know thought that BRCA2 may account for as much as 10-35% of familial ovarian cancers. The BRCA1/2 genes are too large (each one is more than 80 KB in length) with 24 and 27 exons respectively. Many of these exons are too small and sequencing of them separately are time consuming and expensive. The majority of BRCA1/2 mutations also are unique and each family with a defined history of breast or ovarian cancer tends to have its own mutation. We used a new approach for mutation detection of BRCA1/2 genes which using Meta/PCR followed by direct sequencing. In this technique, we amplify each exon of BRCA1/2 separately with primers that each one has a tail in its 5' end. So that these amplicons could be used in a second PCR in which they link to each other to make longer fragments and so on. Then chimeric DNAs (instead of small exons of BRCA1/2 genes) could easily be used for sequencing which lead to rapid and accurate screening for mutation of BRCA1/2 genes. The results can be used as a important prognosis factor for following up the at risk members of family with inherited breast and ovarian cancers.

Development of a conditional knockout mouse model of the Birt-Hogg-Dubé syndrome. *M. Baba*¹, *L. Tessarollo*², *M.E. Palko*², *E. Southon*³, *M. Furihata*¹, *B. Zbar*¹, *L.S. Schmidt*³. 1) Laboratory of Immunobiology, NCI-Frederick, Frederick, MD, 21702; 2) Mouse Cancer Genetics Program, NCI-Frederick, Frederick, MD, 21702; 3) BRP, SAIC-Frederick, Inc., NCI-Frederick, Frederick, MD, 21702.

The Birt-Hogg-Dubé syndrome (BHD) is a rare inherited genodermatosis characterized by hamartomas of the hair follicle (fibrofolliculomas), spontaneous pneumothorax, and an increased risk of renal cancer. The BHD gene encodes a novel 579 amino acid protein, folliculin, with unknown function. Most mutations found in the germline of BHD patients cause frameshifts or premature termination codons predicted to truncate the BHD protein. Mutations in BHD gene orthologs were also found in naturally occurring hereditary multifocal renal cystadenocarcinoma and nodular dermatofibrosis in the German Shepherd dog and in the spontaneous Nihon rat model of inherited renal cancer. Homozygous mutations in the dog or rat model of BHD were embryonic lethal. To study BHD gene function in vivo we are developing a BHD mouse model. We have designed a conditional BHD gene targeting vector to avoid embryonic lethality and have constructed it by recombinogenic engineering. After electroporation with the BHD targeting vector, mouse ES cells were screened by Southern blotting and correctly targeted ES cell clones were injected into blastocysts. We will describe our method and report progress in establishing a conditional BHD knockout mouse model. Funded in part by DHHS#NO1-CO-12400.

Approaches to the identification of endometrial cancer patients at risk for HNPCC. *S.A. Babb, D.G. Mutch, M.A. Powell, R.K. Gibb, J.S. Rader, T.J. Herzog, A.J. Whelan, P.J. Goodfellow.* Washington University, St Louis, MO.

Early onset cancer (<50 years), second malignancies, cancer family history and tumor MSI are hallmarks of HNPCC. At present it is unclear what the best approach is to the identification of endometrial cancer patients with HNPCC. To address this we evaluated clinical and molecular features in large endometrial cancer cohort. 412 endometrial cancers from a single oncology clinic between 1994 and 2002 were assessed for MSI and MLH1 methylation. Detailed family histories were obtained for 164 patients (40%). Clinical and molecular features were similar for the 164 probands with detailed family history (FH) and the remaining 248 individuals (NoFH) with the exception of age of diagnosis. The FH group was younger than the NoFH group (62 versus 66 years, $p=0.0004$; student's t-test). However, the percentage of probands diagnosed before age 50 was not statistically different. Nearly 60% of the FH group reported a first or second-degree relative with an HNPCC-associated malignancy. The mean age of onset for those women was not different from those with no relatives with an HNPCC cancer. Twelve (7%) of the FH group and 5% of the NoFH group had a second HNPCC-associated cancer. The mean age at endometrial cancer diagnosis for those women with a second HNPCC malignancy was not statistically different than for women without a double primary. Among the 12 patients with a second HNPCC cancer, 9 (75%) had first or second degree relative with an HNPCC-associated tumor. Of the 152 women without a second HNPCC cancer, 87 (57%) had relatives with HNPCC tumors. Of the 12 HNPCC double primary cases, 4 were MSI positive and lacked MLH1 methylation and all had relatives with HNPCC-associated cancers. 5 of the 8 other double primary cases had relatives with HNPCC cancers. Only one of the double primary cases was diagnosed before age 50. Together, these data suggest that a combination of age of onset of endometrial cancer, synchronous or metachronous HNPCC-associated tumor, family history of HNPCC-associated tumors, and MSI and MLH1 methylation status may be the best approach to identifying endometrial cancer cases at increased risk for HNPCC.

Unique germline E-cadherin mutations in two Hereditary Diffuse Gastric Cancer families. *C. Baeslach¹, M. Harlan¹, K. Campbell¹, M. Ramirez¹, J. Palascak¹, C. Aronchick², P. Guilford³, B. Humar³, B.M. Boman¹.* 1) Thomas Jefferson University, Philadelphia PA; 2) Pennsylvania Hospital, Philadelphia PA; 3) University of Otago, New Zealand.

Introduction: 10% of gastric cancer has an autosomal dominant pattern that increases cancer risk. Criteria for Hereditary Diffuse Gastric Cancer (HDGC) are: 2 or more documented cases of diffuse gastric cancer in 1st or 2nd degree relatives, with 1 case before 50, OR 3 or more cases in 1st or 2nd degree relatives, independent of age. Germline mutations in CDH1, encoding for E-cadherin, have been found in 11-50% of HDGC families meeting clinical criteria. Presented are 2 HDGC families with unique CDH1 mutations. **Methods:** Family 1-The proband had genetic counseling due to a personal and family history of diffuse gastric cancer. She was diagnosed at 42 with diffuse gastric cancer, her father at 68, paternal aunt at 39, and paternal grandfather at 57. A 2nd paternal aunt had colon cancer at 55 and gastric cancer at 76 and a 3rd paternal aunt had breast cancer at 50. Family 2-The proband was diagnosed with gastric cancer at 36, sister at 30 and father at 33. His paternal grandfather had unconfirmed gastric cancer in his 70s. In both families, clinical criteria were met. **Results:** Family 1, genetic analysis revealed a germline mutation 49-2 AC at the splice receptor site for exon 2. This mutation is predicted to truncate the protein after codon 16. Family 2, genetic analysis of CDH1 revealed a germline mutation in exon 8 1137+1 GA. Although not functionally studied, this mutation is thought to affect splicing of E-cadherin. **Conclusion:** These families exhibit striking histories of diffuse gastric cancer. It is important to identify these families, offer testing, and find mutations. Unfortunately, only 25% of families who meet criteria have an identifiable CDH1 mutation. There are research labs (eg Univ of Otago) outside the US that offer testing to identify CDH1 mutations. The only certified clinical lab in the US must first have research testing and functional gene studies to proceed. As more families are identified with HDGC, genetic testing should lead to reduced mortality from gastric cancer.

Sequence analysis of Succinate Dehydrogenase Subunit A Gene (*SDHA*) for paraganglioma tumor susceptibility.

B.E. Baysal^{1,2}, *E.C. Lawrence*², *J.E. Willett-Brozick*¹, *R.E. Ferrell*². 1) OB/GYN & Reproductive Sci, Magee-Womens Research Inst, Pittsburgh, PA; 2) Dept. Human Genetics, GSPH, Univ. Pittsburgh, Pittsburgh, PA.

Background: Germline heterozygous mutations in three of the four subunits (*SDHB*, *SDHC*, *SDHD*) of succinate dehydrogenase (SDH; mitochondrial complex II) cause majority of hereditary paragangliomas (PGLs). Thus far, no PGL mutations were described in the *SDHA* gene, which encodes the major catalytic subunit of the enzyme. It has also been suggested that there might be two *SDHA* isoforms encoded by distinct loci in the human genome. Therefore, we sought to determine role of *SDHA* mutations in paraganglioma susceptibility in the light of evidence that there might be multiple *SDHA* loci encoding functional protein products.

Methods: We have searched for mutations in the known *SDHA* locus on chromosome 5p15 by genomic sequencing of its 15 exons in subjects with familial/syndromic paragangliomas who did not reveal mutations in the other SDH subunits. The subjects included two cases with familial head and neck paragangliomas; two nonfamilial cases with Carney's triad, who had paragangliomas and gastric leiomyomas; and one nonfamilial case with bilateral paragangliomas, mild mental retardation and premature aging.

Results: No pathogenic mutations have been detected in exons 2-15. However, we have found nine expressed single nucleotide polymorphisms (SNPs) in a set of 15 unrelated chromosomes. Whereas six SNPs were synonymous, three SNPs predicted amino acid alterations. Two amino-acid-altering SNPs jointly predict an allelic variant that is identical to the proposed *SDHA* isoform, that was suggested to be encoded by a second intronless gene.

Conclusions: These findings suggest that a single highly polymorphic locus is responsible for sequence variations in *SDHA* transcripts and that this locus does not appear to play an important role in paraganglioma susceptibility. The full spectrum of allelic variations and the extent of linkage disequilibrium across the *SDHA* gene locus are under further investigation.

FAP-causing mutation in the APC gene that was missed by PTT was detected by DHPLC. S.D. Bercovich¹, T. Naiman¹, R. Shomrat¹, S. Simchoni¹, Y. Yaron^{1,2}, A. Orr-Urtreger^{1,2}. 1) Genetic Institute, Tel Aviv Sourasky Medical Ctr; 2) Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel.

Specific conditions for denaturing-high-performance-liquid-chromatography (DHPLC) analysis of the *Adenomatous Polyposis Coli (APC)* gene were developed and the sensitivity of this method was compared to direct genomic sequencing and protein truncation test (PTT). Genomic DNA was obtained from 36 Familial Adenomatous Polyposis (FAP) patients with known mutations, 35 patients suspected for FAP that were negative for mutation screening by sequencing and/or PTT (Gavert et al, *Hum Mutat.* 2002), 8 new cases and 50 normal controls.

The coding sequences and exon-intron boundaries of exons 1-14 and more than 3Kb of exon 15 were screened using a single DHPLC condition for all fragments. A novel 2031delCAGT frameshift mutation was identified in a patient diagnosed as FAP at the age of 18 years. The position of this mutation close to the origin of the PTT fragment generated a very short truncated protein that was missed by the PTT analysis. DHPLC also detected a missense mutation, A685G (I228V), that was not identified by bi-directional sequencing. Allele separation by sub-cloning and sequencing confirmed this mutation. Additional 4 nonsense and 4 missense mutations were identified in the *APC* gene. One of these missense mutations was localized 3 to a premature stop codon, suggesting that it is not the disease causing mutation, while the contribution of the other 3 missense mutations to FAP is yet unclear. We concluded that DHPLC of the *APC* gene is a reliable method for mutation screening in patients suspected for FAP.

MYH gene mutations in young onset patients (< 50 years old) with microsatellite stable (MSS) colorectal cancer(CRC). *L.A. Boardman¹, R.A. Johnson², L. Wang², K.J. Steenblock², G.M. Petersen³, A.J. French², L.J. Burgart², N.M. Lindor⁴, S.N. Thibodeau².* 1) Internal Medicine, Mayo Clinic College of Medicine, Rochester, MN; 2) Laboratory Medicine and Pathology; Mayo Clinic College of Medicine, Rochester, MN; 3) Health Sciences Research; Mayo Clinic College of Medicine, Rochester, MN; 4) Medical Genetics; Mayo Clinic College of Medicine, Rochester, MN.

Biallelic germline mutations in MYH, a base excision repair enzyme, recently were discovered to be causative for an autosomal recessively inherited syndrome of CRC and multiple adenomatous colon polyps. To date, the vast majority of biallelic germline mutations in MYH have been associated with the a phenotype of multiple adenomas ranging from 20 to 100s of polyps and felt to be an explanation for a sizeable portion of attenuated familial adenomatous polyposis not related to germline APC mutations. Because of the earlier age of onset of CRC associated with hereditary CRC syndromes we evaluated a young onset CRC population in which fewer than 3 lifetime adenomas were present. Here we report the results of germline MYH testing in a young onset patient population who had undergone defective DNA mismatch repair (MMR) testing for suspected HNPCC on the basis of young age of onset (< 50 years of age) of CRC. Germline testing within the regions of exon 7 and exon 13 that contain the two most prevalent MYH mutations, Y165C and G382D, was performed on DNA from two hundred and thirty-two individuals with young onset CRC. Biallelic germline mutations were detected in 1.8 % of the MSS young onset CRC cases tested. Monoallelic germline mutations were detected in 1.3 % of those analyzed. These data suggest that MYH testing in young onset CRC even in the absence of multiple colonic polyps may be beneficial in those tumors that have been shown to be MSS.

Interaction of suppressor of fused (Sufu) with the hedgehog (Hh) and Wnt/Wg pathways in Drosophila and mice.

L.L. Brailey, T.M. Addy, J.M. McGrath, A.E. Bale. Yale University, School of Medicine, New Haven, CT.

The Hh pathway plays a key role in embryonic development and in carcinogenesis. Mutations in Ptch, the Hh receptor, are seen in hereditary and sporadic basal cell carcinoma and medulloblastoma. Sufu, like Ptch, down-regulates Hh signaling and is implicated in human predisposition to medulloblastoma. Mammalian cell biochemical studies show that Sufu may also interact with β -catenin, a member of the Wnt/Wg pathway. We performed genetic interaction studies in *Drosophila* and mice to study modifying effects of Sufu on the Hh and Wnt/Wg pathways *in vivo*.

Studies in *Drosophila* have shown genetic interaction between Sufu and Hh pathway members. We bred Ptch +/- mice to Sufu +/- mice to assess possible genetic interaction in mammals. Consistent with previous data, Sufu +/- mice showed no abnormal phenotype, and Ptch +/- mice were significantly larger than Sufu +/- or wild-type mice ($p < 0.02$). Though not statistically significant based on the current number of mice assessed, Sufu/Ptch double heterozygotes tended to be even larger than Ptch +/- mice. No gross external malformations or tumors have been noted in the mice bred to date.

In *Drosophila*, genetic interaction studies between Sufu and Wg pathway members showed that Sufu homozygosity enhanced the wingless phenotype. Apc is a negative regulator of Wnt/Wg signaling through its effect on β -catenin proteolysis. To test for genetic interaction in mammals, Sufu +/- mice were bred to Apc +/- mice. Apc +/- mice, similar to Apc +/- humans, have intestinal polyps, early carcinoma, and reduced lifespan. Segregation analysis of Apc/Sufu cross offspring showed a trend toward reduced viability of Apc/Sufu double heterozygotes compared to Apc or Sufu +/- mice ($p = 0.18$). A strong trend was seen toward increased adult weight of double heterozygotes over Apc +/- mice ($p = 0.06$). Further study will include comparison of gastrointestinal polyp number, size and aggressiveness and analysis of possible extra-intestinal manifestations in these mice.

Ophthalmologic features of patients with DNA repair defects. *B.P. Brooks^{1,2}, C.C. Chan¹, J. Smith¹, J.J. DiGiovanna³, D. Schmidt³, D. Blain¹, K.H. Kraemer³.* 1) NEI, NIH, DHHS, Bethesda, MD; 2) NHGRI, NIH, DHHS, Bethesda, MD; 3) NCI, NIH, DHHS, Bethesda, MD.

Background: Xeroderma pigmentosum (XP) is an autosomal recessive disorder characterized by defective DNA repair mechanisms and an increased risk for ultraviolet (UV) light-induced malignancies on sun-exposed areas such as the skin and conjunctiva. Trichothiodystrophy (TTD) is a related, autosomal recessive disease characterized by sulfur-deficient brittle hair and nails and a broad spectrum of skin, neurologic, immunologic, and developmental abnormalities. TTD patients do not typically develop skin cancer. It is not well-appreciated that many of these patients--including children--suffer from clinically significant ocular surface disease. **Purposes:** 1) To characterize the ocular surface disease in patients with DNA repair disorders. 2) To describe a non-invasive technique for early detection of conjunctival pre-malignancies in these patients. **Methods:** Clinical examination and conjunctival cytology. **Results:** 14 XP and 5 TTD patients underwent age-appropriate, complete ophthalmologic examinations (7 females, 12 males). Schirmer testing for basal tear secretion was reduced (<10mm wetting) in 4 out of 10 XP patients and 3 of 3 TTD patients. Superficial punctate keratopathy was present in 3 of 12 XP patients and 2 of 3 TTD patients. Corneal pannus--ranging in severity from 1mm corneal neovascularization to complete opacification of the cornea--was observed in 5 of 14 XP and 1 of 5 TTD patients. 4 of 5 conjunctival cytology specimens showed evidence of inflammation (neutrophils and lymphocytes); one specimen showed epithelial dysplasia with mitotic figures. **Conclusions:** 1) Ocular surface disease is a frequent clinical finding in patients with DNA repair disorders--including children, in whom ocular surface problems are uncommon. 2) Conjunctival cytology is a non-invasive histologic technique that may be useful in the early detection of conjunctival pre-malignancy.

Characterizing the localization of Rothmund-Thomson syndrome-associated RECQL4. *L.M. Burks, S.E. Plon.*
Pediatrics, Baylor College of Medicine, Houston, TX.

Deleterious mutations in *RECQL4*, one of five human RecQ helicase homologues, lead to a significant predisposition to osteosarcoma (OS) in patients with Rothmund-Thomson syndrome (RTS). RTS, an inherited cancer predisposition syndrome, is also characterized by a unique rash and congenital skeletal abnormalities. The regulation and function of *RECQL4* in human cells is not known. Therefore, characterizing the localization of *RECQL4* is critical to understanding its normal role in the cell and OS predisposition in RTS patients. Full-length *RECQL4* cDNA was used to create a GFP fusion construct (*GFP-RECQL4*). Fluorescence microscopy was used to analyze GFP-*RECQL4* in unsynchronized HeLa (cervical carcinoma), WI38VA (SV40-transformed fibroblast), or U2OS (osteosarcoma) cell lines. Localization included cell populations that express GFP-*RECQL4* only in the nucleus, cells that express GFP-*RECQL4* only in the cytoplasm, and cells with both nuclear and cytoplasmic expression. These findings were also confirmed with FLAG-*RECQL4* and are in contrast to the sole published report of exclusively nuclear FLAG-*RECQL4* localization in HeLa cells (Kitao *et al.*, 1999). On average, 10-20% of HeLa or WI38VA cells and 20-50% of U2OS cells express GFP-*RECQL4* only in the cytoplasm. We hypothesize that *RECQL4* localization varies with the cell cycle. By scoring random fields of mitotic cells, identified with antibodies against Aurora B Kinase (ABK) or phosphorylated histone H3 (pH3), we find that cells in telophase (ABK+) are more likely to express cytoplasmic GFP-*RECQL4*. For example, 73% of ABK+ WI38VA cells express cytoplasmic GFP-*RECQL4* compared with 32% of ABK- cells (which may represent cells in early G1). By chi square analysis, the distribution of cytoplasmic cells in the marked and unmarked subsets is non-random ($p < 0.001$). Experiments using pH3 antibodies suggest that GFP-*RECQL4* shifts into the cytoplasm during late G2/prophase. Here, we present evidence that *RECQL4* helicase is expressed outside of the nucleus. Our data suggest that *RECQL4* localization is intrinsically regulated with each cell cycle. We propose that *RECQL4* is excluded from the nucleus during the final stages of mitosis, perhaps to prevent *RECQL4* activity on condensed chromosomal DNA.

Polymorphisms in genes associated with estrogen metabolism, synthesis, binding and penetrance of HNPCC among hMSH2 germline mutation carriers in Newfoundland. *P.T. Campbell¹, M.O. Woods², R. Green², J. Green², W. Fitzgerald³, J.R. McLaughlin¹, H.B. Younghusband².* 1) Epidemiology and Biostatistics, Mount Sinai Hospital, Toronto; 2) Discipline of Genetics, Memorial University of Newfoundland; 3) Sir W. Grenfell Hospital, St. Anthony, NL.

Newfoundland (NL) has the highest provincial incidence and mortality rates of colorectal cancer (CRC) in Canada. The high rates may be partly explained by the strong prevalence of hereditary non-polyposis colorectal cancer (HNPCC) families, uncommon in most populations. Several germline mutations in the mismatch repair gene hMSH2 have been identified in these extended NL families (IVS5+3A>T, deletion of exons 4-16, and an exon 8 deletion). The estimated penetrance of these mutations is high, but not complete, so modifying effects likely exist from other genes or environmental sources. The finding that penetrance is consistently lower in women than men with these genotypes, implies an association with estrogens. Recent work suggests that exogenous estrogens are associated with decreased risk of CRC among women with a strong family history of CRC (and HNPCC). Less understood is the HNPCC risk associated with polymorphisms in genes related with endogenous estrogen levels. Several polymorphisms in genes involved with estrogen synthesis, metabolism and binding have been identified. We postulate that polymorphisms in such genes influence HNPCC penetrance through modification of endogenous hormone levels, including estrogens. We have assembled from the Provincial Medical Genetics Program a collection of samples from 150 confirmed hMSH2 mutation carriers for study of modifier genes associated with HNPCC penetrance, with an additional 50 samples anticipated. In addition, we have collected extensive data on pedigree structure, clinical outcomes (including cancer diagnosis, treatment and death), and we are initiating epidemiologic data collection. The current study will estimate penetrance modification according to allelotype of several common polymorphisms in genes associated with estrogen synthesis (CYP17 and CYP19), estrogen metabolism (COMT) and estrogen ligand binding (ER) among confirmed hMSH2 mutation carriers.

Screening of BRCA1 and BRCA2 mutations in 55 Chilean families: three novel mutations. *M.P. Carvalho¹, L. Rubio¹, C. Torrealba¹, C. Alvarez¹, T. Tapia¹, M. Salinas¹, P. Faundez¹, M. Alvarez².* 1) Dept. Cell and Molecular Biology, Faculty of Biological Sciences, Pontificia Universidad Catolica de Chile, Santiago, Chile; 2) Centro de Cancer, Faculty of Medicine, Pontificia Universidad Catlica de Chile, Santiago, Chile.

Several hundreds of germline mutations at the BRCA1 and BRCA2 genes have been described in families affected of breast and/or ovarian cancer, from worldwide populations. The prevalence of BRCA1 and BRCA2 mutations among affected families is variable, depending on the ethnic origin of the population analyzed. The BRCA1 gene has been mapped to chromosome 17q21 and the BRCA2 gene has been mapped to chromosome 13q12.3. We selected 55 Chilean families by standard criteria, and screened the BRCA1 and BRCA2 genes for mutations, through SSCP, heteroduplex, protein truncation test and sequencing. We found 8 truncation mutations in 11 families. Two families have the 185delAG and 6174delT mutations extensively described in Ashkenazi-Jewish. Three mutations previously described in families from Spain were found in 5/11 Chilean families with mutations. These mutations are: E49X in exon 3 (2 families), 6857delAA, and 5373del GTAT (2 families) in exon 11. Three novel truncation mutations, 308insA in exon 5, 3936C>T, and 4970insTG, were found in other three families. These results reveal that only 20% of Chilean families present mutations on the BRCA1 and BRCA2 genes, and between these 45% show common Spanish mutations. This latter result would be expected considering the important Spanish immigration during the XVI and XVII centuries of colonization. (Fondecyt 1011076).

Family history does not affect survival after breast cancer. *P.O. Chappuis^{1, 2}, H.M. Verkooijen⁴, G. Fioretta⁴, G. Vlastos³, E. Rapiti⁴, C. Bouchardy⁴.* 1) Service of Oncology; 2) Service of Medical Genetics; 3) Service of Gynecology, Geneva University Hospitals; 4) Geneva Cancer Registry, Institute for Social and Preventive Medicine, Geneva University; Geneva, Switzerland.

Background: Family history of breast cancer is associated with an increased risk of developing the disease, but its impact on survival after breast cancer remains uncertain. In a population-based study, we compared survival of breast cancer patients without family history of breast cancer, with that of patients at increased familial risk. **Methods:** Data were extracted from the population-based Geneva familial breast cancer registry, which for each patient includes demographic information, tumour characteristics, type of treatment and survival, and occurrence of cancer among first, second, and third degree relatives. We classified patients into three categories according to the number of family members affected with breast or ovarian cancer, their degree of kinship and age at diagnosis. We calculated breast cancer specific survival and used Cox proportional hazards analysis to estimate the effect of the familial risk on breast cancer survival. **Results:** Between 1990 and 2001, 3709 women were diagnosed with breast cancer. The median follow-up was 7 years. For 3355 (90%) women information on family history was retrieved. Of these women, 2478 (74%) had no relatives with breast or ovarian cancer, 690 (21%) had a moderate familial risk and 187 (6%) a high familial risk. Women with a moderate or high familial risk were significantly younger at diagnosis, had smaller tumours and had a higher incidence of ovarian cancer. Ten year disease-specific survival rates of patients with no, moderate and high familial risk were 79% (95% CI: 76-81%), 82% (95% CI: 77-86%), and 81% (95% CI: 73-89%), respectively. After adjustment for age and stage, there was no difference in breast cancer mortality rates for patients with a positive family history compared to those without an increased familial risk. **Conclusion:** In this large population-based study, a family history of breast or ovarian cancer does not affect survival after breast cancer.

Heterogeneity of *MSH2* rearrangements in HNPCC: an update. F. Charbonnier¹, C. Martin², S. Frérot², S. Olschwang³, Q. Wang⁴, C. Boisson³, MP. Buisine⁵, F. Di Fiore¹, M. Nilbert⁶, A. Lindblom⁷, S. Baert^{1, 2}, T. Frebourg^{1, 2}. 1) Inserm U614, Faculty of Medicine, Rouen, France; 2) Department of Genetics, Rouen University Hospital, 76031 Rouen, France; 3) Inserm U434 and Saint Antoine Hospital, Paris, France; 4) Molecular Oncology, Centre Léon Bérard, Lyon, France; 5) Laboratory of Biochemistry and Molecular Biology, University Hospital, Lille, France; 6) Department of Oncology, University Hospital, Lund, Sweden; 7) Department of Clinical Genetics, Karolinska Hospital, Stockholm, Sweden.

We had previously shown, using QMPSF (Quantitative Multiplex PCR of Short Fluorescent Fragments), that *MSH2* rearrangements are involved in at least 10% of the HNPCC families, fulfilling the Amsterdam criteria. We have identified so far 22 distinct exonic deletions of *MSH2*, removing exon(s) 1, 1-2, 1-4, 1-6, 1-7, 1-8, 1-11, 1-15, 2, 3, 3-11, 4-6, 5, 5-6, 7, 7-10, 8, 9-10, 9-16, 11-14, 12-13, 13-15 and 3 duplications involving exon(s) 7, 7-8, 9-10. We identified only one case of a deletion removing selectively the promoter region. We performed a QMPSF scanning of 200 kb of genomic sequences upstream the *MSH2* transcription initiation site in families with exon 1 deletions. This QMPSF scan revealed at least 13 distinct 5' breakpoints located between 200 kb and 3.6 kb upstream the *MSH2* transcription initiation site. Most of the deletions removed the *TACSTD1* gene encoding the EpCAM adhesion molecule. The QMPSF scan greatly facilitated the location of PCR primers to amplify the rearranged allele and characterize the breakpoints. The characterization of the 5' breakpoints in the recurrent exonic deletions (deletions of exon 1, exons 1-2, 1-6, 1-7, 1-8) showed that these rearrangements had been independently generated. In particular, we identified 6 distinct rearrangements removing exons 1-6, whereas the exons 1-6 deletion had previously been shown to be associated in North America to a founder effect. On the basis of exonic rearrangements and breakpoints within the 5' region, we identified 39 distinct *MSH2* genomic alterations. This study demonstrates the remarkable heterogeneity of the *MSH2* rearrangements and indicates that the *MSH2* region is particularly rich in recombinogenic sequences.

Analysis of the MYH gene mutations Y165C and G383D in familial adenomatous polyposis (FAP) patients negative for APC gene mutations. *B. Chong¹, M.A. Young¹, P. Ward¹, C.S. Richards², B.B. Roa¹, M.R. Hegde¹.* 1) Medical Genetics Laboratories, Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX; 2) OHSU DNA Diagnostic Lab Oregon Health & Science University 3181 SW Sam Jackson Park Road, MP-350.

MYH Associated Polyposis is due to autosomal recessive germline mutations in the MYH (MutY) gene, which were identified in ~ 23% of patients with multiple colorectal adenomas. Genetic testing of MYH is indicated for patients wherein: 1) 100 or fewer adenomas are present with or without extracolonic manifestations, particularly if no germ-line APC mutation has been identified, and/or 2) the family history is compatible with autosomal recessive inheritance. The clinical presentation may be consistent with Attenuated Familial Adenomatous Polyposis (AFAP), although only ~10% have identified APC mutations. A small number of patients with apparently classical FAP features were reported to have two mutations in the MYH gene, Y165C and G393D (nomenclature based on MYH transcript NM_012222). These missense mutations have been identified frequently in European Caucasian patients, although various mutations have been identified in different ethnic groups. To estimate the frequency of the Caucasian MYH mutations among patients referred for FAP testing, we analyzed the Y165C and G393D mutations on 129 patients with a clinical diagnosis of FAP and negative APC mutation studies. Analysis was performed using PCR amplification and an automated mini-sequencing method called pyrosequencingTM. We detected mutations in a total of five patients. Two patients were homozygous for the Y165C mutation and one was homozygous for G393D, thereby confirming the diagnosis of MYH-associated polyposis. Two other patients were heterozygous for the Y165C mutation. Thus, the MYH Y165C and G393D mutations were present in approximately 2.3% and 0.8%, respectively, of patient chromosomes in our study. These results suggest that the Y165C and G393D mutations in the MYH gene account for a minority of patients who present with FAP features in a U.S. referral testing population.

Program Nr: 395 from the 2004 ASHG Annual Meeting

The common deletion 657del5 in the Nijmegen breakage syndrome gene *NBS1* in a pediatric malignant lymphoma/leukemia population a Polish study. *K. Chrzanowska, D. Piekutowska-Abramczuk, E. Popowska, M. Gladkowska-Dura, D. Perek, A. Wakulinska, M. Syczewska, M. Krajewska-Walasek, Polish Pediatric Leukaemia/Lymphoma Group.* Department of Genetics, Children's Memorial Health Institute, Warsaw, Poland.

Nijmegen breakage syndrome (NBS) is a human autosomal recessive disease characterized by genome instability (DNA DSB repair defect) and enhanced cancer predisposition, in particular to lymphoma and leukemia. NBS patients seem to be prevalent among Slavs, especially among the Polish population. All Polish patients identified to date carry a homozygous common mutation, 657del5, within the *NBS1* gene. To examine the role of the 657del5 allele in constitutional susceptibility to childhood lymphoma and leukemia we screened remission DNA samples from 519 children with primary malignant lymphoma and leukemia treated at 12 Hematology and Oncology Centers making up the PPLLSG. All samples were examined for the 657del5 mutation by PCR-SSCP assay. The *NBS1* mutation 657del5 on one allele was present in 5 patients: in 2 of 208 (0.96%) children with non-Hodgkin lymphoma (NHL) and 3 of 248 (1.2%) patients with childhood acute lymphoblastic leukemia (ALL); no mutation was found among 63 patients with Hodgkin lymphoma (HL). Our study showed a 2-fold excess of the major *NBS1* mutation 657del5 among pediatric patients with NHL and ALL as compared with the general population in Poland (0.57%). In addition, 5 new NBS patients were identified within that group. Larger studies are needed to evaluate the impact of the *NBS1* gene heterozygosity in susceptibility to childhood cancers of lymphoid origin.

DNMT1 participates in GSTP1 promoter region hypermethylation in prostate carcinoma. *D. Chu*^{1, 2}, *C. Wu*¹. 1) Dept of Biomedical technology and laboratory science, & Graduate Institute of Medical Biotechnology, School of Medical Technology, Chang Gung University, Tao-Yuan, 333 Taiwan; 2) Laboratory of molecular diagnosis, Department of Clinical Pathology, Chang Gung memorial hospital, Lin-Kou, Taiwan.

Hypermethylation in the promoter region flanking GSTP1 gene is a common finding in prostate cancer genome. This genetic lesion leads to null expression of Glutathione-S-transferase. In this study, we transduced human DNA (cytosine-5) methyl transferase 1 (DNMT1) into normal prostate cells to investigate whether DNMT1 participated in the methylation status of prostate cell transformation. If so, this methyltransferase could involve in the oncogenesis process of prostate cancer. DNMT1 protein was introduced into non-malignant prostate cells by way of an artificially synthesized peptide carrier and GSTP1 gene promoter region methylation status was determined using methylation sensitive real-time quantitative PCR protocol before DNMT1 treatment and afterward. Data indicated that DNMT1 protein did enter into cell nucleus and it added methyl group onto the cytosine. Therefore, the originally hypomethylated CpG dinucleotides in the GSTP1 promoter region became hypermethylated. Reduced messenger RNA of GSTP1 gene was observed after treatment. In conclusion, we have successfully introduced DNMT1 into the non-malignant prostate cell nucleuses and hypermethylation did occur in these cells. DNMT1 might be an important factor during early stages of prostate neoplastic transformation.

Prevalence of CDKN2A mutations in familial melanoma. *M. Eliason*^{1, 2}, *A. Larson*^{1, 2}, *S.R. Florell*^{1, 2}, *J.J. Zone*^{1, 2}, *L.A. Cannon-Albright*^{1, 2, 3}, *S.A. Leachman*^{1, 2}. 1) Dermatology, University of Utah Health Sciences Center, Salt Lake City, UT; 2) Huntsman Cancer Institute, University of Utah, Salt Lake City, UT; 3) Genetic Epidemiology, University of Utah, Salt Lake City, UT.

Cyclin-dependent kinase inhibitor 2A (CDKN2A) is the major melanoma predisposition gene yet identified. To determine eligibility for genetic testing of melanoma patients, it is essential to establish the prevalence of mutations in subsets of the melanoma population. It has been suggested that pedigrees with two affected members do not warrant testing due to low pre-test probability, whereas pedigrees with more affected members might benefit. Melanoma pedigrees that contain members with pancreatic adenocarcinoma also may have an increased likelihood of carrying a CDKN2A mutation. To determine the prevalence of CDKN2A mutations in subpopulations of hereditary melanoma, 88 pedigrees (n=223) were CDKN2A mutation tested. Pedigrees included 2 or more affected first-degree relatives and were identified through the Utah Population Database. Genetic testing at the CDKN2A locus (p16 and ARF) was performed by sequence analysis of exons 1, 1, 2, 3, promoter region, splice junctions and a deep intronic region. Only 2.5% of pedigrees with two affected members showed a deleterious CDKN2A mutation, whereas 20% of pedigrees with five or more affected members showed a deleterious CDKN2A mutation. An additional 2.5% and 13% of 2-member and >5-member pedigrees had a mutation of uncertain significance, respectively. Of the pedigrees with a deleterious CDKN2A mutation, 50% had a member with pancreatic adenocarcinoma. Four additional pedigrees had member(s) with pancreatic carcinoma, two of these had a CDKN2A polymorphism and two had no CDKN2A mutation. Our data supports the assertion that genetic testing is not warranted for members of pedigrees with two or fewer affected members. Conversely, genetic testing is warranted for pedigrees with 5 or more affected members. Finally, our results demonstrate a strong association between pancreatic cancer and CDKN2A mutations, suggesting that a family history of pancreatic carcinoma should be included as a criteria in consideration of CDKN2A mutation testing.

Hereditary diffuse gastric cancer, cleft lip/palate and *CDH-1/E-cadherin* mutation. T. Frebourg¹, P. Hochain², S. Manouvrier³, S. Lejeune Dumoulin³, JP. Triboulet⁴, M. Scotté⁵, F. Le Pessot⁶, A. Hédouin¹, V. David⁷, M. Blayau⁷. 1) Department of Genetics, Rouen University Hospital, 76031 Rouen, France; 2) Centre Médico-chirurgical du Cèdre, Bois-Guillaume, France; 3) Department of Genetics, Lille University Hospital, France; 4) Department of Surgery, Lille University Hospital, France; 5) Department of Surgery, Rouen University Hospital, France; 6) Department of Pathology, Rouen University Hospital, France; 7) Molecular Genetics Laboratory, Rennes University Hospital, France.

Hereditary diffuse gastric cancer (HDGC), resulting from *CDH-1/E-cadherin* mutations, represents one of the most aggressive cancers, whose medical management is particularly difficult since, in mutation carriers, the normality of endoscopy and biopsies does not exclude the presence of malignant cells. We report a family with a remarkable clinical presentation. The index case, of 23 years of age, was referred for a rectal stenosis and rapidly deceased in the context of a peritoneal carcinosis. The proband's father had developed at the age of 48 a diffuse gastric cancer. A paternal cousin presented at 22 years epigastric pains which led, considering the familial history, to a systematic endoscopy and biopsies revealing a diffuse gastric cancer. *CDH-1* analysis identified a splicing mutation (531 +2 T/A, intron 4) in the index case, his affected cousin and in the proband's paternal uncle, who was asymptomatic at 53 years. This uncle underwent a prophylactic gastrectomy which revealed an hereditary diffuse gastric cancer with metastatic nodes. The proband's brother, aged of 21 years, was asymptomatic and gastroscopy and the biopsies were normal. He underwent a presymptomatic testing who indicated that he was also a carrier. This led to a prophylactic gastrectomy which revealed microscopic foci of intamucosal signet ring cell adenocarcinoma. Remarkably, the index case, his paternal cousin, his paternal uncle and his brother, all affected, had also a cleft lip/palate. This cosegregation suggests that the cleft lip/palate in this family may result from the *CDH-1* mutation. Indeed, mouse models have shown that the E cadherin plays a key role in palatal shelf adhesion during embryogenesis.

BRCA1 and BRCA2 Genetic Variants in A Control Population of 100 African Americans. *C.A. Frye¹, L.A. Burbidge¹, A.E. Deffenbaugh¹, T.M. Scholl¹, S.V. Tavtigian², B.E. Ward¹, W.W. Noll¹.* 1) Myriad Genetic Laboratories, Salt Lake City, UT; 2) International Agency for Research on Cancer, Lyon, France.

Purpose: Determine the prevalence of BRCA1 and BRCA2 sequence variants in a control population of 100 unrelated African Americans. **Background:** Mutations in BRCA1/2 account for the vast majority of cases of hereditary breast and ovarian cancer (HBOC). A significant percentage of the sequence variants identified are variants whose functional significance is not apparent and are classified as variants of uncertain clinical significance. In the U.S. population overall, 12% of the individuals who are tested for BRCA1/2 mutations are found to carry uncertain variants. In the African American population, this figure is more than 3 times higher. **Methods:** One hundred DNA samples from unrelated African Americans were obtained from the NIGMS Repository of the Coriell Institute for Medical Research. Full sequence analyses of BRCA1 and BRCA2 were performed. **Results:** Forty-three different variants were observed, 9 in BRCA1 and 34 in BRCA2. No nonsense or frameshift mutations were detected. In BRCA1 K719E was seen twice, while 8 other variants each were seen once. In BRCA2 I1364L, H2440R and 5UTR218C>T each were seen seven times; K2339N, I2944F and V3244I each were seen six times; D1902N and Q2384K each were seen four times; C1290Y, N1880K and H2116R each were seen three times; P59A, T1414M, D1923A and V3079I each were seen twice and nineteen other variants each were seen once. **Conclusions:** These mutation prevalence data from a control population of 100 unrelated African Americans are an important resource for accurately classifying sequence variants in BRCA1 and BRCA2. Together with prevalence data, cancer cosegregation data and co-occurrence with deleterious mutations in Myriads high risk clinical database, and other published studies, these data will permit the categorization of a large number of BRCA1 and BRCA2 variants, previously classified as variants of uncertain significance, as benign polymorphisms. This will enhance the clinical utility of BRCA1/2 genetic testing for HBOC in African Americans.

Comparison of Chromosomal Radiosensitivity in Breast Cancer Patients and Matched Controls, Using the G2 Assay. *A.L. Georgiou¹, I. Kesterton¹, J. Barwell¹, L. Pangon¹, J. Ball¹, R. Gilchrist¹, R. Camplejohn¹, E. Solomon¹, J. Berg², S. Hodgson¹, Z. Docherty¹.* 1) Guy's and St Thomas' Hospital, London, United Kingdom; 2) Division of Pathology and Neurosciences, University of Dundee, Ninewells Hospital and Medical School.

There is evidence for an inherited component to breast cancer in women without strongly predisposing mutations in BRCA1 and BRCA2, and one hypothesis is that defects in DNA repair and apoptosis may contribute to such susceptibility. It has been shown that patients with Ataxia Telangiectasia, who have a high predisposition to lymphoid malignancies, have an increased chromosomal sensitivity to ionising radiation as demonstrated by increased chromosome and chromatid breaks. This is thought to be due to a defect in DNA repair by homologous recombination. Previous research has suggested that individuals with breast cancer also have an increased chromosomal radiosensitivity in peripheral blood lymphocytes compared with normal controls and may also have a lower apoptotic response. We are looking for evidence of a defect in apoptotic response and impaired DNA repair in individuals who have developed breast cancer.

We have recruited 100 newly diagnosed breast cancer patients prior to treatment and 100 age and sex matched controls. Results of the classical G2 phase chromosome breakage assay are available for the first 64 matched patients and controls and these have been analysed. At present we have found no significant difference in the number of chromosome breaks (in 50 metaphases) caused by ionising radiation in patients compared to controls when lymphocytes were harvested at 30 minutes after irradiation with both half and 1 Grey irradiation. However there is evidence of a reduction in breaks and gaps when counted together in breast cancer patients compared to controls at the 3-hour harvest when irradiated at half Grey. (Paired t-Test, $P = 0.0067$, one tailed). Our results currently do not agree with previous research that has shown a higher radiosensitivity in breast cancer patients. We will also present data on apoptosis in these patients and controls.

Selective disruption of the FANCE/FANCD2 protein interaction: effect on cellular phenotype. *S.M. Gordon^{1,2}, N. Alon¹, M. Buchwald^{1,2}*. 1) Genetics and Genomic Biology, Hospital for Sick Children, Toronto, ON, Canada; 2) Molecular and Medical Genetics, University of Toronto, Toronto, ON.

Fanconi anaemia (FA) is an autosomal recessive disorder characterized by bone marrow failure, cancer predisposition, and increased cellular sensitivity to DNA crosslinking agents. This genetically heterogeneous syndrome consists of at least eleven complementation groups, the genes for eight of which have been cloned. Several of the gene products including FANCA, FANCC, FANCE, FANCF and FANCG participate in a protein complex, the formation of which is required for the monoubiquitination of FANCD2. The direct interaction of FANCE with both FANCC and FANCD2 previously observed in the yeast two-hybrid system has raised the question of whether FANCE can physically link FANCD2 to FANCC and possibly other components of the FA protein complex. The ability of FANCE to mediate an interaction between FANCC and FANCD2 is demonstrated in the yeast three-hybrid system. Immunoprecipitation experiments confirm the association of FANCC with FANCD2 in mammalian cells. The status of this complex in cell lines derived from patients of different FA complementation groups, as well as the possible involvement of the larger FA protein complex, is under investigation. FANCE mutants capable of interacting with FANCC but not with FANCD2 have been identified by yeast two-hybrid screening of a library of GAL4 AD-FANCE constructs randomly mutagenized by passage through an *E. coli* strain deficient in multiple DNA repair pathways. Exogenous expression of these mutants in FA(E) cell lines and subsequent evaluation of DNA crosslinker sensitivity, FA complex formation, and FANCD2 monoubiquitination will be used to evaluate the contribution of loss of the FANCE/FANCD2 interaction to aspects of the FA cellular phenotype. Supported by CIHR and the Hospital for Sick Children Foundation.

Elevated levels of somatic mutation in homozygotes and heterozygotes for inactivating mutations in the FA/BRCA DNA repair pathway. *S.G. Grant¹, S.L. Wenger², W.S. Rubinstein³, J.L. Latimer⁴, W.L. Bigbee⁴, A.D. Auerbach⁵.* 1) Environ Occup Health, Univ Pittsburgh, Pittsburgh, PA; 2) Clin Cytogenet Lab, West Virginia Univ, Morgantown, WV; 3) Center Genet Med, Northwestern Univ, Chicago, IL; 4) Univ Pittsburgh Cancer Inst, Pittsburgh, PA; 5) Lab Hum Genet Hematol, Rockefeller Univ, New York, NY.

Using the blood-based flow cytometric GPA somatic mutation assay we have shown that Fanconi anemia (FA) patients exhibit an ~100-fold increase in allele-loss variants (arising by gene-specific mutations, epigenetic gene inactivation, chromosome loss and deletion). This characteristic has been used in the diagnosis of FA patients; indeed, in this case, the assay can be applied regardless of GPA allelotype. A variable increase in loss-and-duplication variants was also observed, arising by mitotic recombination and chromosome loss and duplication. Neither an increase in this class of variants nor the quantitative increase in allele-loss variant frequency was specifically associated with FA complementation groups A, C and G. FA heterozygotes also exhibited a significant increase in GPA variant frequency ($P = 0.01$). Although only ~2-fold over controls and difficult to use for screening, this increase may be useful for risk assessment. The breast cancer predisposing genes BRCA1 and BRCA2 are functionally associated with the FA pathway, and their cancer susceptibility provides further evidence for a heterozygous FA phenotype. Indeed, BRCA1/2 breast cancer patients have slightly elevated mutation frequencies, both at the autosomal GPA locus (similar to FA heterozygotes) and at the X-linked HPRT locus (not observed in FA heterozygotes). Perhaps most significantly, however, none of these populations, FA homozygotes, heterozygotes or BRCA1/2 carriers exhibit the association between age and somatic mutational burden observed in normal populations. The biological significance of this lack of age effect may be greatest in the more subtly cancer predisposed heterozygous populations, who are at greatest increased risk for mutagenesis and carcinogenesis in early life, when their mutation frequencies are already equivalent to those of aged normal controls.

Geographic Stratification in the Ancestry of Breast Cancer Patients and Carriers of the BRCA2-999del5

Founder Mutation in Iceland. *J. Gudmundsson¹, A. Helgason¹, P. Sulem¹, O. Johannsson², H. Sigurdsson^{2,3}, J. Hrafnkelsson², J. Johannsson², J. Gulcher¹, U. Thorsteinsdottir¹, S. Stacey¹, L. Amundadottir¹, K. Stefansson¹.* 1) Department of Cancer, deCODE Genetics Inc, Reykjavik, Iceland; 2) Department of Oncology, Landspítali-University Hospital, Reykjavik, Iceland; 3) The Icelandic Cancer Center, Landspítali-University Hospital, Reykjavik, Iceland.

Little is known about the geographic stratification of genetic variation and disease risk within most populations. We have cross-referenced data from genetic-, genealogical-, geographical-, and national cancer registry-databases in order to examine this issue on a population-wide scale using breast cancer as an example. We determined the geographical distribution of all Icelandic breast cancer patients diagnosed from 1955-2003. Using the deCODE Genetics population-based genealogy database, we traced the geographical origins of patients' ancestors 5 generations back. These distributions were compared to those of multiple samples of randomly selected matched controls. We detected an excess of breast cancer patients, and their ancestors, in several adjacent counties in the Southwestern part of Iceland. A subset of the breast cancer cohort was tested for presence of the Icelandic founder mutation BRCA2-999del5. Breast cancer patients carrying this mutation were found in strong excess in one of these Southwestern counties. This localization was even more pronounced in the distribution of the carriers' ancestors. This may indicate the point of entry of this mutation into the Icelandic population. Breast cancer patients negative for the BRCA2-999del5 mutation as well as their ancestors showed a geographic localization to the Southwest of Iceland similar to that of all patients. This is consistent with additional genetic risk factors that show an overall geographic bias in Southwest Iceland. Knowledge of geographic locations of individuals, both current and ancestral, can allow for phenotypic stratification of patients that may aid in the genetic dissection of complex diseases.

Surveillance in HNPCC families with frequently occurring urinary tract cancers. *M. Harlan, C. Baeslach, D. Bagley, N. Cardi, B. Boman.* Thomas Jefferson University, Philadelphia, PA.

Introduction: HNPCC has an increased risk of developing cancer: colorectal, endometrial, stomach, and urinary tract. Specifically, individuals with germline mutations in MSH2 have a 10% lifetime risk to develop urinary tract cancer whereas with MLH1 there is a lower but still increased risk. Life-saving treatment is dependent upon early surveillance among organ systems involved. We report treatment and surveillance of urinary tract cancers in 2 families with a significant history of this cancer. Methods: Family 1: The proband presented for genetic counseling due to personal and family histories of cancer. He had bilateral ureteral cancer at 66, his son at 42 and daughter had endometrial cancer at 33. A sister had breast cancer at 70 and renal pelvis cancer at 74. A brother had CRC in his 40s, mother had CRC and endometrial cancer at 47 and her brother had CRC at 47. Family 2: The proband had a right ureteral cancer at 71, cholangiocarcinoma at 69, left ureteral cancer at 67 and endometrial cancer in her 50s. Her father had CRC at 36, sister at 36, 2 nephews at 42 and 35 and son at 44. Her daughter had ovarian and endometrial cancer at 42. Results: Gene sequencing was performed and results were negative for both families. In family 1, the proband's brother subsequently had southern blot analysis which revealed a mutation in the MSH2 gene (deletion of exons 1-8). This mutation would result in truncation of the protein. The proband in family 2 had MSI/IHC which revealed absence of MLH1 expression; further studies have been recommended. Conclusions: Patients with HNPCC have increased risk to develop urinary tract cancer. Often overlooked, it is crucial that gene carriers understand their risks in order to engage in preventive surveillance measures for early detection and optimal treatment. In these families, urinary tract cancer has developed as early as 42. Fortunately, many affected family members can be treated successfully by ureteroscopic laser resection and surveillance has been maintained endoscopically. Surveillance of unaffected members has included cystoscopy and radiographic imaging of the urinary tract in addition to urinalysis and voided cytology.

Involvement of three Finnish *ATM* founder mutations in breast cancer susceptibility. *K. Heikkinen*¹, *J. Tommiska*², *K. Syrjakoski*³, *J. Kere*⁴, *M. Allinen*¹, *S. Karppinen*¹, *K. Rapakko*¹, *K. Holli*⁵, *O. Kallioniemi*³, *H. Nevanlinna*², *R. Winqvist*¹. 1) Dept of Clinical Genetics, Univ of Oulu/Oulu Univ Hospital, Finland; 2) Dept of Obstetrics and Gynecology, Helsinki Univ Central Hospital; 3) Lab of Cancer Genetics, Inst of Medical Technology, Tampere; 4) Dept of Medical Genetics, Univ of Helsinki; 5) Dept of Oncology, Univ of Tampere/Tampere Univ Hospital.

ATM is a major activator cellular response to DNA damage. Loss of both *ATM* alleles results in ataxia telangiectasia (AT), a severe disease exhibiting progressive neuronal degeneration, immunodeficiency, chromosomal instability, radiosensitivity and increased risk of cancer. Although AT is an autosomal recessive disorder, individuals heterozygous for *ATM* mutations have been reported to have some phenotypic effects, including increased risk for female breast cancer. The aim of this study was to confirm the previously suggested association of *ATM* mutations originally identified in Finnish AT families with hereditary susceptibility to breast cancer. Of seven AT related mutations, 6903insA and 7570G>C were the only ones connected to breast cancer. Additionally, a third mutation, 8734A>G, previously associated with breast cancer susceptibility but not reported in AT patients, was observed. In combination with our previous results *ATM* 6903insA, 7570G>C and 8734A>G mutations were observed altogether in 1.4% of the Finnish breast cancer families (9/630) and in 0.5% of the unselected breast cancers (6/1209). All three mutations were absent from healthy controls (0/1307), and the difference in overall mutation frequency between hereditary and unselected cases versus controls was statistically significant ($p < 0.001$ and $p = 0.012$, respectively). In conclusion, our results support the contribution of *ATM* 6903insA, 7570G>C and 8734A>G mutations in hereditary susceptibility to breast cancer. We also provide evidence for founder effects in the geographical distribution of these mutations. The clustering of 6903insA and 8734A>G to the Tampere region seems particularly strong, and together these mutations may regionally contribute to a significant portion of hereditary breast cancer.

A study of cancer incidence in British Fanconi anemia families. *S.V. Hodgson¹, D.F. Easton², J. Ball³, C.G. Mathew³, M.D. Tischkowitz⁴.* 1) Medical Genetics Unit, St Georges Hosp Med Sch, London, London, United Kingdom; 2) Cancer Research UK Genetic Epidemiology Research Group, Strangeways Research Laboratory, Cambridge, United Kingdom; 3) Division of Medical and Molecular Genetics, GKT School of Medicine, Guy's Hospital, London, United Kingdom; 4) Clinical Genetics Unit, Institute of Child Health, London, United Kingdom.

Fanconi anemia (FA) is an autosomal recessive DNA repair disorder with affected individuals having a high risk of developing acute myeloid leukemia and certain solid tumours. Eleven complementation groups have been identified so far and the genes for eight of these are known (FANCA, C, D2, E, F, G, L and BRCA2). Previous studies of cancer incidence in relatives of Fanconi anemia cases have been limited by small sample sizes and have resulted in conflicting results. A study of British FA families was therefore carried out to investigate this question, since increases in cancer risk in FA heterozygotes would have implications for counseling FA family members, and possibly also for the implementation of preventative screening measures in FA heterozygotes. Thirty-six families took part and data was collected on 575 individuals (276 males, 299 females), representing 18,136 person years. In this cohort, 25 males and 30 females were reported with cancer under the age of 85 years and 36 (65%) cancers could be confirmed from death certificates, cancer registries or clinical records. The cancer incidence in a comparable general population cohort was calculated to be 56.95, and the relative risk of cancer was 0.97 (95% C.I.= 0.71-1.23, $p=0.62$) for FA family members. Analysis of relative risk for individual cancer types in each carrier probability group did not reveal any significant differences but confidence intervals were large. Therefore this study, the largest to date, has not shown a significant difference in overall cancer risk in FA families.

Molecular characterization of colorectal cancer in Newfoundland. *A. Hyde¹, M.O. Woods^{1,2}, F. Curtis¹, J.S. Green¹, D. Robb¹, A. Pollett², P.S. Parfrey¹, S. Gallinger¹, B. Bapat², H.B. Younghusband¹.* 1) Discipline of Genetics, Memorial University of Nfld, St. John's, NL, Canada; 2) Dept of Lab Medicine and Pathobiology, University of Toronto, Toronto, ON, Canada.

Newfoundland males have the highest incidence of colorectal cancer (CRC) in Canada and females the third highest. The most common genetic cause of CRC is hereditary non-polyposis colorectal cancer (HNPCC). Alterations in MLH1, MSH2 and MSH6 make up approximately 95% of identified mutations causing HNPCC. The island of Newfoundland has a relatively homogenous population, composed of multiple genetic isolates which have been valuable in genetic research. A population-based study of the Avalon Peninsula of Newfoundland was undertaken over a two year period to recruit all individuals diagnosed with CRC. The purpose of this study was to determine the proportion of hereditary vs. sporadic CRC cases and to determine the genetic basis of disease in hereditary cases. Seventy-nine subjects were recruited, including 22 from high risk families. Tumours from these individuals were retrieved and examined for microsatellite instability, a hallmark of HNPCC, and for immunochemical analyses. Only seven individuals from the high-risk families had microsatellite instability and showed absence of a MMR protein. This indicated there may be other causes for the high incidence of CRC in these families. Therefore, we examined a cohort of 34 high-risk Newfoundland HNPCC-like families which had been ascertained through the Provincial Genetics Program. Automated sequencing of MLH1, MSH2 and MSH6 was used for initial screening of sequence alterations. All tumors also underwent immunohistochemical analyses to determine MLH1, MSH2 and MSH6 expression. Multiplex Ligation-dependent Probe Amplification was undertaken to identify large genomic deletions in MLH1 and MSH2. One mutation, the deletion of exon 8 in MSH2, was identified in five families. Surprisingly, very few of the high risk families screened had identifiable alterations. This could be because these families segregate mutations in unidentified hereditary CRC genes. Future work will include performing a genome-wide scan on such large kindreds.

Linkage analysis of chromosome 8p in the PROGRESS study families: Identification of a locus in older onset hereditary prostate cancer families. *M. Janer¹, J.L. Stanford^{2,3}, K.A. Deutsch¹, D.M. Friedrichsen², S. Kolb³, M. Badzioch⁴, G.P. Jarvik⁴, L. Hood¹, E.A. Ostrander².* 1) Dept Genotyping, Inst Systems Biology, Seattle, WA; 2) Division of Human Biology, Fred Hutchison Cancer Research Center, Seattle, WA; 3) Division of Public Health Sciences, Fred Hutchison Cancer Research Center, Seattle, WA; 4) Department of Medicine, Division of Medical Genetics, University of Washington, Seattle, WA.

Several regions in the genome have been hypothesized to harbor prostate cancer susceptibility genes. Among those, the short arm of chromosome eight appears to be of particular interest. Numerous studies demonstrate that deletions in 8p are among the most common genomic abnormalities observed in prostate cancer tumors. In addition, several family-based linkage studies have also highlighted 8p. In order to investigate the role of genes on 8p in prostate cancer susceptibility within a set of 254 hereditary prostate cancer families (PROGRESS families), we performed nonparametric analysis using markers spanning the chromosome arm at 4cM intervals. Analysis of the entire data set did not yield statistically significant results. However, 111 families with a mean age at diagnosis 66 years demonstrated NPL scores 2 ($p=0.011$) for four consecutive markers spanning about 20cM. The maximal NPL score was 2.42 ($p=0.010$) at marker D8S1989. Multipoint lod scores were negative in this region but lods greater than 2.0 were observed in markers with high NPL scores. Interestingly, the region described by our linkage study overlaps with the minimal deletion interval reported by Swalwell et al. (2002) in a set of sporadic prostate tumors. Several genes encompassed by this region are putative candidates for susceptibility genes. Among them, NKX3.1 is the most interesting as it is expressed at comparatively lower levels in prostate tumors, particularly those associated with advanced stage disease. We are currently investigating this and other candidate genes within the region.

***VHL* germline mutations in Korean patients with von Hippel-Lindau (VHL) disease and pheochromocytomas.**

H.C. Kang^{1,2}, *I-J. Kim*^{1,2}, *J-H. Park*^{1,2}, *Y. Shin*^{1,2}, *S-G. Jang*^{1,2}, *H-W. Park*^{1,2}, *S-K. Lim*^{1,2}, *S-Y. Han*^{1,2}, *S.K. Oh*³, *D.J. Kim*⁴, *K.W. Lee*⁴, *Y-S. Choi*⁵, *Y-J. Park*³, *M.R. Lee*³, *D-W. Kim*², *J-G. Park*^{1,2,3}. 1) Korean Hereditary Tumor Registry, Cancer Research Institute, Seoul, Korea; 2) Research Institute and Hospital, National Cancer Center, Goyang, Gyeonggi, Korea; 3) Department of Surgery and Department of Internal Medicine, Seoul National University College of Medicine, Seoul, Korea; 4) Department of Internal Medicine, Ajou University School of Medicine, Suwon, Korea; 5) Department of Internal Medicine, Kosin University College of Medicine, Busan, Korea.

von Hippel-Lindau (VHL) disease is an autosomal dominant inherited tumor syndrome characterized by the development of hemangioblastoma; renal cell carcinoma; pheochromocytoma; pancreatic tumors; cysts and cystadenoma in the multiple organs. Pheochromocytomas are catecholamine-secreting tumors that develop from the adrenal medulla. Germline mutations in the *VHL* tumor suppressor gene are responsible for VHL disease. Genotype-phenotype correlations were well established based on the types of mutations in the *VHL* gene. In this study, we investigated for the presence of *VHL* germline mutations in 9 VHL affected patients from 6 families, 1 family with familial pheochromocytoma, and 2 cases of isolated pheochromocytoma or paraganglioma from Korea. Genomic DNA was extracted from peripheral blood lymphocytes, amplified by 6 primer sets spanning all three exons of the *VHL* gene, and sequenced by an automatic sequencer. We found a total of 6 *VHL* germline mutations (5 missense, 1 frameshift), 3 of which were novel types (323_324delGC, P119L, D121N). Three of 6 VHL affected probands had no family history at the time of diagnosis and harbored *VHL* mutations. One family with familial pheochromocytoma had a missense mutation (V84L) previously identified in a family with familial pheochromocytoma from UK. No *VHL* germline mutation was found in 2 cases of isolated pheochromocytoma and paraganglioma. Our results provide more accumulative data for the *VHL* germline mutations and VHL-related phenotypes. To our knowledge, this is the first report of *VHL* germline mutations of Korean patients with VHL disease and pheochromocytomas.

Clinical Testing for Hereditary Paraganglioma. *J.A. Kant¹, J. Uhrmacher¹, B.E. Baysal², F.A. Monzon¹, A.B. Carter¹.* 1) Dept Pathology, Univ Pittsburgh, Pittsburgh, PA; 2) Dept OB-GYN, Univ Pittsburgh, Pittsburgh, PA.

Hereditary paraganglioma (PGL) is an autosomal dominant neoplasia susceptibility syndrome. PGL has been associated with mutations in 3 proteins of the 4-subunit succinate-ubiquinone oxidoreductase (SDH) electron transport complex II - primarily the SDHD and SDHB genes. MRI can be used to follow high-risk mutation-positive patients. Molecular genetic testing for PGL has been offered clinically for several years to ~125 patients from North America with a history of benign or malignant paraganglioma. Bi-directional DNA sequencing of all exons and adjacent intron sequences is performed on the SDHD and/or SDHB genes. The usual reason for testing is to screen probands followed by testing of family members if a mutation is identified. Analysis is occasionally requested on patients with paraganglioma and no obvious family history; there has been one request for prenatal testing. SDHD or SDHB analysis is done after discussion with the submitting professional based on the location of paraganglioma(s) in the proband and family pedigree. SDHD is studied first in those with head and neck tumors and/or a history of paternal transmission. SDHB is studied first when there is maternal transmission and/or abdominal tumors. In the SDHD gene, 5 reported mutations and 6 new variants have been identified including 5 missense, 3 nonsense, 1 frameshift, and 2 splice site changes. In the SDHB gene, 7 reported mutations and 14 new variants have been identified including 11 missense, 3 nonsense, 2 frameshift, and 5 splice site changes. In addition, several polymorphisms have been identified in both genes. 17 probands have shown no mutation in either gene. The clinical significance of new variants is evaluated taking in account predicted effects on the protein, whether disease-associated mutations have been reported at the same amino acid, as well as calculated effects of splice variants on information content. Results are reported following ACMG Recommendations for Interpretation of Sequence Variations. A particularly interesting family without mutation in the SDHD gene demonstrates a haplotype of 3 neutral polymorphic markers which segregate with the paraganglioma phenotype.

A *TP53* truncating germline mutation (R287X) in a family with characteristics of both Hereditary Diffuse Gastric Cancer and Li-Fraumeni Syndrome. I-J. Kim¹, H.C. Kang¹, Y. Shin¹, H-W. Park¹, S-G. Jang¹, S-Y. Han¹, S-K. Lim¹, M.R. Lee², H.J. Chang³, J-L. Ku¹, H-K. Yang², J-G. Park^{1,2,3}. 1) Korean Hereditary Tumor Registry, Cancer Research Institute, Seoul, Korea; 2) Department of Surgery, Seoul National University College of Medicine, Seoul, Korea; 3) Research Institute and Hospital, National Cancer Center, 809 Madu-dong, Ilsan-gu, Gyeonggi, 411-764, Korea.

Mutations in *CDHI* have been associated with hereditary diffuse gastric cancer (HDGC) in Western populations, but have not been shown to play a major role in Asians. Recently, a patient with familial gastric cancer (FGC) was shown to harbor a germline mutation in the *TP53* gene, which encodes TP53 and has been previously associated with Li-Fraumeni Syndrome (LFS). To determine whether mutations in *TP53* are associated with familial gastric cancer (FGC) in Asians, we screened the entire coding region of *TP53* in probands from 23 Korean FGC families by an automatic sequencing or DHPLC (denaturing high performance liquid chromatography). We identified a nonsense (R287X) *TP53* germline mutation in a family whose history is compatible with both HDGC and LFS. Two members of this family (SNU-G2) were afflicted with brain tumors, seven with gastric cancers, two with sarcomas and one with both gastric cancer and a sarcoma. It is possible that the HDGC/LFS phenotype in family SNU-G2 family may be due to an aggressive nonsense mutation (R287X) in exon 8. The R287X *TP53* mutation segregated with the cancer phenotype in the family members from whom DNA samples were available. Immunohistochemical staining for p53 did not show any p53 nuclear protein accumulation in the tumor cells of the liposarcoma or medulloblastoma samples. Although a *TP53* germline missense mutation was previously reported in a case of LFS presenting with a non-familial gastric cancer, this is the first report of a large family with a *TP53* germline mutation associated with both HDGC and LFS. Our result suggests that researchers should be cautious in screening familial gastric cancer families for mutations in *TP53*, as *TP53* mutation-carrying FGC families may also develop LFS-related phenotypes.

Detection of a FANCA SNP haplotype associated with early onset breast cancer. *C. Lazaro*^{1,2}, *Q. Wang*¹, *S. Shah*¹, *Y. Chang*¹, *L. Moreau*³, *A. d'Andrea*³, *D. Bell*¹, *D. Haber*¹, *M. Daley*⁴, *A. Bernards*¹. 1) MGH Center for Cancer Research, Charlestown MA; 2) Medical & Molecular Gen. Cent., IRO, Barcelona, Spain; 3) Pediatric Oncology, Dana-Farber Cancer Institute, Boston, MA; 4) Whitehead Institute for Biomedical Research, Cambridge, MA.

Breast cancer (BC) is the most common type of cancer among women, with an estimated 1 million new cases annually. Having a first degree affected relative is among the most important risk factors for BC, but mutations in known tumor suppressors such as BRCA1 and BRCA2 account for only a small proportion of non-familial cases. It has been suggested that a polygenic model with multiple predisposing alleles, each with a small effect on disease susceptibility, may underlie the 75% unexplained familial cases and the majority of sporadic cases. In an attempt to identify new BC susceptibility genes, we analyzed missense SNPs of candidate genes in a case-control association study. For this project we assembled a database of >300 genes that may be involved in maintaining genome stability. We identified 964 missense SNPs in these genes, including 176 that have a minor allele frequency >0.04. Given the functional links between BRCA2 and Fanconi Anemia (FA) genes, we surveyed missense allele genotypes among FA genes in an exploration panel consisting of ~400 early onset (age at diagnosis <40 years) patients and ~220 controls. Positive findings were confirmed in an independent 200 patient/200 control validation panel. All but three FA genes do not harbor common missense SNPs. Common missense SNPs in FANCD2 and FANCL showed no altered genotype distributions among cases and controls, but several FANCA missense SNPs were strongly associated ($p < 0.001$) with early onset BC. Genotyping of 11 FANCA SNPs and 2 SNPs in the adjacent CDK10 gene allowed the identification of a disease-associated SNP haplotype. Additional studies will need to confirm these findings and assess to what extent the associated haplotype contributes to BC susceptibility.

Barriers to cancer surveillance in women at risk for Hereditary Breast and Ovarian Cancer. *M. Lilley¹, J. Liu¹, D. Gilchrist², D.C. Dover¹, C. King¹, K. Barker³, R. Hughes³.* 1) Alberta Cancer Board, Edmonton, Canada; 2) University of Alberta, Edmonton, Canada; 3) University of Calgary, Calgary, Canada.

OBJECTIVE: This follow-up study examined factors associated with cancer surveillance behaviour. In our previous study of 171 women who had genetic counseling for Hereditary Breast and Ovarian Cancer (HBOC), but with no personal history of breast or ovarian cancer, only 60% of women had annual mammograms, 18% had annual ovarian ultrasounds and 15% annual CA125 blood tests. **METHOD:** Questionnaires were sent to an initial sample of 77 women. To date, 51% of those questionnaires have been returned. **RESULTS:** Only 89% of women believe that they are at higher risk for developing breast cancer than the general population. Sixty-nine percent of this perceived at-risk group had annual mammograms. Fifty-six percent believe that they are at higher risk for developing ovarian cancer than the general population, with only 42% having annual ovarian ultrasounds, and 21% annual CA125 testing. Seventy-seven percent had discussed mammography with their MDs but only 63% of this group had annual mammograms. Fifty-nine percent discussed ovarian ultrasound with their MDs but only 45% of this group had annual ultrasounds. Forty-four percent discussed CA125 tests with their MDs but only 40% of this group had annual blood tests. Eighty-four percent reported that they were encouraged by their MDs to have mammograms. Fifty-six percent and 33% reported being encouraged by their MDs to have ovarian ultrasound, and CA125, respectively. Of the participants who felt encouraged by their MDs, 69% had annual mammograms, 47% had ovarian ultrasounds and 50% had CA125. Of the participants who did not feel encouraged by their MDs, none had annual mammograms, ovarian ultrasounds or CA125. **CONCLUSION:** Women who have received genetic counselling for HBOC do not necessarily believe they are at increased risk for developing breast and ovarian cancer. Among those who acknowledged their increased cancer risk, utilization of ovarian cancer surveillance tests was lower than mammography. Compliance with the cancer surveillance recommendations was greater for women who felt encouraged by their MDs than those who did not.

Clinical manifestation of non-hereditary retinoblastoma is influenced by a parent-of-origin effect in a subset of patients. *D. Lohmann*¹, *A. Schüler*², *C. Jurklies*², *M. Neuhäuser*³, *T. Lehnert*⁴, *S. Weber*⁴. 1) Humangenetik; 2) Augenklinik; 3) IMIBE; 4) Klinische Forschergruppe Universitätsklinikum Essen, Germany.

Mutation analysis is part of routine management in patients with isolated unilateral retinoblastoma (RB). To date, we have identified both oncogenic RB1 gene mutations in tumors from 230 of 263 of patients (87%). In 34 patients (13%), a mutation was also detected in constitutional DNA (peripheral blood), including 14 with obvious mutational mosaicism. To identify any differences in phenotypic expression between patients with and without a constitutional mutation we adopted a data warehouse approach to link up all relevant data including clinical data, histopathology, and genetic findings. Data were extracted from source systems (patient oriented databases), transformed, and loaded into a data mart using business intelligence software (COGNOS). Datasets complete with all relevant data on phenotypic expression were available from 237 of 263 patients. Among other findings we found that the distribution of age at diagnosis in patients with a constitutional mutation was not significantly distinct from that of patients without a constitutional mutation. This contrasts the findings in many hereditary cancers, where age at diagnosis is earlier compared to that of sporadic disease. To identify factors associated with early diagnosis we compared distributions grouped by certain attributes (drilling down). Overall, multifocal RBs were diagnosed earlier than unifocal RBs. However, in several patients with multifocal RB both oncogenic mutations were not detected in blood DNA. The distributions of age at diagnosis of tumors with different RB1 mutations were not distinct. Analysis of age at diagnosis of tumors with LOH showed that several patients with non-hereditary RB and retention of the paternal allele were diagnosed early. This caused an extra peak early in the distribution that was absent in non-hereditary patients with retention of maternal alleles. Our findings suggest that in a subset of patients with non-hereditary RB age at diagnosis of is influenced by a parent-of-origin effect.

A germline intronic mutation in *CDKN2A* affects splicing and predisposes to melanoma. *J.C.Y. Loo*¹, *L. Liu*², *L. Gao*², *A. Hao*², *M. Duvic*³, *D. Hogg*^{1,2,4}. 1) Medical Biophysics, University of Toronto, Toronto, ON, Canada; 2) Clinical Sciences, University of Toronto, Toronto, ON, Canada; 3) Dermatology, M.D. Anderson Cancer Center, Houston, TX; 4) Medicine, University of Toronto, Toronto, ON, Canada.

Cutaneous malignant melanoma (CMM) occurs primarily in European-derived populations. In North America, the lifetime incidence approximates 1/100, and the mortality rate per case is over 2 per 100,000. A melanoma in its early stages can be cured by surgical excision; however, deep melanomas tend to metastasize and are typically unresponsive to traditional therapies. Surveillance of CMM-prone individuals and populations should decrease the morbidity and mortality associated with this disease.

The *CDKN2A* gene at the chromosomal locus *9p21* encodes the p16^{INK4a} and p14^{ARF} cell cycle regulators. Coding mutations of this gene cosegregate in approximately 25% of melanoma families, but the genetic alterations in a subset of *9p21*-linked kindreds remain unknown. One such family, who contributed to the initial mapping of the melanoma susceptibility gene in 1994, has been afflicted with melanomas and multiple primary melanomas for at least five generations. We sequenced all *CDKN2A* exons and the adjacent intronic regions from the genomic DNA of affected family members, but found no coding mutations. RT-PCR of the p16^{INK4a} and p14^{ARF} transcripts each yielded two products: one of expected-sized and one larger product. Sequence analyses of individual RT-PCR products revealed that both aberrant transcripts contain 196 bp of intron 2. Examination of intron 2 at the genomic DNA level uncovered an IVS2-284A>G mutation that predicts a consensus splice acceptor site. Additional splicing of the RNA occurs between a cryptic splice donor site 196 bp downstream of the mutation and the Exon 3 splice acceptor. The IVS2-284A>G mutation cosegregates with melanoma cases within the family. Similar non-coding mutations may account for additional mutation-negative families, thus allowing the detection of additional at-risk kindreds.

A possible causative role for nonhomologous end-joining DNA repair in the occurrence of a complex deletion in

MLH1. S. McVety¹, R. Younan², N. Wong^{1, 3, 5}, G. Chong^{1, 3, 4}, W.D. Foulkes^{1, 3, 4, 5}. 1) Human Genetics, McGill University, Montreal, Canada; 2) Surgery, McGill University, Mtl, Can; 3) Cancer Prevention Centre, SMBD Jewish General Hospital, McGill University, Mtl, Can; 4) Diagnostic Medicine, SMBD Jewish General Hospital, McGill University, Mtl, Can; 5) Genetics, SMBD Jewish General Hospital, McGill University, Mtl, Can.

Hereditary non-polyposis colorectal cancer (HNPCC) is an inherited cancer syndrome caused by a defect in the mismatch repair pathway. The majority of HNPCC mutations have been detected in *MLH1* and *MSH2*. Most reported mutations are substitutions, small insertions and deletions, but standard methods of mutation analysis do not detect large rearrangements. It is now established that large deletions, insertions and rearrangements account for a significant proportion of *MLH1* and *MSH2* mutations.

Large deletions in *MLH1* are frequently attributed to homologous recombination between *Alu* repeats, since *Alu* sequences are present at or near most deletion breakpoints. *MLH1* contains an average of one *Alu* for every 1.5 kb of sequence and it has been suggested that a high density of *Alu* repeats may promote recombination. However, the presence of *Alu* sequences does not *per se* increase the frequency of large deletions. The fact that *Alu* sequences are found near deletion breakpoints in *MLH1* may simply be due to the high frequency of *Alu* in the gene.

Here, we report an unusual rearrangement resulting in the deletion of exons 6, 7 and 8 of *MLH1*, with the retention of part of intron 6 and insertion of two nucleotides at each end of the retained sequence. The 349 bp retained sequence is made up of two closely spaced *Alu* sequences. A class of deletions coupled with the insertion of an inverted sequence derived from the deleted region has previously been identified. Our case is unique in that the retained sequence is not inverted. There is no homology between the deletion breakpoints or insertion junctions and the insertion of base pairs is typical of repair mediated by nonhomologous end-joining (NHEJ). We propose a mechanism involving NHEJ to explain the occurrence of this complex deletion.

Microsatellite Instability Analysis In Colorectal Cancer Patients From Colombia: A Novel C399T Polimorphism In MSH2 Gene. *Y. Montenegro¹, J.L. Ramirez-Castro¹, G. Bedoya², L.F. Isaza^{1,3}, F. Quintero-Rivera^{1,4}, C.M. Muneton-Pena¹.* 1) Medical Genetic Unit; 2) Molecular Genetic Group; 3) Department of Surgery, School of Medicine, University of Antioquia, Hospital Universitario San Vicente de Paul, Medellin, Colombia; 4) Center for Human Genetic Research, Massachusetts General Hospital, HMS, Boston, MA.

Colorectal cancer (CRC) is one of the most common forms of cancer in humans. The familial cancer syndrome known as hereditary nonpolyposis colorectal cancer (HNPCC) is the most common hereditary colon cancer syndrome. HNPCC has been associated with germline mutations in several DNA mismatch repair genes such as MLH1, MSH2, MSH6, PMS1 and PMS2. Mutations of these genes cause microsatellite instability (MSI). MSI accelerates the carcinogenic process through an increase in the mutation rate. Our aim was to analyse colorectal cancer patients for MSI and to do mutation analysis in positive MSI patients for MLH1 and MSH2. A total of 41 patients were analysed using six markers (BAT-25, BAT-26, BAT-40, D17S250, D2S123 and D5S346) and four neutral STR. Mutation in MLH1 and MSH2 genes was examined in the MSI positive patients using direct sequencing with Genetic Analyzer. Eleven out of the 41 patients with CRC were diagnosed with HNPCC. MSI was detected in 14/41 (34.1%) of the tumors. MSI was found to be high (MSI-H) in 11/14 (75.6%) tumors and three (14.4%) were low (MSI-L). No mutations for MLH1 and MSH2 genes were detected in 11 of the MSI-H cases that had HNPCC. A novel polymorphism in exon 3, C339T, at codon 133 (GATGACASP) was detected. This polymorphism was also found in sporadic CRC patients and in healthy individuals. The level of MSI found was almost identical to the previously reported in HNPCC. Our analysis does not exclude mutations in other mismatch repair genes (i.e. MSH6). Additional mutations could also be responsible for HNPCC in our patients. It is also possible that an unusual abnormality in either the MLH1 or MSH2 genes, which can not be identified by the current genetic testing, be responsible for the HNPCC in these patients. Therefore further analysis is required in order to determine the role of this polymorphism in Colombian CRC families.

Population-based characterization of HNPCC - an unbiased analysis of cancer prevalence. *D.W. Neklason¹, G. Mineau¹, W. Samowitz², R. Kerber¹, J. Barlow¹, H. Hanson¹, R.W. Burt¹.* 1) Huntsman Cancer Inst, Univ Utah, Salt Lake City, UT; 2) Department of Pathology, Univ Utah, Salt Lake City, UT.

Hereditary Nonpolyposis Colon Cancer (HNPCC) is cancer syndrome caused by mutations in the DNA mismatch repair genes, primarily MLH1 and MSH2, and hallmarked by different cancers (principally colon and uterine), incomplete penetrance, and an early age of cancer diagnosis. Current estimated cancer risks for HNPCC have been developed mainly from families seeking medical advice. This can lead to biased estimates due to the small family size and a lack of communication or knowledge within families about cancer diagnoses. The objective of this study is to examine pedigrees of HNPCC probands using the Utah Population Database (UPDB), which includes genealogies linked to cancer records from the Utah Cancer Registry, and Utah death and birth certificates. This gives an unbiased perspective by including all cancers reported in the state of Utah back to 1967. Microsatellite instability (MSI) was examined in 383 high-risk colon cancers (diagnosed under age 50, or two first-degree relatives with colon cancer). A combination of family history, age of onset, and immunohistochemistry and sequencing of MLH1 and MSH2 were used to identify likely HNPCC cancer cases from 51 MSI-positive cancers. Family history was available in UPDB (two generations or more) on 36 cases with some kindreds going back 8 generations. Eleven cases (8 kindreds) fulfill Amsterdam II criteria, however 17 cases (14 kindreds) are likely to be HNPCC based on combined molecular results. A detailed analysis of cancer prevalence from the multiple HNPCC families will be presented. In one MSH2 kindred of 6 generations, HNPCC-associated cancers were traced in descendants of 3 of 9 branches. A total of 27 HNPCC-associated cancers were identified in 20 people including 14 colorectal cancers, 5 uterine cancers, and 6 cancers of the urinary tract at average ages of 58.8, 56.4 and 52.5 years respectively. The large number of urinary tract cancers was a surprise as current risk to mutation carriers is estimated at only 4% by age 70. Mutation testing will be required in family members for precise cancer penetrance estimates.

A Retrospective Family Study of Medulloblastoma. *D. Ng¹, T. Stavrou^{1, 2}, L. Liu³, M.D. Taylor⁴, B. Gold⁵, M. Dean⁵, H.S. Nicholson², J. Byrne², J.T. Rutka⁴, D. Hogg³, G.H. Reaman², A.M. Goldstein¹.* 1) Genetic Epidemiology Branch, DCEG, NCI, National Institutes of Health, DHHS, Bethesda, MD, USA; 2) Children's National Medical Center, Washington, DC, USA; 3) University of Toronto, Toronto, Canada; 4) Hospital for Sick Children, Toronto, Canada; 5) Center for Cancer Research, NCI, National Institutes of Health, DHHS, Frederick, MD, USA.

Medulloblastoma is the most common malignant central nervous system tumor of childhood and can occur sporadically or in association with inherited cancer susceptibility disorders such as the nevoid basal cell carcinoma syndrome (NBCCS). To determine whether an association existed between medulloblastoma and as yet undefined genetic syndromes we retrospectively reviewed clinical data on 33 patients with medulloblastoma from Children's National Medical Center (CNMC) diagnosed from 1969-1997 and compared them with their unaffected relatives (n=46). Among this study group, six had tumors showing desmoplastic histology. Two of the six met the diagnostic criteria of NBCCS. One NBCCS patient had a missense mutation of patched-1 (PTCH1); the other had no identifiable PTCH1 mutation. Two patients with isolated desmoplastic medulloblastoma were found to have an insertion and splice site mutation respectively in SUFU (suppressor of fused). Two remaining patients with desmoplastic medulloblastoma had no identifiable mutations by sequencing in PTCH1 or SUFU. All patients with nondesmoplastic medulloblastoma histology received molecular testing for SUFU. A subset (n=5) received mutation screening of PTCH1. None of these patients had an identifiable mutation in PTCH1 or SUFU. Clinical analysis of the 31 medulloblastoma patients without NBCCS revealed an elevated frequency of short stature ($p<0.01$) and shortened lower segment ($p<0.01$) compared with unaffected parents. This was not an unexpected finding since cranial spinal radiation therapy, a common treatment therapy for medulloblastoma, is associated with short stature. There was a paucity of clinical findings among the majority of medulloblastoma patients in this sample to suggest a definable cancer genetic syndrome. Thus, the etiology of sporadic nondesmoplastic medulloblastoma remains undefined.

Do germline monoallelic *MYH* and *MSH6* missense mutations act together in cancer development? R.C. Niessen¹, R.H. Sijmons¹, J. Osinga¹, M. Ligtenberg², F.B.L. Hogervorst³, C.H.C.M. Buys¹, J.H. Kleibeuker⁴, R.M.W. Hofstra¹. 1) Department of Clinical Genetics, University Hospital Groningen, P.O. Box 30.001, 9700 RB Groningen, The Netherlands; 2) Department of Human Genetics, University Medical Centre, Nijmegen, The Netherlands; 3) Netherlands Cancer Institute, Amsterdam, The Netherlands; 4) Department of Gastroenterology, University Hospital Groningen, Groningen, The Netherlands.

The MYH protein, involved in the repair of oxidative DNA damage, interacts with the MMR protein MSH6, thus implying an interaction between the DNA base excision and DNA mismatch repair (MMR) systems. Therefore, it is conceivable that germline mutations of *MYH* and of a MMR gene, in particular *MSH6*, in the same individual may result in an increased cancer risk. We postulate that a heterozygous *MYH* mutation might contribute to cancer susceptibility in carriers of a MMR gene (in particular *MSH6*) mutation. This might be most apparent in the case of missense mutations, as these might result in a less severely impaired MMR system, rather than in cases of truncating mutations. We have studied the frequency of germline *MYH* mutations in colorectal and/or endometrial cancer patients with proven germline missense or truncating mutations of the MMR genes *MLH1*, *MSH2* and *MSH6*. The frequency of monoallelic *MYH* mutations in the Dutch general population is 2%. Among 40 patients carrying a germline missense MMR gene mutation we identified 4 carriers of a monoallelic *MYH* mutation. Among 41 patients with a truncating MMR gene mutation we identified 1 monoallelic *MYH* mutation. More specifically, we identified 3 monoallelic *MYH* mutations in 14 *MSH6* missense mutation carriers (21%, $P < 0.05$ compared with the normal Dutch population), 1 in 7 *MSH2* missense mutation carriers (14%, n.s.) and 1 in 22 *MSH2* truncating mutation carriers (5%, n.s.). No *MYH* mutations were observed in 19 *MLH1* missense mutation carriers, 14 *MLH1* truncating mutation carriers and 5 *MSH6* truncating mutation carriers. Our preliminary results suggest that monoallelic *MYH* mutations in combination with a missense MMR gene mutation, in particular in *MSH6*, may indeed lead to an increased risk to cancer development.

REV3 and RAD51 function in pathways separate from Fanconi anemia for interstrand crosslink repair. *S.B. Olson, A. Hemphill, Y. Akkari, Y. Torimaru, A. Hanlon Newell, R.E. Moses.* Department of Molecular and Medical Genetics, Oregon Health & Sci Univ, Portland, OR.

Fanconi anemia is an autosomal recessive disease characterized by genomic instability, manifest as decreased survival and chromosomal breaks and radial formation on exposure to DNA interstrand crosslinks (ICLs). Findings suggest the involvement of additional DNA repair pathways in ICL repair. This is indeed the case in *Saccharomyces cerevisiae* in which repair of ICLs involves three separate pathways, represented by *REV3*, *RAD51* and *SNMI*. *REV3* protein acts in the post-replication repair (PRR) pathway, and is the catalytic subunit of DNA polymerase zeta, a translesion bypass polymerase. *RAD51* protein is required for homologous recombination (HR). In order to assess the roles of *REV3* and *RAD51* in ICL repair in human fibroblasts, and their relation to the FA pathway, we have used siRNA to deplete the proteins and measured the response to mitomycin C (MMC), an ICL agent. Depletion of either *REV3* or *RAD51* produces a significant increase in cell death and radial formation in normal fibroblasts with MMC treatment. Depletion of *REV3* or *RAD51* in a FANCA cell line produces an added increase in sensitivity and radial formation, indicating a non-epistatic relationship with the FA pathway. When the FA protein *BRCA2* was depleted simultaneously with *RAD51*, there was no increase in sensitivity above that of *RAD51* depletion alone. In contrast, simultaneous depletion of *REV3* and *RAD51* produced an increased cellular sensitivity and radial formation compared to individual depletion. Our findings indicate that *REV3*, *RAD51* and FANCA proteins represent three separate pathways for repair of ICLs, with *RAD51* acting in the FA pathway as well as at least one additional pathway. We also conclude that *RAD51* and *REV3* are not required for radial formation in human cells, indicating that neither bypass or HR functions are needed.

Frequency of founder BRCA mutations in French Canadian breast/ovarian cancer families and identification of a new founder BRCA2 mutation. *K. Oros¹, P. Ghadirian², A.M. Mes-Masson³, W.D. Foulkes¹, D. Provencher³, P. Tonin¹.* 1) Human Genetics, McGill U, Montreal, PQ; 2) Epidemiol Res Unit CR-CHUM (Htel Dieu), Montreal, PQ; 3) CR-CHUM (Hpital Notre-Dame)/Institut du cancer de Montral, Montreal, PQ.

Specific recurrent BRCA1 and BRCA2 mutations in hereditary breast cancer (HBC) and breast-ovarian cancer (HBOC) families of French Canadian (FC) descent, attributed to common founders, contribute to a significant proportion of mutation positive cancer families. We have extended this study of the contribution of the common mutations to a larger cohort of high-risk FC cancer families and included new mutations reported in FC cancer families. The 241 FC families (149 HBC and 92 HBOC) contained at least 3 cases of BC (<65) and/or OC in 1st, 2nd or 3rd degree relatives of an index case affected with BC/OC. DNA from an index case was analyzed for the 3 BRCA1 and 4 BRCA2 mutations previously shown to recur in FC cancer families and 8 BRCA1 and 5 BRCA2 mutations recently identified in FC cancer families. Mutations were identified in 99 (41%) families: 46 BRCA1-positive and 53 BRCA2-positive. There were 53 mutation-positive HBOC families and 46 mutation-positive HBC families. A significant proportion (73%) of mutation positive families harbored a previously reported recurrent mutation (4446C>T, 2953del3insC, 6085G>T and 8765delAG). Seven families harbored the BRCA2 mutation, 3398del5. This mutation was also identified independently in two families from Hereditary Cancer Clinics of Montreal. To assess if carriers of this mutation share a common ancestry, the FC families harboring this mutation were analyzed using microsatellite markers flanking BRCA2. Haplotype analyses suggested that carriers of this mutation share a common ancestry. Taken together, these findings suggest that while FC cancer families are more genetically heterogeneous than previously demonstrated, the recurrent mutations previously identified in FC cancer families remain the most common mutations identified. A mutation screen of FC families that also includes the newly discovered recurrent mutation would account for 80% of mutation positive FC cancer families.

A Preliminary Study on Cytochrome P450 1A1 Gene Polymorphisms as Possible Biomarkers of Cancer Risk Among Filipinos. *C.D. Padilla¹, E.C. Cutiongco¹, C.L.T. Silao¹, C. Ngelangel²*, *Philippine Cancer Genetics Research Group.* 1) Institute of Human Genetics, National Institutes of Health Philippines, University of the Philippines Manila; 2) Oncology Study Group, Institute of Clinical Epidemiology, National Institutes of Health Philippines, University of the Philippines Manila and Section of Medical Oncology, Department of Medicine, Philippine General Hospital and Jose R. Reyes Memorial Medical Center.

Population-based studies on the genetic variations of metabolizing enzymes have shown associations between polymorphic genes and increased susceptibility to some types of cancer. This preliminary report looks into the associations between susceptibility to lung and oral cavity cancer and specific genetic polymorphisms involving the Phase I metabolizing enzyme CYP1A1. Demographics, medical/social/diet histories and occupational exposure data are also presented. To identify these polymorphisms, polymerase chain reactions (PCR) and restriction enzyme polymorphism studies have been employed on DNA obtained from 500 blood samples of Filipino cancer patients and normal controls. Results show that mutant types for CYP1A1 MspI and NcoI suggest protective effects therefore decreased susceptibility to lung cancer. CYP1A1 MspI mutant genotype also suggest protective effects for oral cavity cancer. For the CYP1A1 MspI polymorphism, smoking tends to significantly raise lung cancer risk among those with mutant and heterozygous genotypes while not for those with wild genotypes. The reverse is true of the effects of smoking to oral cancer susceptibility. CYP1A1 NcoI wild genotype susceptibilities to both lung and oral cavity cancers increase with smoking. Further studies using more subjects are needed to determine whether these data are statistically significant.

Turcot syndrome in a family with hMLH1 mutation. *J.G. Pappas¹, T.P. Nicolaidis², E. Reich¹.* 1) Clinical Genetic Services, New York Univ, Sch of Med, New York, NY; 2) Department of Pediatrics, New York University, Sch of Med, New York, NY.

We present a family with multiple members affected with hereditary nonpolyposis colorectal cancer (HNPCC) and glioblastoma (GBM). The proband is a 9 year old boy with glioblastoma multiforme. His father had non polyposis colon cancer diagnosed at 34 year of age. Five generation pedigree revealed that twelve members of the family were diagnosed with early onset colon cancer and three with GBM including the proband. The family fulfills the Amsterdam criteria for HNPCC. Turcot syndrome is the association of colorectal cancer or colorectal polyposis with a primary tumor of the intracranial central nervous system. Turcot syndrome in families with familial adenomatous polyposis and medulloblastoma is associated with mutation in the APC gene. Mutations in the genes associated with HNPCC (hMLH1, hMSH2) are reported in the medical literature in families with Turcot syndrome that the brain tumor is GBM. DNA testing of both the patient and the patients father revealed a missense mutation (position 1731 G>A) of amino acid 577 in the last nucleotide of exon 15 of the hMLH1 gene. This mutation is associated with splicing errors and leads to an out of frame deletion of exon 15 (Wijnen et al., 1996). Further evidence that this deletion was pathogenic was provided by immunohistochemistry on the patients tumor. An immunoperoxidase stain performed with an antibody directed toward DNA mismatch repair enzyme MLH-1 showed aberrant loss of expression in the malignant cells with intact positive control expression in the benign background cells. The missense mutation in hMSH1 in this family with Turcots syndrome has been previously described to cause HNPCC but not Turcots syndrome. The only other mutation in hMLH1 associated with Turcot syndrome and previously described in the medical literature was a three nucleotide deletion (Hamilton et al, 1995). This family further establishes the association of HNPCC and GBM (Turcot syndrome) with mutations in hMLH1.

Replication protein A associates with double-strand DNA breaks in an ATM and DNA-PKcs dependent manner.

I. Pasic^{1, 2}, *M.S. Meyn*^{1, 2, 3}. 1) Molecular and Medical Genetics, University of Toronto, Toronto, ON; 2) Genetics and Genomic Biology, Hospital for Sick Children, Toronto, ON; 3) Paediatrics, University of Toronto, Toronto, ON.

Replication protein A (RPA) is a heterotrimeric single-strand DNA-binding protein involved in DNA replication, recombination, and repair. RPA is one of many proteins phosphorylated in response to ionizing radiation (IR) by the protein kinases ATM and DNA-PKcs. IR-induced phosphorylation modulates RPA's ability to support DNA replication *in vitro* and is thought to re-direct RPA from DNA replication to DNA repair. To better understand the effects of IR-induced RPA phosphorylation on RPA's biological functions, we are studying the effect of ATM and/or DNA-PKcs deficiency on RPA's participation in the repair of double-strand DNA breaks (DSBs).

Using short hairpin RNAs (shRNAs), we have achieved stable, effective, and specific silencing of DNA-PKcs expression in wild type and ATM-deficient human fibroblasts. Silencing is detectable by both Western analysis and immunofluorescence. Silenced cells display increased sensitivity to IR, as predicted from the phenotype of DNA-PKcs mice. Our creation of human cells deficient in both DNA-PKcs and ATM is the first of this kind; a previous study reported synthetic lethality between mutations in ATM and DNA-PKcs in mice.

Using laser micro-beam irradiation, we find that RPA localizes to photo-induced DSBs in wild-type human fibroblasts. In contrast, RPA does not associate with laser-induced DSBs in cells deficient in either ATM or DNA-PKcs, or in cells lacking both kinases. This is the first report of an effect of ATM and/or DNA-PKcs-deficiency on an *in vivo* function of RPA. In order to further elucidate the role of phosphorylation in recruiting RPA to induced DSBs, we now are determining the kinetics of RPA association with induced DSBs in cells depleted for ATM and/or DNA-PKcs, as well as studying the behavior of non-phosphorylatable and constitutively phosphorylated RPA mutants.

Prevalence of Y165C and G382D germline mutations of the *MYH* gene in Canadian Familial Adenomatous Polyposis (FAP) patients without a detectable germline APC mutation. V. Pethe¹, M. Croitoru¹, T. Berk^{2,3}, T. Chappell¹, J. Green⁴, Z. Cohen^{2,3}, S. Gallinger^{1,2,3}, B. Bapat^{1,2,3}. 1) Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto; 2) Familial GI Cancer Registry, Mount Sinai Hospital, Toronto; 3) University of Toronto, Canada; 4) Department of Genetics, Memorial University of Newfoundland, Canada.

Germline mutations in the human base excision repair gene, *MYH*, have been shown to confer an increased susceptibility to colorectal adenomas and carcinomas among a subset of CRC patients. In particular, two non-conservative missense mutation hotspots, Y165C and G382D account for the majority of *MYH* alterations identified to date among patients affected with multiple polyposis and/or CRC. In the present study, we examined the possible contribution of *MYH* mutations in 151 Canadian multiple polyposis patients identified through Familial GI cancer registries. These patients were referred to predictive genetic testing and research program for confirmation of a possible diagnosis of FAP. Patients were previously screened by PTT assay of the entire APC coding region. None of the patients harbored a demonstrable germline APC mutation. Patients were first screened for *MYH* Y165C and G382D mutations by TaqMan- based allelotyping assays and mutations were confirmed by sequencing (Y165C) and BglIII RFLP (G382D) analysis. Thirteen of 151 (8.5%) polyposis patients harbored germline mutation at Y165C or G382D. Among these, 8 patients were biallelic Y165C mutation carriers; 4 heterozygous for G382D and one for Y165C. Heterozygotes were further screened for mutations affecting the second *MYH* allele by dHPLC analysis of the entire coding region followed by sequencing. Two heterozygotes were found to carry novel missense alterations in the 8-oxoG-recognition domain of the *MYH* gene. Interestingly, 3/8 *MYH* Y165C homozygous mutation carriers were from Newfoundland raising the possibility of this being a founder mutation in the Newfoundland multiple polyposis patient population. In summary, our data indicates that genetic screening of *MYH* should be offered to patients with a phenotype resembling FAP/AFAP in the absence of a detectable APC germline mutation.

Program Nr: 427 from the 2004 ASHG Annual Meeting

Cancer variation and position of BRCA1 mutation. *C.M. Phelan, P. Sun, S. Narod.* Research Womens Health, Sunnybrook & Womens Hosp, Toronto, ON, Canada.

Mutations in the BRCA1 gene have been identified in a large number of breast/ breast-ovarian cancer families. These mutations have been shown to confer a high risk of breast and ovarian cancer. However, other cancer types are also observed in these families. We have assessed the occurrence of 16 additional cancer types in 336 North American families with BRCA1 mutations scattered throughout the gene. The cancer types include colon, stomach, pancreatic, prostate, lung, kidney, bladder, thyroid, melanoma, endometrial, testicular, leukemia, lymphoma, liver, skin and cervical cancer. Our aim is to determine whether the position of BRCA1 mutation, particularly within known structural domains, influences the occurrence of additional cancer types in these families. Of the 336 families, the majority were of European descent and 126/336 families were of Ashkenazi Jewish descent. The exon 2 185delAG or exon 20 5382insC mutations were the most common, twenty mutations were located in splice sites and the remainder were deletions/insertions.

Previous studies have reported that mutations toward the 3' end of the gene are associated with lower ovarian cancer risks compared to those in the 5' portion of the gene. Our results agreed with this observation, the ovarian: breast cancer ratio in families with mutations in the 5' end (exons 1-10) = 0.69, higher than in exon 11 = 0.59 or in the 3' end (exons 13-24) = 0.37. We did not observe the highest ovarian:breast cancer ratio associated with mutations in nucleotides 2401-4190 as was reported previously. Among other cancer types, colon cancer risk appeared to be more highly associated with mutations in exon 11 compared to the remainder of the gene while lymphoma risk was highest in the 5' portion of the gene (exons 1-10).

Association of TNF and IL1 with risk of prostate cancer. *S.J. Plummer¹, X. Liu², K.L. DeJulius¹, A. Moreira¹, J.S. Witte², G. Casey¹.* 1) Dept Cancer Biology, Cleveland Clinic, OH; 2) Dept Epidemiology and Biostatistics, UC San Francisco, CA.

Both infection and chronic inflammation have been shown to influence the risk of some types of cancer. Variants in genes involved in response to infectious agents have recently been shown to associate with an increased risk of prostate cancer (RNASEL, MSR1, TLR4). We have undertaken an association study of genes involved more directly in the inflammatory process. The association of prostate cancer with variants in pro-inflammatory cytokines (TNF, IL1, IL6) and an anti-inflammatory cytokine (IL1RN) was studied in a sibling-based population of 655 cases and 482 controls. The IL1-31C variant was associated with a 2.0 fold increased risk of prostate cancer in men diagnosed over the age of 63 ($p=0.03$). The TNF-308A variant was associated with a decreased risk of prostate cancer (OR=0.6, $p=0.03$), with significantly decreased risk (OR=0.36, $p=0.006$) in men with less aggressive prostate cancers as assessed by a combination of Gleason grade and TNM stage. Neither the IL6-174 SNP or IL1RN VNTR showed association with prostate cancer in our population. Previous functional evidence indicates these promoter variants of both IL1 and TNF result in increased levels of the individual pro-inflammatory cytokine, even though their effect on prostate cancer risk is opposing. While TNF plays an important role in inflammation, it also plays diverse roles in other aspects of the innate immune system, including apoptosis and induction of the adaptive immune response. TNF has also been shown to have both tumor promoting and anti tumor effects *in vivo*. These data indicate that a variety of pathways within the innate immune system may be of importance in the etiology of prostate cancer.

***MLH1* and *MSH2* polymorphisms and colorectal cancer risk: A molecular genetic and epidemiological study.** S. Raptis, J. Knight, V. Pethe, Y.M. Chan, M. Manno, S. Gallinger, J. McLaughlin, B. Bapat. Samuel Lunenfeld Research Institute, Mount Sinai Hospital, University of Toronto, Toronto, ON.

Colorectal cancer (CRC) occurs in 1 in every 20 individuals, and is the second leading cause of cancer-related deaths of both men and women in North America. CRC may be inherited, familial, or sporadic in origin, with the sporadic form accounting for 70-80% of all CRCs. One of the most commonly inherited forms of CRC is hereditary nonpolyposis colorectal cancer (HNPCC), an autosomal dominant syndrome characterized by tumors with a genome-wide microsatellite instability (MSI) and caused by germline mutations in the mismatch repair (MMR) genes. Mutations in two MMR genes, *MLH1* and *MSH2*, account for almost 90% of cases among HNPCC patients with known MMR mutations. Previous studies have identified a number of single nucleotide polymorphisms (SNPs) in MMR genes, yet currently, little is known about the functional role of most of these SNPs, or of any relationship that may exist between their presence and the incidence of CRC. Our study addresses this issue using a case-control design to determine the population frequency of the selected SNPs in *MLH1* and *MSH2*, and to examine whether these SNPs have any underlying determinative effect in the incidence of CRC. MMR polymorphisms were selected through the review of public databases, literature annotations, and their location within the functional domains of the genes. Possible interactions among candidate SNPs and family history, MSI status, the age of onset, and the location of the CRC tumor is being examined. The analysis was performed using lymphocyte DNA isolated from over 1000 CRC cases identified through a population-based familial CRC registry, and over 1000 unaffected controls, from Ontario, Canada. Selected SNPs were genotyped using the 5' nuclease allelic discrimination, or TaqMan, assay. Preliminary observations for the selected *MLH1* SNPs- I219V, -93G>A, and the *MSH2* SNP- G322D, indicate no association with the incidence of CRC. However, a possible association with family risk is being further investigated. Results of this study will assist in further elucidating the role of MMR genes in colorectal cancer susceptibility.

Genomic rearrangements in the APC tumor-suppressor gene in familial adenomatous polyposis. *B. Roa¹, E. Chin¹, B. Chong¹, M.A. Young¹, P. Ward¹, C.S. Richards², M. Hegde¹.* 1) Medical Genetics Laboratories, Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) OHSU DNA Diagnostic Lab Oregon Health & Science University 3181 SW Sam Jackson Park Road, MP-350.

Germline mutations of the adenomatous polyposis coli (APC) tumor-suppressor gene result in familial adenomatous polyposis (FAP). The majority of identified APC mutations are single-nucleotide changes, or insertions or deletions of a few bases that result in premature protein truncation. Intragenic APC gene rearrangements have been reported but not well characterized. We performed dosage analysis for APC gene rearrangements in 26 patients with a clinical diagnosis of FAP, who had tested negative by DHPLC mutation scanning and/or bi-directional sequence analysis of the entire APC coding region. Dosage studies were performed initially by Multiplex Ligation-dependent Probe Amplification (MLPA) and confirmed using real-time quantitative PCR analysis of individual exons. APC deletions were detected in ten patients; four patients appear to have a heterozygous deletion of the entire coding region, while six patients showed partial deletions which include one or more exons of the APC gene. In one intriguing case, dosage studies provided evidence of a novel heterozygous duplication that involves exon 4 of APC. Exon 4 appears to be an endpoint for two deletions and one duplication mutation identified in our study, which could suggest a recombination hotspot in the region. The identification of ten genomic rearrangements in this study suggests that deletions and duplications can account for as much as 24% of germline mutations in APC. A diagnostic strategy that includes mutation scanning or sequencing in combination with testing for rearrangements in the APC gene could enhance the test sensitivity as much as 97%. It is interesting that all four patients with heterozygous deletions of the entire coding region are indicated to have an attenuated FAP phenotype. Additional studies are necessary to define the exact frequency of APC gene rearrangements, and to elucidate mutation genotype-phenotype correlations for Familial Adenomatous Polyposis.

ONCOGEN c-erbB-2 AMPLIFICATION IN MALIGNANT BREAST TUMOR IN RELATION WITH HISTOLOGIC PARAMETERS AND SURVIVAL FREE FOR ILLNESS. *A. Rojas-Atencio¹, I. Valbuena¹, K. Urdaneta¹, L. Gonzalez², M. Soto-Quintana¹, F. Alvarez-Nava¹.* 1) Genetica, Univ del Zulia, Zulia, Zulia, Venezuela; 2) Oncology Service Hospital Clinico de Maracaibo.

Recent advances in the understanding of the underlying molecular and genetic alterations in the development and progression of breast cancer has provided the opportunity to develop novel therapeutic strategies for this disease. None of these developments has had a greater recent impact on the c-erb B-2 oncogene. The objective of this study was to evaluate the amplification of the c-erb B-2 oncogene by FISH, relating IHC positive patients with FISH analysis according to histological gradation, presence of positive lymph nodes and evolution of the illness. We analyzed 110 patients by FISH who were positive to amplification c-erb B-2 oncogene by IHC. Our finding indicated that positive amplification c-erb B-2 oncogene had a worse prognosis, than those patients who presented only amplification c-erb B-2 by IHC. And another hand we found a bigger number of positive cases by FISH with histological gradation II and III, as well as in those patients who had infiltration in more than 6 lymph nodes and disease evolution. We conclude that is necessary to emphasize the importance that FISH has in the identification of c-erb B-2 oncogene, mainly if we take into account that an election of therapeutic strategies exists to patients that are inside this group of poor prognosis.

Familial and sporadic Non-Medullary Thyroid Carcinoma. *G. Romeo*¹, *E. Bonora*¹, *C. Evangelisti*¹, *K. Stankov*¹, *G. Lenaz*². 1) Lab. Genetica Medica; 2) Dept. of Biochemistry University of Bologna Medical School.

Thyroid cancers are relatively rare, with age-adjusted incidence rates ranging from 0.9-5.2/100,000 cases per year. At least 80% of these are papillary thyroid carcinomas, more common in women. The major known risk factor for sporadic papillary forms is prior exposure to radiation, with dose-dependent effects. RET rearrangements were identified as specific events in sporadic papillary thyroid carcinogenesis. Familial non-medullary thyroid carcinoma (FNMTC) is characterized by more aggressive phenotype than its sporadic counterpart, and represents 3%-7% of all thyroid carcinomas. Transmission of susceptibility is compatible with autosomal dominant inheritance with reduced penetrance, or with complex inheritance. Thanks to the collaboration of the International Consortium for the Genetics of FNMTC we collected so far 220 pedigrees with two or more affected individuals. Using this unique resource we mapped two predisposing loci, NMTC1 locus (Non Medullary Thyroid Carcinoma) on 2q21 and TCO locus (Thyroid tumors with Cell Oxyphilia) on 19p13.2. The latter locus is associated with recurrence of oxyphilic tumors, characterized by the presence of Hürthle cells, rich in mitochondria. Genes mapping to 19p13.2 were studied to identify TCO susceptibility variants: EDG5 (sphingosine receptor), CYTC (cyt c heme binding), LASS1 (homolog of longevity assurance factor), NIS (sodium iodide symporter). New missense changes were identified in EDG5 and CYTC, but they did not cosegregate with the tumor phenotype and were found with similar frequency in controls. Further analysis of candidate genes is in progress. In parallel, functional studies on XTC-1 cells, derived from oxyphilic thyroid tumors, showed differential activity in mitochondrial respiratory complexes and increased production of reactive oxygen species (ROS), compared to B-CPAP cells derived from papillary thyroid tumor. Recently, a somatic mutation in BRAF gene, coding for a kinase acting in the RET/MAPK pathway, was identified in sporadic papillary thyroid carcinoma. We are currently screening a panel of 250 diverse sporadic thyroid tumors to identify BRAF mutations in our sample.

MEN1-related pancreatic insulinomas can develop in the absence of chromosome instability or microsatellite instability. *P.C. Scacheri¹, A.L. Kennedy¹, K. Chin², M.T. Miller¹, J.G. Hodgson², J.W. Gray², S.J. Marx³, A.M. Spiegel⁴, F.S. Collins¹.* 1) National Human Genome Research Institute, NIH, Bethesda, MD; 2) UCSF Comprehensive Cancer Center, San Francisco, CA; 3) NIDDK, NIH, Bethesda, MD; 4) NIDCD, NIH, Bethesda, MD.

Multiple endocrine neoplasia, type I (MEN1) is an inherited cancer syndrome characterized by tumors arising primarily in endocrine tissues. The responsible gene acts as a tumor suppressor, and tumors in affected heterozygous individuals occur following inactivation of the wild-type allele. Previous studies have shown that Men1 knockout mice develop multiple pancreatic insulinomas, but this occurs many months after loss of both copies of the Men1 gene. These studies imply that loss of Men1 is not alone sufficient for tumor formation, and that additional somatic genetic changes are most likely essential for tumorigenesis. To gain insights to these additional mutations and the mechanisms through which they may be generated, we used array-based comparative genomic hybridization (array CGH) to analyze genomic copy number aberrations in pancreatic insulinomas from Men1 knockout mice. We found that homozygosity for the Men1 allele in tumors often occurs by duplication of the mutant Men1 allele. Although a few tumors showed evidence of chromosomal instability, the majority of Men1-null tumors were apparently chromosomally stable. Evidence for microsatellite instability was also not found in Men1-null tumors. Thus, the somatic genetic changes that are postulated to lead to tumorigenesis in a mouse model of MEN1 are likely to occur either at the nucleotide level, or through epigenetic mechanisms that lead to gene silencing or activation. The lack of detectable CIN and MIN in these Men1-insulinomas is in stark contrast to the situation for many solid tumors.

The Hereditary Paraganglioma syndromes: A small series of patients with SDHB and SDHD mutations. K.

Schneider¹, J. Garber¹, M. Barontini², S. Arun³, R. Dluhy⁴, P.L. Dahia⁵. 1) Dept Population Sci, Dana Farber Cancer Inst, Boston, MA; 2) Center of Epidemiology Investigations, Buenos Aires, Argentina; 3) Boston Medical Center, Boston, MA; 4) Endocrinology, Brigham and Womens Hospital, Boston, MA; 5) Cancer Biology, Dana Farber Cancer Inst, Boston, MA.

About 20% of paragangliomas (hnpgl) and pheochromocytomas (pheo) are caused by dominantly inherited gene mutations. Hnppls can present as non-secreting head and neck neoplasms and pheos can present as catecholamine-secreting adrenal or extra-adrenal tumors. Hnppls and pheos are recognized features of several cancer syndromes including: VHL, MEN2, NF1, and the newly recognized Hereditary Paraganglioma syndromes, PGL1 and PGL2. The PGL1 and PGL4 syndromes are caused by SDHD and SDHB mutations respectively. We describe a series of 10 pheo and hnppl patients with detectable SDHD and SDHB mutations. Mean age of diagnosis among our patients was 33 years (range: 19-45) and presenting symptoms included hypertension, panic attacks, palpitations, headaches, fatigue and swollen lymph nodes. Two patients had SDHD mutations and eight patients had SDHB mutations. Both SDHD mutation carriers had hnppls (in one case, also pheo) and all SDHB-mutation carriers had extra-adrenal pheos. One patient had metastatic disease at presentation and four patients had multiple tumors at presentation or subsequent exams. Four patients reported relatives with pheos or hnppls, although some of these cases were identified after the patients initial diagnoses. Among SDHB mutation carriers, three other cancers were reported among relatives: gastric tumor, renal cell carcinoma (RCC), and papillary thyroid carcinoma. RCC is a recognized feature of PGL4; significance of the other tumors is unclear. Annual monitoring for pheos and hnppls was recommended to at-risk relatives, beginning in adolescence, and predictive genetic testing was also offered. PHEO and HNPGl patients should be referred for genetic counseling, because the identification of inherited pheos and hnppls has important monitoring implications for at-risk relatives.

Second primary nervous system tumours after optic pathway gliomas in Neurofibromatosis Type 1: increased risk after radiotherapy. *S. Sharif*¹, *R. Ferner*², *M. Upadhyaya*³, *J. Birch*⁴, *G. Evans*¹. 1) Genetics, Manchester; 2) Neurology, London; 3) Genetics, Cardiff; 4) CTR, Manchester.

Optic pathway gliomas (OPG), the commonest CNS tumour in NF1 mainly occur in childhood. The implications of OPGs and related treatments in long-term survivors are becoming apparent. The risk of developing further CNS tumours (CNST) is noted. We reviewed all NF1 OPG patients from 2 NF1 clinics to evaluate the risk of subsequent CNSTs and implications of radiotherapy therapy. In one centre (Manchester), we compared the incidence of gliomas in NF1 OPG patients to matched NF1 controls without OPGs, whose follow up was censored when the OPG patients developed their second gliomas. These patients were checked on the cancer registry, to ensure cancer ascertainment. 80 NF1 OPG patients were identified. All case notes were reviewed. 29 were seen, serial neuroimaging reviewed and mutation analysis performed. Prevalence of OPGs was 5.8%, 39% received treatment (72% had radiotherapy alone or in combination). 11/25 had pathogenic mutations clustering towards the 5' and center of the NF1 gene. Second tumour analyses of 58 NF1 OPGs patients, (limited data on 16; OPG excluded in 3; 3 gliomas developed prior to OPG, also excluded) found 26% developed a subsequent non-OPG glioma (average 10.9 years post OPG). Significantly fewer gliomas, 1, occurred in follow up of 162 matched controls without OPGs ($P < 0.001$). 47% of NF1 OPGs with second tumours received radiotherapy, average 14.4 years post radiotherapy. 5 malignant peripheral nerve sheath tumours (MPNST) were seen in 4 NF1 OPG patients, 3 had radiotherapy. 9 of the 18 patients who had radiotherapy after the OPG developed 12 second tumours (gliomas and MPNSTs) in 307.9 years of follow up after radiotherapy. In those without radiotherapy ($n=40$), 8 patients developed 9 tumours in 721.1 years of follow up after diagnosis of the OPG ($p < 0.01$). There is a significantly increased risk of gliomas occurring after OPG. Many were treated with radiotherapy, which may thus be a possible factor. We previously reported the increased risk of NF1 MPNSTs post radiotherapy. This data suggests that radiotherapy should only be used if absolutely essential in NF1.

A promoter SNP in the MLH1 gene is associated with mismatch repair deficient colorectal cancer. *J.A. Shorto¹, J.M. Allan², R. Coggins³, D. Fletcher¹, R. George¹, M. Katory¹, M. Meuth¹, G. Smith⁴, D.T. Bishop³, A. Cox¹.* 1) Institute of Cancer Studies, University of Sheffield Medical School, UK; 2) Epidemiology and Genetics Unit, Department of Biology, University of York, UK; 3) Genetic Epidemiology Division, Cancer Research UK Clinical Centre, Leeds, UK; 4) Biomedical Research Centre, Ninewells Hospital and Medical School, Dundee, UK.

One pathway to colorectal cancer (CRC) malignancy involves the mutation or loss of expression of a DNA mismatch repair (MMR) gene causing microsatellite instability (MSI) and a mutator phenotype. This leads to further mutations and eventually cancer. This pathway is followed in cases of HNPCC and a subset of sporadic CRC patients. In the majority of MMR deficient sporadic cases the mechanism of MMR inactivation is via methylation of the MLH1 gene promoter. A G>A polymorphism at position -93 is located in the core promoter region of MLH1, adjacent to several CpG sites that, when methylated, have been shown to associate with loss of MLH1 expression and CRC development. We hypothesized, therefore, that the -93 variant may also be involved in the pathogenesis of MMR deficient CRC. We genotyped 688 histopathologically confirmed CRC cases and 592 population based controls using the 5' nuclease PCR assay for the G>A SNP at position -93 in the MLH1 gene promoter. The cases were categorized into MMR deficient and MMR proficient tumours using MSI analysis of normal and tumour DNA, and immunohistochemical analysis of MLH1 and MSH2 proteins in tumour sections. There was no association between the -93 SNP and CRC overall OR (odds ratio) = 1.05 (95 % confidence interval (CI) 0.8, 1.4). However we found that the presence of an A allele at -93 is associated with MMR deficient CRC tumour development, OR = 1.8 (95 % CI 1.1, 3.0). Furthermore, a dose response is seen, with ORs of 1.5 (95 % CI 0.8, 2.7) and 5.1 (95 % CI 1.8, 14.2) when one and two A alleles respectively are present. These data suggest that a polymorphism in the promoter region of MLH1 may influence MMR deficient tumour development. Further work is in progress to confirm this result and determine whether the G to A change at -93 affects the methylation status of the MLH1 promoter.

Evaluation of Glutathione-S-Transferase Polymorphisms as Biomarkers of Cancer Risk Among Filipinos: A Preliminary Study. *C.T. Silao¹, E.C. Cutiongco¹, C.D. Padilla¹, C. Ngelangel²*, *Philippine Cancer Genetics Research Group*. 1) Institute of Human Genetics, National Institutes of Health Philippines, University of the Philippines Manila; 2) Oncology Study Group, Institute of Clinical Epidemiology, National Institutes of Health Philippines, University of the Philippines Manila and Section of Medical Oncology, Department of Medicine, Philippine General Hospital and Jose R. Reyes Memorial Medical Center.

This is a molecular epidemiologic study that looks at the putative association between specific genetic polymorphisms and cancer susceptibility. Genetic polymorphism studies were done in the following metabolizing enzymes: GSTM1, GSTP1, and GSTT1. Corresponding demographics, medical histories, social histories, diet histories, and occupational exposure data were collected. Cancer sites included four (4) of the top ten cancers among Filipinos - breast, lung, colorectal, and oral cavity. This initial report focuses on polymorphic genes encoding for glutathione-S-transferases (GST) which have been reported to be involved in modifying cancer risk in human populations. Specifically, we investigated the following GST isoforms: GSTM1, GSTT1, and GSTP1. Frequencies of GSTM1 and GSTT1 null genotype were identified using polymerase chain reaction (PCR), while that of the GSTP1 exon 5 polymorphism was determined using PCR and restriction fragment length polymorphism (RFLP) of DNA obtained from blood samples of Filipino cancer patients and control subjects. Initial frequencies of GSTM1 null genotype (n=891) were more prevalent for both the case (60%) and control (64%) groups than the wild type. GSTT1 polymorphic deletion (n=151) was present in 41-60% of the case groups as compared to the control groups (25-43%). The frequencies of homozygous mutants GSTP1 gene (Ile105Val) did not differ between the case groups (4-9%) and the control groups (5-8%). Among the three GST isoforms, the gene for GSTT1 shows the most potential as a cancer biomarker based on genotypic frequencies of its polymorphic deletion as compared to GSTM1 and GSTP1. More subjects and studies are needed to determine the significance of these initial findings.

Analysis of polymorphisms in DNA repair genes as modifiers of breast cancer risk in BRCA1 and BRCA2 carriers. P. Smith¹, A. Spurdle², P.A. Harrington¹, F. Durocher³, D. Hughes⁴, S. Ginolhac⁴, O. Sinilnikova^{4,5}, C. Szabo⁴, J. Labrie³, I. Coupier⁶, D. Stoppa-Lyonnet⁶, S. Peock¹, M. Cook¹, J.L. Hopper⁷, J. Simard³, D.E. Goldgar⁴, A.M. Dunning¹, G. Chenevix-Trench², D.F. Easton¹, ABCFS, AJBCS, EMBRACE, kConFab, GGC-France and INHERIT collaborators. 1) CR-UK Genetic Epidemiology Unit and Human Cancer Genetics Research Group, University of Cambridge, Strangeways Research Laboratory, Cambridge, U.K; 2) Queensland Institute for Medical Research, Brisbane, Australia; 3) CHUL Research Centre, Laval University, Quebec City, Canada; 4) International Agency for Research on Cancer, Lyon, France; 5) Plate-forme mixte de génétique constitutionnelle des cancers fréquents, Hospices Civils de Lyon - Centre Lon Bérard, Lyon, France; 6) Service de Génétique Oncologique, Institut Curie, Section Mdicale, Paris, France; 7) Centre for Genetic Epidemiology, University of Melbourne, Melbourne, Australia.

Estimates of breast cancer risk in BRCA1 and BRCA2 mutation carriers vary according to the degree of family history, suggestive of modification of cancer risk by other genes. Previous studies have suggested that polymorphisms in RAD51, whose protein product interacts with both BRCA1 and BRCA2, are associated with an increased risk of breast cancer in BRCA2, but not BRCA1, carriers. We genotyped two polymorphisms RAD51 135g>c and 172g>c, together with polymorphisms in DNA repair genes XRCC1, XRCC2, XRCC3, XPD and LIG4, in 1112 BRCA1 and 485 BRCA2 carriers (905 affected with breast cancer, 692 unaffected) from Australia, Canada, USA and Europe. Associations were assessed using Cox Regression and a modified segregation analysis. In contrast to previous analyses, we found no evidence of an increased breast cancer risk in RAD51 135c carriers, in either BRCA2 carriers (hazard ratio 1.31, 95%CI 0.86-1.99) or BRCA1 carriers (HR 0.97, 95%CI 0.79-1.20) . We found some evidence of a higher breast cancer risk (based on 10 carriers) in homozygotes for RAD51 135c (HR 2.81, 95%CI 1.71-4.64). We found no evidence of an association with any of the other 10 SNPs tested. We conclude that these polymorphisms in DNA repair genes are not strongly associated with breast cancer risk in BRCA1 or BRCA2 carriers.

A multi-centre study of cancer incidence in CHEK2 1100delC mutation carriers. *D. Thompson¹, N. Rahman³, M. Stratton³, M. Schutte⁴, H. Meijers-Heijboer⁴, R. Houlston³, R. Eeles³, J. Chang-Claude⁵, A. Dunning², D. Easton¹, CHEK2-Breast Cancer Consortium.* 1) CR-UK Genetic Epidemiology &; 2) CR-UK Human Cancer Genetics Group, Univ. Cambridge, UK; 3) Cancer Genetics Section, Institute of Cancer Research, UK; 4) Dept. Clinical Genetics & Dept. Medical Oncology, Erasmus MC, Rotterdam; 5) Div. Clinical Epidemiology, Deutsches Krebsforschungszentrum, Heidelberg.

The CHEK2 1100delC mutation is associated with an approximately 2-fold increase in breast cancer risk. It has recently also been suggested to be associated with increased risks of colorectal and prostate cancer, but its involvement in these or other types of cancer has not yet been definitely established. We collected cancer information for 706 non-BRCA1/2 breast cancer families (10,726 individuals) from the UK, Germany, Netherlands and the USA. At least one person per family was tested for CHEK2 1100delC, and carriers were found in 38 families. Relative risks (RR) to mutation carriers and non-carriers in the cohort were estimated by maximum likelihood, via the EM-algorithm to allow for unknown genotypes. Excluding breast and ovarian cancer, the cancer risk was borderline significantly higher in carriers than non-carriers (carrier:non-carrier RR ratio=1.8, 95% CI=1.0-3.3). The ratio was 1.1 in females (CI=0.6-2.0), but there was some evidence of a higher risk in male carriers (ratio=2.6, CI=0.9-7.2). The excess carrier risk was more evident before age 60 (ratio=2.2, CI=0.8-6.2) than at older ages (ratio=1.4, CI=0.7-2.7). There was no evidence of an increased risk of ovarian cancer (carrier RR=0.0) or prostate cancer (carrier RR=1.7, CI=0.2-12.5), two sites known to be associated with BRCA1/2 mutations. Colorectal cancer was the only specific site with a significantly higher risk in carriers than in the general population (RR=2.7, CI=1.2-6.1). Additional analyses based on 429 colon cancer cases, 1287 prostate cancer cases and 3696 controls found no associations (colon odds ratio (OR)=0.3, CI=0.0-2.3; prostate OR=0.8, CI=0.4-1.8). We conclude that risks of other cancers in CHEK2 1100delC carriers, if any, are likely to be smaller than for breast cancer.

***MSH6* in breast cancer families with phenotypic features of HNPCC.** P. Vahteristo¹, S. Ojala¹, A. Tamminen¹, J. Tommiska¹, H. Sammalkorpi², S. Kiuru-Kuhlefelt^{2, 4}, H. Eerola³, L.A. Aaltonen², K. Aittomaki^{2, 4}, H. Nevanlinna¹. 1) Dept. Obstetrics & Gynecology, Helsinki University Central Hospital, Helsinki, Finland; 2) Dept. Medical Genetics, Helsinki University, Helsinki, Finland; 3) Dept. Oncology, Helsinki University Central Hospital, Helsinki, Finland; 4) Dept. Medical Genetics, Helsinki University Central Hospital, Helsinki, Finland.

The role of *MSH6* gene for breast cancer predisposition is unknown. Studies on breast cancer risk in HNPCC have given conflicting results and have not been focussed on *MSH6*-carrier families, while breast cancer cases have been described in such families. *MSH6* protein is part of the so called BASC complex (BRCA1-associated genome surveillance complex), which is comprised of BRCA1-associated DNA repair proteins and suggested to serve as a sensor for DNA damage. This functional association with BRCA1 may suggest a role for *MSH6* also in breast cancer predisposition. We and others have also described patients with both breast and colorectal carcinoma and germline *MSH6* mutations. Here we have analyzed a series of 38 breast cancer families with phenotypic features of HNPCC for germline mutations in the *MSH6* gene. No disease associated mutations were detected among breast cancer families. However, a previously reported putatively breast cancer associated Finnish *MSH6* mutation was found in an atypical HNPCC-family, and identified as a novel Finnish *MSH6* founder mutation. The occurrence of the mutation was further evaluated in an extensive set of familial breast and familial colorectal cancer cases. No additional mutation carriers were found. In conclusion, the absence of germline *MSH6* mutations in our set of breast cancer families suggests that *MSH6* mutations do not underlie, or may be very rare, in breast cancer families with phenotypic features of HNPCC. In addition, the new founder mutation Glu995STOP may have a very limited, regional contribution to colorectal cancer in Finland.

Expression of Zic 1 in desmoid tumors. *K. Van Dam*¹, *A. Bastidas*¹, *S. Amini Nik*¹, *A. Jadidizadeh*¹, *R. Scior*², *S. Tejpar*¹, *J-J. Cassiman*¹. 1) Center for Human Genetics, University of Leuven, Leuven, Belgium; 2) Department of Morphology and Molecular Pathology, University of Leuven, Leuven, Belgium.

Zic genes are the vertebrate homologs of *Odd-paired*, the *Drosophila* pair-rule gene. Recent studies of different vertebrate Zic homologs have provided evidence that Zic genes play multiple roles during neural development. They control the differentiation of ectoderm into neuroectoderm, the process of neurulation and the morphogenesis of the CNS. Next to the important and conserved role for Zic genes in neural development, additional expression patterns have been reported in the somitic mesoderm during development of vertebrates. Additionally, Zic-related genes in lower chordates also appear to have additional functions in mesenchyme development. Because of these findings, it was postulated that the Zic family of genes has evolved towards 2 different functions: a well conserved function during the development of neural tissues and an additional function in mesenchymal tissues, although the role for Zic genes in the latter tissues is not yet clear.

In humans, expression of Zic 1 was detected in the developing and adult cerebellum and in medulloblastomas. Because of this specific expression pattern, Zic 1 was suggested to be a potential biomarker of medulloblastomas. In the present study, we report the expression of Zic 1 in desmoid tumors. Desmoid tumors are benign, soft-tissue tumors composed of fibroblast-like cells. We confirmed the high expression levels of Zic 1 in desmoids at the mRNA and protein level and showed the absence of Zic 1 expression in their putative progenitor cells (the fascia). Additionally, Zic 1 expression was found in other fibro-proliferative processes and a possible relationship between Zic 1 expression levels and the proliferation status of fibroblasts was found. In conclusion, we show that the expression of Zic 1 in human tumors is not limited to medulloblastomas and we suggest a possible role for Zic 1 in the proliferation of mesenchymal cells.

Increased risk of breast cancer due to a hyper mutable tract in BRCA2 caused by N863K? *G.R. Vink, A.H.J.T. Bröcker-Vriends, C.J. van Asperen, M.H. Breuning, E. Bakker.* Center for Human and Clinical Genetics, LUMC, Leiden, Netherlands.

Truncating APC mutations are responsible for FAP and mutations in the BRCA1 and BRCA2 genes are responsible for hereditary breast and ovarian cancer. Missense mutations form a great problem in the genetic counseling because of their often unknown pathogenicity. With the PT-test normally only truncating mutations can be detected. However, about 6% of the Ashkenazi Jews are carrier of a missense mutation in the APC gene, which causes a truncated APC protein in the PT-test (c.3920T>A, p.I1307K). Most likely, this truncation is an in vitro phenomenon caused by the T>A transversion. The (A)8 tract, which is formed by this transversion, is not only unstable in vitro, but also in vivo, leading to somatic mutations. Rather than altering the function of the encoded protein, this variant creates a small hyper mutable region in the gene, indirectly causing an increased cancer predisposition. It is thought that I1307K increases the risk for colorectal cancer about 1.5 to 2 times. We identified a similar, but much more uncommon variant in the BRCA2 gene: c.2817T>A, p.N863K. This missense mutation causes, like I1307K in the APC-gene, a truncated BRCA2 protein in the PT-test and also creates an extended adenine nucleotide tract (A8). We therefore believe that the N863K variant in BRCA2 is responsible for the impairment of replication fidelity and increases the cancer risk of carriers by forming a mutational hotspot.

Assessment of the clinical significance of IVS2-6 T >A in BRCA1. *M.P.G. Vreeswijk¹, L. van Driel¹, J.N. Kraan¹, G.R. Vink¹, C.J. van Asperen¹, J. Morreau², C.J. Cornelisse², P. Devilee^{1,2}.* 1) Center for Human and Clinical Genetics, Leiden University Medical Center, Leiden, the Netherlands; 2) Department of Pathology, Leiden University Medical Center, Leiden, the Netherlands.

Germ-line mutations in the breast cancer susceptibility gene BRCA1 account for a large proportion of hereditary breast/ovarian cancer families. A large number of disease-causing germ-line mutations and variants of unknown pathological significance have been identified. Missense and intron variants cannot be readily distinguished as either disease-associated mutations or benign polymorphisms, and are classified as variants of uncertain clinical significance (VUCS). Characterization of the clinical significance of such variants is important for the medical management of patients carrying these variants, as well as for their family members.

Recently, the IVS2-6 T>A intronic change was detected in the BRCA1 gene of a young woman diagnosed with breast cancer at the age of 30. Histological examination of resected breast tissue showed a grade 3 ductal carcinoma with lymphocytic infiltrate and prominent pushing margins, which have been described as hall marks for BRCA1 related tumours. Her mother died of ovarian cancer age 55, whereas her mothers sister died of breast cancer at the age of 34. Splice-site prediction programs predicted a shift of the acceptor splice site of exon 3 with four basepairs upstream of the original start site. Sequence analysis of cDNA from fibroblasts derived from a carrier of the variant, confirmed the altered splice site, leading to an out-of-frame fusion of BRCA1 exon 2 and 3, introducing a stopcodon at the start of exon 3. Preliminary data concerning DNA analysis of the tumour material show LOH of the wildtype allele. Although the analysis of cosegregation is still in progress, these data already strongly suggest that the IVS2-6 T > A intronic change is a pathogenic mutation, predisposing carriers to breast and ovarian cancer.

The analysis of other variants of uncertain clinical significance in BRCA1 is in progress.

Localization of folliculin, the BHD gene product, by cell fractionation studies. *M.B. Warren¹, M. Baba¹, D. Esposito², M.L. Nickerson¹, N. Sharma¹, W. Zhen¹, L.S. Schmidt², B. Zbar¹.* 1) Laboratory of Immunobiology, NCI-Frederick, Frederick, MD, 21702; 2) PEL and BRP, SAIC-Frederick, Inc., NCI-Frederick, Frederick, MD, 21702.

The Birt-Hogg-Dubé syndrome (BHD) is a rare inherited genodermatosis characterized by benign tumors of the hair follicle (fibrofolliculomas), pulmonary cysts, spontaneous pneumothorax, and an increased risk for renal carcinoma. The majority of BHD-associated renal tumors are oncocytic hybrids, with features of chromophobe renal carcinoma and oncocytoma. The BHD gene encodes a novel protein, folliculin, with no homology to any known human proteins or functional domains, but is conserved across species. We investigated the subcellular localization of endogenous folliculin in HEK-293 cells and also the location of HA-tagged folliculin in stably-transfected, tetracycline-inducible HEK-293 cells. We obtained cell fractions by differential centrifugation and evaluated the fractions for folliculin by Western blotting with a polyclonal folliculin-directed antibody. The integrity of cell fractions was monitored with antibodies to cytoplasmic, nuclear, mitochondrial and microsomal proteins. The location of endogenous folliculin in HEK-293 cells and HA-folliculin, in stably-transfected HEK-293 cells induced with tetracycline, was predominantly in the cytoplasm. Future experiments with cell fractions from synchronized cells will evaluate the expression level and localization of folliculin during the cell cycle. Funded in part by DHHS# NO1-CO-12400.

Prevalence of *BRCA* Mutations and Founder Effect in High-Risk Hispanic Families in Southern California. J. Weitzel¹, K. Blazer¹, R. Nelson¹, V. Lagos¹, C. Ricker¹, J. Herzog¹, S. Neuhausen². 1) City of Hope Cancer Center, Duarte, CA; 2) University of California, Irvine, Irvine, CA.

Approximately 12% of the US population is Hispanic with the majority residing in urban centers such as Los Angeles. Breast cancer (BC) is the leading cause of cancer death in female Hispanics. The prevalence of *BRCA* mutations among high-risk Hispanic families is unknown. **Methods:** Eighty-five individuals of Hispanic origin, with a personal or family history of breast and/or ovarian cancer, were enrolled in an IRB-approved registry and underwent cancer risk assessment including *BRCA* testing. Mutation probability was calculated. Haplotype analyses were performed if mutations were observed in two or more unrelated families. **Results:** Seventy-two (85%) probands had BC, 3 (4%) had DCIS, 4 (5%) had ovarian cancer, 1 (1%) had peritoneal cancer and 5 (6%) had a family history but were unaffected with cancer. Mean age at BC diagnosis was 37 (range=23-59). Mean pre-test mutation probability of all 3 models combined was 21% (range=4-70%). Overall, 27 (32%) had deleterious mutations (20 in *BRCA1*, 7 in *BRCA2*), 23 (27%) had one or more unclassified variants, and 35 (41%) had negative results. The average mutation probability of the *BRCA* carriers compared to non- or variant carriers was 33% (sd=21%) and 15% (sd=12%) respectively (p<0.001). The most common deleterious mutation was 185delAG (4 of 27, 15%). The Hispanic 185delAG carrier families share the same haplotype from D17s1320 through *BRCA1*, as do three reference Ashkenazi Jewish families. Haplotype analyses of 3 other recurrent *BRCA1* mutations, IVS5+1GA (n=2), S955X (n=2) and R1443X (n=3), also suggest founder effects. R1443X was previously reported in a Spanish family. **Conclusion:** This is the largest study of Hispanic families in the US, and the results suggest that they have similar model-based *BRCA* mutation probabilities as other studied populations. The *BRCA1*185delAG mutation was prevalent (4.7%) in this clinic-based cohort of predominantly Mexican descent, and shared the Ashkenazi Jewish founder haplotype. We speculate that these individuals may be descendants of Spanish Jews who converted to Christianity to avoid persecution.

Familial renal carcinoma: clinical subtypes and risk for renal carcinoma development. *B. Zbar*¹, *G. Glenn*², *P. Choyke*², *M. Walther*², *J. Peterson*², *W.M. Linehan*². 1) Laboratory of Immunobiology, NCI- Frederick, Frederick, MD; 2) Urologic Oncology Branch, NCI, Bethesda, MD.

Familial renal carcinoma (FRC) refers to families with two or more family members affected with renal cell carcinoma who are not affected with the known forms of inherited renal carcinoma. We reviewed the clinical records of all renal carcinoma families evaluated at the Clinical Center, National Institutes of Health over the past 14 years to define clinical features of affected families and to determine the risk of renal carcinoma development in unaffected first-degree relatives. FRC families could be subdivided by clinical characteristics into several distinct subgroups based on renal tumor histology and tumor multiplicity. The histologic types and distribution of renal tumors found in the FRC subgroups was as follows: 1) single clear cell renal carcinomas; 2) bilateral, multiple clear cell renal carcinomas; 3) single clear cell renal carcinomas and renal oncocytomas; 4) single clear cell renal carcinomas and papillary renal carcinomas; 5) single and multiple renal oncocytomas without the other clinical features of the Birt-Hogg-Dube' syndrome; 6) single or multiple bilateral papillary renal carcinomas; and 7) other. We evaluated 101 first degree unaffected, at-risk members of 24 FRC families for occult renal tumors by computerized tomography and renal ultrasound. We detected 3/101 at-risk members of FRC families to have an occult renal neoplasm. A clear cell renal carcinoma was detected in one patient; in a second patient, a renal oncocytoma was detected. The renal tumor in the third patient was 1 cm in diameter and has not, as yet been resected.

Novel Mutations in FH associated with hereditary leiomyomatosis and renal cell cancer in families in North

America. *M.H. Wei^{1,2}, O. Toure², O. Jian², G. Glenn², C. Torres-Cabala³, L. Middelton⁴, M. Merino³, M. Walther⁴, C. Stolle⁵, L. Schmidt⁶, B. Zbar⁷, M. Linehan⁴, J. Toro².* 1) Program of Division of Cancer Epidemiology and Genetics, SAIC-Frederick, Inc., National Cancer Institute Frederick, Frederick MD; 2) Genetics Epidemiology Branch, Division of Cancer Epidemiology and Genetics, National Cancer Institute, Rockville, MD 20892; 3) Laboratory of Pathology, National Cancer Institute, Bethesda, MD20894; 4) Urologic Oncology Branch, Center for Cancer Research, National Cancer Institute, National Institutes of Health, Bethesda, MD 20894; 5) Children's Hospital of Philadelphia, Philadelphia, PA; 6) Basic Research Program, SAIC-Frederick, Inc., National Cancer Institute Frederick, Frederick, MD 21702; 7) Laboratory of Immunobiology, National Cancer Institute, Frederick, Frederick, MD 21702.

Hereditary leiomyomatosis and renal cell cancer (HLRCC) (OMIM 605839) is the autosomal dominant predisposition to the development of smooth muscle tumors of the skin and uterus and/or renal cancer. We previously showed that mutations in the fumarate hydratase gene (FH) are associated with HLRCC in families in North America. In this study we characterize the clinical and genetic features of 17 new families with HLRCC in North America. Sequence analysis revealed 11 germline mutations in 17 new families with HLRCC. Of these 11 mutations, 6 were novel. These 6 novel mutations consisted of: four missense (A349G, C568T, C1025A, T1126C), one insertion (A ins@ 111) and one splice site mutation (G138+1C). Seven families with HLRCC had renal tumors. The FH mutations associated with 7 families with renal tumors consisted of: R58X in 3 families, C568T in one family, C1025A in one family, T1126C in one family and a G138+1C in one family. FH mutations were associated with a spectrum of renal tumors ranging from papillary type II renal cell carcinoma to collecting duct carcinoma of the kidney. In combination with our previous report, we have identified 28 different germline FH mutations of which 24 are novel. To date our FH mutation detection rate is 90% (47/52) in families with cutaneous leiomyomas and/or papillary or tubopapillary renal tumors with distinct cytological features.

Increased Level of Chromosomal Instability in *BRCA1* Mutation Carriers Following Irradiation Induced DNA Damage. Z. Kote-Jarai¹, A.Y. Salmon^{*1,2}, T. Menghistu¹, M. Copeland¹, K. Bishop³, A. Ardern-Jones³, S. Shanley³, The Carrier Clinic Collaborators³, Y. Lu⁴, J. Shipley⁴, R.A. Eeles^{1,3}. 1) Translational Cancer Genetics, Institute of Cancer Research, Sutton, Surrey, UK; 2) Hadassah Medical Centre, Jerusalem, Israel; 3) Royal Marsden Foundation NHS Trust, London, UK; 4) Cell Biology and Experimental Pathology, Institute of Cancer Research, Sutton, Surrey, UK.

Deleterious mutations in the *BRCA1* gene predispose women to an increased risk of breast cancer. Many functional studies have suggested that *BRCA1* has a role in DNA damage repair and failure in the DNA damage response pathway often leads to the accumulation of chromosomal aberrations. Our aim was to investigate if lymphocytes from *BRCA1* mutation carriers show an increased level of chromosomal instability (CIN) after irradiation induced DNA damage compared with non-carrier controls. Short term cultures of lymphocytes were established from fresh blood samples. Cells were irradiated using a Cobalt source at high dose rate and metaphase spreads were analysed by 24-colour chromosome painting, M-FISH. Image capturing was done by Smart Capture 2 software and chromosomal rearrangements and breaks were analysed by Quips SpectraVysion. In a pilot study we tested two different radiation doses, 4 Gy and 8 Gy, and two different time-points for metaphase spreads after the radiation treatment. The 48h time-point was selected to identify both unstable and stable chromosomal aberrations. The 6 day time-point was chosen, as only stable chromosomal alterations will be detected at this stage. We analysed 181 metaphases from 5 *BRCA1* mutation carriers and 104 metaphases from 5 non-carrier control samples 6 days after 8Gy of irradiation. We found that 7.52 % (0.51) of the chromosomes were involved in rearrangements in the *BRCA1* mutation carriers, versus only 3.57% (0.76) in the control samples, $p=0.0001$. This provides new evidence that heterozygous mutation carriers have a different response to DNA damage compared with non-carriers. Our finding has implications for treatment and screening using modalities that involve irradiation in *BRCA1* mutation carriers. *joint first author.

Identification of genes targeted by ETV6-AML1 chimeric transcription factor. *S. Langlois, G. Boily, J. Larose, D. Sinnott.* Division of Hematology-Oncology, Research Center, Sainte-Justine Hospital, University of Montreal, Canada.

Acute lymphoblastic leukemia (ALL) is the most common pediatric cancer. Moreover, chromosomal abnormalities, such as translocations, are often present in leukemia. The translocation t(12;21) is observed in approximately 25 % of children with pre-B ALL. The resulting chimeric protein, ETV6-AML1, consists of the DNA binding domain of AML1 and the repression domain of ETV6. Very little is known about the implication of ETV6-AML1 in leukemogenesis. We propose that this chimeric transcription factor acts in such a way that it represses transcription of genes usually activated by AML1. The principal objective of this study is to identify target genes of ETV6-AML1, in order to understand the role of this chimeric protein in leukemogenesis. Toward this goal, we have developed a HeLa cellular model, in which ETV6-AML1 expression is under the control of an inducible system (TetON). The mRNA obtained at different ETV6-AML1 induction times (0h, 4h, 12h, 48h) has been hybridized to the HG-U133A (22 000 genes) Affymetrix GeneChip, in order to detect the impact of ETV6-AML1 induction on the global expression profile. Initial analysis of the data led to the identification of 47 potential target genes. The expression of 14 of these candidate genes has been validated by quantitative real-time PCR. Then, we determined the expression profile of these 14 genes in 17 ALL patients with or without the translocation t(12;21), in order to evaluate the behavior of these targets in leukemia in respect to ETV6-AML1 expression status. Preliminary results show a nearly significant difference of expression for JUN, that is less expressed in patients with the translocation. Other putative target genes are being investigated. The promoter region of genes showing a correlation with the translocation in patients will eventually be studied using gene reporter assay, in the HeLa inducible model. Gel shift and super shift will also be carried out to determine whether the genes are direct targets of the ETV6-AML1 chimeric protein.

The human telomeric protein TRF2 is involved in a rapid cellular response to DNA damage. *P.S. Bradshaw¹, D.J. Stavropolous¹, M.S. Meyn^{1, 2, 3}.* 1) Genetics and Genomic Biology, Hospital for Sick Children, Toronto, ON; 2) Molecular and Medical Genetics, University of Toronto, Toronto, ON; 3) Paediatrics, University of Toronto, Toronto, ON.

Human cells use complex signaling networks to sense double-strand breaks (DSBs) in genomic DNA, then activate DNA repair, cell cycle checkpoints, and apoptosis. TRF2 prevents the ends of telomeres from triggering cellular DSB responses by complexing with telomeric DNA. We now report that TRF2 rapidly associates with laser-induced DSBs in non-telomeric DNA of human fibroblasts.

We find that TRF2 forms transient foci that tightly colocalize with DSBs and with DSB-associated foci of ATM, a protein kinase that controls multiple cellular DSB responses. Accumulation of TRF2 at induced DSBs occurs in the absence of functional ATM and DNA-PKcs protein kinases, the MRE11/Rad50/NBS1 complex or the Ku70, WRN and BLM repair proteins. This TRF2 response does not require expression of telomerase, as it occurs in both transformed and primary fibroblasts. The kinetics of YFP-TRF2 accumulation at DSBs were faster than those of GFP-ATM, YFP-NBS1 and of H2AX, a phosphorylated histone thought to be involved in recruiting repair proteins to DSB-containing chromatin. Deletion mapping indicates that the amino-terminal basic domain is required for TRF2 to associate with DSBs, the first known function for this domain.

These observations suggested that TRF2 is temporally and spatially poised to affect DSB activation of ATM damage responses. To test this, we over-expressed TRF2 in primary human fibroblasts. TRF2 over-expression resulted in reduced accumulation of phosphorylated ATM, H2AX and p53 following irradiation.

This work documents, for the first time, a non-telomeric function for TRF2. Our results suggest that TRF2 may interact with DSB-containing chromatin, provide evidence that TRF2 can compete with or attenuate ATM responses to DSBs, and implicate TRF2 in an ATM-independent step in DSB recognition/processing that occurs prior to the association of ATM with DSBs and activation of the ATM-dependent DSB response network.

The unusually high incidence of Germline Arg337His mutation in the p53 Tumor Suppressor gene among Brazilian Patients with adrenocortical tumors can be attributed to Founder Effect. *E.M. Pinto, A.E.C. Billerbeck, B.B. Mendonca, A.C. Latronico.* Endocrinology, Sch Medicine - Univ. Sao Paulo, Sao Paulo, Brazil.

An inherited missense mutation of the p53 tumor suppressor gene (Arg337His) was identified in high frequency (78-97%) in Brazilian children with benign and malignant adrenocortical tumors. Given the high frequency of this germline mutation in Brazilian population with adrenocortical tumor, it is most likely that the Arg337His mutation arose from a single founder. In this study, we analyzed two intragenic highly polymorphic markers (VNTRp53 and p53CA) in 22 apparently unrelated patients with adrenocortical tumors associated with the germline Arg337His mutation and in 60 normal individuals. The region enclosed each intragenic microsatellite were amplified by PCR and analysed by GeneScan Fragment Analysis Software. We found six and fourteen different alleles for the VNTRp53 and p53CA polymorphic markers, respectively. One allele for each marker, both with 122 bp fragment size, were found in 54.5% of the 44 alleles from patients with adrenocortical tumors. In contrast, these VNTRp53 and p53CA alleles were found in 18% and 14% of 120 alleles from normal controls, respectively ($p < 0.01$, chi square test). An identical haplotype for p53 locus was identified in 86% of the apparently unrelated Brazilian patients with adrenocortical tumors carrying the Arg337His mutation. These findings contrast with a previous study that eliminated Founder Effect in 17 unrelated patients with adrenocortical tumors and the Arg337His mutation. In conclusion, we demonstrated a strong evidence of co-segregation between two intragenic polymorphic markers and the germline Arg337His mutation of p53 tumor suppressor. The significant distribution of marker allele frequencies between patients with adrenocortical tumors carrying the Arg337His mutation and normal population indicated that the Arg337His mutation has a single common ancestral in the Brazilian population.

Common fragile site genes and neurological development. *D.I Smith, S. McAvoy, B.E. Armstrong, F. Wang.* Div of Experimental Pathology, Mayo Clinic College of Medicine, Rochester, MN.

The common fragile sites (CFSs) are large unstable genomic regions present in all individuals. Most of the research on the CFSs has focused on their role in promoting genome alterations such as translocations, deletions and gene amplifications in cancer cells. Of the 90 described CFSs, only 9 have been precisely defined at the molecular level. In these characterized CFSs, the regions of instability range in size from 500Kb (FRA7G) to greater than 9Mb (FRA9E). Overall, the nine defined CFSs encompass 23 Mbs of genomic sequence containing 55 interesting genes. These include a number of small genes, such as ARH1, caveolin-1 and IGF2-R that are known to play important roles in the development of certain types of cancer. There are also very large genes such as FHIT (1.5Mbs), LRP1B (1.9 Mbs), WWOX (1.0 Mb) and Parkin (1.4 Mbs) whose roles in cancer development are just being elucidated. CFS genes have also been associated with a number of neurological disorders, including Alzheimers disease, Autosomal Recessive Juvenile Parkinsonism, autism, and several of the ataxias. The 135Kb spinocerebellar ataxia, SCA7, gene was previously located within the centromeric portion of FRA3B. We now demonstrate that SCA1 (476 Kb) is a large conserved CFS gene spanning the FRA6C (6p22.2) CFS. Both SCA1 and SCA7 contain unstable trinucleotide repeats encoding polyglutamine tracts. Non CGG-repeats have not previously been associated with any type of chromosomal instability. We examined each of the unstable trinucleotide repeats associated with disease and found that a number of these are contained within relatively large genes mapping to chromosomal bands known to contain a CFS. Many genes containing unstable trinucleotide repeats are associated with neurological disorders, thus this provides further support that CFS genes play important roles in neurological development. The presence of these important neurological genes in highly unstable CFS regions suggests that they are probably highly susceptible to alterations during cancer development . There may also be an important connection between normal neurological development and changes observed in developing cancer cells.

Chromosome 12, Frequently Deleted in Human Pancreatic Cancer, May Encode a Tumor Suppressor Gene that Suppresses Angiogenesis. *S. Yamanaka*^{1,3}, *M. Sunamura*², *T. Furukawa*¹, *L. Sun*², *L.P. Lefter*^{1,2}, *T. Abe*^{1,2}, *T. Yatsuoka*^{1,2}, *H. Fijimura*², *E. Shibuya*², *N. Kotobuki*⁴, *M. Oshimura*⁴, *A. Sakurada*³, *M. Sato*³, *T. Kondo*³, *S. Matsuno*², *A. Horii*¹. 1) Dept Mol Pathol, Tohoku Univ Sch Med, Sendai, Japan; 2) Dept Gastroentero Surg, Tohoku Univ Sch Med; 3) Dept Thorac Surg, IDAC, Tohoku Univ; 4) Dept Cell Tech, Tottori Univ, Yonago, Japan.

Several lines of evidence have suggested that the long arm of chromosome 12 may carry a tumor suppressor gene(s) that plays a role in pancreatic ductal carcinogenesis. We have previously found a significant association between LOH of the 12q arm and a poor prognosis in pancreatic cancer patients. In this study, we introduced a normal copy of chromosome 12 into some pancreatic ductal carcinoma cells. Both anchorage-dependent and -independent proliferations as well as invasiveness were similar throughout the hybrid clones when compared with their corresponding parental cells. In sharp contrast, significant suppression of tumorigenesis was observed after inoculation of the hybrid clones into nude mice. Measurements made up to one month later showed that there was a significant delay in the growth of tumors into which the introduced normal copy of chromosome 12 had been restored. More significantly, using our dorsal skin chamber and an intravital microscopy system experiment in SCID mice, we demonstrated and visualized directly that implantation of the hybrids failed to promote the angiogenic phenotype encountered in the parental cells. Gene expression profiling using the cDNA microarray system identified a set of 24 genes differentially expressed between the hybrids and parental cells. An additional set of 18 genes was also identified that were differentially expressed between the hybrid clone that lost its growth suppression activity and one that retained such activity. Another set of 25 genes mapped on 12q was detected that showed high expression levels in the hybrid clones retaining growth suppressive activity. In summary, this study provides the first functional evidence of the existence of an additional tumor suppressor gene(s) on chromosome 12 whose absence is responsible for the pathogenesis in pancreatic ductal carcinogenesis.

Non Hodgking Lymphoma: incidence of Bcl-2/IgH rearrangements in Mexican patients and its relevance as marker for minimal residual disease. *R. Arana*^{1, 2}, *G. Ignacio*³, *S. Baltazar*³, *M. Rubio*³, *E. Baez*³, *J. Duque*³, *F. Tripp*³, *S. Rivas*³, *O. Garces*³, *L. Solis*³, *V. Moran*⁴, *S. Kofman*^{1, 2}. 1) Genetics, Hospital General de Mexico, Mexico City, D.F., Mexico; 2) Facultad de Medicina, UNAM; 3) Grupo Multicentrico Mexicano de Hematologia; 4) Escuela de Medicina, Universidad Panamericana, Mexico.

The follicular lymphoma is characterized by the t(14;18)(q32;q21), which joins JH segments of the heavy chains of immunoglobulins (IgH) gene with the Bcl-2 gene. However, this translocation is also present in the non Hodgking lymphomas (NHL) of intermedium and high grade in 15 to 30% of cases. **OBJETIVE:** To determine the incidence of the Bcl2-IgH rearrangement in Mexican patients with follicular lymphoma and with NHL of intermedium and high grade. **PATIENTS AND METHODS:** 292 patients (151 male and 141 female) were evaluated with the following diagnosis: 152 had low grade lymphoma, 113 intermedium to high grade lymphoma and in 27 the grade was not determined. The analysis was made in blood samples (BS) in 64 cases (24%) or bone marrow (BM) in 228 (76%). Genomic DNA was obtained and the Bcl-2/IgH rearrangement was amplified by both PCR and nested PCR using primers for JH and exon-intron 3 region of Bcl-2 (MBR and MCR regions). In 135 out of 292 patients in clinical remission, the Bcl-2/IgH rearrangement was used as marker to determine minimal residual disease stage in cases ranging from 8 to 32 months of evolution. The incidence and tissue type analysis was compared using chi-square statistics. **RESULTS AND DISCUSSION:** In the low grade follicular NHL the Bcl-2/IgH rearrangement was positive in 79% of the cases with a breakage in the MBR region in 115 cases and in MCR in only 5 cases. In the intermedium to high grade NHL cases it was present in 33%; with a breakage in 35 cases in MBR y 2 in MCR. Regarding the tissue type (BS or BM) it was positive in 86% of cases in BM and in 42% in BS, with $p < 0.0001$. The frequency of Bcl-2/IgH rearrangement in cases of follicular lymphoma in Mexican patients was high, highlighting the relevance of the molecular analysis in the diagnosis and its use as a marker for minimal residual disease cases..

Testicular seminoma and DAZ microdeletion. *T. Boudawara*¹, *N.B. Abdelmoula*², *L. Keskes*², *T. Bienvenu*³, *A. Amouri*⁴, *A. Bahloul*⁵, *T. Rebai*². 1) Laboratoire d'Anapath, Hopital Habib Bourguiba, Sfax, Tunisia; 2) Laboratoire d'Histologie Faculte de Mdecine de Sfax, Tunisia; 3) Laboratoire de Biochimie et de Gntique Moleculaire Hopital de Cochin Paris, France; 4) Laboratoire de Cytogenetique Institut Pasteur de Tunis, Tunisia; 5) Service d'Urologie, Hopital Habib Bourguiba, Sfax, Tunisia.

Testicular germ cell cancer is etiologically linked to genital malformations and male infertility and is most probably caused by a disruption of embryonic programming and gonadal development during fetal life. In some cases, germ cell neoplasia is associated with a relative reduction of Y chromosomal material or other abnormalities of the Y chromosome which contains genes critical for germ cell differentiation and spermatogenesis. Here we report a 33 years old man who complained of primary infertility of 5 years. He was found azoospermic by seminal analysis according to WHO guidelines. Physical examination, hormonal investigations and testicular ultrasonography were with normal findings. Bilateral testicular biopsy established the diagnosis of in situ seminoma at the right side and showed lack of all germ cells in both testes and presence of an abundant proliferation of Leydig cells. After genetic counseling, the patient's karyotype, analyzed using standard cytogenetic methods, was normal: 46,XY but analysis of his genomic DNA, tested using PCR-denaturing gradient gel electrophoresis method, showed microdeletion of the DAZ gene. The patient was member of a very large family characterized by multiple men with infertility (three brothers and two cousins). Only one cousin who was oligospermic has been genetically investigated and found deleted of the DAZ gene. It has been suggested that DAZ microdeletions, in addition to causing infertility with a variable phenotypic expression, predispose also to germ cell neoplasia. We will discuss through this observation, vertical transmission of Yq microdeletions and the susceptibility of DAZ microdeleted men to develop testicular tumors.

Molecular profiling of oral cancer using DD-PCR and microarray techniques. *S. Chakraborty*¹, *S. Swamy*², *A. Moinuddin*³, *K.S. Gopinath*², *A. Kumar*¹. 1) MRDG, Indian Institute of Science, Bangalore, Karnataka, India; 2) Bangalore Institute of Oncology, Bangalore, India; 3) R.L. Jalappa Hospital and Research Center, Kolar, India.

Oral squamous cell carcinoma (OSCC) is the sixth most common malignancy and a major cause of cancer morbidity and mortality worldwide. In India, it is the leading cancer in males and the third most common in females, due to the widespread habits of tobacco chewing and smoking in conjunction with alcohol consumption. Although the risk factors for oral cancer are well established, its clear cut molecular mechanism remains elusive. The overall five year survival period of OSCC is among the lowest for all major cancers which has not changed in the past two decades. Thus finding a biological tumor marker to increase the early diagnosis and treatment is of paramount importance. Given the high incidence of oral cancer in the Indian population, we have set out to elucidate the genetic and biochemical alterations that underlie its onset and progression. In order to obtain a tissue specific gene expression profile, we have employed the DD-PCR and microarray techniques. The DD-PCR profiling showed 51 genes which were either upregulated or downregulated in OSCC. Northern and Reverse Northern analyses revealed that 31/51 genes were truly differential. Of 31 genes, one upregulated and two downregulated genes were validated by Semi-quantitative RT-PCR in a panel of 16 matched normal and tumor samples. We are in the process of sequencing and validating rest of the genes. To obtain a global profile of the molecular changes inherent in OSCC, cDNA microarray analysis was carried out, using three paired samples of clinically confirmed cases on human 19k gene arrays. The study revealed more than 300 genes to be deregulated which are known to be involved in a variety of cellular functions. We are in the process of validating the microarray data. (Financial support from the CSIR and ICMR is gratefully acknowledged).

Clinical prognosis of breast cancer patients with ATM missense mutations. *J. Feng¹, A. Singh³, M. Jung³, C. Buzin¹, J. Moulds³, Y. Zhang², E. Gehan², A. Dritschilo³, S. Sommer¹.* 1) Dept Molecular Genetics, City of Hope Natl Medical Ctr, Duarte, CA; 2) Dept Biostatistics, Lombardi Cancer Center, Washington, DC; 3) Dept Radiation Medicine, Georgetown University Medical Center, Washington, DC.

Ataxia-Telangiectasia (A-T) is an autosomal recessive disorder characterized by progressive cerebellar degeneration, telangiectasias, radiosensitivity, immunodeficiency, and a predisposition to cancer development. Epidemiologic studies of families of A-T patients have demonstrated an increased risk of breast cancer in females. Furthermore, an elevated frequency of missense ATM gene mutations has been observed in patients with sporadic breast cancer. In a recently reported series, we observed a significant elevation of cohort-specific mutations in 90 breast cancer patients as compared to ethnically matched controls (relative risk: 3.2; attributable risk: 13%). Subsequently we have retrospectively reviewed the records of breast cancer cases for correlation with clinical features. The 11 year disease-free survival was 43% and 93% for patients with and without mutations respectively ($p=0.001$), suggesting that ATM mutations confer a negative clinical prognosis in breast cancer.

Germline in-frame deletion of exons 18-22 in retinoblastoma. *K. Heimdal¹, L. Steele², P.A. Andresen³, R.S. Tranheim⁴, L. Walaas³, P.N. Ray², A. Heiberg¹, N.A. Eide⁴.* 1) Dept Medical Genetics, Rikshospitalet, Oslo, Norway; 2) Molecular Genetics Laboratory, Hospital for Sick Children, Toronto, ON, Canada; 3) Dept Pathology, Rikshospitalet, Oslo, Norway; 4) Dept Ophthalmology, Ullevål University Hospital, Oslo, Norway.

Identification of RB1 mutations is useful in genetic counseling. Generally, the penetrance of RB1 mutations is very high (>95%), however, low-penetrance families have been described. We report the results of molecular findings in a family where a 19-year-old female developed unilateral retinoblastoma. The tumour presented as uveitis and the diagnosis was made by demonstration of calcifications in the tumour and retinoblastoma cells in a fine needle aspirate. A second cousin on the paternal side had unilateral retinoblastoma at 2 years. The tumour was treated with chemotherapy and local and external radiotherapy. The patient is free of disease at 6 years. Testing by direct mutation analyses of DNA from peripheral blood demonstrated a heterozygous deletion of exons 18-22 of the RB1 gene. Deletion analysis with FISH for chromosome region 13q14 was normal. DNA from the cytology specimen was not available for molecular testing. The mutation was not present in the affected paternal second cousin but was inherited from the maternal side. The results of direct mutation analysis have been confirmed by haplotyping using flanking and intragenic markers. The mutation has not been described previously. We believe this is an RB1 mutation with reduced penetrance. The mutation is predicted to lead to an in-frame deletion and a partially dysfunctioning retinoblastoma protein. In-frame deletion of exons 24 and 25 has been reported previously in a large Chinese retinoblastoma family showing markedly reduced penetrance. Further studies of the mutation may give useful information about RB1 function. The use of mutation data in genetic counselling in this family is complicated due to limited information on penetrance and expression. So far, known mutation carriers have not developed malignancies other than retinoblastoma.

Role the androgen receptor in germline susceptibility to prostate cancer. *M. Zeegers¹, A. Nieder², L. Kiemeny³, H. Ostrer⁴*. 1) University of Birmingham, UK; 2) University of Miami, FL; 3) University Medical Centre Nijmegen, NL; 4) New York University School of Medicine, NY.

Many published studies suggested an association between (CAG)_n and (GGN)_n polymorphisms in the AR gene and prostate cancer. To quantify this association, we performed a meta-analysis to provide both relative and absolute quantitative summary estimates with sufficient power. Publications were identified through database and hand searches for epidemiologic studies published until February, 2004. For each study, we calculated mean differences in repeat length between cases and controls, continuous odds ratios (OR_c) per one CAG or GGN repeat decrement and discrete odds ratios (OR_d) to compare prostate cancer risk in men with short CAG repeats (21 repeats) versus long CAG repeats (>21 repeats) and short GGN repeats (16 repeats) versus long GGN repeats (>16). The study specific estimates were combined by random effects meta-regression analyses. 19 case-control studies were included in this review comprising a total of 4,274 cases and 5,275 controls. Prostate cancer cases had on average 0.26 fewer CAG repeats and 0.09 fewer GGN repeats than controls. The OR_c of prostate cancer per 1 repeat decrement were 1.02 and 1.01 for CAG and GGN repeats, respectively. The summary OR_d were 1.19 (95th centile CI=1.07-1.31) and 1.31 (95th centile CI=1.06-1.61), for CAG and GGN repeat polymorphisms, respectively. Although the presence of shorter repeats appeared to be modestly associated with prostate cancer risk, the absolute difference in number of repeats between cases and controls is less than one repeat.

Genetics and Cancer Research: an overview 1985-2004. *L. Bouchard*¹, *R. Dalpe*², *M. Sampson*³. 1) Sociology/Inst Pop Health, University of Ottawa, Ottawa, ON, Canada; 2) Political Sciences, University of Montreal, Montreal, QC; 3) Chalmers Research Group, Children Hospital Research Institute, Ottawa, ON.

Aim:To trace the evolution of the genetic & common components of cancer research, specially breast(B)& colorectal(C)Cancer since 1985, through a bibliometric study.**Method:**We use previously validated keywords to identify scientific publications and exploiting OVID Medline indexing features, classified them as systematic reviews, clinical trial, commentaries and guidelines. We compare their number for all Ca, B&C Ca, Genetic B&C. **Results:** Since 1985, about 1 million articles have been indexed on all Ca; 250,000 on B&C; 60,000 on these Cancers' genetic. Breast Ca papers accounted for 10% of the whole. **Preclin. res.:** 170,000 for all; 38,000 for B&C; 12,000 for Genetic. **Syst. rev.:** 7000 for all; 2000 for B&C; 500 for Genetic. **Guidelines:** 2000 for all; 500 for B&C, 100 for Genetic. **Comments:** 4000 for all; 1000 for B&C; 200 for Genetic. 60-70% of genetic papers related to breast Ca. Scientific production of genetic research on B&C Ca counts 5000 publications from 1985-89 and over 20,000 during 2000-04. The 5 cancer journals with the highest impact were: CA J Clin, J Natl Inst, Nat Rev CA, J Clin Oncol, Adv CA Res. These 5 journals account for 2% of preclin. studies in the genetic Ca; 8,7% of clin. trials; 9,6% of guidelines; 21,1% of comments. **Discussion:** 25% of Ca research has concentrated on B&C Ca, a fifth including a genetic component. We saw a growth of scientific publications since 1990 in genetic research, notably in clin. trials, syst. rev., guidelines and comments. Production has doubled between 1990-94 & 95-99, although this growth has slowed down since 2000. The Ca journals with the HI factors represent the translation of research to practice, with a concentration of clin. trials, treatment guidelines and comments. A bibliometric study correlating the number of publications with the relative mean impact factor has explored features of scientific productivity and research performance. The search strategy used for C Ca or genetic Ca has not been published before and requires further refinement. Precision of bibliographic searches is rarely perfect and we relied on them for classification. Our results are convergent with others studies.

Mutation pattern in DNA binding domain of p53 gene in squamous-cell carcinoma of the esophagus in Kashmir (India), a high incidence area in the world. *S. Gochhait¹, M.M. Mir², N.A. Dar², S.A. Zargar³, A.G. Ahangar⁴, R.*

Bamezai¹. 1) NCAHG, SLS, Jawaharlal Nehru University, New Delhi, Delhi, India; 2) Department of Clinical Biochemistry, Sher-I-Kashmir Institute of Medical Sciences, Soura, Srinagar, J&K, India; 3) Department of Gastroenterology, Sher-I-Kashmir Institute of Medical Sciences, Soura, Srinagar, J&K, India; 4) Department of Cardiovascular Thoracic Surgery, Sher-I-Kashmir Institute of Medical Sciences, Soura, Srinagar, J&K, India.

A high incidence of esophageal cancer in Kashmir valley (India) has been attributed to an exposure to nitroso compounds (or their precursors), amines and nitrates present in the staple food, hot salted tea (Noon Chai) and the pipe (Hukka) smoke. However, till date, no attempt has been made to study the presence of mutations in tumours of patients with esophageal cancer from Kashmir valley, following a distinct life style and dietary habits. Here, we make a preliminary attempt to study esophageal squamous cell carcinoma (ESCC) tissues of 55 patients from Kashmir valley for mutations in exons 5-8 (the DNA binding domain) of a tumour suppressor gene, p53. Direct sequencing analysis revealed the presence of mutation in 36.36% tumours. Of the 20 mutations in 20 patients, 17 were single base substitutions (11 transitions + 6 transversion) and 3 deletions. Seventeen single base variations represented 12 missense mutations leading to amino acid substitution, 2 nonsense mutations and 3 variations located in intron 6, one of which resulted in a splicing variant. There was a high prevalence of mutation in exon 5 (65%) and surprisingly an absence of mutation in exon 8. The frequency of mutation when compared between males (25%) and females (57.89%) turned out to be significant ($p=0.016$), apparently putting females at a higher risk of carrying p53 mutation. The mutation pattern (when compared to IARC database) suggested that both the sexes have differential proneness to the induction of mutation by the exposure to carcinogens, to which they are equally exposed through diet and life style, an observation, which would need a further study of a larger set of samples from Kashmiri population.

Differentially expressed genes identified by comparison of mRNAs from an adrenocortical cell line (NCI-H295A) and normal human adrenal. *M.N. Gouvea¹, A.S. Barbosa², B.B. Mendonca², C.J. Lin².* 1) Dept Patologia, Fac Medicina, Univ Sao Paulo, Sao Paulo, Brazil; 2) Lab Hormonios e Genetica Molecular - LIM/42 - Hosp Clinicas - Fac Medicina, Univ Sao Paulo - SP - Brazil.

Adenocarcinoma of adrenal cortex is a rare pathological condition accounting for 0.05% - 0.2% of all cancers. These tumors are usually associated with unfavorable prognosis. Distinction between localized malignant tumors and benign adrenocortical neoplasms, based on clinical and radiological data, can be difficult. Several genetic, molecular and imunohistochemical markers have been evaluated for their usefulness in outcome prediction. However, none has been shown to reliably distinguish carcinomas from adenomas. The aim of this study is to identify genes differentially expressed in malignant adrenocortical tumors. Using the mRNA differential display we compared mRNAs isolated from NCI-H295A cells - a steroid-producing cell line derived from an invasive primary adrenocortical neoplasm with a commercially available RNA prepared using a pool of normal human adrenal. In NCI-H295A cells we observed overexpression of transcripts involved in important biological processes such as regulation of cell cycle (ERH), transcription regulation (VEGFA), maintainance of cell function (SNAP91), peroxisome organization and biogenesis (PAF1). In opposition, in normal adrenal we found higher abundance of transcripts for genes related to cell cycle arrest (AFX1), mitogenesis and differentiation (EGR-1), cytoskeleton and cell motility (DNAI1), cholesterol biosynthesis (DHCR24), and protein biosynthesis (RPL27A). In conclusion, our preliminary comparison of transcriptomes revealed substantial differences between normal adrenals and a cell line derived from an adrenocortical carcinoma. These differentially expressed transcripts will be further validated in tumoral samples in order to assess their roles in tumorigenesis and in the prediction of tumoral outcome. Interestingly, approximately 10% of our transcripts showed no homology to known genes deposited in public sequence databases. Such transcripts might represent genes not described so far and might have a role in the tumorigenesis of adrenal cortex.

A new treatment to improve the treatment of women with ER-negative/ PR-negative breast cancer. *S. Toth-Fejel, C. Hardin, P. Muller, T. Jackson, R. Pommier.* Surgery, Division Surgical Oncology, Oregon Health Sci Univ, Portland, OR.

We have shown that 228 uM dehydroepiandrosterone-sulfate (DHEAS) plus an aromatase inhibitor resulted in significant cell death in four estrogen receptor negative and progesterone receptor negative, but androgen receptor positive (ER negative/PR negative/AR positive) breast cancer cell lines (22% in HCC 1937 cells, 30.6 % in HCC 38 cells, 69% in HCC 1143 and 54 % in HCC 1954 cells. The inhibitory effect of DHEAS on these cells was nullified by the addition of the AR antagonist Casodex. For example, when these cells were treated with DHEAS, aromatase inhibitor and Casodex, the absolute percentage of cells undergoing cell death (apoptosis) decreased in both cell lines from 54.5% to 27.7% in the HCC 1143 cells and from 63 % to 22.8 % in HCC 1937 cells. These results implicate the AR as responsible for regulating of the cell death process. Preliminary immunoblotting data for the expression of apoptosis intermediaries has been completed showing that cell lines HCC 1143 and HCC 1954 increase in TRAIL and BAX expression above untreated cultures, when normalized to B-actin levels following 72 hours of DHEAS treatment. Of clinical relevance, within our breast cancer patient data base, 44% of ER negative patients are AR positive, indicating that there may be wide applicability of this treatment.

Linkage Analysis of Hereditary Prostate Cancer (HPC) to Xq27-28 in the ICPCG families. *J. Bailey-Wilson*¹, *B. Chang*², *J. Xu*², *International Consortium for Prostate Cancer Genetics*. 1) Inherited Disease Research Branch, NIH/NHGRI, Baltimore, MD; 2) Center for Human Genomics, Wake Forest University School of Medicine, Winston-Salem, NC.

The *HPCX* locus at Xq27-28 was first reported in a combined data set of 360 HPC families from North America, Sweden and Finland (Xu et al., 1998) but replication has been inconsistent. The purpose of the International Consortium for Prostate Cancer Genetics (ICPCG), an international collaborative effort to pool pedigrees with hereditary prostate cancer, is to replicate linkage findings for prostate cancer in a highly-powered dataset. Using a method we developed to combine multiple studies that used different genetic markers, a consensus map of the Xq region incorporating these markers was generated based on the UCSC physical map. The genetic distance of the markers was based on the deCode map. Each individual group then performed parametric and non-parametric linkage analyses at each CentiMorgan (cM) along the consensus map using the GENEHUNTER-PLUS computer program, and submitted the family-specific linkage results at each cM to the Data Coordinating Center. We then estimated overall parametric heterogeneity LOD scores using Smiths A-test and the compound LOD of Vieland et al. (2001) and non-parametric allele-sharing LOD scores using the ASM program. Eleven independent sets of data for a total of 1260 prostate cancer families were used. The maximum multipoint HLOD and compound LOD obtained from families not included in the original linkage report were 0.82 and 1.67 near DXS984 at 145.8 cM; using all families these scores were 1.57 and 2.65 near DXS8091 at 167.3 cM. The non-parametric multipoint allele-sharing LODs were 1.32 near DXS984 and 2.0 near DXS1227 at 150.37 cM in the new and all families, respectively. Subset analyses taking account of age at diagnosis, compatibility with X-linked inheritance, etc. are ongoing. The linkage peaks were broad and support the presence of an HPC locus at Xq27-28, indicating the utility of the ICPCG data resource. (Supported by PHS U01-CA89600).

Screen for prostate cancer susceptibility genes in 1,139 families: ICPCG combined genome-wide screen. *J. Xu, The International Consortium for Prostate Cancer Genetics. Ctr Human Genomics, Wake Forest Univ Sch of Med, Winston Salem, NC.*

Evidence for the existence of major prostate cancer susceptibility genes has been provided by multiple segregation analyses. Genome-wide screens for such major susceptibility genes have been performed in over ten independent study populations. However, few chromosomal regions have been consistently identified and replicated across these different studies. This may be expected considering the complexity of familial prostate cancer, resulting from factors such as genetic heterogeneity, incomplete penetrance, and a high phenocopy rate due to the extremely high prevalence of this disease. As a means to increase power to detect major prostate cancer genes, we combined linkage data available for the large number of prostate cancer families collected by the International Consortium for Prostate Cancer Genetics (ICPCG), an international cooperative study involving over 75 investigators from 19 institutions. Using a method we developed to combine multiple individual genome-wide screen studies performed using different genetic markers, a consensus map incorporating these markers was generated based on the UCSC physical map. The genetic distance of the markers was based on deCode map. Each individual group then re-performed parametric and non-parametric linkage analyses at each CentiMorgan (cM) across the genome using the Genehunter computer program, and submitted the family-specific linkage results at each cM to the Data Coordinating Center (DCC). The DCC then estimated overall parametric linkage score using HOMOG and non-parametric linkage score using ASM. Nine independent studies, with a total of 1,139 prostate cancer families, were included for this combined analysis. Initial analyses of these combined data identified two regions with HLOD over 1.5 on chromosomes 2 and 11 in the complete set of families. Higher HLOD scores were observed in subsets of families, e.g. among the 578 families with family mean age at diagnosis less than 65, an HLOD of 2.66 was observed at Xq11 in close proximity to the AR gene. Further analyses of this extensive dataset incorporating additional family, ethnic and clinical variables are underway. (Supported by PHS U01-CA89600).

High incidence of hidden chromosomal aberrations detected by FISH profiles (TEL/AML1, p16, MLL, BCR/ABL) in acute lymphoblastic leukemia. *E.H. Cho¹, H.Y. Woo², S.G. Lee¹, S.Y. Kong¹, S.H. Kim¹.* 1) Department of Laboratory Medicine, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, Korea; 2) Department of Laboratory Medicine, Kangbuk Samsung Hospital, Seoul, Korea.

Cytogenetic analysis in ALL is often hampered by few malignant metaphases, poor morphology, cryptic chromosomal rearrangements and sometimes by only normal metaphases derived from normal cells. To find hidden aberrations, we have analyzed 64 ALL patients with normal karyotype[49] or no metastasis[15] using FISH profile tests (FISH for TEL/AML, p16 deletion, MLL rearrangement and BCR/ABL). 40 (70%) of 64 cases showed abnormal FISH results. The cases of abnormal signals were 27 for TEL/AML1, 21 for p16, 15 for MLL and 7 for BCR/ABL. Cases with intended rearrangement of tested FISH probes were 7 for TEL/AML1 translocations, 17 for p16 deletions (homozygous loss[9], hemizygous loss[8]), 7 for MLL break apart signals and 1 for BCR/ABL translocation. FISH studies also showed unintended abnormal signals involving the loci tested, which were additional copies of p16[2], MLL[3] and BCR[1]. FISH for TEL/AML1 showed additional copies of AML1[5], AML1 amplification[2] and loss of TEL[2]. 5 cases showed signal pattern suggesting massive hyperdiploid. FISH for TEL/AML1 was most informative among tested FISH probes (detection rate;42%) and showed variable abnormal signals. There were 10 cases with only abnormality in FISH for p16 deletion among FISH profile test, which suggest the addition of FISH p16 probe to other commonly used FISH profile tests in ALL could be highly informative. This study showed very high incidence of hidden chromosomal aberrations could be detected by FISH profiles in ALL cases with normal karyotype or no metastasis.

Prevalence and Prognostic Value of Microsatellite Instability in Sporadic Rectal Tumours. *R. Coura^{1, 2}, S.L. Cossio², J.C. Prolla³, M.A. Rosito³, L. Meurer³, P. Ashton Prolla^{1,2,4}.* 1) PPG Genetica e Biologia Molecular, UFRGS, Porto Alegre, RS, Brazil; 2) Servio de Gentica Mdica, HCPA, Porto Alegre, RS, Brazil; 3) HCPA, Porto Alegre, RS, Brazil; 4) Departamento de Gentica, UFRGS, Porto Alegre, RS, Brazil.

Colorectal cancer (CRC) is the third tumor in frequency and the second in mortality in developed countries. In Brazil, it is one of the six most common cancers and the third in mortality. Among all cases of CRC, about 85% are sporadic. Prognostic evaluation is currently based only on clinical-pathological and morphological parameters, since the prognostic value of molecular markers requires further elucidation. Mutations in mismatch repair genes (MMR) are associated with hereditary CRC (particularly HNPCC), but they can also be observed in some cases of sporadic CRC. These MMR mutations (in hMSH2 and hMLH1, especially) result in a replication error phenotype, which consequently generates microsatellite instability (MSI). MSI frequency in HNPCC is more than 90% and, in sporadic CRC it is about 15%. Tumours with MSI tend to present better prognosis: greater survival rates, minor metastasis occurrence and greater response to certain chemotherapeutic regimens. In this study we evaluate the prevalence and prognostic value of a panel of five markers for MSI analysis in sporadic CRC. MSI was analysed by PCR and SSCP. The sample consisted of 42 patients with rectal cancer was completely analysed for two mononucleotide markers, BAT-25 and BAT-26. We found a MSI frequency of 7.1% and 7.5% for BAT-25 and BAT-26, respectively. Both markers were simultaneously unstable in 2.4% of patients. These results are in agreement with the literature that reports MSI frequency of less than 10% in sporadic CRC. Furthermore, about 7.7% and 15% of patients with CRC under the age of 55 showed BAT-25 and BAT-26 MSI, respectively. This corroborates with literature reports that point out the early age as a predictive factor of the presence of MSI. Three additional markers (D2S123, D5S346 and D17S250) are being analysed. Prognostic value and correlations with clinical-pathological and morphological parameters will be determined. Support: CNPq, CAPES, HCPA.

Identification of candidate genes in 6p22 that are targeted by amplification in the progression of retinoblastoma.

C. Grasemann^{1,2}, *S. Gratiyas*¹, *H. Stephan*², *A. Schueler*³, *L. Klein-Hitpass*⁴, *H. Rieder*⁵, *A. Eggert*², *D.R. Lohmann*¹. 1) Dept Human Genetics, University of Duisburg-Essen, Essen, Germany; 2) Children's Hospital, University of Duisburg-Essen; 3) Dept Ophthalmology, University of Duisburg-Essen; 4) Dept Cell Biology, University of Duisburg-Essen; 5) Dept Hum Genetics, Philipps University Marburg, Marburg, Germany.

Mutations in both alleles of the RB-gene are required for development of retinoblastoma (Rb), a childhood cancer of the eye. Additional genetic alterations occur during progression of this tumor. These include gains of genetic material on 1q31-q32 and on 6p22-p23. Recently, the minimal region of amplification on 6p was narrowed down to a region of 0.6 Mb containing the KIF13A, which codes for a motor protein. To identify other genes targeted by gains in this region we determined the relative gene dosage on 6p22.3 in 78 Rb by CGH and quantitative Multiplex PCR (QM-PCR). Microarray Analysis was used to investigate RNA expression in 23 tumors. QM-PCR analysis included 14 loci in a 2 Mb region on 6p22.3 - 21. Relative gene dosage was calculated based on two control loci on 6q and 10 q. Results obtained with normal controls (peripheral blood DNA) were used for normalization. We found that 38 of 78 Rb showed unaltered gene dosage for all loci. In 24 of 78 samples an increased gene dosage was identified for all loci on chromosome 6p, a finding consistent with the presence of an isochromosome 6p. In 16 tumors, gains were restricted to some of the 6p-loci. QM-PCR data were positively correlated with CGH results in 47 Rb ($r = 0.8$). The minimal region of gain centered at 6p22.3. Gains were most pronounced for the DEK and E2F3 gene. RNA expression was analyzed in 23 Rb with Affymetrix CHIP U133A. In all these samples, KIF13A RNA was low or absent ($n=3$). For the other analyzed genes on 6p RNA expression values were positively correlated ($r = 0.78$) with DNA-dosage (QM-PCR). Significance Analysis of Microarrays (SAM) identified DEK, NUP153 and TTRAP as potential target genes of amplification on 6p. In summary, we have identified four genes, DEK, E2F3, TTRAP and NUP 153, as potential targets of increased gene dosage in 6p in Rb.

Systematic functional testing of the 3p21.3 critical region for tumour suppression of lung cancer. *A. ter Elst, B.E. Hiemstra, W. Kamming, I. Davelaar, A.Y. van der Veen, G.J. te Meerman, C.H.C.M. Buys.* Medical Genetics, University of Groningen, Groningen, Groningen, Netherlands.

The short arm of chromosome 3 shows allelic imbalances in 75-100% of lung tumours. This is seen as the first chromosomal change in lung tumour development. And is also found in 50% of histologically normal tissue of smokers and former-smokers, but not in controls. A critical region of 370 kb has been defined in the 3p21.3 region. This region contains 19 well-defined genes. We are systematically testing this region for tumour suppressor activity. We first introduce PACs from the critical region into a well-transfectable lung cancer cell line. We use PACs to make it likely that the genes are accompanied by their main regulatory sequences. We have isolated eight PACs overlapping a 440 kb homozygous deletion in the SCLC cell line GLC20, including the whole of the critical region. Stable transfectants are being checked for complete PAC integration, purity, single site of integration and absence of amplification. Transfectant cell clones meeting all criteria are then injected into nude mice for tumourigenicity studies. In a first experiment 24 mice have been injected subcutaneously on both sides. For one side we used two transfectant clones containing one and the same PAC from the centromeric part of the critical region, for the other side two transfectants each containing a different PAC from the middle part of the deletion. The tumours were carefully isolated, measured and weighed, four weeks after injection. The mean weight of the tumours caused by transfectants containing the centromeric PAC was significantly reduced in comparison with that of the tumours caused by transfectants containing PACs from the middle of the deletion. This PAC still contains six genes (RASSF1, BLU, NPR2L, PL6, 101F6 and CACNA2D2). Our result suggests that among these, is/are a gene/genes that are more important for tumour development than the genes GNAI2, SEMA3B, IFRD2, HYAL3 and NAT6, that are on the other PACs. Experiments with overlapping PACs may delimit the true critical region, although combined effects of several genes at 3p21.3 cannot be excluded.

***BRCA1* and *BRCA2* mutations in African and African American breast cancer patients.** J.D. Fackenthal¹, F. Hagos¹, H. Kim², B. Zhang¹, Q. Niu¹, C.A. Adebamowo³, T.O. Ogundiran³, A.A. Adenipekun³, R. Oyesegun³, O. Campbell³, E.U. Akang³, D. Fackenthal², S. Das², S. Neuhausen⁴, C. Rotimi⁵, O.I. Olopade¹. 1) Department of Medicine, University of Chicago, Chicago, IL; 2) Department of Human Genetics, University of Chicago, Chicago, IL; 3) University College Hospital, Ibadan, Nigeria; 4) Center for Cancer Genetics Research and Prevention, University of California Irvine, Irvine, CA; 5) National Human Genome Center at Howard University College of Medicine, Washington, DC.

Breast cancer in women of African descent strikes at an earlier average age and has a higher mortality rate than seen in other groups. To address whether this results from a distinctive hereditary risk, we identified the germline variants in the *BRCA1* and *BRCA2* genes in 57 African American and 38 Nigerian breast cancer patients using DHPLC and direct sequencing. Nine of the 95 (9.5%) carried protein-truncating *BRCA1* or *BRCA2* mutations, a potentially significant contribution considering patients were not selected by family history. In addition to the known deleterious mutations, this cohort carried a large number of unclassified variants and polymorphisms. In the African American subset, 39/57 (68.4%) and 47/57 (82.5%) of patients carried at least one variant in *BRCA1* or *BRCA2*, respectively. Likewise, in the Nigerian cohort, 23/38 (60.5%) and 31/38 (81.6%) of patients carried at least one variant in *BRCA1* or *BRCA2*, respectively. To address the potential clinical significance of these variants, we determined the genotypes of all patients along with 96 Nigerian control samples for 24 *BRCA1* or *BRCA2* variants by primer extension analysis. None of the variants showed statistically significant difference in variant frequencies between patients and controls. Taken together, we conclude that *BRCA1* and *BRCA2* mutations may play a significant role in breast cancer patients of African descent, yet much of the high genetic diversity of these genes reflects the genetic diversity of the ancestral populations rather than deleterious alleles particular to patient populations. Supported by NCIRO1 CA89085.

Lack of contribution of causative BRCA1 mutations to tumor phenotype in African American women. *L.R. Hoffman¹, R.E. Ellsworth¹, J. Hooke², C.D. Shriver².* 1) Clinical Breast Care Project, Windber Research Institute, Windber, PA; 2) Clinical Breast Care Project, Walter Reed Army Medical Center, Washington, DC.

Breast cancer displays different characteristics in African American women than in Caucasian women, including earlier onset and a less favorable clinical outcome. Biological characteristics of tumors in African American women such as early age of onset, and high-grade, larger and more aggressive tumors with lymph node involvement, and frequent negative estrogen receptor (ER) status, mimic tumors from women with BRCA1 mutations. Breast cancer specimens from African American women with invasive (stage I-IV) breast cancer (n = 20) enrolled in the Clinical Breast Care Project at Walter Reed Army Medical Center (an equal-access health care facility) were evaluated histologically for BRCA1-like characteristics, including high grade, high mitotic index, pushing tumor margins, and lymphocytic infiltrate. The entire coding region of the BRCA1 gene in these patients was examined by double-stranded sequencing and the results examined within the context of the Breast Cancer Information Core Database. Sequencing revealed a number of sequence variants, the majority within exon 11. These DNA changes include the unclassified variants H476R, previously seen only in Africans or African Americans; K820E, frequently seen in African and African Americans; and M1628V, not previously reported in African or African American populations. In addition to patients with invasive breast cancer, examination of the DNA from African American patients with ductal carcinoma in situ (n = 8) revealed the presence of BRCA1 polymorphisms in all patients, although no mutations, unclassified or otherwise, were detected. The absence of an association of causative BRCA1 mutations with the BRCA1-like phenotype suggests that, while BRCA1 mutations may be involved in breast cancer development in some African Americans, the contribution of BRCA1 is limited. Thus, genetic factors other than BRCA1 mutations likely exist that contribute to tumor etiology in African American women.

Standardization of assays for mutation screening of the BRCA1 gene amongst seven Ontario molecular genetics laboratories.

P.J. Ainsworth¹, D.J. Allingham-Hawkins¹, I.L. Andrulis², B. Bapat^{1,2}, J. Beck³, N. Carson¹, R.F. Carter¹, J.A. Dolling¹, H.E. Feilotter¹, D. Kennedy¹, J. Miyazaki¹, H. Ozcelik^{1,2}, M.D. Speevak¹, S.A.M. Taylor¹. 1) Laboratory Genetics Subcommittee, Ontario Ministry of Health Predictive Cancer Genetics Services, ON, Canada; 2) Ontario Cancer Genetics Network, Cancer Care Ontario, Toronto, ON, Canada; 3) Coriell Cell Repositories, Camden, NJ, USA.

The development of standardized assays and quality assurance surveys for large genes is complicated by the cost and complexity of mutation screening protocols. As a result some quality assurance testing programs have limited their challenges to assays of ethnic specific mutations only, which will not adequately address the entire testing protocol. In Ontario testing for BRCA1 gene mutations is provided to at risk individuals through seven provincial laboratories who have agreed upon testing protocols. The Ontario BRCA1 assay is based on the protein truncation test and sequencing of exons 2 and 5 of the BRCA1 gene. The seven laboratories agreed to participate in a quality assurance survey to determine if all were able to perform BRCA1 analysis to an equivalent standard. The laboratories were presented with 5 anonymized cases and given 12 weeks to complete their analyses. The cases included normal individuals and those with truncating mutations detectable through analysis of DNA or RNA. The cost to each laboratory of participating was \$5000 Cdn. Criteria for evaluation of the laboratory results and reports were established before being assessed by internal and external reviewers. The results of the study indicated that the laboratories were more similar in their abilities to produce an equivalent laboratory result than in the format of their reports. The study also exposed a limitation of the PTT test to detect mutations in the 5' end of BRCA1. Amongst its conclusions the study identified several options to consider for future surveys of large genes, they include developing a uniform template for the submission of laboratory data and reviewing a portion of a large gene on a rotating basis per challenge rather than the whole gene in a single challenge.

Development of a fluorescent multiplex assay for detection of MSI-High tumors. *J. Bacher¹, L. Flanagan¹, R. Smalley², N. Nassif¹, L. Burgart², R. Halberg¹, S. Thibodeau².* 1) Promega Corp, Madison, WI; 2) Mayo Clinic, Rochester, MN.

Determining whether a tumor exhibits MSI is useful for identifying patients with HNPCC and sporadic gastrointestinal cancers with defective DNA mismatch repair (MMR), aids in establishing a clinical prognosis and response to chemotherapy. A panel of markers was suggested for MSI analysis by a NCI workshop in 1997, but this panel has limitations resulting from the inclusion of dinucleotide markers that are less sensitive and specific for detection of tumors with MMR deficiencies compared to other types of markers. This study demonstrates that mononucleotides are the most sensitive and specific markers for detection of tumors with defects in MMR and identifies an optimal panel of markers for detection of MSI-High tumors. A set of 266 mono-, di-, tetra- and penta-nucleotide repeat microsatellite markers were used to screen for MSI in colorectal tumors. The best markers for detection of MSI-H tumors were selected for a MSI Analysis System, which includes five mononucleotide markers: BAT-25, BAT-26, NR-21, NR-24 and MONO-27. In addition, two pentanucleotide markers were added to identify sample mix-ups and/or contamination. We classified 153 colorectal tumors using the new MSI Analysis System and compared the results to those obtained with a panel of 10 microsatellite markers combined with IHC analysis. We observed 99% concordance between the two methods with nearly 100% accuracy in detection of MSI-H tumors. Approximately 5% of the MSI-H tumors had normal levels of four MMR proteins and as a result would have been misclassified based solely on IHC analysis, emphasizing the importance of performing MSI testing. The new MSI Analysis System offers several distinct advantages over other methods of MSI testing in that it is extremely sensitive and specific, amenable to high-throughput analysis, meets the 2004 NCI guidelines on MSI testing and overcomes problems inherent to the original NCI marker panel. The use of a single multiplex fluorescent MSI assay reduces the time and costs involved in MSI testing while increasing reliability and accuracy and thus should facilitate widespread screening for MSI in tumors of patients with gastrointestinal cancers.

VHL molecular testing: Real-Time PCR is an alternative quantitative method for the detection of large genomic rearrangements. A. Casarin¹, M. Martella¹, R. Polli¹, E. Leonardi¹, G. Opocher², A. Murgia¹. 1) Pediatrics, University of Padua, Padua, Italy; 2) Medical and Surgical Sciences, University of Padua, Italy.

Von Hippel-Lindau syndrome is an autosomal dominant familial cancer syndrome caused by mutations of the VHL gene (3p25). As a referral center for von Hippel-Lindau disease, we have analysed the VHL gene in a large series of unrelated individuals with clinically confirmed VHL or isolated VHL-related tumors. Disease-causing mutations have been detected in 55/55 of the clinical VHL individuals and in 9/123 of the monosymptomatic cases. A substantial fraction of these mutations (22/64; 34%) is represented by whole- or partial-gene deletions or by insertion/duplication rearrangements, not detectable by commonly used mutation scanning techniques. A comprehensive approach to the molecular analysis of VHL must therefore include a gene-dosage evaluation, currently obtained with a complex and time-consuming quantitative Southern blot analysis. With the aim of obtaining a reliable alternative strategy for the identification of large genomic rearrangements of the VHL gene we have developed a quantitative Real-Time PCR method. We have been able to set standard conditions for the analysis of each VHL exon, with the use of exonic primers and both TaqMan MGB and SYBR Green chemistries, on ABI Prism 7000 Sequence Detection System. The results we have obtained with this new method have consistently and reproducibly confirmed what found on normal controls and on deleted samples previously tested by quantitative Southern blot. The analysis of complex rearrangements is still underway and might need a precise characterization of the breakpoint regions. The precision and the high sensitivity of the Real-Time PCR represent clear advantages over previously applied techniques and could justify its use as a fast quantitative screening tool for VHL genetic testing. The possibility to determine the exact genomic dosage for each individual exon may allow a more precise mapping of the deleted regions and could be used to possibly refine the genotype-phenotype correlation in subjects with partial-gene deletions.

Abnormal expression of Period 1 (PER 1) in endometrial carcinoma. *J.G. Chang^{1,5}, K.T. Yeh², M.Y. Yang⁴, T.C. Liu⁴, W.L. Chan¹, R.C. Hsu³, P.H. Chou³, T.H. Chen³, S.F. Lin⁴.* 1) Dep Molec Med, China Medical University Hospi, Taichung, Taiwan; 2) Department of Pathology, Changhua Christian Hospital, Changhua, Taiwan; 3) Department of Obstetrics and Gynecology, Changhua Christian Hospital, Changhua, Taiwan; 4) Division of Hematology-Oncology, Department of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; 5) Taipei Institute of Pathology, Taipei, Taiwan.

The development of endometrial carcinoma (EC) is a multiple-step process, which includes inactivation of tumor suppressor genes, activation of oncogenes, and disturbance of cancer-related genes. Recent studies have shown that the circadian cycle may influence cancer development and prognosis. The human circadian cycle is controlled by at least 8 circadian genes. In this study, we analyzed the expression of one circadian gene-PER1 in 35 EC and paired non-cancerous tissues by real-time quantitative reverse transcription polymerase chain reaction and immunohistochemical study. The results showed that the expression levels of PER1 in EC were significantly impaired. Mutational analysis of the whole gene and methylation analysis of cytosine-phosphate guanosine (CpG) sites at the promoter area were further performed to investigate the possible mechanisms. However, 4 polymorphisms were found in both cancerous and non-cancerous tissues, which had no relationship with the expression of PER1. In the promoter area of the PER1 gene, the CpG sites were methylated in 31.4% of EC, but in 11.4% of paired non-cancerous tissues ($P < 0.05$). Our results suggest that the down regulated PER1 expression in EC was partly due to the inactivation of the PER1 gene by methylation, and partly was inactivated by other unknown mechanism. We also analyzed the relationship among the expressions of PER1, P53, MYC, cyclin A, cyclin B and cyclin D1. We found that no definite relationship among them. Based on these results, we suggest that the down regulation of the PER1 gene may play a role in the development of some endometrial carcinomas, and it may result in disturbance of cell cycle.

Identification of novel mutations in *MYH* in North American patients demonstrates a requirement for whole-gene mutation screening. *K. Eliason*¹, *T. Judkins*¹, *B.C. Hendrickson*¹, *E. Lyon*², *M. Norton*¹, *V. Thompson*¹, *S. Gresko*¹, *B. Leclair*¹, *J. Barrus*¹, *S. David*³, *A. Livingston*³, *J. Reid*¹, *B.E. Ward*¹, *W.W. Noll*¹, *T. Scholl*¹. 1) Myriad Genetic Laboratories, Salt Lake City, UT; 2) Department of Pathology, University of Utah, Salt Lake City, UT; 3) Department of Chemistry, University of Utah, Salt Lake City, UT.

Germline mutations in the base excision repair gene *MYH* have recently been shown to confer susceptibility to colorectal adenomas and carcinomas. The most prevalent mutations in patients of British ancestry are G382D and Y165C. A set of 219 anonymous North American patient specimens submitted to confirm FAP diagnoses and negative for APC mutations were screened for Y165C and G382D. Thirteen instances of biallelic (5.9%) and 15 instances of heterozygous mutations (6.8%) were identified. Nine of the specimens with heterozygous mutations carried a second mutation after whole-gene sequencing, including two novel termination codons, E182X and Q300X, and a novel deletion mutation, IVS13+25del30. Several previously reported mutations were also detected. These results demonstrate a requirement for whole-gene screening as two thirds of the heterozygous patients carried a second mutation detected by sequencing. A further 100 of these specimens that were Y165C and G382D negative were evaluated by whole-gene sequencing. One instance of homozygous 1395delGGA, and one instance each of heterozygous mutations 1103delC and a novel splicing mutation IVS12-2AG were detected. Several novel missense variants of uncertain clinical significance were also identified.

A set of 306 anonymous patient samples negative for *MLH1* and *MSH2* clinical testing were screened for mutations in *MYH*. Thirteen (4.3%) samples had Y165C and/or G382D mutations, including one homozygous Y165C and two compound heterozygotes. One of the remaining ten heterozygotes was found also to carry 891+3AC. Sequencing 50 of these specimens that did not carry Y165C or G382D revealed an additional mutation, 1103delC. When compared with control specimens, those submitted for HNPCC testing show an overrepresentation of heterozygous *MYH* mutations (p0.05) and warrant further study.

Importance of confirming BCR/ABL fusion in the Diagnosis of Chronic Myeloid Leukemia. *M. Fang*¹, *D. Slater*², *J. Delach*¹, *P. Benn*¹. 1) Genetics & Developmental Biol, Univ Connecticut Health Ctr, Farmington, CT; 2) Backus Hospital, CT.

The presence of Philadelphia chromosome is a hallmark for the diagnosis of chronic myeloid leukemia (CML). Variant translocations are generally considered as bearing the same clinical course and outcome as simple t(9;22) translocations. In Ph-negative CML cases, BCR/ABL fusion gene or transcripts are usually detectable. We hereby report a cytogenetically ascertained Ph-positive case with typical pathological features of a myeloproliferative disorder consistent with CML. The patient received treatment with Hydrea, interferon, and Gleevec and achieved hematological remission but no cytogenetic remission at all for over seven years. Recently, molecular and molecular cytogenetic studies revealed absence of BCR/ABL fusion gene and transcripts. Furthermore, the Ph chromosome was found to be a derivative chromosome from a constitutional t(12;22) translocation instead of the variant t(9;22;12) translocation. This translocation was also inherited by the patient's son. Reevaluation of the patients clinical, hematological and morphological features in combination resulted in the diagnosis of idiopathic thrombocythemia. The patient subsequently received adjusted therapy and remains in hematological remission and in good clinical condition. We conclude that confirmation of BCR/ABL fusion gene or transcript can be very important in the diagnosis of CML even in the apparent presence of a Ph chromosome.

Further development and validation of a high-throughput targeted *BRCA1/BRCA2* mutation screening panel for women of African ancestry. *L. Gayol, M.E. Ahearn, T. Donenberg, B. Morel, J.F. Arena, L. Baumbach.* Univ Miami Sch Medicine, Miami, FL.

Recent evidence from our laboratory (Baumbach *et al.* AJHG 2003 73:#364), as well as others, suggest that certain *BRCA1/BRCA2* mutations and variants appear to be either at increased frequency or specific to women of African ancestry (AA) at-risk for breast cancer. Results agree that deleterious mutations in *BRCA1* or *BRCA2* are less frequent in these patients, suggesting that additional variants should be evaluated for their potential disease role. These observations have led to development of a screening panel for selected *BRCA1* and *BRCA2* mutations/variants in AA women. This panel is designed to detect 36 *BRCA1* mutations and unclassified variants, and 23 *BRCA2* mutations and unclassified variants, either previously detected in our laboratory, or found in a thorough review of all published English literature. The screening strategy is based on a combination of DNA sequencing, SSCP, and real-time PCR. Site-directed mutagenesis has been used to synthesize mutation-positive controls (as needed). Currently, the mutation-screening panel is comprised of 5 DNA sequencing reactions for *BRCA1*/ 4 DNA sequencing reactions for *BRCA2*, which together detect 86% of the mutations and variants, the remainder being detected by real-time PCR and/or SSCP. We have analyzed 40 patients using this panel, with another 70 to be completed by October. Two truncating mutations were detected in the 40 patients analyzed: *BRCA1* 943ins10 (founder mutation) and a rare *BRCA2* mutation (6828 delTT). Several rare missense mutations in *BRCA1* and *BRCA2* were also detected in one patient each, as well as a number of other recurrent missense mutations and unclassified variants in this cohort. We will present our cumulative study results in greater than 100 AA breast cancer patients. Eventual application of this panel to a large population-based study should contribute significant new information regarding frequencies and conferred risks of selected *BRCA1/BRCA2* mutations and variants. *The mutation screening panel has been granted preliminary patent protection through the University of Miami Office of Technology Transfer..*

Genetic testing for large germline deletions should be a clinical routine: *SDHD* and *SDHB* deletions as novel etiologies of heritable pheochromocytoma/paraganglioma syndrome (PC-PGL) as a model. *S.R. McWhinney*^{2,3}, *R. Pilarski*^{1, 2, 4}, *S. Forrester*⁵, *M. Schneider*⁵, *M.M. Sarquis*⁶, *E.P. Dias*⁷, *C. Eng*^{1, 2, 3, 4}. 1) Clinical Cancer Genetics Program; 2) Human Cancer Genetics Program; 3) Molecular Genetics; 4) Division of Human Genetics, Internal Medicine, Ohio State University, Columbus; 5) Pediatrics, S Illinois Univ Sch Med, Springfield; 6) Medicine, Federal University of Minas Gerais, Brazil; 7) Department of Endocrinology, Hospital Felcio Rocho Belo Horizonte, Federal University of Minas Gerais, Brazil.

Pheochromocytomas (PC) are catecholamine-secreting tumors that are primarily located in the adrenal medulla. Over 30% of PCs are hereditary. These neuroendocrine tumors are major components of 3 inherited cancer syndromes: multiple endocrine neoplasia type 2 (MEN 2), von Hippel-Lindau disease (VHL) and PC-PGL. Germline mutations in *RET*, *VHL*, and *SDHB*, *SDHC*, and *SDHD* are associated with MEN 2, VHL, and PC-PGL, respectively. The majority (>70%) of hereditary extra-adrenal PCs (secreting paragangliomas (PGL)) are accounted for by germline intragenic mutations in *SDHB*, *SDHC*, or *SDHD*. Therefore, a subset of hereditary PGL is not accounted for. Here we report 2 unrelated hereditary PGL families, one with a germline whole-gene deletion of *SDHD* (Fam4194), the other a partial deletion of *SDHB* (BRZ01). Although they were initially designated mutation negative for all the PC-associated genes after PCR-based analysis, we suspected that a large deletion or rearrangement might be present. Genotyping around the PC-associated genes indicated that Fam4194 and BRZ01 were consistent with linkage to *SDHD* and *SDHB*, respectively. Using fine structure genotyping and semi-quantitative duplex PCR analysis, we found that the deletion in both families segregated with the affected individuals. In addition, quantitative RT-PCR demonstrated a 4-fold decreased transcript expression in the proband compared to her unaffected mother, confirming the veracity of *SDHD* deletion in Fam4194. We were unable to obtain RNA from BRZ01. Therefore, including *SDHB* and *SDHD* deletion analysis could increase gene testing sensitivity for PGL patients, which would aid in genetic counseling and management of the patient and family.

Molecular Epidemiology of BRCA1 and BRCA2 Mutations in French Canadian Breast/Ovarian Families. *J. Simard¹, M. Dumont¹, A-M. Moisan¹, F. Durocher¹, R. Laframboise¹, M. Plante¹, J. Chiquette², B. Lesprance³, R. Pichette³, J. Lépine⁴, P. Bessette⁵, P. Voyer⁶, P. Bridge⁷, D. Goldgar⁸, INHERIT BRCA^s¹.* 1) CHUQ and Laval University, Quebec; 2) CHA, Hopital St-Sacrement, Quebec; 3) Hopital du Sacré-Coeur de Montréal; 4) Centre Hospitalier Régional de Rimouski; 5) Centre Universitaire de Santé de l'Estrie; 6) Carrefour de Santé de Jonquiere; 7) Alberta Childrens Hospital, Calgary; 8) International Agency for Research on Cancer, France.

Our study was designed to estimate the prevalence of deleterious mutations in BRCA1 and BRCA2 in French Canadian breast/ovarian cancer high risk families. To date, close to a thousand individuals from 251 families have been tested for at least 24 BRCA1 and BRCA2 deleterious mutations detected in the French Canadian founder population. Fifty-three possess a family history in both maternal and paternal sides, whereas in 61 families none of the individuals tested were affected. Our analysis led to the detection of the founder mutation R1443X (BRCA1) allele in 18 families, the 8765delAG (BRCA2) allele in 28 families. Eight additional truncating mutations were found in BRCA1 (n=5) and BRCA2 (n=3) by target sequencing. The complete sequence of all exons and splicing sites of BRCA1 and BRCA2 was done in 179 affected individuals or obligate carriers from 163 families, leading to the detection of 8 novel frameshift mutations and 25 sequence variants, in which 6 have been recently reclassified as polymorphisms. Based on our current extensive Southern blot and/or multiplex ligation probe amplification analyses, there is no evidence supporting the existence of any deleterious BRCA1/2 recurrent genomic rearrangement in the French Canadian population. The proportion of BRCA1/2-positive families among those showing within 1st or 2nd degree relatives of the index case an history of 3 (n=74), 4 or 5 (n=107) and 6 (n=53) of breast cancer cases, was 13.5%, 16% and 53%, whereas a mutation was found in 47% and 53% of families with 1(n=72) or 2 (n=30) ovarian cancer case(s). Note that a deleterious BRCA1/2 mutation was found in 58% of families with at least one (n=19) male breast cancer case.

Comparison of mRNA expression patterns in lymphoblasts from *BRCA1* mutation carriers and their wild-type relatives. *D.L. Stredrick*¹, *M.H. Greene*², *J.P. Struewing*^{1,2}. 1) Laboratory of Population Genetics, and; 2) Clinical Genetics Branch, National Cancer Institute, Bethesda, MD.

BRCA1 mutations are labor-intensive and costly to identify, but they are present in 3-5% of newly-diagnosed patients, and confer a very high risk of breast and ovarian cancer. mRNA expression studies have shown small, yet distinguishable differences between breast and ovarian cancers occurring in *BRCA1* mutation carriers versus non-carriers, and in one study of breast fibroblasts from 9 mutation carriers and 5 non-carriers after exposure to ionizing radiation. The ability to demonstrate differences between mutation carriers and non-carriers using expression analysis may provide a more efficient method for identifying carriers, and possibly give a more in-depth understanding of the normal function of *BRCA1*. We used Affymetrix U133A/B chips to compare mRNA expression in EBV lymphoblasts from 21 *BRCA1* mutation carriers and 21 of their wild-type relatives. Analysis was performed using BRB-ArrayTools, developed by the Biometric Research Branch of the NCI. Because large expression differences were not expected in the heterozygous carriers, *a priori* lists of candidate genes from the literature were used to guide the interpretation of our results. Two probe sets targeting the *BRCA1* gene revealed a significant, 20-25% lower expression among mutation carriers. After normalization using robust microarray normalization ("rma", part of Bioconductor), only 73 of 44,000 (0.16%) probe sets targeting other genes varied by 1.4-fold or more between the two groups, while scaling using MAS5 (target 500) revealed 3,236 (7.2%) probe sets that varied by this amount. Genes differentially expressed between the carriers and non-carriers were more likely to be on the *a priori* lists only when using significance analysis of microarrays (SAM) to compare the classes. Class prediction using leave-one-out cross-validation correctly classified 75% or fewer of the samples. Validation of the distinguishing genes will be performed using quantitative RT-PCR. More detailed analyses of these data are underway in an effort to determine the potential utility of this strategy.

Molecular genetic testing for hereditary leiomyomatosis and renal cell carcinoma in the clinical laboratory. *H. Sun¹, E. Fan¹, D. Melvin¹, R. Colliton¹, K. Hurley², L. Middleton², G. Glenn³, M-H. Wei^{3,4}, L. Schmidt⁴, B. Zbar⁵, J. Toro³, W.M. Linehan², C.A. Stolle¹.* 1) Path and Laboratory Medicine, Children's Hosp Philadelphia, Philadelphia, PA; 2) Urologic Oncology Branch, CCR, NCI, Bethesda, MD; 3) Genetic Epidemiology Branch, DCEG, NCI, Rockville, MD; 4) BRP, SAIC Frederick, Inc., NCI-Frederick, Frederick, MD; 5) Laboratory of Immunobiology, CCR, NCI-Frederick, Frederick, MD.

Hereditary leiomyomatosis and renal cell carcinoma (HLRCC) is an autosomal dominant condition in which affected individuals develop benign smooth muscle tumors of the skin; affected females frequently develop leiomyomata of the uterus (fibroids). Predisposition to type II papillary RCC has been observed in some families as an aggressive form of kidney cancer. Although several groups have recently identified mutations in the fumarate hydratase (FH) gene in patients with HLRCC, clinical molecular genetic testing has not been previously available. We have validated a molecular diagnostic test for HLRCC based on PCR amplification of 10 coding exons, conformation sensitive gel electrophoresis, and DNA sequence analysis of shifted exons. To date we have analyzed 51 patients for point mutations in the FH gene, including 20 probands and 31 at risk family members. Point mutations were detected in 18 of 20 probands for a mutation detection rate of 90%. Among the mutations identified, 7 were novel including 4 missense (R117G, R190C, A342D, and S376P), 1 nonsense (S102X), 1 frameshift (ins A nt 110-111; FS38->X51), and 1 splice site (138 +1 G>C) mutation. Novel missense mutations were considered potentially disease causing since they resulted in non-conservative amino acid substitutions, altered evolutionarily conserved amino acid residues, and were not found in over 100 normal alleles. Two patients did not exhibit a detectable point mutation. Preliminary Southern blot analysis failed to detect a partial or complete deletion of the FH gene. Since loss of expression of the FH gene may result in HLRCC, additional methods, such as quantitative PCR analysis of mRNA levels or PR-PCR analysis of mRNA splicing products, may be helpful for detecting mutations in these patients.

CHK2 1100delC Mutation and Inherited Breast Cancer Susceptibility in Alberta, Canada. *B. H Sun¹, S. Zhang², L. Bai¹, K. McLachlan¹, M. Lilley³, J. Liu¹, M. Somerville⁴, D. Gilchrist⁴, R. Hughes¹.* 1) Oncology, Univ. Calgary, AB; 2) Public Health Sci., Univ. Toronto, ON; 3) Population Health Info., Edmonton, AB; 4) Genetics, Univ. Alberta, Edmonton, AB.

Introduction: Mutations in BRCA1 and BRCA2 genes confer a high risk for developing breast and ovarian cancer, but account for only 25% of hereditary breast ovarian cancer (HBOC). The discovery of germline CHK2 gene mutations in breast cancer patients from HBOC families suggests that this may be the third BRCA gene to be identified. CHK2 gene encodes a cell-cycle checkpoint kinase that is a key mediator of cellular response to DNA damage. A recent CHK2 Breast Cancer Case-Control Consortium has demonstrated a frameshift mutation of CHK2 gene, 1100delC, which abrogates checkpoint kinase activity, is associated with an increased frequency of breast cancer. Analysis of this variant in Alberta Families with hereditary breast cancer is important to determine if it is predictive of cancer risk in our population. **Subjects:** Cases-135 females diagnosed with breast cancer from HBOC families without BRCA gene mutations. Controls- 279 healthy, age-matched females who underwent routine blood testing in the Calgary region. **Methods:** Long-range PCR was used to amplify CHK2 exons 10 to 14 that contains regions with high homology to CHK2 pseudogenes. Second set of PCR primers used that contain one base substitution used to generate a restriction enzyme site for ScaI within the wild-type allele of CHK2 exon 10. CHK2 1100delC mutation was detected by agarose gel analysis of ScaI digested PCR products. **Results:** The age range in case group is 30-87 years with an average of 57.7 11.9 years. The age range in control group is 30-88 years with an average of 57.9 12.5 years. The frequency of CHK2 1100delC was 1/135 (0.74%) in cases with a family history of breast cancer, compared to a frequency of 1/279 (0.36%) in healthy controls (odds ratio 2.07; 95% CI 0.13-33.35; $p > 0.05$). **Conclusions:** CHK2 1100delC is not a common cause of familial breast cancer. No significant difference between the case and control groups in our population was identified.

Significant contribution of germline *BRCA2* rearrangements in male breast cancer families. *M. Tosi*¹, *I. Tournier*¹, *B. Bressac-de Paillerets*², *H. Sobol*³, *D. Stoppa-Lyonnet*⁴, *R. Lidereau*⁵, *M. Barrois*², *S. Mazoyer*⁶, *F. Coulet*⁷, *A. Hardouin*⁸, *A. Chompret*², *P. Chappuis*⁹, *T. Frébourg*¹. 1) Faculté de Médecine & Pharmacie, Inserm U614, Rouen, France; 2) Service de Génétique, Institut Gustave Roussy, Villejuif, France; 3) Inserm EPI 9939 Institut Paoli-Calmettes, Marseille; 4) Service de Génétique Oncologique, Institut Curie, Paris; 5) Centre René Huguenin, Inserm E0017, Saint-Cloud, France; 6) Laboratoire de Génétique, Unité Mixte de Recherche 5641 CNRS, Lyon, France; 7) Génétique Moléculaire, Hôpital Tenon, Paris, France; 8) Centre François Baclesse, Caen, France; 9) Service d'Oncologie, Hôpital Universitaire de Genève, Suisse.

While screening for large deletions or duplications of the *BRCA1* gene is becoming a routine component of the molecular diagnosis of familial breast cancer, little is known about the occurrence of such rearrangements in *BRCA2*. Because of the high frequency of *BRCA2* mutations in breast cancer families with at least one case of male breast cancer, we selected a cohort of 39 such families, tested negative for mutations in the coding regions of *BRCA1* and *BRCA2*, and developed an assay for *BRCA2* rearrangements, based on quantitative multiplex PCR of short fluorescent fragments (QMPSF). We found three rearrangements: a deletion of exons 12 and 13, a duplication of exons 1 and 2 and a complete deletion of *BRCA2*. We determined the boundaries of the deletion of exons 12 and 13, showing that it resulted from unequal recombination between *Alu* sequences. We mapped the complete *BRCA2* deletion, which extends over at least 298 kilobases and demonstrated that it does not affect *APRIN/AS3*, previously characterized as a tumor suppressor gene, but it comprises several loci corresponding to proven or putative transcripts of unknown functional significance. We found no *BRCA2* rearrangement in a cohort of 91 families with breast and ovarian cancer, in which we had previously found 5 distinct germline rearrangements of *BRCA1*. These data suggest that screening for *BRCA2* rearrangements should be performed in male breast cancer families tested negative for *BRCA1/2* mutations and possibly also in other families with multiple cases of breast cancer.

A new family with both juvenile polyposis and hereditary haemorrhagic telangiectasia caused by a mutation in MADH4. *G. Viot*¹, *S. Epelboin*², *F. Soubrier*³, *A. Handra-Luca*⁴, *S. Olschwang*⁴. 1) Dept Genetics, Hosp Necker, Paris, France; 2) Gynecology, hosp Saint Vincent de Paul, Paris, France; 3) Unity of Molecular Genetic, Hosp Tenon, Paris, France; 4) Unity of Molecular Genetic, Hosp Saint Antoine, Paris, France.

In 1980, the association of juvenile polyposis (JP) and hereditary haemorrhagic telangiectasia (HHT) was reported for the first time. JP is caused by mutations in MADH4 (encoding SMAD4) and BMPR1A genes; HHT by mutations in ENG (endoglin) or ACVRL1 (ALK1). The genetic aetiology of the association of both disorders was unknown until recently when Gallione et al. reported mutations in MADH4 resulting in this combined syndrome. We report a new three generations family with 8 affected members. All of them met criteria of HHT (pulmonary arteriovenous malformation, cutaneous telangiectasia, epistaxis). Because one of the probands exhibited a colorectal cancer, endoscopy was performed for all members. Only those with HHT had hamartomatous polyps throughout the gastrointestinal tract. Subtotal colectomy was performed for 4 of them. No mutation in the ENG or ACVR1 genes was found. On the other hand, one mutation (G1571T, W524L) was identified in the 11th exon of the MADH4 gene, which has never been previously reported. This new report confirms that the genetic testing of the MADH4 gene is recommending in all patients presenting both HHT and JP.

Loss of Heterozygosity in Primary Breast Carcinomas and Metastatic Tumors of the Axillary Lymph Nodes. *R.E. Ellsworth¹, D.L. Ellsworth¹, B. Deyarmin¹, M. Sarachine¹, P. Brown¹, J. Hooke², C.D. Shriver²*. 1) Clinical Breast Care Project, Windber Research Inst, Windber, PA; 2) Clinical Breast Care Project Walter Reed Army Medical Center, Washington, DC.

Despite tremendous advances in early detection and treatment, breast cancer remains the second leading cause of cancer-related death in women. While a number of clinical parameters have been identified, axillary lymph node status remains the most important prognostic factor in predicting disease outcome. Many studies have examined chromosomal aberrations in primary tumors and correlated these findings with lymph node status and clinical outcome, but chromosomal changes particular to axillary lymph nodes have not been well studied. In this study, we used loss of heterozygosity (LOH) analysis to examine 26 of the most commonly deleted regions in breast cancer in both primary breast tumors and metastatic tumors in the axillary lymph nodes. DNA was isolated after laser-assisted microdissection of pure tumor cell populations to improve the accuracy of LOH detection. Of note, chromosomal regions 9p21 and 13q12.3 were lost in some primary tumors but never in the lymph node tumors, suggesting that genes within these regions may not be necessary for lymphogenic spread. In contrast, both primary and lymph node tumors retained regions 14q31, 7q31 and 11p15, regions known to harbor the MTA1 gene, which serves to promote metastasis, and the SPAM1 and MMP26 genes, both responsible for extracellular matrix degradation and possibly tumor dissemination. Finally, the primary tumors showed significantly more loss than did the lymph node tumors especially at chromosomal regions 8p22-21.3, and 22q12.3, suggesting that the detachment of cells with metastatic potential may be an early event in tumor progression, occurring before the accumulation of gross genetic alterations.

Program Nr: 487 from the 2004 ASHG Annual Meeting

High Resolution Array CGH Profiling of Small Cell Lung Cancer Cell Lines. *E.H.L. Lee, B.P. Coe, S. Lam, C. MacAulay, W. Lam.* Cancer Genetics and Dev. Biol., BC Cancer Agency, Vancouver, BC, Canada.

Small-cell lung cancer (SCLC) represents ~25% of all lung cancers and is rarely cured with present therapies. The median survival time is only ~12-16 months. There is a need to identify molecular targets for prognosis and therapy of the disease to increase survival rates. Array comparative genomic hybridization (aCGH) is currently the highest resolution method for detecting genomic alterations in human cancers. We have developed a CGH array consisting of 32,433 overlapping BAC clones covering the entire human genome. 15 SCLC cell lines were profiled using the SMRT array in order to identify and implicate genes contributing to the disease phenotype. To this end, DNA from the cell lines was isolated in sufficient quantities for SMRT array CGH profiling. In-house SeeGH software allowed identification of multiple recurrent gains and losses of genetic material, including previous reported alterations at the hTERT, ATM, and MYC loci. In addition, we were able to resolve chromosome breakpoints to within a single BAC clone and we detected novel micro-amplifications and micro-deletions as small as 200kb that would be undetectable with conventional methodologies. These novel genetic alterations will further our understanding of the biology of SCLC.

Genome-wide loss of heterozygosity analysis of *WT1*-wildtype and *WT1*-mutant Wilms tumors. *E.C. Ruteshouser*¹, *B.W. Hendrickson*^{1,2}, *S. Colella*^{1,2}, *R. Krahe*^{1,2}, *V. Huff*^d. 1) Department of Molecular Genetics, Section of Cancer Genetics, The University of Texas M. D. Anderson Cancer Center, Houston, TX; 2) Human Cancer Genetics Program, Department of Molecular Virology, Immunology, and Medical Genetics, Comprehensive Cancer Center, Ohio State University, Columbus, OH.

Wilms tumor (WT) is genetically heterogeneous, and the one known WT gene, *WT1* at 11p13, is altered in only 20% of WT. Previous loss of heterozygosity (LOH) analyses have revealed the existence of additional putative WT genes at 11p15, 16q, and 1p, but these analyses examined only one or a handful of chromosomes, or looked at LOH at only a few markers per chromosome. Because *WT1* is a transcriptional regulator with effects on the expression of a variety of target genes, we hypothesized that tumors carrying *WT1* mutations would display lower levels of LOH than *WT1*-wildtype tumors since mutations in *WT1* would result in the dysregulation of expression of genes which would, in *WT1*-wildtype tumors, otherwise be dysregulated via genetic alterations including LOH. Accordingly, we conducted a genome-wide scan for LOH in WT using 420 microsatellite markers spaced at an average of 10 cM throughout the genome and analyzed the data for two genetically defined subsets of WT: those with mutations in *WT1* and those with no detectable *WT1* alteration. Our findings indicate that the incidence of LOH throughout the genome is dramatically lower in our group of WT with *WT1* mutations. In *WT1*-wildtype tumors, we observed the expected LOH at 11p, 16q, and 1p, and in addition localized a previously unobserved region of LOH at 9q. Using additional 9q markers located within this region of interest, we sublocalized the region of 9q LOH to the 15.5 Mb between D9S283 and D9S1784, a region containing several potential tumor-suppressor genes. As a result, we have established for the first time that *WT1*-mutant and *WT1*-wildtype WT differ significantly in their patterns of LOH throughout the genome, suggesting that the genomic regions showing LOH in *WT1*-wildtype tumors harbor genes whose expression is regulated by the pleiotropic effects of *WT1*. Our results implicate 9q22.3 - q31.1 as a region containing such a gene.

Whole genome array CGH identifies micro-genetic alterations in cancer. *J.J. Davies, C. Garnis, E. Vucic, C. Baldwin, R.J. deLeeuw, S.K. Watson, C. MacAulay, W.L. Lam.* British Columbia Cancer Agency, Vancouver, BC, Canada.

Array-based comparative genomic hybridization (CGH) is a technique that is widely used to study genomic DNA copy number changes. By competitively hybridizing differentially labeled tumor and normal reference DNA to an array, one can determine a tumor's genomic integrity at specific marker loci. In the past, changes in genetic copy number were inferred for gaps between marker loci. Recently we have constructed a DNA array that covers the entire human genome with >32,000 overlapping genomic segments in the form of DNA derived from bacterial artificial chromosome (BAC) clones. The contiguous arrangement of clones allows for the complete assessment of an entire genome in a single experiment, thereby removing the assumption of continuity between marker loci. At this unprecedented resolution, we have identified minute genetic aberrations that have evaded characterization by conventional cytogenetic techniques. Fingerprint verified BAC clones were converted to amplified fragment pools (AFPs) via linker mediated PCR. Following re-verification by AFP sequencing, the AFPs were spotted onto aldehyde slides in triplicate. Differentially labeled sample and reference DNA were hybridized to the array followed by imaging and analysis. Software called SeeGH was created to visualize the substantial amount of data describing each genome. Using this comprehensive approach, we have detected minute aberrations in the genome that have not been previously reported. These alterations include micro-amplifications and deletions harboring known tumor suppressors and oncogenes, and novel candidate genes. Minute genetic alterations were discovered in lung, oral, breast, prostate and lymphoid cancers. Our findings demonstrate the need to move beyond conventional marker-based genome comparison, which rely on inference of continuity between interval markers; and that sub-megabase micro-amplifications and deletions are common events in cancer. This work is a component of a cancer genomics project, supported by funds from Genome Canada/Genome British Columbia.

FANCA sequence variations in high-risk non-BRCA1/2 French Canadian families. *S. Desjardins, M. Ouellet, Y. Labrie, G. Ouellette, J. Simard, INHERIT BRCA's, F. Durocher.* Cancer Genomics Laboratory, CHUL Research Ctr, CHUQ, Laval University, Quebec, PQ, Canada.

Sequence alterations in FANCA account for more than 60% of Fanconi Anemia cases, a rare recessive disease characterized by bone marrow failure, genomic instability and predisposition to cancer. FANCA is implicated in DNA repair as part of the FANC complex and has been shown to directly interact with BRCA1. A growing number of evidence links Fanconi Anemia with BRCA1 and BRCA2 genes, which are known to be involved in inherited susceptibility to breast and ovarian cancer. Since a minority of inherited breast cancers is attributable to BRCA1 and BRCA2 mutations, FANCA therefore becomes an attractive candidate for breast cancer susceptibility. We thus analyzed the FANCA gene in more than 40 high-risk French Canadian families in which no BRCA1 or BRCA2 mutations have been identified. A total of 13 sequence variants were found: 8 polymorphisms (3 silent and 5 missense changes) and 5 changes that could affect splicing. Three known missense changes (Thr266Ala, Ala412Val and Ser501Gly) and 2 possible alternative splicing events fall within the BRCA1- and BRG1-interacting region, which is a subunit of the SWI/SNF complex implicated in chromatin remodelling. The other 2 missense variants (Ser1088Phe and Thr1328Ala) and the other 3 possible alternative splicing events take place within the FANCC-interacting region, which is essential for the formation of the FANC complex and DNA repair. The Ser1088Phe variant has already been associated with Fanconi Anemia. The alternative mRNA forms have been analysed by specific probe hybridization and their presence has been investigated in 13 cell lines and 12 normal tissues. Multiplex ligation-dependent probe amplification (MLPA) was used to verify the integrity of the genomic DNA, as FANCA has also been shown to present a high rate of ALU-mediated genomic deletions. Sequence variants in FANCA could therefore be potential spoilers of the Fanconi-BRCA pathway and as a result, they could have an impact in non BRCA1/2 breast cancer families.

Characterization of sequence variants in high-risk non-BRCA1/2 French Canadian families. *Y. Labrie¹, F. Durocher¹, P. Soucy¹, D. Labuda², J. Simard¹, INHERIT BRCA's.* 1) Cancer Genomics Laboratory, CHUL Research Ctr, CHUQ, Laval University, and; 2) Centre de cancérologie Charles Bruneau, Ste-Justine Hospital, Québec, Canada.

Ataxia telangiectasia-mutated and Rad3-related (ATR) is a member of the PI3K-related family which plays, along with ATM, a central role in cell-cycle regulation, by transmitting DNA damage signals to downstream effectors of cell-cycle progression. Furthermore, ATR has been shown to phosphorylate BRCA1. These findings therefore render ATR an attractive candidate susceptibility gene for breast cancer, and thus the goal of this study was to evaluate the possible involvement of ATR sequence variants on breast cancer susceptibility. The complete sequence of the 47 exons and flanking intronic sequences of the ATR gene was therefore analyzed in 55 affected individuals from 55 high-risk French Canadian families in which no mutation in either BRCA1 or BRCA2 has been identified. No putative deleterious mutation leading to a premature termination of the protein was identified in the coding region. However, 42 sequence variants were identified, among which 16 are coding variants, 14 being novel changes. All coding variants were also analyzed in a cohort of 100 healthy unrelated individuals of French Canadian origin. In the affected cohort, 5 variants, all with a rare allele frequency of less than 5%, seem to deviate significantly from Hardy-Weinberg expectations, with an excess of rare homozygotes. Moreover, among the 16 coding variants, 6 are non-conservative changes and 2 are located in the FAT and kinase domains involved in the ATR protein activity. Protein sequence alignments with 14 other species show that 2 changes are conserved in at least 2 other species. Among the 10 silent coding polymorphisms identified, five display a frequency greater than 10%. Additional studies in international cohorts are currently underway to further evaluate the implication of these sequence variants in cancer susceptibility.

DNA damage induced by curcumin in the presence of copper in an in vitro murine model evaluated by comet assay. *P. Urbina-Cano*¹, *L. Bobadilla-Morales*¹, *M. Ramírez-Herrera*², *A. Corona-Rivera*¹. 1) Laboratorio de Genética Humana, Departamento de Fisiología, CUCS, Universidad de Guadalajara. México; 2) Laboratorio de Neurofisiología, Departamento de Fisiología, CUCS, Universidad de Guadalajara. México.

Curcumin had shown a wide range of pharmacological properties including anti-inflammatory, anti-tumor and antioxidant effects. More specifically, because of their antioxidant properties, inhibit oxidative damage to cellular DNA, and thereby, prevent mutagenesis and tumorigenesis. Most of its biological effects are due to its antioxidant and radical scavenging properties. Some antioxidants are capable of causing strand breakage in DNA in the presence of transition metal ions as copper. Such activity could be physiologically relevant in view of elevated copper ion concentrations in various diseased conditions. The goal of our study was to investigate the effect of curcumin 50M in the presence of increasing concentrations of Cu (II) to cellular DNA with the alkaline comet assay. Murine lymphocytes were incubated with curcumin 50M and different concentrations of Cu (II) (10M, 100M and 200M) for 1h at 37C in a CO2 incubator. The cells were washed and resuspended in PBS. To detect cellular DNA damage alkaline micro-gel electrophoresis (comet assay) was performed essentially as described by Singh and coworkers. To evaluate the DNA damage, comets were Propidium Iodide stained and tail length measured. Tail length average show that curcumin in the presence of Cu (II) 100 M and 200 M but not 10 M induced DNA damage to murine lymphocytes. Curcumin 50 M in the presence of Cu (II) 100 M caused the highest DNA damage. The curcumin 50 M was also able to directly induce DNA damage to murine lymphocytes. Our data suggest that curcumin in the presence of copper increases murine lymphocytes DNA damage detected by comet assay.

Genomic Deletions Involving Homologous Alu Sequences May Be More Common in MSH2 than in MLH1. *L. Li^{1, 3}, S. Mcvety³, R. Younan^{2, 4}, I. Thiffault^{1, 3, 4}, D. DuSart⁵, P. Hutter⁶, F.B. Hogervorst⁷, G. Chong^{1, 3, 4}, W.D. Foulkes^{1, 3, 4}.* 1) Program in Cancer Genetics; 2) Dept. of Surgery; 3) Dept. of Human Genetics; McGill University, Montreal, QC, Canada; 4) Dept. of Diagnostic Medicine, SMBD-Jewish General Hospital, Montreal, QC, Canada; 5) Murdoch Childrens Research Institute, Royal Childrens Hospital, Victoria, Australia; 6) Institut Central des Hpitaux Valaisans, Sion, Switzerland; 7) Family Cancer Clinic, Netherlands Cancer Institute, Amsterdam, Netherlands.

Genomic rearrangement is an important component of the mutation spectrum of mismatch repair genes MSH2 and MLH1, and has been implicated in several reported founder mutations in hereditary non-polyposis colorectal cancer (HNPCC). In this study, we identified the DNA breakpoints in the MLH1 and MSH2 genes in 10 patients, who tested positive for large genomic deletions by Southern hybridization, protein truncation test (PTT) or multiplex ligation-dependent probe amplification (MLPA). Long-range polymerase chain reaction and sequencing revealed distinct characteristics of the sequences mediating the deletions in the two genes. Among the 5 cases of MSH2 deletions, 4 result from intragenic homologous recombination mediated by repetitive Alu sequences. A notable feature of these Alu mediated deletions is that the core sequences immediately adjacent to the breakpoints from both ends share high identity. However, in one case of MSH2 deletion, the upstream and downstream breakpoints are located in Alu and L1 elements, respectively, and the two sequences do not share significant homology. The molecular mechanism underlying the 5 cases of genomic deletions in MLH1 appear to be more complex. The DNA breakpoints are located in Alu, L elements as well as non-repetitive sequences. No specific sequence pattern has been observed. Our study suggests that the intragenic deletions in MLH1 result from more complex recombination events compared to the deletions in MSH2. Dissecting the molecular basis of large genomic deletion in MLH1 and MSH2 will ultimately contribute to improving the diagnostic approach for this type of mutation and moreover, may provide mechanistic insights into their origin.

Insulin-like growth factor-1 (*IGF1*) genotype predicts breast volume after pregnancy and hormonal contraception and is associated with circulating IGF-1 levels: implications for risk of early-onset breast cancer in young women from hereditary breast cancer families. *H. Jernstrom¹, T. Sandberg¹, A. Borg¹, H. Olsson².* 1)

Department of Oncology, Jubileum Institute, Lund University, Lund, Sweden; 2) Departments of Oncology and Cancer Epidemiology, Jubileum Institute, Lund University, Lund, Sweden.

BRCA1/2 mutations predispose to early-onset breast cancer, especially after oral contraceptive (OC) use and pregnancy. However, the majority of breast cancers might be due to more prevalent low penetrance genes, which may also modify the risk in BRCA mutation carriers. The absence of the *IGF1* 19-repeat allele has been associated with high insulin-like growth factor-1 (IGF-1) levels during OC use. High IGF-1 levels are linked to early-onset breast cancer and larger breast volumes in the general population. The goal of this study was to elucidate the relationships between *IGF1* genotype, early-onset breast cancer, breast volume, circulating IGF-1 levels and OC use in a prospective cohort of 258 healthy women 40 years-old from high-risk breast cancer families. All women completed a questionnaire including information on reproductive factors and OC use. We measured height, weight, breast volumes and plasma IGF-1 levels. IGF-1 levels were similar among parous and nulliparous women not using OCs. Thirteen percent had no *IGF1* 19-repeat allele. There was an interaction between *IGF1* genotype and OC use on IGF-1 levels ($p=0.026$) in nulliparous women and another interaction between *IGF1* genotype and parity on breast volume ($p = 0.01$). Absence of the 19-repeat allele was associated with high IGF-1 levels in nulliparous OC users and with larger breast volumes in parous women and OC users. Incident breast cancers were also more common in women without the 19-repeat allele (Log-rank $p = 0.002$). Our results suggest that lack of the *IGF1* 19-repeat allele modifies IGF-1 levels, breast volume and possibly early-onset breast cancer risk after hormone exposure in young high-risk women.

Overexpression of Her2 and Ki67 is associated with breast tumor aggressiveness. *N. Tian*¹, *S. Yan*², *Q. Wang*³, *W. Qiao*⁴, *S.W. Fu*⁵. 1) Surgery, Fugu Hospital, Fugu, Shaanxi, China; 2) Dept. of OB and GYN, Affiliated Teaching Hospital, Tibet Nationalities Institute, Xianyang, Shaanxi, China; 3) Dept. of Surgery, Shengmu Hospital, Shengmu, Shaanxi, China; 4) Dept. of Medicine, The 2nd Affiliated Hospital, Xi'an Jiaotong University, Xi'an, Shaanxi, China; 5) Dept. Biochemistry & Molecular Biology, George Washington University, Washington, DC.

The aggressiveness and metastasis of breast cancer is the most insidious and life-threatening risk for breast cancer patients. Clearly, the aberrant expression of genes controlling cell growth and proliferation in tumor cells plays an important role. This study was to explore the potential effects of the expression of Her2 and Ki67 genes in breast cancer. Formalin-fixed, paraffin-embedded human breast tumor tissues were used, and immunohistochemical staining were carried out using ABC method to determine the expression of HER-2, Ki67, in primary breast carcinoma patients. The X^2 test was used to compare immunohistochemical results for Her2 and Ki67 with clinico-pathologic characteristics, such as patient age, tumor size, lymph node status, histological grade, and ER and PR status. Of the 87 primary invasive ductal carcinomas, 24.6% and 61.4% were positive for HER2 overexpression and Ki67 expression, respectively. HER2 overexpression was significantly correlated with tumor size ($p = 0.002$), number of positive lymph nodes ($p = 0.004$), and histological grade ($p < 0.0001$). There was an inverse association between HER2 overexpression, and ER expression ($p < 0.002$) as well as PR expression ($p < 0.003$). Ki67 expression was significantly correlated with histological grade ($p = 0.003$), whereas no association was found between Ki67 expression and tumor size, number of positive lymph nodes, ER or PR expression. Further analysis indicated that there was a significant association between expression of Her2 and that of Ki67 ($p < 0.001$), and Her2 overexpression and Ki67 protein accumulation are associated with aggressive breast cancer.

Using Brother Pairs Discordant for Prostate Cancer to Identify Prostate Cancer Susceptibility Genes. K.A.

Zuhlke¹, J.A. Douglas², S.B. Gruber^{1,2,3}, J. Beebe-Dimmer^{3,4}, D.P. Wood⁴, K.A. Cooney^{1,4}. 1) Internal Medicine; 2) Human Genetics; 3) Epidemiology; 4) Urology, University of Michigan, Ann Arbor, MI.

Family history is a well-recognized risk factor for prostate cancer. To identify cancer susceptibility genes, we have established the University of Michigan Prostate Cancer Genetics Project (PCGP), a family-based study of hereditary prostate cancer. Within a subset of PCGP families, we have identified sets of brother pairs discordant for prostate cancer affection status in order to study susceptibility genes with moderate penetrance. We have recently genotyped 717 brothers with and without prostate cancer from PCGP families using one common single nucleotide polymorphism (SNP) from each of five prostate cancer candidate genes: CYP17 (10q24.3), CYP19 (15q21.1), BRCA1 (17q21), CYP11A (15q23-24), and LHB (19q13.32). Genotyping was performed using the ABI PRISM 7900HT Sequence Detection System. There were 377 men with prostate cancer and 340 unaffected brothers from 266 families included in this analysis. Families were primarily Caucasian, although 12 African American and 2 Asian families were also included. To date, we have detected significant associations between prostate cancer and SNPs in BRCA1 and CYP17 using the Family Based Association Test (FBAT) package. Both SNPs display significant association with prostate cancer in an affecteds-only analysis ($p = 0.020$ and $p = 0.010$). The SNPs in BRCA1 ($p = 0.019$) and CYP17 ($p = 0.003$) are also significant when unaffected brothers are included. Although preliminary, the findings with regard to BRCA1 are consistent with our evidence of linkage to 17q21 in a set of overlapping families from the U of M PCGP. Given the latter linkage result, our family-based association study design which protects against spurious associations arising from population admixture, and other independent reports of association and/or linkage, both genes merit further exploration and testing in the current sample and a future replication sample. This work may lead to the identification of a set of SNPs that could be used for prostate cancer risk stratification in men with a family history of the disease.

Characterization of variation across the human TP53 gene. *L. Burdett*¹, *S. Presswala*¹, *V. Llaca*¹, *M. Yeager*¹, *D. Gerhardt*², *R. Strausberg*³, *V. Kristensen*⁴, *C. Perou*⁵, *A. Borrensens-Dale*⁴, *S. Chanock*⁶. 1) Core Genotyping Facility/GAI, SAIC-Frederick/NCI, Gaithersburg MD; 2) OCG/NCI/NIH Bethesda MD; 3) TIGR Gaithersburg MD; 4) Dept of Genetics, Norwegian Radium Hospital, Oslo Norway; 5) Lineberger Cancer Center, UNC, Chapel Hill NC; 6) POB/NCI/NIH, Bethesda MD.

Characterization of variation across the TP53 gene was performed to set a baseline for studies of the gene in breast cancer patients. Resequencing of 7000bp of TP53 (including all exons, 2500bp 5' and 1000bp 3') in a panel of 102 individuals of 4 self-described ethnic groups (N=24 African/African-Americans, N=31 Caucasians, N=23 Hispanics, and N=24 Pacific Rim) and N=94 Norwegian woman revealed several novel single nucleotide polymorphisms. The variant encoding the arginine of the well-studied R72P polymorphism was observed at allele frequency of 0.54 across the populations with a range of 0.29 for African-Americans to 0.73 for Caucasians. Fifteen SNPs were observed at a frequency greater than 5% and were used to characterize haplotypes. Phase was estimated and then confirmed by pedigree analysis of 16 CEPH families. There were 3 haplotypes that explain 80% of haplotypic variation in the Caucasians, of which two are the major haplotypes in the Hispanic group studied. The Pacific Rim group contains 2 major haplotypes, only one of which overlaps with the Caucasians. As may be expected, the African/ African-American group contains more haplotypes overall, with lower frequency than in the other groups. Two htSNPs, rs1614984 and rs1042522, describe 95% of the haplotypes for Caucasians as well as the Hispanic. The Pacific Rim group requires one additional htSNP and 4 are required for the African/African American group with only one htSNP, rs1614984, overlapping with the htSNPs of the other groups. Further sequence analysis of the genes neighboring TP53, show an LD block that extends 5' through two neighboring genes, FLJ10385 and EFNB3, and in the 3' direction into ATP1B2.

ATM haplotypes and breast cancer in Jewish high risk women. *E. Friedman*^{1,3}, *M. Koren*¹, *G. Kimmel*², *S. Eisenberg-Barzilai*¹, *R. Shamir*². 1) Oncogenetics Unit, Inst Gen, Chaim Sheba Medical Ctr, Tel Hashomer, Israel; 2) Department of Mathematics, Tel-Aviv University, Tel-Aviv, Israel; 3) Sackler school of medicine, Tel-Aviv University Tel-Aviv Israel.

The contribution of ATM gene mutations to breast cancer risk in the average- and high-risk populations is unsettled. To shed light on this issue, we constructed ATM haplotypes using 8 intragenic SNPs spanning the 142Kb genomic region of the ATM gene in unaffected, ethnically diverse non-Ashkenazi Jewish individuals (controls - n=111), using a novel expectation-maximization algorithm (GEBRIL). Of the 15 haplotypes noted, 4 were encountered in frequencies of 5% or more, and combined accounting for more than .% of all haplotypes, with extensive LD among all ethnically diverse groups. Subsequently, ATM haplotyping of high risk Jewish individuals of Ashkenazi [n=107, all breast cancer patients all carriers of BRCA1 (n=33) or BRCA2 (n=64) mutations] and non Ashkenazi (n=227; 115 breast cancer, 112 unaffected of whom none was a BRCA1/2 mutation carrier) origin was carried out. The results showed that one haplotype, coined haplotype 2 SPECIFY!!! was significantly more common in high risk, affected and unaffected, women (20%) than controls (5%) (p=0.0005), and was noted in 31% of high risk cancer cases, (p=0.0005 Vs controls and p=0.03 vs high risk unaffected). Analysis of ATM haplotype distribution by age at diagnosis (<40; 41-49; >50+ years) in BRCA1 (n=33) and BRCA2 (n=64) affected mutation carriers failed to demonstrate specific haplotype clustering by age at diagnosis in either group. This preliminary study suggests that a specific ATM haplotype is associated with elevated breast cancer risk in Jewish non-Ashkenazim and that ATM probably does not function as an age at diagnosis modifier of BRCA1/2 Jewish Ashkenazi mutation carriers.

RAD51 haplotypes and breast cancer risk in Jewish women. *I. Gal¹, R. Gershoni-Baruch², G. Kimmel³, M.Z. Papa⁴, E. Dagan², R. Shamir³, E. Friedman¹.* 1) The Susanne Levy Gertner Oncogenetics Unit, Institute of Genetics, Tel-Hashomer, Israel; 2) The Genetics Institute, Rambam Medical Center, Haifa, Israel; 3) Faculty of Exact Sciences, School of Computer Science, Tel-Aviv University, Tel-Aviv, Israel; 4) The Department of Oncological Surgery, Sheba Medical Center, Tel-Hashomer, Israel.

While the precise genes involved in determining breast cancer risk, are mostly unknown, one strong candidate is the RAD51 gene. To further evaluate RAD51 putative role in breast cancer susceptibility, RAD51 haplotypes were determined in Jewish non-Ashkenazi high risk women and among Jewish BRCA1 BRCA2 mutation carriers. The study population encompassed women at high risk for breast/ovarian cancer and an ethnically matched control group. Four SNP's spanning the entire RAD51 genomic region was scored using the Pyrosequencing technology, and the resulting haplotypes were constructed using the GERBIL algorithm. A total of 550 women were genotyped: 144 BRCA1 mutation carriers (71 with breast/ovarian cancer); 85 BRCA2 mutation carriers (26 with breast/ovarian cancer); 191 non-Ashkenazi high risk women (127 with breast/ovarian cancer); 130 unaffected controls. Control group genotyping showed that all SNP's maintained the Hardy Weinberg Equilibrium, and did not show any ethnic differences. Using GEBRIL three frequent haplotypes could be constructed: haplotype 1-CCTG (47.6%), haplotype 2-TGGG (39%) and haplotype 3-TGTA (13.4%). Haplotype 3 was present in 7.3% (19/260 haplotypes) of controls (n=130) and in 15.5% (131/840 haplotypes) of all cases (n=420) (p= 0.0021). Compared with controls, haplotype 3 was significantly more prevalent among breast cancer cases (regardless of BRCA mutational status) 16% (72/448 haplotypes) (n=224, P=0.0023), among non carrier breast cancer patients 17% (43/252 haplotypes)(n=126, p=0.0024), and among BRCA1/2 mutation carriers regardless of disease status 15% of 97 affected mutation carriers (p=0.026), and 16% among 132 asymptomatic carriers (p=0.006)]. It seems that a specific RAD51 haplotype is associated with an increased breast cancer risk in Jewish high risk women and in BRCA1/2 mutation carriers.

Support for an Ashkenazi Jewish origin for the *BRCA1*185delAG* mutation observed in the non-Jewish San Luis Valley population. *I. Makryianni*¹, *N. Hamel*^{1,2}, *W. Foulkes*^{1,2}, *S. Graw*³. 1) Department of Human Genetics, McGill University, Montreal, Canada; 2) Department of Medicine, McGill University Health Centre, Montreal, Canada; 3) Eleanor Roosevelt Institute, University of Denver, Denver, Colorado.

Numerous *BRCA1* mutations predispose to breast and ovarian cancer. *BRCA1*185delAG* is the most frequent *BRCA1* mutation in the Ashkenazi Jewish (AJ) population. In a Chilean family with no known Jewish ancestry, Ah Mew et al. (Clin Genet 2002; 62: 151-56) found that *BRCA1*185delAG* occurred on a haplotype identical to that observed in the AJ population. This mutation has also been identified in the Hispanic population of the San Luis Valley of southern Colorado and northern New Mexico. In this study we set out to determine whether *BRCA1*185delAG* found in this region has occurred on the previously recognised AJ haplotype. The San Luis Valley was first settled by the de Onate expedition in 1598 and some of these settlers may have had Jewish ancestors. However, individuals involved in this study did not report any Jewish ancestry. Individuals diagnosed with either breast cancer or ovarian cancer met the ASCO genetic testing for cancer predisposition inclusion criteria prior to genetic testing. Myriad Genetics identified the *BRCA1*185delAG* mutations. We genotyped these individuals for 7 markers located within or near *BRCA1*. Unrelated AJ *185delAG* carriers were used as positive controls to reconstruct haplotypes. We found that genotypes observed in all carriers of *BRCA1*185delAG* from the San Luis Valley studied here were consistent with the conserved haplotype found in AJ carrier controls. In addition, one non-carrier included in the analysis did not have the conserved alleles at the 7 loci. Our results suggest that individuals from the San Luis Valley likely have at least one Jewish ancestor. In addition, it is possible that some of the de Onate settlers may indeed have been Ashkenazi Jewish. These results are consistent with previous findings which indicate that non-Jewish populations could actually have Jewish ancestors-thus further exemplifying the difficulty in defining ethnicity.

Sequence variants in TLR1, TLR6 and TLR10 are associated with prostate cancer susceptibility. *J. Sun¹, K. Augustsson-Blter², S.L. Zheng¹, M. Hedelin², L. Li¹, H.O. Adami², G. Li¹, J.E. Johnsson⁴, B. Chang¹, D.A. Meyers¹, W.B. Isaacs⁵, J. Xu¹, H. Grnberg³.* 1) Ctr Human Genomics, Wake Forest Univ Sch of Med, Winston Salem, NC; 2) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 3) Department of Radiation Sciences, Oncology, University of Ume, Ume, Sweden; 4) Department of Urology and Clinical Medicine, rebro University Hospital, Sweden and Regional Oncological Center, University Hopsital Uppsala, Sweden; 5) Department of Urology, Johns Hopkins Medical Institutions, Baltimore, MD.

Chronic inflammation has been suggested as a causal factor in many human cancers, including prostate. Toll like receptors (TLRs) are essential in triggering innate immunity by sensing the invasion of pathogens as well as cross-talk between the innate and adaptive immunity. Our previous finding of an association of *TLR4* sequence variants and prostate cancer (PCa) risk provides further evidence for a role of TLRs in PCa development. In this study, we hypothesize that sequence variants in the *TLR6*, *TLR1*, and *TLR10* cluster are associated with PCa risk. These three genes reside within a 54 kb region on 4p14 and code for proteins with a high degree of homology in their overall amino acid sequences. The first step of our haplotype tagging SNP (htSNP) approach was to select 33 SNPs covering the three genes and genotype these in 96 Swedish control subjects. Six distinct haplotype blocks were observed and 16 htSNPs could capture >95% haplotype information. These 16 htSNPs were then genotyped in 1,383 newly diagnosed PCa patients and 780 age and residence matched controls. Allele frequencies in 10 of these 16 SNPs were significantly different between cases and controls, with P-values ranging from 0.02-0.003. Two of these htSNPs were nonsynonymous changes in *TLR1*. Haplotype analysis in each block provided stronger evidence. These results provided strong evidence for association of this TLR gene cluster with PCa risk, although it is difficult to dissect which and how many of these positive SNPs confer independent risk. Further functional studies are needed to pinpoint the causal variants in this gene cluster.

Germline sequence variants of NKX3.1 in hereditary prostate cancer families. *S.L. Zheng¹, B.L. Chang¹, G. Li¹, S.D. Isaacs², K.E. Wiley², D.A. Meyers¹, P.C. Walsh², W.B. Isaacs², J. Xu¹.* 1) Ctr Human Genetics, Wake Forest Univ Sch Med, Winston-Salem, NC; 2) Department of Urology, Johns Hopkins Medical Institutions, Baltimore, MD.

NKX3.1, a gene mapped to 8p21, is a member of the NK class of homeodomain proteins and is expressed primarily in the adult prostate. Previous studies suggested that NKX3.1 exerts a growth-suppression and differentiation effect on prostate epithelial cells. Because of known functions and location within a chromosomal region where evidence for prostate cancer linkage and loss of heterozygosity is found, we hypothesize that sequence variants in the *NKX3.1* gene may increase prostate cancer (PCa) risk. To test this hypothesis, we first re-sequenced the promoter, two exons, and exon-intron junctions of the *NKX3.1* gene to identify sequence variants among 188 probands of hereditary prostate cancer (HPC) families recruited at Johns Hopkins Hospital; each family has at least three first-degree relatives affected with PCa. Three non-synonymous changes were identified; including A17T, R52C, and T164A. The A17T and T164 were observed once and in the same subject, who has an African American (AA) background. The R52C variant has been previously reported and was observed multiple times among both European American and AA subjects. In addition, one synonymous change, two variants in the promoter, and 4 variants in the 3UTR were found. We then genotyped all these variants in the 188 HPC families and tested for their co-segregation with PCa risk using both linkage and family-based association tests. Parametric linkage analysis using these 10 variants and one microsatellite marker on each side provided strong evidence for linkage, with a maximum LOD score assuming heterogeneity to be 2.77 ($P=0.0004$) at the 3UTR. For the family-based association tests, five variants, including the three nonsynonymous changes were too rare to be informative. No significant association was found for the remaining variants, suggesting multiple founders (haplotypes) co-segregate with PCa. These results provide evidence that germline sequence variants in NKX3.1 play a role in prostate cancer susceptibility.

Heritable Variation of HER2/ERBB2 as a Determinant of Breast Cancer Histology. *J.P. Breyer¹, J.B. Elmore¹, B.L. Yaspan², Q. Cai⁵, K. Godfrey², K.M. Bradley¹, Y-T. Gao³, D.C. Airey⁴, W. Zheng⁵, J.R. Smith⁵.* 1) Department of Medicine, Vanderbilt University Medical Center, Vanderbilt University, Nashville, TN; 2) Department of Cancer Biology, Vanderbilt University, Nashville, TN; 3) Department of Epidemiology, Shanghai Cancer Institute, Shanghai, PRC; 4) Department of Pharmacology, Vanderbilt University Medical Center, Nashville, TN; 5) Department of Medicine and Vanderbilt-Ingram Cancer Center, Vanderbilt University, Nashville, TN.

Epithelial-derived neoplasms can develop multiple histologic patterns, each with distinct gene expression profiles and clinical sequelae. The epithelial growth factor receptor and ligand family has been broadly implicated in the development and progression of these cancers, particularly adenocarcinoma of the breast. Here we demonstrate that the HER2 member of this gene family is a determinant of breast cancer histology. In a study population of 2503 breast cancer cases and controls from the city of Shanghai, China, the two major population haplotypes of HER2 (frequencies of 0.27 and 0.59) are associated with lobular and ductal carcinoma ($P=0.039$ and $P=0.003$, respectively), the primary histologic types of breast cancer. Further, survival in breast cancer is modified by these haplotypes, the lobular-associated haplotype being relatively protective ($P=0.008$). The same haplotypes predominate in Caucasian populations. The data suggests that common genetic variation at HER2 guides breast carcinoma type, and warrants further investigation of genes in this pathway in common epithelial cancers.

Program Nr: 504 from the 2004 ASHG Annual Meeting

Genetics study of breast cancer cell lines of MCF_7 (P53+/+) and MDA_MB_468 (P53 mutant) on analyzing replicate genome data of Affymetrix HG-U133A with the design of target MDM2 oligonucleotides, control oligonucleotides and negative control. *K. Chen.* Med Stat S. Hemat/Oncology D., Dept Med; Comprehensive Cancer Center, The U of AL at B'hm, Birmingham, AL.

The study is a genetic identification of the characterized genomes for the two breast cancer cell lines MCF_7 and MDA_MB_468 based on the replicate typing outcome of Affymetrix HG-U133A. The study goal includes the linkage and epistasis content of that the analysis will follow the spatial statistical inference after accomplishing the current genome-wise genetic screening. The per cell line difference in genomes has been doing the 4 comparisons among the three groups of target MDM2 (mouse double minute 2) oligonucleotides (oligo), control oligo and negative control, as well as the between-cell-line differentiation. The presentation is focused on how to manage in analysis for the output of the microarray laboratory with the following defect performance, in addition to the usual bioinformatics issues. Employed Affymetrix HG-U133A of probe_set array of lot 2004204 was typed for target replicates for both cell lines and for the replicates for both controls for mutant cell line, in all 4 array trays; of probe_set array of lot 2004300 was typed two days later for the rest including all original (i.e. non-replicates) for the three cases for both cell lines and replicates for both controls of the wild type cell line, in all 8 array trays.

16q Loss in Retinoblastoma Implicates CDH11 as a Tumor Suppressor Gene. *M.N. Marchong^{1,4}, D. Chen², T.W. Corson^{3,4}, C. Lee⁴, M. Harmandayan⁴, E. Bowles^{1,4}, N. Chen², B.L. Gallie^{1,2,3,4}.* 1) Department of Medical Biophysics, University of Toronto, Toronto, ON, Canada; 2) Department of Ophthalmology, Toronto Western Research Institute, Toronto, ON, Canada; 3) Department of Medical Genetics and Microbiology, University of Toronto, ON, Canada; 4) Department of Cancer Informatics, Ontario Cancer Institute / Princess Margaret Hospital, Toronto, ON, Canada.

Additional genomic alterations accompany loss of both RB1 alleles in retinoblastoma. Previous comparative genomic hybridization (CGH) studies of 50 retinoblastoma revealed 14% genomic loss at chromosome 16q22. We narrowed the minimal region of 16q22 loss to 2.62 Mb by loss of heterozygosity and quantitative multiplex-PCR for sequence tagged site (STS) markers. The highest frequency losses were the STS WI-5835, within intron 2 of the CDH11 gene, and D16S422, within intron 2 of the CDH13 gene. Over 50% of 72 tumors displayed loss within the CDH11 gene, a significantly higher proportion of loss than that detected by CGH. Immunoblot and RT-PCR showed decrease/loss of the intact form of cadherin-11 in 8/14 tumors tested and in 3/8 advanced large TAg-induced murine retinoblastoma (TAg-RB) tumors, while cadherin-13 exhibited no change in expression compared to healthy adult retina. Immunohistochemical analysis of TAg-RB tumors showed that while cadherin-11 is strongly expressed in the inner nuclear layer (INL) of early developing tumors at 4 weeks of age, this expression is lost in foci within late stage tumors at 21 weeks of age. Timing as well as origin of tumor development in the retina is significant due to the fact that retinoblastoma is a developmental disease that arises in the INL of the retina. Our data thus far suggest that CDH11 is expressed in early tumors, but as the tumors progress, deletion of one allele is common, perhaps with mutation of the remaining allele resulting in loss of cadherin-11 protein expression. We have therefore narrowed genomic loss at 16q22 down to a 2.62 Mb minimal region in which one gene, CDH11, exhibits characteristics of a tumor suppressor role in retinoblastoma.

Association of Interleukin-1 receptor antagonist (IL-1Ra) polymorphism in patients with prostate cancer and benign prostatic hyperplasia; A case control study from north India. *R.D. Mittal, D.K. Mishra, H.K. Bid, D.S.L. Srivastava, A. Mandhani.* Department of Urology, SGPGIMS, Lucknow, Uttar Pradesh, India.

Prostate cancer is the most commonly diagnosed noncutaneous cancer. It is a multifactorial and polygenic disease. Different studies suggest that immunological components play a key role in the development of cancers of gastric, cervical and ovary. Polymorphism in IL-1Ra gene has been reported to be associated with different malignant diseases. However, there is scarcity of data depicting role of IL-1Ra in prostate cancer till date. The present study was undertaken to assess the association between prostate cancer and IL-1Ra polymorphism and to evaluate whether frequency of any particular allele has susceptibility to prostate cancer (CaP) and Benign prostate hyperplasia (BPH). In a case control study we analysed the polymorphism of an 86-base pair repeat in intron 2 of the IL-1Ra gene in 96 men with prostate cancer (CaP), 74 with benign hyperplasia (BPH) and 98 healthy controls. Genomic DNA fragments were amplified by polymerase chain reaction. Our study demonstrated a significant dominance of genotype B/B (410 bp) in CaP and BPH patients as compared to normal healthy individuals (57.3% and 56.8% vs 22.4%). However A/A genotype (240 bp) was found to be dominant in normal controls (55.1% vs 6.5% and 16.2%). We found no significant association of IL-1Ra polymorphism with tumor stage and histological grade. Our study suggests that presence of Type B/B genotype may be a risk factor for CaP as well as for BPH while A/A genotype may be protective as observed in healthy individuals. Thus, IL-1Ra gene may be a useful marker for possible screening and risk evaluation in large cohort studies of various populations.

Prostate Cancer and Genetic Variants in *Hepsin* and *CEACAM1*: An Association Study. P. Pal¹, C.H. Jin², R. Kaushal¹, H. Xi¹, G. Sun¹, L. Jin¹, B. Suarez², W.J. Catalona³, R. Deka¹. 1) Dept Environmental Health, Univ Cincinnati, Cincinnati, OH; 2) Dept Psychiatry & Genetics, Washington Univ, St. Louis, MO; 3) Dept Urology, Northwestern Univ Feinberg School of Medicine, Chicago, IL.

Prostate cancer (PC) is the most commonly diagnosed non-cutaneous malignancy among men in the western world. Genes implicated in cell growth, proliferation and differentiation are important candidates in carcinogenesis. We investigated two genes, *Hepsin*, a transmembrane serine protease and *CEACAM1* (carcinoembryonic antigen-related cell adhesion molecule 1), located at 19q2, a region linked with an aggressive phenotype of PC. cDNA microarray studies indicate that *Hepsin* is over-expressed in PC. Down regulation of *CEACAM1* protein in cancer cells is well substantiated. We conducted a case-control association study of PC using 6 SNPs in *Hepsin* and 6 in *CEACAM1*. Four intronic SNPs and one each from 3 and 5 UTR of *Hepsin* were selected. For *CEACAM1*, 3 non-synonymous SNPs located in exon 3, 2 intronic and one located in the 3 UTR were genotyped. The study sample consists of 577 histologically confirmed PC cases from 299 multiplex sibships and 576 unrelated controls, all of Caucasian ancestry. We randomly selected one of the affected sibs from each sibship to form the unrelated cases. Genotype frequencies at all markers were in conformity with Hardy-Weinberg expectations. Minor allele frequencies at two of the *Hepsin* SNPs were <10%, the range at the other four being 25% to 43%. We found significant association with one of the *Hepsin* intronic SNPs (rs2305747, $p = 0.008$), haplotype analysis revealed one major haplotype significantly more prevalent in PC cases ($p = 0.003$; OR = 1.501). At *CEACAM1*, only the three coding SNPs were polymorphic, with minor allele frequencies of ~1% at two and 16% at the third marker. We detected weak association with a minor haplotype at *CEACAM1* ($p = 0.03$). This is the first association study investigating *Hepsin* and *CEACAM1* in PC, and our results suggest that these genes have possible roles in prostate tumorigenesis. Supported by Urological Research Foundation, St. Louis, MO.

Hepatosplenic T-cell lymphoma in a 71-year-old man with X-linked lymphoproliferative disease. *R.D. Klein, M. Ghofrani, A. Bale, T. Duffy, J.G. Howe.* Yale University School of Medicine, New Haven, CT.

X-linked lymphoproliferative disease (XLP) is an X-linked recessive immune deficiency that is characterized by vulnerability to fulminant infections with the Epstein-Barr (EBV) virus. Malignant lymphomas (usually B-cell) and immunoglobulin deficiencies are also observed in the syndrome, most often in association with EBV infection. The disease is caused by mutations in SH2D1A, which is believed to play a role in signal transduction within activated T cells. Affected individuals live to a median age of 10, with few surviving into adulthood. We describe a 71-year-old man with a non-contributory medical history and an apparent XLP mutation who died of a rare T-cell lymphoma. After experiencing a flu-like illness four months earlier, the patient over a six-month period developed persistent fever, fatigue, and weakness, followed by progressive weight loss, anemia, and death from hepatic and renal failure. Diagnostic evaluations during his illness, including liver and bone marrow biopsies and flow cytometry were unrevealing. A limited post-mortem examination attributed the cause of death to hepatosplenic T-cell lymphoma. Serologies demonstrated past infection with EBV, but there was no evidence for EBV infection in the tumor tissue by in situ hybridization with an oligonucleotide probe to EBER-1. During the autopsy, it was found that the patient's 7-year-old grandson had died several years earlier of hepatic failure secondary to an overwhelming EBV infection. The boy had been clinically diagnosed with XLP, although genetic testing was not performed. Sequencing of the SH2D1A gene of both patients revealed a previously undescribed missense mutation, 463G>C. The mutation changes arginine to glutamine at codon 55, a known mutational hotspot. Reported lymphomas in XLP are most often derived from B-cells, and are usually EBV related. The finding of an extremely rare T-cell lymphoma in a 71-year-old man in association with an apparent XLP mutation, indicates a broader phenotype for XLP than has previously been recognized.

A genome-wide scan for linkage disequilibrium based association with breast cancer in an eastern Finnish population. *J. Hartikainen*^{1, 2}, *A. Dunning*³, *H. Tuhkanen*^{1, 2}, *V. Kataja*², *M. Eskelinen*⁴, *V.-M. Kosma*¹, *A. Mannermaa*^{1, 5}. 1) Department of Clinical Pathology and Forensic medicine, University of Kuopio and Kuopio University Hospital, Kuopio, Finland; 2) Department of Oncology, University of Kuopio and Kuopio University Hospital, Kuopio, Finland; 3) Cancer Research UK Human Genetics Research Group, Department of Oncology, Strangeways Research Laboratory, University of Cambridge, United Kingdom; 4) Department of Surgery, University of Kuopio and Kuopio University Hospital, Kuopio, Finland; 5) Department of Clinical Genetics, University of Oulu and Oulu University Hospital, Oulu, Finland.

Breast cancer is the most common of cancers among women in industrialised countries. Many of breast cancer risk factors are known but the majority of the genetic background is still unknown. Linkage disequilibrium based association is a powerful tool for mapping disease genes and is suitable for mapping complex traits in founder populations.

Our aim was to find new genetic medium or low-penetrance breast cancer risk factors in an eastern Finnish population by identifying chromosomal regions that are associated with breast cancer. Our case-control set is from the province of Northern Savo in the late-settlement area of eastern Finland. This population is relatively young and genetically homogeneous. We used 435 autosomal microsatellite markers spaced by an average of 10 cM in a set of 49 breast cancer cases and 50 controls.

In the first-stage scan we found 21 markers in LD with breast cancer (P-values 0.003-0.046 in Fishers exact test). In the second-stage scan with markers flanking 21 positive loci four significant markers were found (P-values 0.013-0.046 in Fishers exact test). Haplotype analysis using global-score method with two, three or four markers also revealed four positive marker combinations (simulated P-value for global score 0.003-0.021). Our results suggest four breast cancer associated regions in three chromosomes in an eastern Finnish population.

Failure to Replicate Linkage of Hereditary Prostate Cancer to 20q13 in the ICPCG Family Collection. *B. Chang*¹, *D. Schaid*², *The International Consortium for Prostate Cancer Genetics*. 1) Ctr Human Genomics, Wake Forest Univ Sch Med, Winston-Salem, NC; 2) Division of Biostatistics, Mayo Clinic, Rochester, MN.

The International Consortium for Prostate Cancer Genetics (ICPCG) is an international collaborative effort to pool pedigrees with hereditary prostate cancer in order to replicate linkage findings for prostate cancer. A strength of the ICPCG is the large number of well-characterized pedigrees, allowing linkage analyses within large subsets. Given the heterogeneity and complexity of prostate cancer, the historical difficulties of synthesizing different studies reporting positive and negative linkage replication, and the use of different statistical analysis methods and different stratification criteria, the ICPCG provides a valuable resource to evaluate linkage for hereditary prostate cancer. To date, linkage of chromosome 20 (HPC20) to hereditary prostate cancer has been one of the strongest linkage signals, yet the efforts to replicate this linkage have been limited. This paper reports a linkage analysis of chromosome 20 markers for 1,234 pedigrees with multiple cases of prostate cancer ascertained through the ICPCG, and represents the most thorough attempt to confirm or refute linkage to chromosome 20. From the original 158 Mayo pedigrees in which linkage was detected, the maximum heterogeneity lod score, under a recessive model, was 2.78. In contrast, for the 1,076 pedigrees not included in the original study, the maximum heterogeneity lod score (recessive model) was 0.06. Although a few small linkage signals for chromosome 20 were found in various strata of this pooled analysis, in general this large study failed to replicate linkage to HPC20. This study illustrates the value of the ICPCG family collection to evaluate reported linkage signals and suggests that the HPC20 region does not make a major contribution to prostate cancer susceptibility. (Supported by PHS U01-CA89600).

Detection of ultra rare somatic mutations in the p53 gene by Bi-PAP-A. *J. Shi, Q. Liu, S.S. Sommer.* Department of Molecular Genetics and Molecular Diagnosis, City of Hope National Medical Center, Duarte, CA 91010-3000.

Ultra sensitive detection of somatic mutations can facilitate: i) early cancer detection; ii) cancer chemotherapy; and iii) assessment of environmental mutagen exposure. Bi-PAP-A (**B**i-directional **P**yrophosphorolysis **A**ctivated **P**olymerization **A**llele-specific Amplification) can detect mutations at 1 part per billion. The sensitivity of Bi-PAP-A derives from the serial coupling of pyrophosphorolysis and DNA polymerization. Eight Bi-PAP-A assays were developed for the p53 gene. Based on the IARC TP53 mutation database, four of them were hotspots of mutation in tumors. The sensitivity (minimum copies of the mutated template with a detectable mutated product), and specificity (maximum copy number of the wild-type template with undetectable product) of each assay were tested using mutated and wild type human genomic DNA extracted from blood samples. Low levels of somatic mutations were found at three assays that are not hotspots of mutation in tumor, indicating the frequency of somatic mutation in these samples was lower than 3 parts in 10^7 . For three of the assays, including two of the hotspots in tumors, the mutation frequency was approximately 1 part in 10^6 . For the remaining two assays, which were hotspots of mutation in p53 gene, frequency of somatic mutation was greater than 1 part in 10^4 . Inter-individual variation in mutation frequency can be dramatic, greater than 14 fold in some assays. The marked inter-locus and inter-individual variations in somatic mutation frequencies in the p53 gene have implications for human carcinogenesis. Bi-PAP-A is a convenient and general method that has the desirable properties of allele-specific PCR with a sensitivity that is typically enhanced by a million fold.

Complex segregation analysis and linkage mapping of nasopharyngeal carcinoma in Guangdong, China. *Y. Yao¹, W. Jia³, A. Collins², B.J. Feng³, X.J. Yu³, L.X. Huang³, Q.S. Feng³, P. Huang³, M.H. Yao⁴, F. Zhang³, W. Huang⁵, Y.X. Zeng³.* 1) Dept Epidemiology, Johns Hopkins Univ, Baltimore, MD, USA; 2) 3Human Genetics, University of Southampton, Southampton General Hospital, UK;; 3) Departments of Experimental Research , Cancer Center, Sun Yat-sen University, GuangZhou, China;; 4) Departments of Information, Cancer Center, Sun Yat-sen University, GuangZhou, China;; 5) Chinese National Human Genome Center at Shanghai, Shanghai, China.

The purpose of this study is to investigate the fit of single gene, polygenic and multifactorial models to the observed pattern of transmission of NPC in a hospital-based family history study conducted by the Cancer Center of Sun Yat-Sen University (CCSYU) in Guangzhou, China. Complex segregation analysis of a total of 1,903 Cantonese families ascertained at CCSYU was conducted using a unified mixed model after the pedigrees were partitioned into 3,737 nuclear families. The mixed model assumes that a phenotype is influenced by the additive and independent effect of a major gene, together with a multifactorial component (genetic and environmental) and a random environmental effect. Segregation analysis results do not provide strong evidence for a major gene and the observed data is best explained by a multifactorial mode of inheritance for NPC. We also performed a genome scan on 32 multiplex NPC families. A linkage signal was detected by parametric linkage analyses on chromosome 4 with a LOD score of 3.06 and HLOD of 3.21 at marker D4S405. Fine scale mapping with additional markers flanking D4S405 resulted in a LOD of 3.92 and HLOD of 3.99 for the region 4p15.1-q12. Furthermore, multipoint NPL analysis gave a LOD score of 3.54 at D4S405 and 4.2 at D4S3002, which is 4.5 cM away from D4S405. Our previous analyses indicated that a susceptibility locus on 4p15.1-q12 may account for a subset of hereditary NPC by linkage analysis although the location of the gene may not be precise due to limited sample size. Covariate-based linkage analysis will be performed to identify the source of heterogeneity. Information EBV infection and age of onset included in the model.

Methylation status of hMLH1 repair gene promoter in esophageal pathologies including cancer. *Y.R. Ahuja^{1,2}, M. Vasavi³, V. Bhavani⁴, B. Prabhakar⁵, P. Rupender⁴, B. Ravi Shankar³, S. Radha³, Q. Hasan^{3,4}*. 1) VMRC, Vasavi Hosp, Hyderabad, India; 2) Stem Cell & Mol Biol Lab, NIMS, Hyd, India; 3) Depts of Genetics & Mol Med, GE & Pathol, Kamineni Hosp, Hyd, India; 4) Depts of Genetics & Dept of GE, BMMRC, Hyd, India; 5) Dept of GE, Osmania Gen Hosp, Hyd, India.

More than 30 percent of the adult population suffers from esophageal pathologies. Esophageal cancer is one of the most fatal cancers in the world. Cancer may arise either by gene mutations or by epigenetic events like methylation that alter the gene expression status. The mismatch repair (MMR) system maintains genomic integrity and defects in MMR genes are responsible for genetic instability. Promoter hypermethylation of hMLH1 has been associated with increased genetic instability. The aim of this study was to assess the methylation status of the repair gene hMLH1 in esophageal cancer and other inflammatory pathologies of the esophagus. 67 individuals referred for endoscopy of the upper GI tract were enrolled in the study. Endoscopic biopsy material was sent for histopathological analysis and for molecular analysis. DNA extracted from biopsy was subjected to HpaII restriction digestion, amplified using primers specific for hMLH1 promoter by methylation specific PCR assay (MSP). Individuals were categorized by endoscopy and histopathology into cancer (30), esophagitis (23) and normal (14). MSP assay showed a hypermethylated hMLH1 promoter in 66.7% of cancer cases, 56.5% of cases with different grades of esophagitis and 21.4% of cases with dyspepsia with normal endoscopy. Chi-square test showed that hMLH1 hypermethylation was significantly higher in cancer and esophagitis compared to endoscopically normal tissue ($p < 0.005$, $p < 0.03$ respec). However, there was no significant difference between cancer and esophagitis. hMLH1 hypermethylation is known to cause defective DNA MMR resulting in genetic instability. Our results indicate that altered methylation at hMLH1 locus is not confined to esophageal cancer but is also seen in non-malignant inflammatory pathologies of the esophagus, suggesting that factors effecting repair are not cancer specific.

Analysis of epigenetic changes in *MGMT* gene in retinoblastoma tumors. *P. Kadam*¹, *Y.F.L. Ling*², *P.S. Lai*¹. 1) Paediatrics, National University Singapore, Singapore, Singapore, Singapore; 2) Singapore National Eye Centre, Singapore.

Retinoblastoma is a malignant childhood tumor caused by inactivation of *RB1* gene. *RB1* gene is commonly inactivated by point mutations and chromosomal mechanisms that result in loss of heterozygosity (LOH). Besides this, hypermethylation of the CpG rich island of *RB1* gene promoter has also been reported in retinoblastoma tumors. Recent studies have shown that other candidate genes may also be involved in tumorigenesis in retinoblastomas. The DNA repair gene, *MGMT* has been reportedly silenced by promoter hypermethylation in a number of cancers such as gliomas, non-small cell cancer of the lung, colorectal cancers and lymphomas. In this study, we investigated the presence of hypermethylation of *MGMT* promoter in retinoblastoma tumors in patients from Singapore. A series of 36 tumors was studied by methylation-specific PCR (MSP) analysis. Aberrant methylation of at least one *MGMT* locus was found in 9 (25%) retinoblastoma tumors which included 4 hereditary and 5 non-hereditary cases. Of the methylated samples, LOH in *RB1* locus was present in 7 tumors and point mutations were found in 8 tumors while hypermethylation of *RB1* promoter was found in 1 tumor only. We also investigated the presence of G>A transitions in *RB1* gene as previous reports have suggested that epigenetic silencing of *MGMT* may lead to this type of mutagenic effect. G>A transitions in *RB1* were found in 5 (55.5%) of tumors hypermethylated at *MGMT*. No significant correlation was found between *MGMT* hypermethylation and age of onset, tumor types or genetic mode of origin of disease. Thus, this study suggest that hypermethylation of *MGMT* is involved in retinoblastoma development but its occurrence does not seem to be preferentially associated with any inherited disease genotype or clinical phenotype.

Characterization of Cytosine Methylation in Lung Cancer using MALDI-TOF mass spectrometry. *D. van den Boom*¹, *M. Nelson*¹, *T. Liloglou*², *J. Field*², *M. Ehrich*¹. 1) Dept Molecular Biology, SEQUENOM, Inc, San Diego, CA; 2) Roy Castle Lung Cancer Research Programme, The University of Liverpool Cancer Research Centre, Liverpool, UK.

Methylation is considered to be one of the major epigenetic processes pivotal to our understanding of carcinogenesis. It is now widely accepted that there is a relationship between DNA methylation, chromatin changes and human malignancies. DNA methylation has the potential to become an important clinical marker in cancer molecular diagnostics. We applied a novel method for high throughput DNA methylation analysis that utilizes MALDI-TOF mass spectrometry (MS) analysis of base-specifically cleaved amplification products for the characterization of cytosine methylation differences between normal and neoplastic lung cancer tissue. In a candidate gene approach, we selected 47 CpG islands covering over 1426 CpG positions and compared the relative methylation ratio in 48 non-small cell lung cancer (NSCLC) samples with their corresponding adjacent normal tissue. Our study demonstrates that base-specific cleavage analyzed by MALDI-TOF MS provides an elegant means to identify methylated sites in a high-throughput fashion. At the same time, the method allowed us to quantitate the ratio of methylation at each CpG individually or at groups of CpGs. We will show that hierarchical clustering based on these methylation ratios allows separation of tumor samples and normal tissue. Furthermore, we applied tree-based procedures to isolate CpG positions that allow for classification of samples with high accuracy.

Correlation of CHEK2 Protein Expression and 1100delC Mutation Status with Tumor Characteristics among Unselected Breast Cancer Patients. *O. Kilpivaara¹, J. Bartkova², H. Eerola^{1, 3}, K. Syrjäkoski⁴, P. Vahteristo¹, J. Lukas², C. Blomqvist^{3, 5}, K. Holli⁶, P. Heikkilä⁷, G. Sauter⁸, O.-P. Kallioniemi⁹, J. Bartek², H. Nevanlinna¹.* 1) Dept. Obstetrics & Gynecology, Helsinki University Central Hospital (HUCH), Helsinki, Finland; 2) Inst. Cancer Biology, Danish Cancer Society, Copenhagen, Denmark; 3) Dept. Oncology, HUCH; 4) Lab. Cancer Genetics, Inst. Medical Technology, Tampere University and Tampere University Hospital, Finland; 5) Dept. Oncology, Uppsala University Hospital, Sweden; 6) School of Medicine, Tampere University and Tampere University Hospital, Finland; 7) Dept. Pathology, University of Helsinki; 8) Inst. Pathology, University of Basel, Switzerland; 9) Medical Biotechnology, VTT Technical Research Centre of Finland and University of Turku, Finland.

The CHEK2 kinase is a tumor suppressor whose activation in response to DNA double strand breaks contributes to cell cycle arrest or apoptosis. The 1100delC mutation is associated with familial breast cancer, and tumors from mutation carriers show reduced or absent CHEK2 protein expression. We have here studied CHEK2 protein expression by immunohistochemistry on a tissue microarray of 611 unselected breast tumors, and also evaluated the tumor characteristics among 1297 unselected breast cancer patients defined for the 1100delC germ line mutation status (2.5% carrier frequency). CHEK2 protein expression was reduced in 21.1% of the unselected breast cancers studied. Tumors with reduced CHEK2 expression had more often larger primary tumor size (pT3-pT4, $p=0.002$) compared to tumors with normal staining. A similar trend for larger tumor size was seen among the 37 breast tumors from 1100delC germ line mutation carriers. Tumors from 1100delC mutation carriers were of higher grade than those of non-carriers ($p=0.02$). The 1100delC germ line mutation also associated strongly with bilateral breast cancer. No significant correlation was seen between CHEK2 status and hormone receptor status, histology, lymph node status, or overall survival. The reduction or loss of CHEK2 function may contribute to progression of breast carcinomas.

Association between sequence variation at the human Frizzled-1 (*FZD-1*) locus and prostate cancer. C.H. Bunker¹, S.P. Moffett¹, J.P. Oakley¹, C.S. Nestlerode¹, A.L. Patrick², J.M. Zmuda¹. 1) University of Pittsburgh, Pittsburgh, PA; 2) Tobago Health Studies Office, Scarborough, Tobago.

Inappropriate activation of the canonical Wnt/-Catenin signaling pathway has been identified as an important feature in human neoplasia. Canonical Wnt-signaling is mediated through a family of integral membrane receptors known as Frizzleds, which activate target gene transcription via downstream -Catenin. The Frizzled-1 mRNA is highly expressed in adult prostate and the *FZD-1* locus maps to human chromosome 7q21, where modest evidence for linkage to hereditary prostate cancer has been reported (M. Janer et al., *The Prostate* 57:309, 2003). We directly sequenced 3.3 kb of the human *FZD-1* locus using genomic DNA extracted from peripheral blood mononuclear cells from 24 men with prostate cancer and 24 negative controls. All men were participants in the Tobago Prostate Survey, an ongoing population-based screening study of Afro-Caribbean men between the ages of 40-79 years on the island of Tobago. To date, 3083 of 5121 eligible men in the population have been screened with serum prostate specific antigen (PSA) and digital rectal examination (DRE) yielding a 10% prevalence of screening detected prostate cancer. We identified a CCG (Proline) repeat (range 4-5 repeats) at Codon 89, and 23 single nucleotide polymorphisms (SNPs). Fifteen of the SNPs were located within a 650bp region upstream from translation start site. In preliminary genetic association analyses of the most common allelic variants (minor allele frequency 0.04), four of the five common variants showed statistically significant evidence (P<0.05) of allele frequency difference between cases and controls. Three of these four variants were located in the putative 5' promoter region. Five proline repeats were observed in 56% of cases compared with 34% of controls (p<0.05). In conclusion, we have identified several common allelic variants at the human *FZD-1* locus. Preliminary analyses suggest a novel association with prostate cancer in men of African origin. Further studies with larger sample size and additional markers within and flanking the *FZD-1* locus are needed to confirm these results.

Detection of large rearrangement mutations in *BRCA1* and *BRCA2* in 528 high risk families from North America by quantitative PCR based gene dose analysis. *T. Judkins, B.C. Hendrickson, D. Gonzales, K. Eliason, J. McCulloch, B.E. Ward, T. Scholl.* Myriad Genetic Laboratories, Salt Lake City, UT.

Large rearrangement mutations are estimated to account for 5-10% of all mutations in *BRCA1* and *BRCA2*. For point mutations in the *BRCA* genes, North American hereditary breast/ovarian cancer patients carry a broader spectrum of mutations in comparison with many European populations where founder mutations can predominate. Prevalent founder rearrangement mutations have also been described in European patients. Here, the spectrum and prevalence of rearrangement mutations in the *BRCA* genes was determined in a set of high risk North American patients. Five hundred twenty-eight anonymous specimens that were negative by clinical direct DNA sequencing of *BRCA1* and *BRCA2* were selected for study. These patients were affected with breast or ovarian cancer before fifty years of age and reported at least two family members affected with cancer. Genomic DNA from these patients was analyzed by multiplexed quantitative PCR assays to determine gene dose across both *BRCA1* and *BRCA2* by interrogating all exons and the promoters of both genes. Approximately 6% of patients carried rearrangement mutations, corresponding to approximately 14% of all mutations when mutations detected by sequencing are included for patients similarly stratified. The most common rearrangement detected was a *BRCA1* duplication of exon 13 which accounted for over one-third of all the rearrangements detected. This particular mutation is known to be prevalent in patients with various ancestries. Novel rearrangement mutations were among others detected and included the duplication of exons 5-13 in *BRCA1*, the complete deletion of *BRCA1*, and the deletion of exons 1-23 of *BRCA1*. These results concur with previous reports on the prevalence of rearrangement mutations.

Macronodular adrenocortical hyperplasia associated with an inactivating mutation of the fumarate hydratase gene and loss of its 1q42.3-43 locus. L. Matyakhina¹, R.J. Freedman^{1, 2}, I. Bourdeau¹, A. Chidake², M. Walther³, J. Toro⁴, W.M. Linehan³, C.A. Stratakis^{1, 2}. 1) Developmental Endocrinology Branch, NICHD, Bethesda, MD; 2) Inter-Institute Endocrinology Training Program, NICHD, Bethesda, MD; 3) Surgical Urology Branch, NCI, Bethesda, MD; 4) Section on Electron Microscopy, Laboratory of Pathology, NCI, Bethesda, MD.

Hereditary leiomyomatosis and renal cell cancer (HLRCC) is an autosomal dominant disorder characterized by cutaneous and/or uterine leiomyomas, occasional leiomyosarcomas, renal cancer, and possibly other tumors. Recently, mutations in the fumarate hydratase gene (*FH*), on chromosome 1q42.3-43, have been found to be responsible for this disorder in a number of kindreds. Massive macronodular adrenocortical disease (MMAD) or ACTH-independent macronodular adrenal hyperplasia (AIMAH) is a heterogeneous condition associated with Cushing syndrome (CS) and bilateral enlargement or adenomas of the adrenal glands. In MMAD, cortisol secretion is often mediated by gastric inhibitory polypeptide (GIP), vasopressin, catecholamines, and other hormones due to aberrant, adrenocortical expression of their receptors. Although this mechanism may underlie pathophysiology of CS in the majority of CS cases, no consistent genetic defects have been identified in the few families with MMAD that have been reported. We report the case of a patient with HLRCC with a novel, inactivating *FH* mutation, who presented with atypical, periodic CS due to bilateral, ACTH-independent adrenocortical hyperplasia. Clinical and histological investigations showed features consistent with MMAD. The tumor tissue harbored the germline *FH* mutation and demonstrated allelic losses of the 1q42.3-43 *FH* locus. We conclude that in an HLRCC patient bilateral adrenal enlargement and CS were due to MMAD. This pathology was most likely due to the *FH* germline mutation because in tumor cells only the mutant allele was retained, consistent with the Knudsons hypothesis and *FH*'s tumor suppressor role. HLRCC should be added to the growing list of monogenic disorders that may be associated with a genetic predisposition to the development of adrenocortical tumors.

Evaluation of *RAD51* alterations and *BRCA2* BRC variants in hereditary susceptibility to breast and ovarian cancer. *K. Rapakko, S.-M. Karppinen, K. Heikkinen, R. Winqvist.* Dept Clinical Genetics, University of Oulu/OYS, Oulu, Finland.

Breast and ovarian cancer are among the most frequent malignancies affecting women, and about 5-10% of the cases appear to be due to inherited mutations in various cancer susceptibility genes. *BRCA1* and *BRCA2* mutations are particularly important in families with a large number of early-onset cancers, but play a much lesser role in smaller cancer families and in families without cases of ovarian cancer, thus indicating involvement of additional cancer susceptibility genes. In addition, variation in disease penetrance has frequently been observed among *BRCA1* and *BRCA2* mutation carriers, suggesting the influence of cancer risk modifying factors.

BRCA2 regulates the activity of *RAD51*, the human homolog of *E. coli* RecA. The interaction occurs through the conserved BRC repeat motifs of *BRCA2*. The *BRCA2-RAD51* complex is essential for homology-dependent recombinational repair of DNA double-strand breaks that occur frequently in dividing cells. Erroneous repair of these lesions can lead to cancer. In the current study we have screened 192 patients of 129 Finnish breast and ovarian cancer families for possible cancer associated germline mutations in the *RAD51* gene, and also specifically in the BRC motifs of the *BRCA2* gene. Furthermore, we have elucidated the role of the previously described 135G>C single-nucleotide polymorphism in the 5 untranslated region of *RAD51* on cancer predisposition.

Mutational Analysis of HPC1/RNASEL and the Macrophage Scavenger Receptor 1 Genes in Asian-Indian Sporadic Prostate Cancer and Benign Prostatic Hyperplasia. *H. Rennert¹, C. Sadowl¹, M.J. Finley¹, R. Mittal², A. Mandhani², T.R. Rebbeck¹, B. Mittal².* 1) University of Pennsylvania, Philadelphia, PA; 2) Sanjay Gandhi Post Graduate Institution of Medical Sciences, Lucknow, India.

The HPC1/RNASEL gene on 1q25 and the Macrophage Scavenger Receptor1 (MSR1) on 8p22 were recently reported as candidate genes for hereditary prostate cancer. We evaluated the role of these genes in prostate cancer risk in the Asian-Indian population. DNA samples from 90 Asian-Indian patients with sporadic prostate cancer and 58 patients with benign prostatic hyperplasia as well as 47 age-matched controls were genotyped using the Wave (Transgenomic) DHPLC system and sequencing. In RNASEL, a total of 8 variants were identified including, 4 exonic (151insCAAT, 1078A>G, 1260C>T and 1623T>G) and 4 intronic (IVS1+59A>G, IVS4+4T>C, IVS5-27T>C and IVS6+47G>A) changes. The 4-bp insertion mutation, 151insCAAT, at codon 151 in RNASEL exon 1, results in a premature truncation at codon 157. This mutation was present in approximately 1% of the study subjects. Of the 4 exonic changes, one previously reported common missense change (Asp541Glu) was identified. The common RNASEL missense variant, Arg462Gln, was not identified in this study. In MSR1, a total of 7 variants were identified including, 4 exonic (171C>T, 542T>A, 732G>A and 823C>G) and 3 intronic (5UTR-33A>G, IVS2-10G>A and IVS7+36G>A) changes. Of the 4 MSR1 exonic changes, only Pro275Ala was previously reported. No deleterious mutations were detected in MSR1. These results demonstrate that sequence variants in these genes also exists in Asian-Indian populations, however, their pattern and distribution is different than those reported for other populations. Further studies, however, are needed to determine their role in prostate cancer etiology in Asian-Indians.

Identification of NF1 Gene Mutations Using Universal Microarray-based Combinatorial Sequencing-by-Hybridization. A. Schirinzi^{1,2}, S. Drmanac³, S. Huang³, D. Swanson³, R. Drmanac³, A. De Luca², B. Dallapiccola², S. Surrey¹, P. Fortina¹. 1) Department of Medicine, Thomas Jefferson University, Philadelphia, PA; 2) Dipartimento di Medicina Sperimentale e Patologia, Universita' La Sapienza and Istituto CSS Mendel, Rome, Italy; 3) Callida Genomics, Sunnyvale, CA, USA.

Neurofibromatosis type 1 (NF1) is a common autosomal dominant disorders occurring with a frequency of 1 in 3500 individuals. The disease results from mutations in the NF1 gene which encodes neurofibromin, a negative regulator of the ras-dependent pathway. Mutation detection presents a considerable challenge due to the large size of NF1 gene and the presence of pseudogenes. Here we demonstrate a method to detect mutations in the NF1 gene using an array-based approach referred to as combinatorial sequencing-by-hybridization (cSBH). A universal probe set (i.e., all possible 6-mers) is arrayed on a glass slide and a second probe set (i.e., all possible 5-mers) is in solution and labeled with a fluorophore. Ligation occurs only when a complementary DNA strand from the patients PCR product anneals to both array-bound and solution phase, labeled probe. After ligation, 11 nt long positive labeled probes are created and detected using a standard arrayer which scores fluorescent signals at each register. Software then deduces the DNA sequence by a tiling approach in which the same regions are sequenced in multiple overlapping 11-mer probes. We generated 25 PCR products of 150-584 bp from patient DNA to confirm mutations previously identified by DHPLC and direct DNA sequence analysis. Furthermore, using cSBH, we analyzed the entire gene coding region (~12 kb) by pooling of PCR products encompassing the 60 exons from the NF1 gene. Continuous sequence readout of up to 3.6 kb was obtained on a single slide. Using this approach, we confirmed NF1 gene mutations in all 25 patient samples. The universal chip used for cSBH successfully detects base substitutions, insertions, and small deletions. Also, by using cSBH, analysis of the entire NF1 gene is fast and efficient, reducing time and cost. cSBH is a viable alternative to current techniques used in many diagnostic laboratories requiring DNA sequence characterization.

Profiling multigenic variation in androgen pathway as a risk factor for prostate cancer. E. Seppala¹, N. Mononen¹, T. Ikonen¹, V. Autio², P. Ellonen³, J. Saharinen³, J. Saarela³, M.P. Matikainen⁴, T.L.J. Tammela⁴, O. Kallioniemi⁵, J. Schleutker¹. 1) Lab of Cancer Genetics, Inst Medical Technology, Univ of Tampere and Tampere University Hospital, Finland; 2) Research Unit, Tampere Univ Hospital, Finland; 3) Dept of Molecular Medicine, National Public Health Inst, Helsinki, Finland; 4) Div of Urology, Tampere Univ Hospital and Medical School, Univ of Tampere, Finland; 5) Technical Res Centre and Univ Turku, Finland.

In order to study the impact of genetic variation along the androgen pathway on prostate cancer (prca) risk we have so far screened eleven candidate genes (*SRD5A2*, *CYP17*, *CYP19*, *HSD3B1*, *HSD3B2*, *HSD17B2*, *HSD17B3*, *HSD17B5*, *CYP11A*, *KLK3*, *ARSDR1*) for germ line mutations and polymorphisms using 64 DNA samples from Finnish prca patients by SSCP. In previous reports, many genes along this pathway have been associated with prca risk but the analyses have been carried out in rather limited sample sets. Here, the found variants were genotyped in an extensive set of 1892 samples using either allele specific primer extension on micro array or TaqMan 5nuclease assay. The allele frequencies of the variants are compared in cases of unselected prca (n=848, diagnosed in Pirkanmaa district in 1999-2001), familial prca (n=121) and population controls (n=923). Our main goal is to find out the multivariant joint effects. Preliminary results from separate analyses of the *HSD17B5* gene variants suggested that P180S may have a protective role (OR=0.7, p=.060) whereas Q5H did not associate with the cancer risk (OR=0.9, p=.375). Likewise, no statistically significant association between prca risk and any of the other variants tested so far (*SRD5A2* V89L and A49T, *LHB* I15T, *AR* R726L, *CYP17* -34T>C, *HSD17B2* A111T or *KLK3* D102N) was observed. However, the T201M variant of the *CYP17* gene did associate with prca risk (controls *versus* unselected cases, OR= 2.0, p=.04). We also tested the joint effect of the two *SRD5A2* variants by comparing the frequencies of AA/LL genotype *versus* AT+TT/VL+VV among the unselected prca cases (n=80, n=40, respectively) and controls (n=82, n=46, respectively) but no statistically significant effect was observed (p= 0.7).

Population based study of HNPCC mutations in Newfoundland. *P.A. Williams¹, M.O. Woods¹, R.C. Green¹, J.R. McLaughlin², P.S. Parfrey³, H.B. Younghusband¹*. 1) Genetics, Memorial University, St. John's, NL, Canada; 2) Mount Sinai Hospital, Toronto, ON, Canada; 3) PRC, Memorial University, St. John's, NL, Canada.

Hereditary Non-Polyposis Colorectal Cancer (HNPCC) is an autosomal dominant condition that increases an individual's lifetime risk of developing cancer. HNPCC is caused by mutations in genes in the Mismatch Repair (MMR) pathway. Five genes have been found to contain HNPCC causing mutations - *MLH1*, *MSH2*, *MSH6*, *MSH3*, and *PMS2*. Mutations in *MLH1*, *MSH2* and *MSH6* account for 95% of HNPCC cases. The Newfoundland Colon Cancer Registry (NFCCR) was created to accumulate molecular, as well as family history data, for the population of Newfoundland for the purpose of identifying those who are at high risk for hereditary cancer. All colorectal cancer patients diagnosed from 1999 to 2003 were invited to participate in the registry. Upon completion the registry will consist of approximately 600 probands, with accompanying molecular data. All participants have had a DNA sample banked and their tumours have been characterized for microsatellite instability (MSI), a hallmark feature of HNPCC. As well, immunohistological data for *MLH1*, *MSH2* and *MSH6* has been obtained. The risk status of the patients was determined as high risk if they fulfilled any of the following criteria: 1) belonging to a high family risk category such as Amsterdam I or Amsterdam II, 2) tumour samples which had deficient staining for one of the three MMR proteins listed above, or 3) tumour samples displaying MSI. Those identified as high risk were then subjected to mutation analysis. Samples were initially tested for large genomic deletions in *MLH1* and *MSH2* via Multiplex Ligation-dependent Probe Amplification (MLPA). Samples negative for a deletion were tested for the *MSH2* IVS5+3AT mutation, common in the Newfoundland population, by Restriction Fragment Length Polymorphism. Samples showing no mutation for the first two methods were then screened for mutations by direct sequencing of *MLH1*, *MSH2* and *MSH6*. To date, 113 samples have been tested via MLPA, and have shown no deletions. One of the samples had the *MSH2* IVS5+3AT. Currently, automated sequencing has been undertaken for *MLH1*, *MSH2*, and *MSH6*.

High Resolution Analysis of OSCCs Using the Whole Genome SMRT Array. *C.S.M. Baldwin¹, C. Garnis¹, M.P. Rosin¹, L. Zhang², W.L. Lam¹.* 1) Cancer Genetics, BC Cancer Research Centre, Vancouver, BC; 2) 2Department of Oral Biological & Medical Sciences, University of British Columbia, Vancouver, BC.

Each year, there are ~300,000 cases of oral squamous cell carcinoma (OSCC) world-wide. Most cases are not diagnosed or treated until the advanced stages of disease, resulting in a 5-year survival rate of just 50%. If diagnosed at the pre-malignant stages, prognosis and survival rates improve. Identification of novel genetic alterations in OSCCs will provide new targets for early diagnosis and treatment. LOH studies on OSCCs have identified the earliest genetic alterations to occur on 9p, 3p and 17p. However, LOH is not designed to distinguish copy number gains from losses and the resolution is limited. Conventional CGH, although able to distinguish between copy number increases and decreases, also has limited resolution. We present a new genome-wide approach to fine-map alterations with ~80kb resolution to identify novel genes involved in OSCC. **OBJECTIVE:** The objective of this study is to detect novel regions of alteration in OSCCs using our high resolution human whole genome BAC array CGH technology in order to elucidate the genetic mechanisms underlying OSCC. **METHODS:** We utilized the Submega Base Resolution Tiling-set (SMRT) array comprised of 32,433 over-lapping BAC clones spanning the entire human genome. DNA from each BAC clone was PCR-amplified and spotted in triplicate onto two glass slides. OSCC DNA and normal reference DNA were labeled with cyanine-dyes, co-hybridized onto the SMRT array, and scanned for each dye to determine the hybridization signal intensity ratios for each loci. The data was plotted to reveal copy number gains and losses across the entire human genome. **CONCLUSION:** We profiled 20 OSCCs using the SMRT array. Alignment of genomic profiles revealed recurrent known (3p, 9p, 11q, 7p) and novel alterations. Genome profiling OSCCs using the SMRT array revealed novel and known copy number alterations. Further expression analysis will elucidate the biological mechanisms underlying OSCC progression. This work was supported by funds from Genome Canada/BC, CIHR and NICDR.

Screening for germline mutations in the *PTEN*, *MSR1* and *KLF6* genes in prostate cancer patients. A. Bar-Shira¹, H. Matzkin^{2,3}, N. Matarasso^{1,3}, S.D. Bercovich¹, A. Orr-Urtreger^{1,3}. 1) Genetic Institute; 2) Department of Urology; Tel Aviv Sourasky Medical Center; 3) Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel.

Prostate cancer is the most commonly diagnosed malignancy in men in the western world, including Jewish men in Israel, and one of the leading causes of cancer-related death. Multiple risk factors including age, race, environmental exposure and a positive family history contribute to the high incidence of prostate cancer. Despite the sporadic nature of this disease, 10-15% of men with prostate cancer have one or more affected first-degree relatives. At least ten genome-wide linkage scans in hereditary prostate cancer families have revealed prostate cancer-susceptibility chromosomal loci possibly harboring candidate hereditary prostate cancer genes. Mutations in these genes likely account for 9% of prostate cancer diagnosed in men through age 85. The Jewish population, with its unique structure and origin, has been most valuable for the identification of cancer predisposition mutations. All cancer-susceptibility founder mutations detected in Jews were identified in genes associated with cancer in the population-at-large. *PTEN*, *MSR1* and *KLF6* genes were recently suggested as candidate susceptibility genes for hereditary and sporadic prostate cancer. In order to identify germline mutations and polymorphisms in these genes, DNA from 300 Ashkenazi and non-Ashkenazi Jewish prostate cancer patients was screened using DHPLC. The sequence of the *MSR1* gene was intact in all patients. Two sequence variations were detected in the *PTEN* gene, a missense and a silent mutation. In the *KLF6* gene, five changes were detected in 17 patients, including a pre-mature stop codon and a missense mutation. Our results suggest that germline mutations in the *MSR1* and *PTEN* genes do not play a role in hereditary susceptibility to prostate cancer in Jews, and that mutations in *KLF6* may occasionally be found in these patients. These results further emphasize the complexity of the genetic background for prostate cancer pathogenesis.

Extending the basal phenotype of BRCA1-related breast cancer: relevance for the re-classification of breast cancer. *J.S. Brunet^{1,2}, J. Arnes³, T. Nielsen⁴, D. Huntsman⁴, N. Wong⁵, L.R. Bgin⁶, L.A. Akslen³, W.D. Foulkes^{1,5}.* 1) Prog. in Cancer Genetics, McGill Univ. Montreal, QC, Canada; 2) Algorithmic Pharma, Laval, QC, Canada; 3) The Gade Institute, Haukeland University Hospital, Bergen, Norway; 4) Div. Medical Genetics and BC Cancer Agency, Univ. British Columbia, Vancouver, BC, Canada; 5) Cancer Prevention Centre, SMBD-Jewish General Hospital, Montreal, QC, Canada; 6) Sacre Coeur Hospital, Cartierville, QC, Canada.

BRCA1-related breast cancers are associated with the expression of cytokeratin (CK5/6), thus such tumours could be described as basaloid. Other markers e.g. cyclin E, p27 and glomeruloid microvascular proliferation are also associated with both CK5/6 expression and BRCA1 mutations and all three are independent adverse prognostic factors following breast cancer. In this study, we extended the basal phenotype by studying three other markers: EGFR, P-cadherin and MDM2. We used our existing retrospective cohort of 292 Ashkenazi Jewish breast cancer patients who have been tested for BRCA1 mutations. For EGFR and MDM2, a tissue microarray of 230 cases was used, for P-cadherin (P-cad), standard slides were used.

We found that both EGFR and P-cad were strongly associated with both CK5/6 and BRCA1 (ORs > 6.0 for all comparisons) but notably, cytoplasmic MDM2 staining was more strongly associated with some features of the basal phenotype (CK5/6, cyclin E, ORs >7.0, both P values <.0001) than with others (BRCA1 mutation, OR = 2.1, P = .18), implying a BRCA1-associated and a non-BRCA1-associated basal pathway. Furthermore, as noted for tumours expressing CK5/6 and/or carrying BRCA1 mutations, P-cad did not obey the size-nodes rule, in that large P-cad-positive breast cancers were not more likely to be node-positive than are small ones. In a multivariable Cox model including interaction terms for P-cad, tumour size and nodal status, P-cad was only associated with a poor prognosis in small, node-negative breast tumours, supporting the concept that basaloid breast cancers possess biological features that differentiate them from other types of breast cancer. This could be relevant both for the diagnosis and treatment of such cancers, and for BRCA1/2 testing prioritisation.

Cancer risk modifying effect of BARD1 SNPs in women carrying a BRCA1 mutation. *I. Coupier¹, D. Hughes², P-Y. Cousin¹, V. Gaborieau², D. Goldgar², O. Sinilnikova^{2,3}, D. Stoppa-Lyonnet¹, and. Groupe Genetique et Cancer⁴.* 1) Genetique Oncologique, Institut Curie, Paris, France; 2) Unite Epidemiologie Genetique, Centre de Recherche International sur le Cancer, Lyon, France; 3) Plate-forme mixte de genetique constitutionnelle des cancers frequents, HCL/CLB, Lyon, France; 4) B Bressac-de-Paillerets, A Chompret, YJ Bignon, JP Peyrat, J Fournier, C Lasset, S Giraud, D Muller, JP Fricker, A Hardouin, P Berthet, C Maugard, C Nogues, R Lidereau, M Longy, S Olschwang, C Toulas, R Guimbaud, S Mazoyer, G Lenoir.

Germline mutations in the BRCA1/2 genes strongly predispose heterozygous carriers to breast and ovarian cancer. The penetrance of these cancers is highly variable both between and within BRCA1/2 mutation carrier families. Such variations suggest that cancer risk associated with BRCA1/2 mutations can be modified by environmental and/or genetic factors. BRCA1 is a large protein with various interacting protein partners. Variants in the genes coding these proteins are thus good candidates to be modifier genetic factors. We have focused on SNPs of BARD1, whose protein interacts with the ring domain of BRCA1 and has an ubiquitin ligase activity. The study included 682 women recruited and identified as carriers of BRCA1 germline mutations. Of these 682 women, 110 have been diagnosed with ovarian cancer, 339 with breast cancer, 62 with both breast and ovarian cancers, and 171 women were breast and ovarian cancer free at the time of the last follow-up. Clinical characteristics of these women were available. Five BARD1 coding SNPs: P24S, T351T, R378S, H506H, V507M and, one non coding SNP, IVS5-14 A/G, were analysed. The SNPs were typed by TaqmanTM (ABI) using the ABI Prism 7700 Sequence Detection System or direct sequencing. The data were analysed by disease free survival analysis using a Cox proportional hazards model. A borderline significant association of the IVS5-14 A/G BARD1 variant with risk of ovarian cancer (HR = 1.9; CI = 1.20-2.68) was found. The identification of modifying factors on breast cancer risk in BRCA1 mutation carriers should help to refine individual risk estimation and might be helpful for clinical management.

Evaluation of RIZ in 1p36 as a Tumour Suppressor Gene for Pheochromocytomas and Abdominal

Paragangliomas. *J. Geli¹, B. Nord¹, T. Frisk¹, E. Edstrom Elder², T.J. Ekstrom³, T. Carling⁴, M. Backdahl², C.*

Larsson¹. 1) Center for Molecular Medicine, Karolinska Institute, Stockholm, Sweden; 2) Department of Surgery, Karolinska Hospital, Stockholm, Sweden; 3) Department of Clinical Neuroscience, Center for Molecular Medicine, Karolinska Institute, Stockholm Sweden; 4) Department of Surgery, Uppsala University Hospital, Uppsala, Sweden.

Pheochromocytomas and abdominal paragangliomas are rare catecholamine-producing tumours arising from neural crest derived chromaffin cells. Frequent deletions of several distinct regions on the short arm of chromosome 1, suggest their involvement in the tumorigenesis process. One potential candidate gene is the RIZ1 tumour suppressor in 1p36. A panel of 18 pheochromocytomas (10 benign, 4 malignant, 4 hereditary), and 11 abdominal paragangliomas (4 benign, 7 malignant) were characterised for somatic deletions and mRNA expression status of RIZ using loss of heterozygosity (LOH) analysis and real time quantitative PCR, respectively. Furthermore we have evaluated the RIZ1 promoter CpG island for methylation utilizing methylation specific PCR (MSP). Intragenic LOH at RIZ was detected in 10 of the 16 informative cases (63%) including 8 out of 12 pheochromocytomas (67%), and in 2 out of 4 paragangliomas (50%). RIZ1 mRNA appeared to be significantly underexpressed in the tumor samples compared to normal controls. We could not demonstrate RIZ1 promoter methylation in any of the samples indicating that promoter hypermethylation is unlikely to be the underlying cause to the frequent expressional silencing. The recurrent inactivation of the putative tumor suppressor RIZ1 suggests that this event may be a significant contributing factor to the tumour development in pheochromocytomas and abdominal paragangliomas.

Altered expression of cytokinesis gene, *SEPT9*, in breast cancer cells. *M.E. Gonzalez, L.M. Kalikin, E.M. Petty.* Int Med, Univ Mich, Ann Arbor, MI.

SEPT9 belongs to a highly conserved family of septins. It is essential for cell division and is implicated in leukemia. We cloned *SEPT9* from a region of allelic imbalance in breast and ovarian cancers. Its homologous to a murine proto-oncogene, *Sept9*, involved in lymphomas. *Sept9* is amplified and overexpressed in MMTV-pTg mammary adenocarcinomas. We hypothesized that altered expression of *SEPT9* variants might contribute to human breast cancer. To explore *SEPT9*'s role we examined endogenous expression of *SEPT9* variants in breast cancer cells and ectopic expression of isoforms in *in vitro* models. Semi-quantitative duplex PCR and Southern blot analysis demonstrated significant *SEPT9* amplification in 11 of 18 breast cancer cell lines (BCCs) compared to 0 of 4 immortalized normal human mammary epithelial cell lines (IHMECs) (p0.05). *SEPT9* was highly expressed in 60% of BCCs versus 25% of IHMECs by semi-quantitative duplex RT-PCR. High expression of *SEPT9v1*, *SEPT9v2*, and *SEPT9v4* was seen in BCCs compared to IHMECs. *SEPT9v3* and *SEPT9v5* were expressed in few BCCs and IHMECs. No sequence alterations were found to explain expression patterns. Using our polyclonal *SEPT9v1* Ab and a polyclonal *SEPT9* Ab that recognizes all isoforms (from W. Trimble), we analyzed immunoblots for protein expression and found high *SEPT9v1* expression in many BCCs compared to IHMECs (p0.025). *SEPT9*, *SEPT9v1*, and *SEPT9v2*-FLAG retroviral constructs were generated to express isoforms in epithelial cell culture models. Most notably, expression of pLNCX2-*SEPT9* and pLNCX2-*SEPT9v1*, but not vector controls, in RK3E and A2780 cells strikingly changed rounded epithelial phenotypes to elongated spindle shaped ones. Ectopic expression of *SEPT9v1*, not *SEPT9* or *SEPT9v2*, significantly increased invasiveness through a basement membrane matrix (Matrigel) compared to controls. Taken together, these findings suggest that preferential expression of alternatively spliced forms of *SEPT9* are important in breast cancer and specifically, that increased expression of *SEPT9v1* may contribute to malignant progression. Further studies are underway to explore this hypothesis and elucidate how altered expression of *SEPT9* variants arise and may impact cell division to drive oncogenesis.

Preliminary evidence for a prostate cancer susceptibility gene on chromosome 7p12.1 using unselected Ashkenazi

Jewish prostate cancer cases. *N. Hamel*^{1,4}, *K. Kotar*^{1,2,4}, *C.M. Greenwood*³, *W.D. Foulkes*^{1,2,4}. 1) Dept. Medicine, Montreal General Hosp, McGill Univ., Montreal, QC, Canada; 2) Cancer Prevention Centre, SMBD-Jewish General Hospital, McGill Univ., Montreal, QC, Canada; 3) Genetics and Genomic Biology, Hospital for Sick Children, Toronto, ON, Canada; 4) Program in Cancer Genetics, McGill Univ. Montreal, QC, Canada.

Prostate cancer is a common malignancy for which no clear susceptibility genes have been identified. Numerous genome-wide scans have indicated that prostate cancer is likely to be extremely heterogeneous genetically. Confining analysis to isolated populations with a limited number of founders can reduce locus heterogeneity and thereby increase detection power. Using this approach, a potential prostate cancer susceptibility locus was recently reported to exist on chromosome 7q11-21 by linkage analysis for 36 Ashkenazi Jewish (AJ) families.

Using the same rationale, we have been assembling a series of AJ prostate cancer cases unselected for family history. We are currently testing 160 cases and a group of 200 Israeli controls for 12 microsatellite markers on chromosome 7 for which significant linkage results were reported from fine mapping in the above analysis of AJ families. Preliminary results were obtained from a subset of cases and controls using the program PHASE (version 2.1) for 7 of the 12 markers (D7S1818, D7S1830, D7S502, D7S3046, D7S634, D7S2212, D7S820), spanning a 39-megabase interval. With 90 cases/90 controls, the overall permutation P value for all 7 markers was .00667. For p-arm markers D7S1818 and D7S1830 alone, and no exclusions for missing data, the P value was .0025 (400 permutations), whereas for the five q-arm markers D7S502 to D7S820, the P value was 0.36. When we compared the allele frequencies in cases and controls at each marker, only D7S1830 gave a significant result: χ^2 (6 DF) = 43.8, $P < .0001$. These preliminary findings, combined with reported HLOD data obtained from AJ families, suggest that a prostate cancer susceptibility gene may be located on 7p12.1.

TBX3 and its isoform, TBX3+2a, are Functionally Distinctive in Inhibition of Senescence and are Overexpressed in a Subset of Breast Cancer Cell Lines. *T. Huang¹, W. Fan¹, X. huang¹, C. Chen², J. Gray².* 1) Div Human Genetics, Univ California, Irvine, Irvine, CA; 2) Laboratory Medicine and Radiation Oncology, Cancer Genetics and Breast Oncology, UCSF Comprehensive Cancer Center, University of San Francisco, San Francisco, CA and Life Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA.

TBX3 is a transcription factor of the T-box gene family. Mutations of TBX3 cause Ulnar-Mammary syndrome (UMS, MIN 181450) in humans, an autosomal dominant disorder characterized by the absence or underdevelopment of the mammary glands and other congenital anomalies. Recently, it was found that TBX3 was able to immortalize mouse embryo fibroblast cells. In addition, TBX2, a homologue of TBX3, is very active in preventing senescence in rodent cells and was found to be amplified in some human breast cancers, suggesting TBX3 plays a role in breast cancer. This study examined the function of TBX3 and its isoforms, TBX3+2a. TBX3+2a differs from TBX3 in the DNA binding domain with an extra 20 amino acids produced by alternative splicing. We first examined the tissue expression and alternative splicing patterns of these two isoforms. We found that TBX3 and TBX3+2a are widely expressed in human and mouse and alternative splicing could be tissue-specific and species specific. Overexpression of TBX3 is able to immortalize mouse embryo fibroblast cells, while TBX3+2a shows an acceleration of senescence, a functional difference that may be explained by the fact that these two isoforms may have different downstream targets. TBX3, but not TBX3+2a, is able to bind to the previously identified T-box binding site in a gel shift assay. A subset of human breast cancer cell lines overexpresses TBX3. Our results indicate that TBX3 and TBX3+2a are functionally distinctive in inhibition of senescence of mouse embryo fibroblast cells and may play a role in breast cancer.

Comparison of Lung Adenocarcinoma and Squamous Cell Carcinoma Genomes. *W.W. Lockwood¹, C. Garnis¹, Y. Ge¹, S. Lam², C. MacAulay², W.L. Lam¹.* 1) Cancer Genetics, British Columbia Cancer Agency, Vancouver, B.C., Canada; 2) Cancer Imaging, British Columbia Cancer Agency, Vancouver, B.C., Canada.

Lung cancer is a worldwide problem and the most common cause of cancer-related deaths in North America. Non-small cell lung cancer (NSCLC) accounts for the majority of these cases, with squamous cell carcinoma (SqCC) and adenocarcinoma (AC) as the two major sub-types. SqCC develops more rapidly and arises near the central airways while AC originates from the epithelium of the lung periphery. The variation in progression and development of SqCC and AC may be due to underlying differences in genetic alterations between the two subtypes. Genetic abnormalities associated with each subtype have been reported. In this study, we compare SqCC and AC genomes using the newly developed sub-megabase resolution tiling-set (SMRT) array for whole genome comparative genomic hybridization (CGH) analysis. The SMRT array consists of 32,433 overlapping human bacterial artificial chromosome clones which span the entire human genome and allows detection of sub-megabase genetic changes. Using this technique, we generated profiles for 15 AC and 9 SqCC cell lines in order to distinguish the genetic features that characterize each subtype. While the two sample sets share recurrent regions of alteration, copy number changes specific to each subtype were also evident. SMRT array CGH enabled the detection of many novel aberrations which in turn define minimal regions of recurrent alterations that are potentially involved in tumorigenesis. Our results show that there are different genetic changes associated with SqCC and AC. This information could be used to tailor diagnosis and contribute to the understanding of the biology of the disease.

Frequent genetic alterations in both stromal and epithelial compartments of human epithelial ovarian cancer. A. Mannermaa^{1, 7}, H. Tuhkanen^{1, 2}, M. Anttila^{1, 3}, A. Kuronen⁴, M. Juhola⁴, R. Tammi⁵, M. Tammi⁵, V. Kataja², S. Helisalmi⁶, V.-M. Kosma¹. 1) Dept. of Clinical Pathology and Forensic Medicine, University of Kuopio and Kuopio University Hospital, Kuopio, Finland; 2) Dept. of Oncology, University of Kuopio and Kuopio University Hospital, Kuopio, Finland; 3) Dept. of Gynaecology and Obstetrics, University of Kuopio and Kuopio University Hospital, Kuopio, Finland; 4) Jyväskylä Central Hospital, Jyväskylä, Finland; 5) Dept. of Anatomy, University of Kuopio, Kuopio, Finland; 6) Dept. of Neurology and Neurosciences, University of Kuopio, Kuopio, Finland; 7) Dept. of Clinical Genetics, Oulu University Hospital and University of Oulu, Oulu, Finland.

We have shown that at 3p21.3 in ovarian cancer, allelic imbalance is found in 60-87% of the informative epithelial tumor cells of epithelial ovarian cancer and in adjacent stromal cells allelic imbalance is found at a frequency almost as high (52-80%)*. Our aim was to investigate the level and frequency of quantitative changes on cancer associated genes on both malignant epithelium and surrounding stroma in ovarian cancer by using MLPA technique (Multiplex Ligation dependent Probe Amplification). Altogether 110 genes covering all human chromosomes were analyzed from 24 epithelial and 13 stromal samples. We detected at least one altered gene in every tumor sample. No alterations from normal uterine tissue was found. The mean number of quantitative changes per tumor was 23.6 in epithelium and 10.8 in stroma. More specifically, there were in average 13.7 amplifications in epithelial cells and 6.6 in stromal cells. The mean number of deletions per tumor were 9.9 in epithelial cells and 4.2 in stromal cells. The most frequently altered gene was DCC in 18q21, which was lost in more than 60% of the samples. Although there was a clear trend for similar alterations in both epithelial and stromal parts of the tumor, we identified tumors where certain genes were altered only in stromal cells. Our study shows that stromal cells adjacent to epithelial ovarian cancer have undergone frequent genetic alterations and thus should be considered as an active part of the malignancy. *Tuhkanen et al. *Int J Cancer* (2004):109:247-52.

Detection of circulating tumour cells and lymph node micrometastasis in patients with bladder transitional cell carcinoma. *M. Marin-Aguilera*¹, *L. Mengual*¹, *M.J. Ribal*¹, *F. Algaba*¹, *E. Ars*¹, *R. Oliva*², *P.L. Fernández*², *H. Villavicencio*¹, *A. Alcaraz*¹. 1) Fundació Puigvert. Barcelona. Spain; 2) Hospital Clínic. Barcelona. Spain.

Transitional cell carcinoma (TCC) of the bladder is the fourth most common solid malignancy in males from industrialized countries and approximately 50% of patients with muscle-invasive disease treated by radical cystectomy die because of metastatic TCC. It remains unclear whether some tumour cell-derived mRNA transcripts detected in blood by PCR are appropriate molecular dissemination markers. We analyzed cytokeratin 20 (*CK20*) expression by RT-PCR as a method to detect circulating and residual tumour cells in blood, lymph nodes and bone marrow from patients with muscle invasive TCC. We studied 57 patients with invasive TCC treated with radical cystectomy and 9 patients with non-invasive TCC. None of them presented metastasis in preoperative clinical staging. Twenty-two blood samples, 5 bone marrow samples and 5 lymph node samples from patients with no history of TCC served as negative controls. Four blood samples from patients with known metastatic disease were the positive controls.

None of the negative controls expressed *CK20*. In bone marrow samples, 19% of patients showed *CK20* expression. In peripheral blood 30% of patients expressed *CK20* and only one of them had a non-invasive TCC. Three of the 4 positive controls showed *CK20* expression in peripheral blood. Lymph node pathological status was positive in 42% of patients with invasive TCC and all of them showed expression of *CK20* except for one case. Of the pathologically negative lymph nodes, *CK20* was detected in 46,6%.

CK20 RT-PCR assay appears to be a highly sensitive and specific method for detecting circulating tumour cells and residual disease in lymph node from patients with invasive bladder cancer. However, it is necessary to further evaluate *CK20* transcripts as a molecular tumour marker in blood performing the follow-up of the patients to assess the clinical significance of the disseminated cells.

Partially degraded RNA from bladder washings is suitable to study gene expression patterns of bladder cancer using DNA microarrays. *L. Mengual¹, M. Buset¹, E. Ars¹, M.J. Ribal¹, F. Algaba¹, Y. Arce¹, L. Sumoy², J.J. Lozano², B. Miñana², M. Marín-Aguilera¹, M. Fernández¹, L. Sedano¹, H. Villavicencio¹, A. Alcaraz¹.* 1) Molecular Biology Lab., Fundació Puigvert; 2) Microarrays Lab., Centre de Regulació Genòmica. Barcelona. Spain.

The determination of gene expression profiles in bladder cancer using DNA microarrays is usually performed with RNA isolated from tumour samples. The study by microarray technology of bladder fluids in contact with the tumour, such as urine or bladder washings, could be of interest because they may be obtained with minimally invasive or non-invasive procedures. However, the isolation of high quality RNA from such samples constitutes a frequent problem. The aims of this study were to determine if gene expression profiles were modified by RNA degradation and to correlate gene expression profiles between exfoliated cells from bladder washings and bladder cells tumours. Total bladder tumour and bladder washing RNA from the same patient was heat shocked to obtain 4 degradation levels. We amplified these RNAs by using the T3N9 method suitable for degraded RNAs. Finally, we hybridised cDNA microarrays with probes generated with this amplified RNA. After the microarray data was filtered and normalized, the top and bottom 5% (426) of ranked clones were compared in all samples. Our results showed that even with the badly degraded RNA we detected most of the differentially expressed genes found in intact samples (mean 63% in tissue samples and mean 79% in bladder washings). Furthermore, we could detect a high percentage of differentially expressed genes (mean 54%) in common between bladder washings and tumours. Expression differences for 10 genes were independently confirmed by real-time PCR. Our results suggest that gene expression profiles obtained from partially degraded RNA samples with conserved ribosomal bands have a high degree of similarity compared to intact samples when using the T3N9 amplification method. Also, we show that there is a good correlation between gene expression patterns in bladder washings and tumours, making the bladder washing a suitable sample to study gene expression profiles of bladder cancer.

BRCA unknown variants impact on splicing. *V. Moncoutier¹, D. Michaux¹, S. Pagès Berhouet¹, C. Dehainault¹, A. Laugé¹, I. Coupier¹, M. Gauthier Villars¹, D. Stoppa Lyonnet^{1, 2}, C. Houdayer¹.* 1) Genetics; 2) Inserm U509, Institut Curie, Paris, France.

Breast cancer is a leading cause of cancer deaths among women, and it is estimated that 5%-10% of cases are caused by inherited mutations in the breast cancer susceptibility genes BRCA1, 2 (BRCA). Most of the deleterious BRCA mutations leads to a truncated protein. Surprisingly, splicing mutations would account for a mere 5% of BRCA mutational spectrum, as opposed to NF1 or ATM that exhibit 50% of splicing mutations. However, BRCA molecular analysis in at-risk women shows that nearly half of BRCA sequence variations are of uncertain clinical significance, i.e. the so-called Unknown Variants (UV). Therefore, we embarked upon systematic characterization of UV at the RNA level and report here our preliminary results on 20 BRCA UVs, located outside the AG/GT canonical sites. We used a combination of web-based tools (Splice Site Finder, Splice Site Prediction, GeneSplicer, MaxEntScan, ESE Finder and Rescue ESE) and RT PCR analyses. Total RNA was extracted from lymphoblastoid cell lines. For each patient, one cell line was treated with puromycin and one cell line was left untreated to optimize the detection of unstable transcripts. Following electrophoresis, all RT PCR fragments were gel-cut and sequenced. We also looked for the presence of polymorphisms at the cDNA level to detect a possible hemizygoty due to an unstable mutant transcript. To study allelic imbalance, an allele-specific RT PCR with Locked Nucleic Acid primers is under development. We found that 8 of the 20 UVs were actually leading to splice alterations, that ranged from exon skipping to more complex defects such as intron retention or a combination of both defects. Our preliminary results suggest that a putative impact of UVs on splicing should be systematically looked for. This study will be enlarged to 50 unselected UVs identified during the course of BRCA molecular diagnosis, with the aim of defining a strategy for a routine-based diagnosis, possibly by a combination of first line in silico analysis followed by RT PCR analysis.

Genomic Alterations Identified by cDNA Microarray Analysis in Cervical Cancer: MMP Genes are Targets of 11q22 Amplicon. *G. Narayan*¹, *V. Bourdon*², *S. Chaganti*², *H. Arias-Pulido*⁴, *S. Nandula*¹, *P.H. Rao*³, *A. Schneider*⁵, *M. Durst*⁵, *L. Gissmann*⁶, *M. Mansukhani*¹, *R.S. Chaganti*², *V.V. Murty*¹. 1) Dept Pathology, Columbia Univ, New York, NY; 2) Memorial Sloan-Kettering Cancer Center, New York, NY; 3) Baylor College of Medicine, Houston, TX; 4) University of New Mexico, Albuquerque, NM; 5) Friedrich Schiller Univ, Jena, Germany; 6) Deutsches Krebsforschungszentrum, Angewandte Tumorstudiologie, Im Neuenheimer Feld 242, Heidelberg, Germany.

Cervical cancer (CC) is a leading cause of cancer-related deaths in women worldwide. CC displays a myriad of cytogenetic abnormalities including chromosomal and gene amplifications, mutations in certain genes as well as epigenetic changes. Despite this, the molecular basis of CC development is still poorly understood. Here, we analyzed 29 CC specimens by microarray comparative genomic hybridization on an array containing 9,206 cDNA clones to identify gene dosage alterations. This analysis identified DNA copy number increase in 445 clones and deletions in 121 clones in 3 or more tumors. The chromosomes X, 1, 5, 3, 19, and 20 were most commonly showed overrepresented genes. A number of these amplified genes associated with distinct biological processes in tumor formation. This analysis also further identified 17 potential amplicons (4 on X chromosome, 3 on chromosome 1, one each at 3q27-q29, 5p13, 5q31, 8q24, 11q22-q23, 14q32, 17q21-q22, 19p13, 19q13.3, and 20q13.2). The deleted genes were commonly mapped to the chromosome regions 4q13.3, 2q33-q27, and 13q14.1 suggesting that these sites harbor candidate tumor suppressor genes. The deleted genes include tumor suppressors (FHIT and ZDHHC2), apoptosis (CASP1), transcription factors, immune response, cell-cell interaction, and DNA repair genes. A number of the amplified and deleted genes were further validated by fluorescence in situ hybridization, Southern and/or northern blot analysis, and RT-PCR. Characterization of an 800 kb size amplicon mapped to 11q22 identified matrix metalloproteinases MMP1, MMP12, and MMP13 as critical target genes of this amplicon. Thus, we have identified number critical genes of relevance to CC development.

Effect of NF2 missense mutations on nuclear transport. *B. Schmucker, M. Kressel.* Institute of Anatomy, University of Erlangen, Germany.

Tumor suppressor proteins are regulated by a number of different strategies to prevent abnormal cellular growth. Many of them shuttle between the nucleus and the cytoplasm thus regulating their function. Alteration of nuclear transport, e.g. mutations in the nuclear localisation sequences (BRCA1 gene), truncation of the nuclear export signal (APC gene) or defect in nuclear-cytoplasmic targeting (p53) lead to initiation or progression of cancer. Previously, we identified a C-terminal nuclear export signal (NES) in the Neurofibromatosis 2 protein (NF2) and demonstrated that NF2 shuttles between the nucleus and the cytoplasm. To investigate the impact of frameshift mutations (most common genetic alteration in NF2 patients) on nuclear transport, we created a full-length NF2 construct terminated at residue 535 (L535X). Despite truncation 5 of the NES, the construct localized at the plasma membrane and did not enter the nucleus. Additionally, missense mutations which were found in NF2 tumors in combination with loss of the remaining NF2 allele, were expressed and analyzed for nuclear transport: L46R, L54P, F62S, L64P, K79E, E392V, K533T, L535P. However, only a slightly increased nuclear localization was observed compared to wt protein with a relatively stronger effect of mutations mapping to exon 2. Recently, protein 4.1 was shown to exhibit a NES in a region highly homologous to NF2 exon 2. Mutagenesis of this homologous domain in NF2 wt-protein (L54P-L56Q; L54A-L55A-L56A) did not alter the nuclear localization. Any putative NES within exon 2 was additionally excluded by an Rev-nuclear export assay (as developed by Henderson et Eleftheriou 2000). Furthermore, we analyzed the NF2 BlueBox mutation, a 7 amino acid stretch in the FERM domain of NF2, known to increase proliferation and induce malignant transformation. However, no effect of this mutation on nuclear uptake was observed. Since phosphorylation of serine 518 is suggested to convert Merlin from antiproliferative to growth-permissive state, we investigated S518D and S518A mutations, mimicking constitutively phosphorylated and dephosphorylated NF2, respectively. No alteration of nuclear transport was detected, indicating that nuclear entry of NF2 is not dependent on phosphorylation.

Premature senescence identified as a primary tumor-protective response of breast carcinoma cells following

inducible oncogenic ERBB2-signalling. *C. Spangenberg¹, T. Trost¹, E. Lausch¹, S. Schmitt², S. Fees¹, J.G.*

Hengstler³, E.O. Bockamp², D. Prawitt¹, B. Zabel¹. 1) Children's Hospital, University of Mainz, Germany; 2) Institute of Toxicology, University of Mainz, Germany; 3) Institute of Toxicology, University of Leipzig, Germany.

ERBB2 is a member of the epidermal growth factor receptor family of receptor tyrosine kinases. It is causally implicated in the development of a subset of breast cancer and other epithelial malignancies. Enhanced ERBB2 expression leading to aberrant signalling can frequently be attributed to genomic amplification of the *ERBB2*-locus on chromosome 17q21. In the work presented we apply a tetracycline-controlled expression system to inducibly express oncogenic ERBB2 (NeuT) in MCF-7 breast carcinoma cells. Expression of NeuT results in prominent phenotypic alterations in several independent MCF7/Tet-NeuT clones 16-48h after addition of tetracycline to the culture medium. Interestingly, oncogenic ERBB2 signalling in these cells does not lead to a mitogenic response but instead induces features of premature senescence, like cell cycle arrest and expression of senescence associated beta-galactosidase. Further molecular analysis provide direct evidence that upregulation of the cyclin dependent kinase inhibitor P21 via the P38 MAPK pathway is necessary to elicit premature senescence in response to oncogenic ERBB2 signalling. Premature senescence represents a tumor-protective program that has previously been shown to be induced by overexpression of other oncogenes, like activated forms of RAS or RAF. Taken together our results indicate that ERBB2-driven mammary tumorigenesis might involve additional hits functionally inactivating the cellular premature senescence response. These lesions may center around the P21 molecule or target downstream effectors of senescence.

Transcriptome analysis of a candidate ovarian cancer (OC) tumor suppressor gene region at 17q25. *P. Tonin¹, K. Dewar^{1,2}, V. Forgetta², D. Provencher³, A.-M. Mes-Masson³, N. Presneau¹.* 1) Dept Human Genetics, McGill U., Montreal, PQ; 2) McGill U. and Genome Quebec Innovation Centre, Montreal, PQ; 3) CR-CHUM (Hopital Notre Dame)/Institut du cancer de Montreal, Montreal, PQ.

Loss of heterozygosity (LOH) analysis was performed in OC to further characterize a previously identified candidate tumor suppressor gene region encompassing D17S801 at 17q25.1. LOH of at least 1 informative marker was observed for 100 of 140 OC samples in an analysis of 6 polymorphic markers (cen-D17S1839-D17S785-D17S1817-D17S801-D17S751-D17S722-tel). The combined analysis revealed a 453 Kb minimal region of deletion (MRD) bounded by D17S1817 and D17S751. Human and mouse genome assemblies were used to resolve marker inconsistencies of the D17S1839-D17S722 interval and identify candidates for expression analysis. The region contains 32 known and strongly predicted genes, 9 of which overlap the MRD. The two reference genomic sequences share nearly identical gene structures. The organization of the region is highly collinear. The 17q25 region does not show any large internal duplications. A 1.5 Kb inverted duplicated sequence of 87% nucleotide identity was observed in a 13 kb region surrounding D17S801. Transcriptome analysis by Affymetrix GeneChip and RT-PCR methods of 3 well characterized OC cell lines and primary cultures of normal ovarian surface epithelial cells was performed with 32 candidates spanning the D17S1839-D17S722 interval. RT-PCR analysis of 8 known or strongly predicted genes residing in the MRD in 10 OC samples, that exhibited LOH of the MRD, identified FLJ22341, as a strong candidate. Differential expression by RT-PCR of FLJ22341 was also observed in 1 of 3 EOC cell lines but not by microarray expression analysis. The proximal repeat sequence of D17S801 occurs 8 Kb upstream of the putative promoter region of FLJ22341. RT-PCR analysis of the OC samples and cell lines also identified DKFZP434P0316, a gene that maps proximal to the MRD, as a candidate. While Affymetrix technology was useful for initially eliminating less promising candidates, subsequent RT-PCR analysis of well-characterized OC samples was essential to prioritize candidates for further study.

The influence of the polymorphisms of the enzymes that regulate the homeostasis of folic acid on the plasmatic levels of Homocysteine in children with acute lymphoblastic leukemia. *F. Garcia Bournissen¹, M. Primeau¹, A. Moghrabi¹, M. Krajinovic^{1, 2}.* 1) Service d'Hematologie-Oncologie, Centre de Cancerologie Charles-Bruneau et Centre de Recherche, Hopital Sainte-Justine; 2) Departement de Pediatrie, Universite de Montreal.

INTRODUCTION: Acute lymphoblastic leukemia (ALL) is the most frequent cancer of childhood, with a current cure rate of 80%. However, ALL treatment can be associated with both resistance and toxicity. It has been suggested that intrathecal methotrexate (MTX) could contribute to a decline in neurocognitive functioning. Homocysteinemia, due to its pathogenic effect on vascular endothelium, is thought to play a role in the development of this toxicity. Several enzymes are essential to maintain the homocysteine (Hcy) levels. Their different functional forms, associated with common genetic polymorphisms may act as predisposing factors of MTX-related neurotoxicity. **MATERIAL AND METHODS:** Sixty children treated with DFCI-2000 protocols were included in the prospective study conducted at the Ste-Justine Hospital (Montreal) in the 2001-03 period. Hcy levels were measured by fluorescence polarization immunoassay in plasma samples obtained at diagnosis and 24hs following a high MTX dose. The polymorphisms in genes relevant for Hcy homeostasis were analyzed including methionine synthase (MTR), methionine synthase reductase (MTRR), methylene tetrahydrofolate reductase (MTHFR), cystathionine beta-synthase (CBS) and endothelial nitric oxide synthase (eNOS). MTHFR C677T and A1298T, MTR A2756G, eNOS T-786C and G849T, and MTRR A66G were studied by PCR-ASO. The presence of a CBS 68bp insertion was detected by PCR followed by gel electrophoresis. Statistical analyses were carried out by repeated measures ANOVA. **RESULTS:** An increase in Hcy levels following MTX administration was observed ($p < 0.001$) as expected. Regarding genotype-Hcy relationship (within subject effect), the presence of the TT genotype of eNOS T-786C polymorphism was significantly associated with the increase of Hcy levels from the baseline values ($p = 0.01$). **CONCLUSION:** The potential predictive role of eNOS TT-786 homozygosity should be confirmed in clinical setting.

Identification of single nucleotide polymorphisms (SNPs) associated with adverse effects (AEs) of gefitinib

(Iressa). *M. Isomura*¹, *M. Fukuoka*², *S. Sone*³, *M. Matsuura*¹, *T. Noda*¹, *T. Muto*¹, *Y. Miki*¹. 1) Genome Center, Cancer Inst., Toshima, Tokyo, Japan; 2) Dep. Medical Oncology, Kinki Univ., Osaka, Japan; 3) Dep. Internal Medicine, Tokushima Univ., Tokushima, Japan.

The efficacy of gefitinib (Iressa) in NSCLC has been well demonstrated in clinical studies. However, AEs of gefitinib treatment were also observed. A method for predicting AEs may be a useful tool. In order to predict AEs of gefitinib, we conducted large-scale SNP typing analyses; 42 patients (pts) with NSCLC were enrolled. All pts received oral gefitinib 250 mg/day for 16 weeks. AEs were evaluated every 7 days (NCI-CTC grading). Gefitinib concentration in peripheral blood was measured on day 28. To identify SNPs associated with AEs, DNA was isolated from peripheral blood and genotypes of 3,717 SNPs over 512 genes were determined by Invader assay. Association between SNPs and AEs was examined using Fishers exact test. During treatment, 23/42 pts exhibited diarrhea. In 22/23 pts diarrhea was mild and manageable (CTC grade 2), and less severe than with traditional chemotherapy. Genotyping analyses showed a strong association between diarrhea and 7 SNPs located within SLC22A4 gene ($p=0.000025$, odds ratio: 22.3). Among those, 3 SNPs were located within the putative regulatory region of SLC22A4 and the rest were within the intronic region, suggesting these polymorphisms may alter gene expression. The SNPs belonged to 1 of 3 major haplotypes observed at the locus, suggesting a specific haplotype may harbor genetic alteration responsible for developing diarrhea. For other AEs the number of affected pts was too small to analyze for an association with SNPs. Two SNPs on SLC22A7 gene were strongly associated with gefitinib blood concentration ($p=0.00056$, odds ratio: 15.1). No correlation was seen between appearance of diarrhea and high gefitinib blood concentration. By using these SNPs the appearance of diarrhea on gefitinib could be precisely predicted. Both genes belonged to same gene family, suggesting this family is involved in pharmacokinetics and/or pharmacodynamics of gefitinib. Iressa is a trademark of the AstraZeneca group of companies.

ESOPHAGEAL SQUAMOUS CELL CARCINOMA AND IL1B GENE PROMOTER REGION

POLYMORPHISMS. *K. Azim, K. Brophy, R. McManus, D. Kelleher, J.V. Reynolds.* Institute of Molecular Med, Trinity College Dublin, Dublin, Ireland.

Purpose: To estimate the distribution of IL-1B -511 C-T biallelic single nucleotide polymorphism (SNP) in patients with cancer of the esophagus and a control population of Irish origin. **Methods:** In a retrospective case-control study design we selected 222 esophageal cancer cases and 228 controls. DNA was extracted and genotyping was performed using PCR-RFLP and TAQMAN chemistry. The study had local Ethical Committee approval and informed consent was obtained from all study subjects. **Results:** The distribution of CC homozygotes (51.8% in cases, 39.9% in controls) and CT heterozygotes (36.5% in cases, 48.2% in controls) was significantly different in the two study groups ($p = 0.028$). However, this difference was reflected only in squamous cell cancer patients ($n=88$, $p = 0.001$), CC homozygotes (63.6% in cases, 39.9% in controls) and CT heterozygotes (26.1% in cases, 48.2% in controls). There was no difference in the distribution of genotypes in adenocarcinoma cases and controls ($n = 128$, $p = 0.712$). Genotypes were not associated with stage of disease but larger tumor sizes were observed in patients carrying C allele compared to patients carrying T allele (Mean tumor size; CC = 4.02cm, CT = 3.44 cm, TT = 2.76 cm. $p = 0.017$). **Conclusion:** The distribution of histological types of esophageal cancer is geographical as well as race and gender related. Although the last three decades have witnessed an increase in incidence of adenocarcinomas in Caucasian population for unknown reasons, squamous cell carcinoma of the esophagus has been related to smoking, diet, and alcohol consumption. Polymorphisms in IL 1B gene cluster have been implicated in many diseases including cancers. This study shows individuals carrying CC genotype of IL 1B gene may be at higher risk of developing squamous cell esophageal cancer in some way that needs further investigation.

A Study of the Association Between the Glycine N-Methyltransferase (GNMT) Gene Polymorphism and the Susceptibility to Prostate Cancer. *Y.-M.A. Chen¹, Y.-C. Huang¹, M.-Y. Chung², Y.-H. Chang³, J.-S.W. Huang^{3,4}, M.-T.D. Ho⁵, C.-C. Pan⁵, T.-L. Wu⁶.* 1) Institute of Public Health, National Yang-Ming University, Taipei, Taiwan; 2) Department of Medical Research and Education, Taipei Veterans General Hospital, Taipei, Taiwan; 3) Department of Surgery, Taipei Veterans General Hospital, Taipei, Taiwan; 4) Faculty of Medicine, National Yang-Ming University, Taipei, Taiwan; 5) Department of Pathology and Laboratory Medicine, Taipei Veterans General Hospital, Taipei, Taiwan; 6) Department of Surgery, Kaohsiung Veterans General Hospital, Kaohsiung, Taiwan.

Glycine N-methyltransferase (GNMT), a protein with multiple functions. We have previously reported on diminished GNMT expression levels in both human hepatocellular carcinoma (HCC) cell lines and tumorous tissues. Since GNMT only expresses in prostate, liver, kidney and pancreas. Here we were a) investigate the GNMT expression levels in prostate cell lines and tissues and b) study the association between the GNMT polymorphism and the susceptibility to prostate cancer (PCa). The results of Western blot showed that none of 8 PCa and 2 normal prostate cell lines expressed GNMT while its mRNA can be detected by RT-PCR in all the PCa cell lines. Immunohistochemical staining with GNMT monoclonal antibody 14-1 showed that GNMT was undetectable in 75% (33/44) of the tumor adjacent tissue and 84% (38/44) of the tumor tissues from PCa patients. The case-control study which comprised 163 PCa patients and 226 age-matched controls of GNMT SNP1 genotype showed that the odds ratio (OR) of developing PCa in persons with C/C genotype was 1.40 (95% CI= 0.88-2.23) when we used both C/T and T/T genotypes as a reference. In addition, 4 of 20 (20.0%) and 6 of 21 (28.6%) PCa tumor tissues had LOH of the INS/DEL and STRP1 genotype. The expression of GNMT was found to be downregulated in PCa cell lines and tissues. 20.0-28.6% of PCa tumor tissues had LOH of the genetic markers of GNMT. The C-allele of SNP1 maybe associated with increased PCa risk. Therefore, GNMT is a tumor susceptibility gene for PCa.

Large scale, high throughput genotyping for testis and bladder tumour candidate genes. *M.J.H. Coenen¹, F. de Vegt², K.K. Aben², M.M.V.A.P. Schijvenaars¹, C. de Kovel¹, L.A.L.M. Kiemeny², B. Franke¹.* 1) Human Genetics, UMC Nijmegen, Nijmegen, Netherlands; 2) Department of Epidemiology and Biostatistics, UMC Nijmegen, Nijmegen, Netherlands.

The effect of environmental/life-style factors on the etiology of tumours is modified by a persons genetic susceptibility. This genetic susceptibility has been studied in small-scale studies mainly concerning genes involved in carcinogen metabolism. Now that high throughput technologies have become available we want to perform large scale genotyping to identify genetic variations (in combination with life-style factors) that increase the risk for testis and bladder tumours using a SNP microarray approach. To identify genetic markers in combination with life-style factors a case/control study will be performed with 700 bladder cancer patients; 500 testicular germ cell tumour patients and age/sex matched controls. All cases and controls will be genotyped using a microarray containing genetic variants (single nucleotide polymorphisms (SNPs)) of about 150 genes known to be involved in cancer related pathways (for instance genes active in carcinogen metabolism, DNA repair or cell cycle control). In each of these 150 genes three SNPs have been selected using information from publicly available databases and the Celera SNP database. We have preferentially selected functional SNPs which are known or suspected to change gene product function or regulation. Genotyping will be performed by SNP microarray analysis. This enables us to analyse 400-500 SNPs simultaneously. The SNPs are genotyped by a four-colour microarray-based mini-sequencing assay. Cyclic mini-sequencing is performed with 5 tagged primers followed by capture of the products on microarrays by hybridisation to complementary tag oligonucleotides. Finally statistical analysis will be utilised to identify individual SNPs as well as patterns of SNPs which are associated with testis and bladder tumours. We hypothesise that the combination of large scale genotyping with information regarding environmental risk factors will give a better insight into the pathogenic mechanisms of testis and bladder tumours.

The XRCC2 R188H variant has a significant effect on survival from breast cancer. A. Cox¹, S. Rafii¹, G. MacPherson¹, S. Balasubramanian², M. Meuth¹. 1) Inst Cancer Studies, Med Sch, Univ Sheffield, Sheffield, UK; 2) Academic Surgical Oncology Unit, Med Sch, Univ Sheffield, Sheffield, UK.

The protein products of the breast cancer genes, BRCA1 and BRCA2, are known to be involved in the repair of double strand breaks (DSB) in DNA. We and others have shown that common variants of genes of the DSB repair pathway can act as low penetrance breast cancer susceptibility alleles. Two large studies have shown that the rare allele of XRCC2 R188H variant is associated with breast cancer (with combined odds ratio for the rare homozygote of 2.11 (95% confidence interval (CI) 1.06, 4.20). The arginine residue at position 188 is necessary for efficient repair of DSB in vitro. DSB repair genes are also strong candidates to affect treatment outcome and survival. Therefore we tested the hypothesis that coding germ-line variants in DSB repair genes were associated with survival from breast cancer. Blood DNA samples were obtained from 1008 women with histopathologically confirmed breast cancer attending surgical clinics at the Royal Hallamshire Hospital in Sheffield UK, between November 1998 and June 2002. Extensive demographic, epidemiological and pathological data were also recorded. Mortality data was obtained from Trent Cancer Registry in April 2004. We genotyped this cohort for coding SNPs in a panel of DSB repair genes using the TaqmanTM (Applied Biosystems) 5 nuclease PCR assay. Survival in different genotype groups was compared using Cox regression analysis, controlling for known prognostic factors. Coding SNPs in the genes ATM, BRCA2, LIG4, XRCC3, and RAD51 had no significant effect on survival in this study. However, women homozygous for the rare allele of the XRCC2 R188H SNP had poorer survival compared to women homozygous for the common allele (hazard ratio (HR) 2.54, (95% CI 1.54, 4.21). There was no significant effect of heterozygosity of this allele (HR 1.30, 95%CI 0.78, 2.17). While this result requires confirmation, the association of the H allele with both breast cancer susceptibility and poor survival suggests that DNA repair capacity may be an important factor determining outcome in breast cancer.

IFN- Intron-1 polymorphism in sporadic breast cancer patients and an in-vitro expression profile. *A. Dhir, A. Saha, A. Ranjan, V. Gupta, N.K. Bairwa, R. Bamezai.* NCAHG, SLS, Jawaharlal Nehru University, New Delhi, Delhi, India.

The first intervening sequence (Intron-1) of interferon gamma (IFN-) gene is comprised of a tissue non-specific enhancer element. Its influence on the expression of interferon has not been very clear although previous reports have suggested an increase in the interferon level associated with an allele of 12 repeats of CA, (CA)₁₂, in this region of the gene. Here we have attempted to study the prevalence of (CA)_n polymorphism in the intron-1 of IFN- gene in a case control study of sporadic breast cancer patients to find out the difference in the rate of prevalence at germline and somatic level in this region of the gene, considered to modulate the expression of this critical cytokine, influencing tumor growth and progression. The (CA)₁₂ allele was observed in 50% of patients in comparison to 15% controls (p=0.0001) as a germline pattern. Further, 9/54 (17%) tumor samples depicted an allelic variation and the presence of mutations in the 5'flanking region (+874, as per HUGO nomenclature) of the (CA)_n repeat as a somatic event. An analysis of the influence of (CA)₁₂ repeat on the expression in a reporter assay suggested this allelic form to be a downregulator of the expression when compared to other allelic forms. The observation of presence of (CA)₁₂ repeat in the intron-1 of IFN- gene in a significant percentage of patients when compared to normals and the association of this allelic form with downregulation of IFN- , points clearly to the downregulation of the Th1 surveillance of immune response in such individuals. The present study provides an initial evidence of how a genotype background of one of the critical cytokines in immune response could probably influence the nature of tumor growth and proliferation in sporadic breast tumors. This would be in addition to a variety of factors, which play their respective roles in containing the tumor growth and their failure results into an uncontrolled tumor growth and invasion in other sites of the body.

Cytochrome P4502D6 G1846T/A polymorphism is associated with susceptibility to breast cancer in Mexican patients. *M.P. Gallegos Sr¹, L. Arnaud-López¹, L.E. Figuera², I.P. Dávalos-Rodríguez², G.M. Zúñiga-González¹.* 1) Medicina Molec, CIBO IMSS, Guadalajara Jalisco, Mexico; 2) Genética, CIBO, IMSS, Guadalajara, Jalisco, Méx.

Breast cancer is the most frequent malignancy among women. Given genetic factors such as BRCA1 and BRCA2 as well as reproductive history constitute only 30% of the cause, environmental elements could play a significant role in the development of breast cancer. Likewise, the relevant enzymes involved in the biotransformation of xenobiotics (from tobacco smoke, diet or other environmental sources) might play a role in breast carcinogenesis. Some individuals with modified ability to metabolize these carcinogens could have a different risk for breast cancer. We investigated the role of cytochromes P-450 CYP2D6 G1846T/A polymorphism in breast carcinogenesis. A case-control study was conducted on 104 women with breast carcinoma and 100 healthy controls. The prevalence of genotype G1846T/A in normal controls and cancer patients was studied using the PCR method. In the study groups, 48% were found to carry G1846/G1846 in the control and 19% in the patients, while 38% carried G1846/T/A1846 in controls and 48% in patients group and 14% were T/A1846/T/A1846 in control and 33% in patients group. The CYP2D6 G1846T/A polymorphism low acetylator was found to be a significant risk determinant of breast carcinoma (OR = 3.9, 95% CI 1.8-8.3). These data suggest that CYP2D6 G1846T/A polymorphism could play a role in the susceptibility to breast carcinoma in Mexican population.

MDR1 C3435T polymorphism as a risk factor for childhood acute lymphoblastic leukemia. *F. Rivas Jr.^{1,2}, M. Ortiz^{2,3}, K. Rodarte^{2,3}, R. Ortiz^{2,4}, J.C. Aguilar⁵, M.A. Esparza⁵, B. Lopez⁵, N. Olivares⁶, F. Rivas².* 1) School of Medicine, Universidad de Colima, Colima; 2) Western Biomedical Research Center, Instituto Mexicano del Seguro Social; 3) Graduate Studies Program in Human Genetics, Universidad de Guadalajara; 4) Graduate Studies Program in Immunology, Universidad de Guadalajara; 5) Servicio de Hematología, Hospital de Especialidades CMNO-IMSS; 6) Hospital General de Occidente, Secretaria de Salud Jalisco, Guadalajara, Jalisco, Mexico.

Xenobiotic and drug transporter molecules are attractive candidate risk factors for cancer susceptibility. One of such molecules is the ATP binding cassette family P-glycoprotein (P-gp), coded by the MDR1 gene at 7q21.1. The C3435T SNP at this gene correlates with P-gp expression and activity in different tissues. The T allele relates with low P-gp, probably due to linkage with a yet unknown mutant. It has been proposed as a risk factor for the occurrence of childhood acute lymphoblastic leukemia (ALL) and other malignancies, while the C allele (increased P-gp) would be associated with a worse outcome. In this study allele and genotype frequencies from 52 ALL children were compared with those from 82 healthy unrelated Mestizo individuals living in Guadalajara Mexico. MDR1 C3435T was typed by PCR-RFLP (*MboI*) in DNA samples extracted from peripheral blood. Allele frequencies were 101/164 (62%) C and 63/164 (38%) T in controls; and 56/104 (54%) C and 48/104 (46%) T in the ALL patients ($p=0.25$). Genotype counts were 32 (39%) CC, 37 (45%) CT, and 13 (16%) TT in controls. These proportions do not deviate from Hardy-Weinberg Expectations. Genotypes in cases: 11 (21%) CC, 34 (65%) CT, and 7 (14%) TT did not differ from those in controls ($p\sim 0.06$). The T phenotype (CT+TT), however, was significantly higher ($p=0.034$) in ALL children than in controls, with an OR=2.39 ($CI_{95}=1.00-5.75$). Besides describing population genetic estimates for this SNP for the first time in Mexicans, the present results suggest that the MDR1 C3435T SNP influences an individual's susceptibility to ALL, likely through differential P-gp expression.

Genetic polymorphism of Glutathione S-Transferase genes (GSTM1, GSTT1, and GSTP1) and susceptibility to prostate cancer in northern India. *D.S.L. Srivastava¹, A. Mandhani¹, B. Mittal², R.D. Mittal¹.* 1) Department of Urology, Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow-226014, Uttar Pradesh, India; 2) Department of Genetics, Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow-226014, Uttar Pradesh, India.

Glutathione-S-transferases (GSTs) are active in the detoxification of wide variety of endogenous or exogenous carcinogens. The genetic polymorphism of GSTM1, GSTT1 and GSTP1 genes has been studied earlier to evaluate the relative risk of various cancers. In the present study, we examined the association of the GST gene polymorphisms with sporadic prostate cancer patients. Our study included 127 individuals with histologically confirmed prostate cancer and 144 age-matched controls from North India. DNA was isolated from peripheral blood by standard phenol chloroform method. GSTT1 and GSTM1 null genotypes were identified by multiplex PCR and GSTP1 313 A/G polymorphism was determined by PCR/RFLP. We observed significant association in null alleles of the GSTM1 (OR=2.239, 95% CI= 1.37-3.65, P = 0.001) and GSTT1 (OR=1.891, 95% CI= 1.089-3.282, P = 0.026) with prostate cancer risk; as well as 313 G alleles of the GSTP1 gene (OR = 2.48, 95% CI= 1.51-4.08, P= 0.000). The combined analysis of the above three genotypes showed further increase in the risk of prostate cancer. (OR = 7.23, 95% CI = 2.42-22.63, P= 0.000). Our study demonstrated that GSTP1 313 G polymorphism, and null alleles of GSTM1 and GSTT1 are strong predisposing risk factors for sporadic prostate cancer in North India.

Molecular studies on frequency of single nucleotide polymorphism of cyclin D1 gene (G870A) in Iranian patients with gastric cancer. *M. Vosoughi¹, F. Sharifpanah¹, F. Tirgari², N. Abedin¹, M. Karimi³, L. Emadian¹, A.*

Mohagheghi³, B. Noorinayer¹, M.R. Zali¹. 1) Cancer Genetics Department, Research Center for Gastroenterology and Liver Diseases (RCGLD), Tehran, Iran; 2) Cancer Institute of Tehran, Tehran University of Medical Science, Tehran, Iran; 3) Biotechnology Department, Pasteur Institute of Iran, Tehran, Iran.

Introduction: Cyclin D1 is a key regulator of cell cycle progression and a demonstrated oncogene. Over-expression of cyclin D1 is implicated in the pathogenesis of several cancers, including gastric cancer. Cyclin D1 regulates cell cycle progression by activating cyclin-dependent kinases 4 and 6 (CDK4 and CDK6), which in turn phosphorylates the retinoblastoma protein (pRb). This reaction inactivates pRb and is postulated to lead to progression through a G1S checkpoint, committing the cell to DNA replication. Single nucleotide polymorphisms, may modulate expression of cyclin D1 transcripts. Our aim in this study was to investigate the association of cyclin D1 (G870A) single nucleotide polymorphism with susceptibility to gastric cancer among a sample of Iranian patients and compares the results with normal group. **Methods:** We investigated the association between G870A polymorphism of the CDN1 gene and gastric cancer. 96 patients and corresponding control matched for their age, sex and ethnicity were enrolled. Genomic DNA was extracted and specific primers designed for the target region were used. RFLP was used to detect the presence or the absence of the polymorphism. **Results:** 36.5% of cases were of wild type genotype while 48% were heterozygous and 12.5% were of GG (polymorphic) genotype. The respective numbers for our controls were 30%, 45% and 25%. **Conclusion:** Our preliminary result shows that the G870A polymorphism of the cyclin D1 gene has no apparent association with gastric cancer among a sample of Iranian patients. Further investigation involving more patients and investigating other polymorphisms of this gene are required to delineate the true role of CDN1 polymorphisms in the pathogenesis of gastric cancer.

Cancer Genetic Counseling: the experience of three Brazilian Services. *E.I. Palmero¹, L. Kalakun², F.R. Vargas³, J.C.C. Rocha⁴, P. Ashton-Prolla^{1,2,5}.* 1) Post-Graduate Course in Genetics and Molecular Biology, UFRGS; 2) Service of Medical Genetics HCPA; 3) Oncogenetics Program, INCA; 4) Genetics Department, Hospital do Cancer A.C. Camargo; 5) Department of Genetics UFRGS.

Cancer Genetic Counseling (CGC) in Brazil is presently being provided by university centers and private clinics. This research aimed to study and compare the individual structure and characteristics of three different CGC services in the public arena, in different States of Brazil. The three services presented similarities, such as carrying out clinical and laboratory research; having specific professionals working together in the counseling process; evaluating individual and familiar risks for hereditary cancer; organizing the process of genetic counseling itself and offering genetic predisposition testing under the auspicious of research projects. All services presented differences in the type of population at risk being evaluated, reflecting mainly in the way people are being referred to these services. In one of them, the only non-symptomatic patients to have access to CGC are families of the patients being treated in the same hospital, whereas in the other two services of CGC, counseling is available to anyone who presents motivation and has a risk factor for hereditary cancer. In conclusion, public and private CGC services in Brazil are few and, generally, they are within tertiary hospitals which are primarily developed to treat already diagnosed cancer patients. Although in this framework there is a potential for cancer prevention of non-symptomatic families of a patient at risk for hereditary cancer, the CGC in these services follows a traditional retrospective model with several limitations. Passive screening of the whole population and highly complex tertiary institutions with restrictive costs are among them. This study emphasizes the importance of the way the oncology settings are structured in Brazil, as well as the need for collaborative studies covering the whole country, to obtain a comprehensive profile of the hereditary cancer syndromes in the Brazilian population. Support: HCPA, CAPES, CNPq.

HY1553, a novel CDK inhibitor isolated from *Streptomyces* sp., induces G1 arrest and apoptosis in HeLa cells. C. Lee, M. Kim, S. Moon, H. Lim, Y. Cho. Dept Medical Genetics, Hanyang Univ, Seoul, Korea.

Proliferative disorders, such as cancer, are recognized as diseases of the cell cycle. In the course of screening for a novel cell cycle inhibitor, HY1553 was found from the culture broth of *Streptomyces*. The molecular ion of HY1553 was identified at m/z 248(C₁₂H₁₆O₁₆).

Inhibition of cancer cell proliferation: The antiproliferative effects of HY1553 were assessed in four human cancer cells and normal lymphocytes using MTT assay. The growth of all cancer cells tested was inhibited in a concentration-dependent manner. The estimated IC₅₀ determined for HY1553 in these cancer cell lines ranged from 60 to 96.8 μ M. Interestingly, HY1553 demonstrated no antiproliferative effect on the normal lymphocyte cells used as control.

Inhibition of cell cycle regulation: The cell cycle analysis was performed on HeLa cells, after exposure to HY1553 at 32 μ M for 48 h. Flow cytometric analysis revealed an appreciable arrest of cells in G1 phase. The HeLa cell population increased gradually from 34% at 0 h, to 47% at 48 h in the G1 phase, after exposure to 32 μ M of HY1553. Accordingly, treatment with HY1553 induced a G1 phase arrest of the cell cycle progression of the HeLa cells by up-regulation of p21. Furthermore, HY1553 decreases the levels of CDK4/6, and cyclin D in Western blot analyses.

Induction of apoptosis: When HeLa cells were incubated with 80 μ M of HY1553 for 48 h, an apoptotic DNA fragmentation was observed in the HeLa cells using TUNEL assay. HY1553 induced up-regulation of Bax, and activation of procaspase-9. Furthermore, HY1553 induced proteolytic cleavage of procaspase-3 into its active form, and subsequent cleavage of PARP. The activation of caspase-9 is likely to occur via the mitochondria pathway which leads to cytochrome c release, followed by cleavage of procaspase-9.

The BOADICEA model of genetic susceptibility to breast and ovarian cancer: updating and validation. A.C.

Antoniou¹, P.D.P. Pharoah², D.F. Easton¹, on behalf of the Boadicea collaborators. 1) CR-UK Genetic Epidemiology Unit, Cambridge University, United Kingdom; 2) Human Cancer Genetics Group, Cambridge University, UK.

We previously derived a model of breast and ovarian cancer susceptibility using segregation analysis based on a population based series of 1484 breast cancer cases and 156 high-risk families from the UK. We have updated this model using additional data from two UK population based studies of breast cancer and family data from BRCA1/2 carriers identified in 22 population based studies of breast and ovarian cancer. The combined dataset includes 2785 families (301 BRCA1, 236 BRCA2 positive). According to the model, susceptibility to breast cancer is explained by mutations in BRCA1 and BRCA2 plus a polygenic effect (joint multiplicative effects of many genes of small effect). Incidence rates were smoothed using locally weighted regression techniques to avoid large variations between adjacent intervals. A birth cohort effect on the cancer risks is implemented, whereby each individual is assumed to develop cancer according to calendar period-specific incidence rates. The variance of the polygenic component declines with age, from 3.2 at age 30 to 1.3 at age 60. The predicted familial relative risks and BRCA1/2 prevalence among cases are close to those observed in population studies. The model predicts that the average breast cancer risks in BRCA1/2 carriers increase in more recent birth cohorts. For example, the average cumulative breast cancer risk to BRCA1 carriers is 50% for women born in 1920-29 and 58% for women born after 1950).

SISE matters: a method for measuring the information content of kinships when assessing the likelihood of HNPCC. *R.C. Green.* Memorial University, St. John's, NL, Canada.

Hereditary non polyposis colon cancer (HNPCC) is a significant cause of colorectal and other malignancies. The diagnosis of HNPCC relies on finding multiple cases of colorectal or other specific cancers within a family. In the absence of a significant family history, a diagnosis of HNPCC is seldom entertained. We postulate that small kinships with low information content are more likely to be designated at low risk of an inherited predisposition than are large kinships. This leads to under-diagnosis of HNPCC in small families and results in inadequate treatment, follow-up and family counselling. We have developed an objective quantitative measurement of the information content of individual pedigrees called the SISE coefficient (Sum of Information on Seventy year old Equivalents). The SISE coefficient of a family is a function of the number of informative relatives of the index case, of their ages and of the age-dependent penetrance of HNPCC mutations. For example a large family with a preponderance of young people and a SISE of 6.0 is as informative as a family where the index case has only 6 relatives, all first degree and older than 70 years. A population based series of 538 colorectal cancer cases was assessed by analysis of family history for the likelihood of carrying an HNPCC mutation and by measuring the SISE coefficient. Risk of HNPCC was designated as high (19 Amsterdam criteria families), intermediate (262 families) or low (257 families). Families with a low SISE coefficient were significantly more likely to be designated at low risk of HNPCC ($p < 0.001$). Using a cumulative binomial distribution function, we estimated the likelihood of observing multiple cancers in families of different SISE coefficients. In an HNPCC family with a SISE coefficient of 8.0 there is a 10% probability that < 2 HNPCC cancers will be observed (excluding the index case). In our series, 53% of "low risk" families had a SISE coefficient of 8.0 or less. The SISE coefficient can therefore be used to indicate the potential for a false negative diagnosis of HNPCC.

***BRCA1* and *BRCA2* mutations in an ethnically diverse cohort of high-risk women: evaluation of risk prediction models in African American and Caucasian families.** *H.J. Kim*¹, *R. Nanda*¹, *P.L. Schumm*², *S. Cummings*¹, *O.I. Olopade*¹. 1) Section of Hematology/Oncology, Department of Medicine, The University of Chicago, Chicago, IL; 2) Department of Health Studies, The University of Chicago, Chicago, IL.

To evaluate the performance of two risk prediction models, BRCAPRO and IBIS, in African American (AA) and Caucasian families (CA), we performed a retrospective analysis of genetic tests performed in our high-risk clinic from 1997 to date. Families included had at least 2 individuals with breast and/or ovarian cancers in 1st- and 2nd-degree relatives. For each family, the individual with the highest probability of being a mutation carrier based on the age of onset was selected for genetic testing. We used receiver operating characteristics (ROC) curve analyses to evaluate the performance of the models. There were 102 CA, 48 AA, 33 Ashkenazi Jewish (AJ), and 10 other minority families. This represents the largest cohort of ethnically diverse families reported to date. Excluding unclassified variants (UVs), genetic susceptibility to breast cancer could be explained by *BRCA1* mutations in 25.9% of all families, while 15.0% had *BRCA2* mutations. The mutation rate of *BRCA1* among AA was lower than in CA (14.6% vs 26.5%), while that of *BRCA2* was similar between the 2 groups (12.5% vs 13.7%). As expected, AA had the highest rate of UVs, while AJ had the highest mutation rates (45.5% for *BRCA1* and 24.2% for *BRCA2*). Among 6 Hispanic families one had a *BRCA2* mutation, and among 3 Asian families one had a *BRCA1* mutation. The likelihood of having a mutation in either gene was strongly associated with the number of breast/ovarian cancer cases in 1st- and 2nd-degree relatives and early age of onset of breast cancer. ROC curve analyses showed that BRCAPRO performed as well in AA as in other ethnic groups. Data from the IBIS model will be compared to BRCAPRO. Thus, *BRCA1/2* mutations occur in women of diverse ethnic origins, and genetic testing should be an integral part of comprehensive cancer risk management without regard to the ethnicity of the family. Future work will evaluate the clinical utility of different risk assessment tools in ethnically diverse populations seen in high-risk clinics in US, especially AA.

Patient Interest in Assessment of Familial Prostate Cancer Risk in Calgary, Alberta. *K. McLachlan¹, B. Donnelly^{2,3}, K. Carlson², J. Dushiniski², F. Elliott², W. Hyndman², G. Kozak², J. Lee², D. Metcalfe², P. Wilkin², R. Barr², R. Hughes³.* 1) Population Health Information, Tom Baker Cancer Centre, Calgary, AB, Canada; 2) Surgery, Univ. Calgary, AB; 3) Oncology, Univ. Calgary, AB.

This study examined the interest of men diagnosed with prostate cancer in undergoing a formal assessment of familial cancer risk. **SUBJECTS:** 1141 men from the Calgary region who had biopsies for prostate cancer diagnosis within the past 3 years. **METHODS:** Letters of invitation to participate in a prostate cancer followup study + familial cancer risk assessment were mailed together with a 1 page family history questionnaire. **RESULTS:** 431 men (37.8%) agreed to participate in the follow-up study including 283 men (24.8%) who provided familial cancer histories for genetic risk assessment. The family cancer histories were categorized into 3 groups: a) no risk (single case > 60 yr), b) possible risk (2 males with prostate cancer or one male diagnosed < 50 yr), c) probable (3 or more cancer diagnoses suggestive of hereditary prostate cancer HPC, or hereditary breast & ovarian cancer HBOC). The later 2 groups were asked complete a more detailed family history questionnaire for further assessment. **Results:** After review of the family history information, 28.8% were considered sporadic cases (82 men), 17.2 % (49 men) had a possible familial cancer risk and 54% (120 men) had family cancer histories suggestive of hereditary cancer syndromes (HPC, HBOC). The mean age of the men with possible or probable familial cancer risk was 58.8 yr + 10.5 yr SD. **CONCLUSION:** This population-based study found that approximately 11% of men diagnosed with prostate cancer in the Calgary region had family histories suggestive of hereditary cancer risk. Education (genetic counselling), risk reduction (vitamin E, selenium, cox-2 inhibitors), and early detection (DRE, PSA) may reduce the cancer-related morbidity and mortality for this group of high risk families. **Funding:** Alberta Health and Wellness, Alberta Cancer Board, Calgary Prostate Cancer Foundation.

Accuracy of Computerized BRCA1/2 Risk Assessment Models. *S.R. Nanda, N. Scanlan, G. Sheridan, P.J. Ainsworth, J.H. Jung, A. Sluyters.* Cancer Genetics, London Health Sciences Centre, London, ON. Canada.

Due to the increasing demand for BRCA1/2 genetic testing, breast cancer risk prediction models are being increasingly used. Cancergene version 3.4 (<http://www3.utsouthwestern.edu/cancergene/>) is a program that uses several mathematical risk assessment models (BRCAPRO, FHAT and Myriad II) to predict the probability of an individual carrying a BRCA1/2 mutation. The aim of this study was to determine the accuracy of these models in correctly predicting BRCA1/2 mutation status in our Southwestern Ontario population. The family histories of all probands seen through the Cancer Genetics clinic at London Health Sciences Centre, who underwent complete BRCA1/2 testing and had results available, were entered into Cancergene (n=667). A specific protocol was used to enter the pedigrees. From this, the probands personal risk of having a BRCA1/2 mutation was calculated using the models identified above. A family risk was determined by running the program on the highest risk individual in each family and based on Mendelian autosomal dominant inheritance the risk of the original proband was calculated using all three models. Among the probands (84.74% of whom were affected with cancer), 12.89% had a BRCA1/2 mutation and 87.11% did not test positive for a mutation. If a cut-off of 0.1 was used to determine testing eligibility, 37.21% of the positive probands and 65.82% of all probands would not have received testing based on their total BRCAPRO score. The sensitivity of the personal risk for total BRCAPRO was 62.79% and the specificity was 70.05%. The Myriad and FHAT models showed similar trends. Many limitations were encountered when using Cancergene. A specific limitation was that only first and second degree relatives could be entered into pedigrees. In addition, the program did not account for half siblings or consanguinity. This study suggests that one cannot solely rely on mathematical models for an accurate risk assessment. Clinical judgement is essential to establish a family's BRCA1/2 testing eligibility.

The genetic contribution of colorectal cancer in a Newfoundland region. *P.S. Parfrey¹, F. Curtis¹, S. Stuckless¹, A. Hyde², M.O. Woods², H.B. Younghusband², D. Robb³, R.C. Green², J.S. Green².* 1) Clinical Epidemiology, Memorial University of Newfoundland, St. John's, NL, Canada; 2) Genetics, Memorial University of Newfoundland; 3) Pathology, Memorial University of Newfoundland.

To determine the potential genetic contribution of colorectal cancer in the Avalon Peninsula, all patients < 70 years who presented with nonpolyposis colorectal cancer in 1997/8 (N=179) were identified and 79 provided detailed family histories. Nine probands (11%) had HNPCC, defined by Amsterdam I and II criteria; 51% of 79 family members had developed an HNPCC cancer by age 70 years. Thirteen (16%) families fulfilled Amsterdam II criteria modified for age (at least one cancer 60 years) and for cancer (HNPCC cancer defined by revised Bethesda); 30% of 116 members had developed cancer by age 70. 23 (29%) families were at intermediate risk based on revised Bethesda guidelines (excluding age/cancer modified group). Of 221 members, 10% had developed cancer by age 70. The low risk group was classified by informativeness of family structure, defined by the presence of at least 6 family members potentially at 50% risk of inheriting HNPCC who survived to 60 years or developed cancer. Nine (11%) families were uninformative; 8% of 61 members had developed cancer by age 70. The remaining 24 (30%) families were at low risk as confirmed by an informative family history. 3% of 294 members developed cancer by 70 years. The Hazard ratios for cancer in first and second degree relatives of probands compared to the low risk informative group, were 21.1(95% CI-10.0-44.6) for Amsterdam I + II, 10.9(CI 5.3-22.3) for age/cancer modified families, 3.8(1.8-8.3) for revised Bethesda criteria, and 1.8(0.5-6.6) for low risk uninformative families. 29% of probands from families defined by Amsterdam I and II demonstrated microsatellite instability, as did 33% of those from age/cancer modified group, 23% of revised Bethesda, and 14% of low risk group. In this population based study it is likely the genetic contribution of nonpolyposis colorectal cancer in Newfoundland is high, and that mutations in novel genes, associated with microsatellite stability, predispose to HNPCC.

Classification of unclassified variants in *BRCA1* and *BRCA2*. A. Spurdle¹, S. Healey¹, A. Bekessy^{1,5}, A. Marsh¹, kConFab², S. Tavtigian³, D. Goldgar³, P. Waring², M. Jenkins⁴, A. Tesoriero⁴, M. Southey⁴, J. Hopper⁴, P. Lovelock^{1,5}, M. Brown⁵, G. Chenevix-Trench¹. 1) Cancer & Cell Biology Division, Queensland Inst Med Research, Brisbane, QLD, Australia; 2) Peter MacCallum Cancer Institute, Melbourne; 3) International Agency for Research into Cancer, Lyon; 4) Centre for Genetic Epidemiology, University of Melbourne; 5) Department of Biochemistry, University of Queensland, Brisbane.

Many *BRCA1* and *BRCA2* sequence variants found in multiple-case breast cancer families are missense variants of unknown pathogenicity, termed unclassified variants (UVs). These create a dilemma for genetic counseling, and constitute about 8% of *BRCA1* and 18% of *BRCA2* variants detected among families ascertained by kConFab, an Australian national consortium for familial breast cancer research. We have started a genetic and histopathological analysis of these UVs, aiming to classify some variants as neutral/low clinical significance and to prioritize the rest for functional assays to assist in classification. Our approach has been to: a) evaluate the variant frequency in controls; b) undertake *in silico* analyses to investigate evolutionary conservation of sequence, and possible impact on structure or splicing; c) genotype as many family members as possible for penetrance and Bayesian causality analyses; d) examine tumours for loss of variant or wild type allele; e) use histopathological analysis to identify tumours with a *BRCA1*-like phenotype. Results from preliminary analysis of 10 *BRCA1* and 16 *BRCA2* UVs indicate that at least 5 *BRCA1* and 12 *BRCA2* variants are unlikely to act as high-risk deleterious alleles since they occur commonly in control individuals without cancer, and/or are absent in multiple affected family members, and/or show loss of the variant in tumour tissue. In the subset of 5 *BRCA1* variants considered unlikely pathogenic, 4/4 variants examined did not exhibit a *BRCA1*-like histopathological phenotype, and cross-species sequence comparison supported neutrality for the 5th variant. These data suggest that a combination of genetic, histopathological and evolutionary approaches will facilitate assessment of the pathogenicity of *BRCA1* and *BRCA2* UVs.

Homozygosity for *RNASEL* R462Q increases the risk of sporadic prostate cancer in Ashkenazi Jewish men. L.

Edelmann¹, Y. Yang¹, S. Lehrer², R.G. Stock², R.J. Desnick¹, R. Kornreich¹. 1) Department of Human Genetics, Mount Sinai School of Medicine, New York, NY; 2) Department of Radiation Oncology, Mount Sinai School of Medicine of Medicine, New York, NY.

Ribonuclease L (*RNASEL*) is involved in interferon antiviral activities and cell proliferation and presumably functions as a tumor suppressor gene. Alterations in the *RNASEL* gene have been implicated as predisposing factors in hereditary prostate cancer (HPC), while the genetic influences on sporadic prostate cancer (SPC) remain largely unknown. We genotyped 228 SPC patients of Ashkenazi Jewish (AJ) descent and 1,008 unrelated AJ healthy controls for known alterations in *RNASEL* including the R462Q variant that has 30% of wild-type enzyme activity, the AJ frameshift mutation 471delAAAG, and the E265X nonsense mutation, all of which have been reported to be associated with HPC. Importantly, after subtracting the 471delAAAG carriers, the frequency of R462Q homozygosity in AJ males with SPC was more than twice that of the controls and was statistically significant (13.6%; vs. 6.2%; OR = 2.40; P = 0.004), suggesting that R462Q homozygosity is a predisposing factor for the development of SPC. Neither 471delAAAG (q=0.024) nor the E265X (q=0.002) were found to have increased incidence in the AJ SPC patients. Genotyping of polymorphic markers tightly linked to the *RNASEL* locus on 1q25 indicated that R462Q was present on multiple distinct haplotypes in the AJ controls and SPC patients. These findings suggest that R462Q did not originate from a single founder in the AJ population and are consistent with the increased cancer predisposition associated with R462Q homozygosity. The high frequency of R462Q homozygosity in the AJ population (8%) as well as other populations, including Caucasian (~11%) and African American (~1%), suggest that this substitution may be a common risk factor for prostate cancer and that distinguishing between HPC and SPC with such alleles may be difficult, as it would depend on the genotype of close male relatives and the penetrance of the phenotype.

X chromosome inactivation in blood and tumor from females with colorectal cancer. *G.P.S. Knudsen¹, J. Pedersen¹, L. Thorstensen², T. Lvig³, R.A. Lothe^{2,4}, G.I. Meling⁵, K.H. rstavik^{1,6}*. 1) Department of Medical Genetics, Faculty division RH, University of Oslo, Norway; 2) Department of Genetics, Institute for Cancer Research, The Norwegian Radium Hospital, Oslo, Norway; 3) Institute of Forensic Medicine, University of Oslo, Rikshospitalet, Norway; 4) Department of Molecular Biosciences, University of Oslo, Norway; 5) Department of Surgery, Akershus University Hospital, University of Oslo, Nordbyhagen, Norway; 6) Department of Medical Genetics, Rikshospitalet, Oslo, Norway.

X chromosome inactivation occurs in early embryonic life and leads to a random X inactivation pattern in most females. Skewed X inactivation may arise due to chance, genetic factors or as a result of selection in favour or against cells with a specific genotype. X inactivation analysis has been used for clonality assessment of various tumors. A monoclonal tumor consists of cells with the same X chromosome as the active X, and thus shows a skewed X inactivation pattern. Colorectal carcinomas have been reported to be of both monoclonal and polyclonal origin. We investigated the clonality of colorectal carcinomas in females and compared X inactivation patterns in tumors with that of blood to see if monoclonality might be biased by constitutional skewed X inactivation. Informative X inactivation results were obtained by assessment of the methylation status of the androgen receptor in blood and tumor from 74 female colorectal cancer patients. We found no difference in frequency of skewed X inactivation (defined as skewed when 80 % of the cells have a preferential inactivation of one of the two X chromosomes) in blood between patients (39%) and controls (36%), but the frequency of skewed X inactivation was higher in blood than in tumor (16%) ($p < 0.001$). This indicates a polyclonal origin of the tumors and no biased monoclonality. We found skewing more frequently in tumors with microsatellite stability (11 of 59) than in tumors with microsatellite instability (none of 14) ($p = 0.109$). This might indicate that the hypermethylation of various promoters associated with microsatellite instability also affects the androgen receptor locus on the X chromosome.

Penetrance estimates of deleterious BRCA1 and BRCA2 mutations in high-risk French Canadian families. F.

Durocher¹, A. Antoniou², P. Smith², M. Dumont¹, R. Laframboise¹, J. Chiquette³, M. Plante¹, J. Simard¹, D. Easton², INHERIT BRCA_s. 1) Centre Hospitalier Universitaire de Quebec, Laval University, Quebec, Canada; 2) CR-UK Genetic Epidemiology Unit, Strangeways Research Laboratory, Cambridge, U.K; 3) Hôpital Saint-Sacrement, CHA, Quebec, Canada.

We used data from 251 French Canadian families with multiple affected individuals to estimate age-specific breast and ovarian cancer risks in BRCA1 and BRCA2 mutation carriers. Families were included in the analyses if an initial mutation carrier was identified in the family, and at least one other family member had been tested subsequently. There were 25 eligible families with BRCA1 mutations and 28 families with BRCA2 mutations. We estimated log-relative risks of breast and ovarian cancer in mutation carriers compared to the population risks by maximum likelihood, using a modified segregation analysis implemented in the computer program MENDEL. We maximised the conditional likelihood of all phenotypic and genotypic information in the family given all disease phenotypes and the genotypic information up to the point where the first mutation carrier was identified. The cumulative risk of breast cancer by age 70 in BRCA1 mutation carriers was estimated to be 91% (95% CI: 36-99%) and the ovarian cancer risk 9% (0-41%). The corresponding risks in BRCA2 mutation carriers were 84% (0-98%) and 37% (0-78%). The estimated breast cancer risks are in line with those found in multiple-case families, but somewhat higher than those obtained from the meta-analysis of families of BRCA1/2 carriers identified through population-based studies (Antoniou et al (2003), AJHG 72:1117). The BRCA1 ovarian cancer risk is also lower than previously reported. However, none of these estimates is significantly different from the meta-analysis estimates and thus our data are in agreement with those previously reported in other populations.

Genome-Wide Discovery of Loci Influencing Chemotherapy Cytotoxicity. *J. Watters*¹, *A. Kraja*², *M. Meucci*¹, *M. Province*², *H. McLeod*¹. 1) Dept of Medicine, Washington Univ, St Louis, MO; 2) Dept of Biostatistics, Washington Univ, St Louis, MO.

While numerous genes are likely to influence chemotherapy response, current candidate gene-based pharmacogenetics approaches require a priori knowledge and the selection of a small number of candidate genes for hypothesis testing. In this study, a novel *ex vivo* familial genetics strategy utilizing lymphoblastoid cells derived from the CEPH reference pedigrees was employed to discover genetic determinants of cytotoxicity to the mechanistically distinct chemotherapy agents 5-fluorouracil and docetaxel. The sensitivity of CEPH cells to drug-induced cell death was shown to be similar to that observed in the NCI-60 panel of tumor cell lines, and 5-fluorouracil and docetaxel were shown to cause apoptotic cell death involving caspase-3 cleavage in CEPH cells. Cytotoxicity to 5-fluorouracil and docetaxel were shown to be heritable traits in CEPH families, with heritability values ranging from 0.26 to 0.65 for 5-fluorouracil and 0.21 to 0.70 for docetaxel, varying with dose. Genome-wide linkage analysis was also used to map a QTL influencing the cellular effects of 5-fluorouracil to chromosome 9q13-q22 (LOD=3.44), and two QTLs influencing the cellular effects of docetaxel to chromosomes 5q11-21 (LOD=2.21) and 9q13-q22 (LOD=2.73). Utilizing SNP genotype data provided by the SNP consortium and the International HapMap project, family-based tests for association were employed to identify positional candidate genes. Finally, whole-genome expression profiling was used to identify candidate genes that were differentially expressed between resistant and sensitive cell lines. Alteration of gene expression by siRNA and confirmation in an independent sample set are currently being used to validate candidate genes. This study identifies genomic regions and candidate genes likely influence chemotherapy cytotoxicity using a combination of genome-wide linkage analysis, SNP association tests, and gene expression profiling, thus providing a widely applicable strategy for pharmacogenomic discovery without the requirement for a priori candidate gene selection.

A *Prkar1a* down-regulation in vitro system for the study of protein kinase A-related tumorigenicity in mouse cells and in Carney complex. *F.D. Weinberg, K.J. Griffin, A. Binstock, A.J. Bauer, L. Matyakhina, C.A. Stratakis.* National Institutes of Health, Bethesda, MD.

Carney Complex (CNC) is a multiple neoplasia syndrome associated with skin pigmentation defects and other abnormalities. The *PRKARIA* gene, encoding the type 1 regulatory subunit of protein kinase A (PKA), is mutated in approximately half of the cases and may function as a tumor-suppressor gene. To establish an animal model specific to CNC, heterozygote *Prkar1a* +/- mice were generated using flanking loxP sites. Mouse embryonic fibroblast (MEF) cell lines were generated at 13 days post-conception. Down-regulation of the *Prkar1a* gene was attempted in these cells using short interfering RNAs (siRNA) specific to the gene. First, a control siRNA against vinculin led to down-regulation of the vinculin protein in these MEFs. After transfection with the siRNA directed against *Prkar1a*, down-regulation of *Prkar1a* at the mRNA level was also shown; interestingly, this affected the mRNA levels of the other subunits (*Prkar1b*, *Prkar2b*, *Prkar2a*, and *Prkaca*). Protein levels of *prkar1* were also decreased along with corresponding changes in the protein levels of the other PKA subunits. *Prkar1a* -/- MEFs are spontaneously immortalized; current work is aiming at elucidating growth and proliferation characteristics of *Prkar1a* +/- cells at baseline and after further down regulation of the *Prkar1a* gene; cell cycle, proliferation and morphology experiments are currently pending in cells transfected with the siRNAs. We conclude that we have generated a system of *Prkar1a* down-regulation employing siRNAs in proliferating, primary MEFs. Future studies will use these cells in an attempt to link *Prkar1a* down-regulation with the abnormal growth and proliferation phenotype of human and mouse mesenchymal and other cells.

Renal oncocytomas as a model to study the regulation of mitochondrial proliferation. *S. Zanssen¹, X. Hong¹, E. Kessel¹, B. Gunawan², L. Fuzesi², D. Warburton^{3,4}, E. Schon^{1,4}.* 1) Department of Neurology, Columbia University, 630 West 168th Street, New York, NY 10032, USA;; 2) Department of Pathology, University of Goettingen, Germany; 3) Department of Pediatrics, Columbia University, 630 West 168th Street, New York, NY 10032, USA;; 4) Department of Genetics and Development, Columbia University, 630 West 168th Street, New York, NY 10032, USA;.

Mitochondrial defects have been associated with severe neurodegenerative disorders with human cancers. A variety of encephalomyopathies have been linked to alterations of mtDNA. The predominantly neurological symptoms are not produced by the mutations per se, but by an unregulated proliferation of pathologic mitochondria. We are using oncocytomas, which are mostly benign epithelial tumors whose predominant feature is a massive accumulation of mitochondria in the cytoplasm, as a way to search for unknown genes that play a role in regulation of mitochondrial proliferation. We studied three oncocytomas with 11q13 rearrangements. Fluorescent in situ hybridization (FISH) using BAC clones in the region showed that the 11q13 breakpoints in all three tumors are near the CCND1 (BCL1) gene. None of the breakpoints disrupts any known gene other than CCND1, but gene prediction programs suggest several human genes in the breakpoint region. The rearrangement in one tumor consisted of a segmental duplication that included 11q13, presenting several mitochondrially-targeted genes immediately distal to CCND1 as interesting candidate genes.

MICROTIA AND AURAL ATRESIA. AUDIOLOGICAL FINDING. *F. Castillo-Lorca*¹, *M. Diaz-Garcia*², *G. Garcia-Sanchez*¹, *A. Garcia-Huerta*¹, *L. Hernandez-Gomez*³, *C.F. Martinez-Cruz*^{4,5}. 1) Departamento de Genetica. Instituto de la Comunicacion Humana. Centro Nacional de Rehabilitacion SSa. Mexico; 2) Departamento de Investigacion. Instituto de la Comunicacion Humana. Centro Nacional de Rehabilitacion SSa. Mexico; 3) Servicio de Audiologia. Instituto de la Comunicacion Humana. Centro Nacional de Rehabilitacion SSa. Mexico; 4) Servicio de Comunicacion Humana. Departamento de Seguimiento Pediatrico. Instituto Nacional de Perinatologia SSa. Mexico; 5) Servicio de Pediatria. HGZ No.53 Los Reyes la Paz. Instituto Mexicano del Seguro Social. Mexico.

Microtia is a birth defect that affects one in 8000-10,000 children. It typically affects males and is more frequent on the right ear. The microtia happens in the first trimester of pregnancy while the ears are developing. In some cases it is hereditary. Aural atresia is the absence of an opening for the ear canal. It doesn't mean that there is no canal, but rather that it is not open to the outside. The rate of occurrence is 1 in 10,000 to 1 in 20,000 live births. Unilateral atresia is three times more common than bilateral atresia, more common on the right side, and males are more commonly affected. Associated with a variety of syndromes and disorders as well as occurring in isolation. Many investigations point that microtia with atresia cause severe conductive hearing loss. We studied 130 patients with different microtia types, with or without atresia, 79 men (60.8%) and 51 women (39.4%). With mean age of 9.36 years. All patients were tested with conventional audiometry. The most frequent findings were: Microtia-Atresia type II (68.8 % right and 65.8 % left side); with regard to hearing loss it was of conductive type (86.9%), severe (92.8 %), ascending (67.5 %). All the ears with microtia-atresia showed hearing loss and only 72 % with stenosis. We didn't find association between gender and severity of the microtia; severity and side of the microtia, malformation of the auditory external canal and affected side, X² (P> 0.05). In the present study 99.2 % of the patients with microtia and aural atresia had some degree of hearing loss in the affected ear.

BRANQUIO-OTO-RENAL SYNDROME IN MEXICAN PATIENTS. A. Garcia-Huerta¹, A. Alcala Vazquez¹, C.F. Martinez-Cruz^{2,3}, L. Hernandez-Gomez⁴, F. Castillo-Lorca¹, G. Garcia-Sanchez¹. 1) Departamento de Genetica. Instituto de la Comunicacion Humana. Centro Nacional de Rehabilitacion. Mexico; 2) Servicio de Comunicacion Humana. Departamenmto de Seguimiento Pediatrico. Instituto de Perinatologia. Mexico; 3) Servicio de Pediatria. HGZ No.53 Los Reyes la Paz. Instituto Mexicano del Seguro Social. Mexico; 4) Servicio de Audiologia. Instituto de la Comunicacion Humana. Centro Nacional de Rehabilitacion. Mexico.

Branchio-oto-renal syndrome is the second most common type of autosomal dominant syndromic hearing loss. It consists of conductive, sensorineural, or mixed hearing loss in association with branchial cleft cysts or fistulae, malformations of the external ear including preauricular pits, and renal anomalies. Penetrance is high, but expressivity is extremely variable. Approximately 40% of persons with the BOR phenotype have mutations in the EYA1 gene (chromosomal locus 8q13), suggesting that BOR may be caused by mutations at other loci. Molecular genetic testing is available clinically. We analyzed 8 patients with branchio-oto-renal syndrome. 6 had branchial cysts or fistulas; 4 were bilateral; 2 had preauricular pits, 1 with auricular appendage and 2 cases of low set ears. We had 3 cases of bilateral microtia; 1 bilateral malformation of the ossicles and 1 bilateral malformed cochlea. We found hemifacial microsomia, facial palsy, mandibular hypoplasia and submucous cleft palate, among others. They did not have renal malformations. All patients had hearing loss, mainly sensorineural. The family history was negative in all patients. Therefore, it would be interesting to carry out genetic molecular testings, cause here in Mexico does not exist similar studies in patients with BOR.

VAN DER WOUDE SYNDROME. IN A MEXICAN FAMILY. *G. Garcia-Sanchez¹, C.F. Martinez-Cruz^{2,3}, A. Garcia-Huerta¹, F. Castillo-Lorca¹, L. Hernandez-Gomez⁴, M.R. Baez-Reyes⁵*. 1) Departamento de Genetica. Instituto de la Comunicacion Humana. Centro Nacional de Rehabilitacion. Mexico; 2) Servicio de Comunicacion Humana. Departamenmto de Seguimiento Pediatrico. Instituto Perinatologia. Mexico; 3) Servicio de Pediatria. HGZ No.53 Los Reyes la Paz. Instituto Mexicano del Seguro Social. Mexico; 4) Servicio de Audiologia. Instituto de la Comunicacion Humana. Centro Nacional de Rehabilitacion SSa. Mexico; 5) Servicio de Genetica. Departamento de Investigacion. Instituto Nacional de Perinatologia SSa. Mexico.

Van der Woude syndrome (VWS) is a dominantly inherited developmental disorder characterized by pits and/or sinuses of the lower lip, cleft lip/palate (CL/P), cleft palate (CP), bifid uvula, and hypodontia. The expression of VWS, which has incomplete penetrance, is highly variable. It is the most common cleft syndrome. Most reported cases of VWS have been linked to chromosome 1q32-q41 (VWS1), but a second VWS locus (VWS2) has been mapped to 1p34, performed direct sequence analysis of genes and presumptive transcripts in the 350-kb VWS critical region identified by linkage analysis and identified mutations in the gene encoding interferon regulatory factor-6 (IRF6). Mutation analysis demonstrated that popliteal pterygium syndrome can be caused by mutations in the same gene and is therefore allelic to van der Woude syndrome. We report a Mexican family with 6 affected members with VWS in 3 generations (autosomal dominant inheritance). We found the proband, his grandfather and paternal uncle with lip pits, his father had unilateral cleft lip and palate. His sister had cleft palate and his brother had bifid uvula. All three clinical features occurred together in an affected individual. This family has all the VWS features, proving the variable expressivity of the syndrome. Molecular testings are outstanding.

RADIOLOGICAL FINDINGS IN SPINE OF PATIENTS WITH MICROTIA AND AURAL ATRESIA. L.

Hernandez-Gomez¹, S.G. Juarez-Garcia², G. Garcia-Sanchez², M. Diaz-Garcia³, C.F. Martinez-Cruz^{4,5}. 1) Servicio de Audiología. Instituto de la Comunicación Humana. Centro Nacional de Rehabilitación SSA. Mexico; 2) Departamento de Genética. Instituto de la Comunicación Humana. Centro Nacional de Rehabilitación SSA. Mexico; 3) Departamento de Investigación. Instituto de la Comunicación Humana. Centro Nacional de Rehabilitación SSA. Mexico; 4) Servicio de Comunicación Humana. Departamento de Seguimiento Pediátrico. Instituto Nacional de Perinatología SSA. Mexico; 5) Servicio de Pediatría. HGZ No.53 Los Reyes la Paz. Instituto Mexicano del Seguro Social. Mexico.

Microtia is a birth defect that affects one in 8000-10,000 children. It typically affects males and is more frequent on the right ear. The microtia happens in the first trimester of pregnancy while the ears are developing. In some cases it is hereditary. Aural atresia is the absence of an opening for the ear canal. It doesn't mean that there is no canal, but rather that it is not open to the outside. The rate of occurrence is 1 in 10,000 to 1 in 20,000 live births. Unilateral atresia is three times more common than bilateral atresia, more common on the right side, and males are more commonly affected. Associated with a variety of syndromes and disorders as well as occurring in isolation. We studied 57 Mexican patients with different microtia types, 60% men (n=34) and 40% women (n=23) with an age average of 2 to 17 years. 31.5% (n=18) with right microtia, 17.5% (n=10) with left microtia and 51% with bilateral microtia. Microtia type I in 39% (n=22) and types II-III in 61% (n=35). With regard to the presence of spine malformations in the x-rays, 33% (n=19) had any malformation, and 67% had not. Statistically significant (Fisher exact test $P < 0.10$).

STICKLER SYNDROME. A MEXICAN FAMILY REPORT. *C.F. Martinez-Cruz^{1,2}, G. Garcia-Sanchez³, A. Garcia-Huerta³, F. Castillo-Lorca³, L. Hernandez-Gomez⁴.* 1) Servicio de Comunicacion Humana. Departamento de Seguimiento Pediatrico. Instituto Nacional de Perinatologia SSa. Mexico; 2) Servicio de Pediatria. HGZ No.53 Los Reyes la Paz. Instituto Mexicano del Seguro Social. Mexico; 3) Departamento de Genetica. Instituto de la Comunicacion Humana. Centro Nacional de Rehabilitacion SSa. Mexico; 4) Servicio de Audiologia. Instituto de la Comunicacion Humana. Centro Nacional de Rehabilitacion SSa. Mexico.

Stickler syndrome consists of progressive sensorineural hearing loss, cleft palate, and spondyloepiphyseal dysplasia resulting in osteoarthritis. Three types are recognized, based on the molecular genetic defect: STL1 (COL2A1), STL2 (COL11A2) and STL3 (COL11A1). STL1 and STL3 have severe myopia, which predisposes to retinal detachment, but this aspect of the phenotype is absent in STL2 because the COL11A2 gene is not expressed in the eye. Causative mutations have been found in the genes causing STL1, STL2, and STL3. Molecular genetic testing is available clinically. We report a Mexican family in which father and his two children are affected (autosomal dominant inheritance). All three patients had sensorineural bilateral profound, prelingual hearing loss, the younger child had severe myopia, the father and his elder child had retinal detachment and the younger child had cleft palate. In this family the Stickler syndrome is probably due to mutations in anyone of the genes STL1 or STL3.

Recognition of patterns of congenital syndromes through analyzing data from the OMIM database. X. Ji¹, J. Li-Ling². 1) Laboratory for Conservation and Utilization of Bio-resources, Yunnan University, Kunming 650091, CHINA; 2) Department of Medical Genetics, China Medical University, Shenyang 110001, CHINA.

Clustered features seen in various congenital syndromes may provide important information about mechanisms of embryonic development and pathogenesis of many isolated features. Summary of the patterns of such syndromes may also provide unique clues for the construction of genetic networks. In this study, clinical synopses of more than 4,500 syndromes (containing more than 50,000 individual features), as summarized by the Online Mendelian Inheritance in Man (OMIM) database (version of 15th March 2004), were extracted, checked and classified manually based on medical knowledge. Subsequently, statistical analysis was performed to identify the correlations between OMIM entries, clinical synopses, and their underlying genetic defects. An effort was also made to correlate the patterns of such syndromes with mechanisms of embryonic development. According to which feature or up-level category it was classified into, each OMIM entry was assigned a feature- or category-classification profile. Such profiles were then compared with each other to produce a similarity/distance matrices. Finally, hierarchical trees were constructed with neighbor-joining method based on the distance matrices (Detailed results may be viewed at: <http://www.bioinfo.tsinghua.edu.cn/~rich/science/omim/01/index.html>). Utilization of bioinformatics approaches such as pattern recognition and phylogenic trees has recognized particular patterns of disease occurrence. These have included midline defects, midline-radial ray abnormality, neurology-endocrine-immunity association, etc. Our analysis seems mostly fit the generalization made by Opitz, that most features seen in congenital syndromes are of midline defects, and that genetic defects in various forms and scales may cause congenital syndromes in a similar pattern. Notably, data from OMIM are probably only partial due to insufficient data, observational bias and natural selection. Our analysis of the OMIM, 'Phenotypic companion to the HGP', may provide a foundation for further studies into this direction.

Omodysplasia: report of the first Brazilian case. *L.M.J. Albano¹, L.A.N. Oliveira², D.R. Bertola¹, A.C. Paula¹, T.P. Delboni¹, C.A. Kim¹.* 1) Genetics Clinic Unit, Inst da Crianca, Hosp das Clinicas, Sao Paulo, Brazil; 2) Radiology, Instituto da Crianca, HC-FMUSP, Sao Paulo, Brazil.

Omodysplasia, an heterogeneous disorder with an autosomal recessive and dominant pattern of inheritance, constitutes an osteochondrodysplasia characterized by craniofacial dysmorphisms (depressed nasal bridge, broad base of the nose, long philtrum), shortened humeri and femora and a characteristic radial dislocation with radioulnar diastasis. The autosomal dominant form seems to be much rarer than the recessive one with abnormalities limited to the upper limbs, and the recessive presents a generalized involvement of the limbs and severe dwarfism. Both types share the facial characteristics, the typical defect of the distal humerus and the complex deformity of the elbows. Less than 25 recessive cases were reported in the literature so far. We report the first male Brazilian recessive case complaining of pain in his shoulders, hip and legs: a 9y3mo-old boy from healthy and consanguineous parents presenting short stature, frontal bossing, depressed nasal bridge, small nose and midfacial flatening, shortened arms, limited extension of the elbows and knees, tiptoe gait, intellectual impairment and motor development delay. Skeletal survey showed shortened humeri bilaterally with abnormal sloping of the distal articular surface, shallow olecranon fossae with partially subluxed radii and radioulnar diastasis; short femora with metaphyseal widening and small laterally displaced patellae. Our case reinforces the findings stressed by some authors that the recessive form is the most common type, there is a male preponderance, and metacarpal shortening was not observed in recessive cases. As the facial features of omodysplasia overlap with achondroplasia and Robinow syndrome these conditions should be considered in the differential diagnosis as well as other ryzomelic dwarfisms.

Tibial camptomelia, oligodactyly and fibular aplasia in a male newborn. *W. Courtens¹, A. Jespers², I. Harrewijn², D. Puylaert³, F. Vanhoenacker⁴.* 1) Medical Genetics, University Hospital Antwerp, Antwerp,Belgium; 2) Department of Neonatology, University Childrens Hospital Queen Paola, Antwerp,Belgium; 3) Department of Orthopedics, University Childrens Hospital Queen Paola, Antwerp,Belgium; 4) Department of Radiology, University Hospital Antwerp, Antwerp, Belgium.

We report on a male newborn with a rarely described congenital limb deficiency syndrome consisting of an anterior bowing of the right lower limb at the distal third of the tibia with associated overlying soft tissue dimpling, oligodactyly of the right foot (presence of only 4 toes; the Vth ray was lacking), and a left-sided oligosyndactyly of the hand: there was a nearly complete syndactyly of fingers I-II and IV-V, the presence of only 4 metacarpal bones, the presence of only two distal phalanges of the IVth finger (attached to the Vth finger) ; and a cutaneous syndactyly between fingers III and IV-V, extending until the proximal interphalangeal joint. The right hand and left lower limb were clinically normal. At X-ray examination absence of the right fibula, absence of the right-sided Vth metatarsal and phalanges, and bowing and shortening of the right-sided tibia were noted. The femorae, humerae, ulnae, and radii were normal. The infant had no facial dysmorphism (except a mild micrognathia), nor other associated anomalies. A limb deficiency syndrome comparable to this case, has been reported by Hecht and Scott (1981) in half-sibs and was recognized as limb deficiency-heart malformation syndrome in OMIM [246570]. No other cases with a diagnosis of a similar syndrome were reported in this database so far. We found another two reports describing three cases comparable to our case and reviewed these cases. Since there was no associated heartdefect, except in one case, and since they all had three major findings in common, we propose to name it fibular aplasia-oligosyndactyly-tibial camptomelia syndrome. Additional case reports are needed to further delineate this rare limb deficiency syndrome.

Ollier disease. Report of the first Mexican familial case. *R. E' Vega¹, I.P. Davalos^{2,3}, L.E. Figuera^{2,3}, N.O. Davalos^{3,4}.* 1) Servicio de Traumatología y Ortopedia, Hospital Regional Valentin Gomez Farias, ISSSTE; 2) Division de Genetica, CIBO, IMSS; 3) Doctorado en Genetica Humana, CUCS, Universidad de Guadalajara; 4) Servicio de Genetica, Hospital General Regional Valentin Gomez Farias, ISSSTE. Guadalajara, Jalisco, Mexico.

The Ollier Disease (OD) or Multiple Enchondromatosis [OMIM #166000] is a rare skeletal disease, it was first described by Ollier as a chondrodysplasia. Enchondromas, characteristics of OD, are common benign cartilage tumors, that can occur as solitary lesions or as multiple lesions, they can occur anywhere, but are most common in the hands. OD can be present at birth, but it may not become apparent until early childhood. Enchondromas involving long bone are common, leading to progressive skeletal deformities and pathologic fractures with . It occurs in all races with no sex predominance. The condition is sporadic although 5 familial occurrences of Ollier disease have been reported. CASE REPORT: The propositus 74 male years-old. Clinically showed asymmetry in length and shape of involved limb. Radiologically revealed irregular, elongated tumorous radio lucent defects in metaphyses of tubular bones. Short tubular bones in hands and feet. The purpose of this paper is to describe a first familial case with OD with 17 affected members in 6 generations (M:11; F:6) suggesting an autosomal dominant inheritance with variable expressivity. All affected revealed skeletal anomalies such as pathologic fracture, irregular calcification within enchondromas lesions. Enchondromas are usually in or surrounding the growth-plate cartilage. It has been suggested that the defect can result from abnormal regulation of proliferation and terminal differentiation of chondrocytes in the adjoining growth plate. OD could be caused by a mutation in the PTH/PTHrP type I receptor (OMIM #166000). Gene map locus 3p22-p21.1. It remains to do molecular analysis on this family in order to determine if its defect is linked to this locus.

FIRST FAMILIAL CASE OF CANTU CRANIOFACIOCARDIOSKELETAL SYNDROME. *C.L. Garcia-Gonzalez^{1,3}, D. Garcia-Cruz^{2,3}, M.G. Lopez-Cardona^{1,3}, J.M. Cantu³, G. Castañeda-Cisneros^{1,3}, L.E. Figuera^{2,3}, J. Sanchez-Corona^{1,3}.* 1) Medicina Molecular, CIBO, IMSS, Guadalajara, Jalisco, Mexico; 2) Genetica, CIBO, IMSS, Guadalajara, Jalisco, Mexico; 3) Doctorado Genetica Humana, CUCS, U de G; Guadalajara, Jalisco, Mexico.

In 1982, some of us (Clin. Genet. 22: 172, 1982) described a craniofaciocardioskeletal dysmorphic syndrome in four unrelated girls, which was later catalogued as Cantu syndrome (MIM N 114620). It is characterized by mild mental retardation, short stature, macrocranium, prominent forehead, hypertelorism, exophthalmos, cardiac anomalies, cutis laxa, wrinkled palms and soles, joint hyperextensibility, wide ribs, and small vertebral bodies. The cases were all sporadic. The parents were nonconsanguineous. The father's age at the birth of each case was above 45, suggesting a dominant de novo mutation. We recently studied a girl aged 6 10/12 years who showed a similar syndrome in which the mother, maternal grandfather and brother presented similar facial and/or clinical characteristics. At the proposita's birth was detected hypoxia and suspected cardiopathy. Her psychomotor development has been delayed. Clinically she presented macrodolichocephaly, scarce hair with some alopecic areas, peculiar facies with prominent forehead, scarce eyebrows, antimongoloid palpebral fissures, short neck, low-set posterior hair, barrel-shaped thorax, nipple hypertelorism, wrinkled palms and soles, clitoris hypertrophy, hypoplastic labia majora, hyperelastic skin, joint hyperextensibility, wide ribs and small vertebral bodies. The doppler colour echocardiogram revealed a mild pulmonary stenosis. A cranial CAT showed megalencephaly, arachnoidal cysts and a skin biopsy increased elastic fibres. This is the first familial report of the Cantu craniofaciocardioskeletal syndrome. Some imagenological and histological features not previously described in this syndrome are also reported.

New radiological features in Kabuki (Niikawa-Kuroki) syndrome. *D. Genevieve¹, D. Sanlaville¹, M. Le Merrer¹, J. Amiel¹, P. Parent², S. Lyonnet¹, A. Munnich¹, V. Cormier-Daire¹.* 1) Departement de Genetique, Hopital Necker-Enfants Malades, Paris, France; 2) Service de Genetique, Hopital de Brest, Brest, France.

Kabuki syndrome (KS) is a rare multiple congenital anomaly/mental retardation syndrome with an estimated frequency of 1/32,000 in Japan. Five major criteria delineate KS namely characteristic facial dysmorphism, postnatal short stature, moderate mental retardation, dermatoglyphic and skeletal anomalies. Classical skeletal features are observed in largely 98% of cases and include scoliosis, sagittal cleft of vertebral body, short fifth finger with short middle phalanx, short metacarpal, coarse carpal bone, cone shaped epiphysis and advanced or delayed bone age. Here, we report on a series of 12 sporadic KS patients and focus on previously unreported radiological features namely abnormal shaped, round and irregular middle phalanx of the fifth finger (6/12), delayed bone age (8/12), flat superior and inferior femoral epiphyses (6/9), irregular internal femoral inferior epiphysis (5/9) and long and thin femoral neck (9/10). These radiological features, in combination with the previously skeletal anomalies reported in KS, can be used as helpful diagnostic criteria in KS.

COL2A1 mutation in spondyloepiphyseal dysplasia with hydrocephalus and pulmonary hypertension. *J. Hoover-Fong*¹, *I. Berkowitz*², *J. Hyland*³, *R. Lachman*⁴. 1) Inst Genetic Medicine, Greenberg Ctr Skeletal Dysplasias, Johns Hopkins U, Baltimore; 2) Johns Hopkins U, Baltimore; 3) Tulane U Health Sci Ctr, New Orleans; 4) Intl Skeletal Dysplasia Reg, Cedars-Sinai Med Ctr, LA.

This patient had disproportionate short trunk dwarfism, very short chest, midface hypoplasia, diffuse delayed ossification, and flat, ovoid vertebrae. These features were consistent with a spondyloepiphyseal dysplasia (SED), likely spondyloepiphyseal dysplasia congenital (SEDC). Her clinical course was complicated by chronic restrictive pulmonary insufficiency requiring tracheotomy and mechanical ventilation, poor weight gain and recurrent infections, all found in severe SEDC. Beside mild hyperopia, her eyes were normal and palate intact. Atypical features were non-communicating hydrocephalus requiring VP shunt placement and pulmonary hypertension, refractory to all medical therapy including nitric oxide. Despite maximal care, she died at 7 mos. Sequencing COL2A1 revealed a novel 36 bp insertion in exon 48 at cDNA position c.3315. The gly-X-Y amino acid sequence was maintained. Type II collagen is in articular cartilage, spine nucleus pulposus and eye vitreous. COL2A1 produces 1(II) polypeptide chains which form a triple helix homotrimer, twisting from carboxy (C) to amino (N) terminus. COL2A1 mutations are found in SEDs ranging from mild early-onset arthritis, to more severe yet viable Kniest dysplasia, SED Strudwick, and SEDC, to perinatal lethal hypochondrogenesis and achondrogenesis type II. These are dominant negative mutations, with a trend (not absolute) of worsening phenotype as nearing the C terminus. Deletion, splice, duplication, insertion, and most commonly missense mutations (often disrupting gly-X-Y) are described in SEDs. Despite maintaining the gly-X-Y motif, the proximity of our patient's mutation to the C terminus likely explains her severe phenotype. Hydrocephalus and pulmonary hypertension are not described in SEDC. It is possible our patient had one of the lethal SEDs and survived due to extraordinary measures. Perhaps hypochondrogenesis and/or achondrogenesis type II are associated with hydrocephalus and pulmonary hypertension, but unappreciated due to early lethality.

Neonatal Marfan Syndrome: two cases with some unusual clinical findings. *B. Lo¹, G. Maegawa¹, P. Satodia¹, H. Whyte¹, M. Semer¹, J. Hutchinson¹, G. Wilson¹, G. Gross¹, G. Matyas², A. Hinek¹, S. Unger³, D. Chitayat^{1,4}.* 1) Div Clinical Genetics, Hosp Sick Children, Toronto, ON, Canada; 2) Division of Metab and Molec Pediatrics, Univ. Children's Hosp, Zurich, Switzerland; 3) Div of Molec Pediatrics, Univ. Hosp CHUV, Lausanne, Switzerland; 4) Prenatal Diag. and Medical Genetics Program, Mount Sinai Hosp, ON, Canada.

Marfan syndrome is an AD disorder of connective tissue caused by mutations in the fibrillin-1 gene. We report two cases with some unusual clinical finds.. Case1: female born at 37 weeks gestation with loose redundant facial skin, deep-set eyes, arachnodactyly, joint contractures and the hepatic veins connecting to the rt atrium which has not been previously reported in nMFS. A Rt cong. diaphragmatic hernia was diagnosed prenatally at 28 weeks gestation. The baby developed collapse of much of the Lt lung and lower segment of lower Rt. lobe. A missense mut c. 3202T>G on exon 25 of FBN-1 gene was detected. This mut. occurs in a calcium binding epidermal growth factor like domain 11. The fibroblast immunostaining findings showed a disorganization of collagen and elastin and lacking of fibrillin-1 fibers. Case 2: male infant born at term with dolicomacrocephaly, deep set eyes, loose redundant skin over the head and neck, pectus carinatum, marked arachnodactyly, joint contractures, mitral valve regurgitation and dilatation of the aortic and pulmonary roots. The brain MRI revealed interdigitation of the interhemispheric fissure suggesting a partial absence of the falx and a cerebellum displaced upwards which was at first time in nMFS. His neurological examination was normal. At 3 months, the patient died secondary to severe mitral valve insufficiency. A novel G > A transition mut. was identified and it is predicted to affect the invariant +1 position of the splice donor site in intron 30 leading to skipping of exon 30 of the FBN-1 gene. We have two novel mut. in two nMF with some unusual clinical findings such as the brain MRI finds. and the abnormal vascular hepatic vein connection seen in case. It is early to make association of these novel mutation to the these new clinical findings. Further nMFS patients with these muts. should be described.

Expanding the spectrum of phenotypes associated with *COL10A1* mutations - Schmid type of metaphyseal chondrodysplasia with normal height. *O. Mäkitie*^{1,2}, *M. Susic*¹, *W.G. Cole*¹. 1) Research Institute and Division of Orthopaedics, The Hospital for Sick Children, Toronto, ON, Canada; 2) Hospital for Children and Adolescents, University of Helsinki, Helsinki, Finland.

Schmid type of metaphyseal chondrodysplasia (MCDS; MIM# 156500) is an autosomal dominant chondrodysplasia characterized by progressive growth failure resulting in short-limbed short stature (adult height 135-145 cm), and by lower limb deformity which often requires surgical intervention. Radiographic features include widened and irregular growth plates especially in the distal and proximal femora. MCDS results from autosomal dominant mutations in *COL10A1*, the gene encoding for the 1() chains of type X collagen. Type X collagen is a short-chain, non-fibrillar collagen synthesized specifically by hypertrophic chondrocytes at sites of endochondral ossification.

We describe a patient with MCDS and a novel *COL10A1* mutation who had an unusually mild presentation with normal height, late onset of symptoms and lack of lower limb deformity. This female was born at term to healthy parents. Her early growth and development were unremarkable. From age 4 years she was noticed to have a limp and was at age 8 years referred to orthopaedic assessment because of bilateral hip pain and abnormal gait. She was found to have restricted hip movements but no lower limb deformity. Radiographically she had short femoral necks and coxa vara bilaterally; the proximal femoral growth plates showed evidence of mechanical failure and stress fracture. Otherwise her radiographs showed very little metaphyseal involvement. Her height at age 9.6 years was 127 cm (-1.7 SDS). *COL10A1* sequence analysis showed a heterozygous nucleotide substitution 1942G>A which results in a single amino-acid substitution D648N.

Our findings suggest that 1) the clinical variability of *COL10A1* associated skeletal dysplasia is greater than previously thought, and that 2) type X collagen plays a key role in femoral neck development and may be an important determinant of its length, width and neck-shaft angle which have important implications to susceptibility to hip fracture.

Clinical and molecular evaluation of Small Patella Syndrome. *I. McIntosh¹, J. Zaveri¹, R.S. Lachman², J.E. Hoover-Fong¹.* 1) Inst Genetic Medicine & Greenberg Ctr, JHMI, Baltimore, MD; 2) Cedars-Sinai, Los Angeles, CA.

Small patella syndrome (SPS; Scott-Taor syndrome, ischio-pubic-patellar syndrome, ischiopatellar dysplasia) is characterized by patellar hypoplasia/aplasia, infra-acetabular axe-cut notches and abnormal ossification of the ischio-pubic joint. Additional clinical features include a wide gap between toes 1 and 2, pes planus, and short 4th and 5th metatarsals. Heterozygous mutations of TBX4 have been identified in individuals with SPS (AJHG 74:1239). The distinction between similar diagnoses is of crucial importance when the prognoses differ significantly. We describe a family of 3 affected individuals in 2 generations in which the 32 year old female proband presented with the diagnosis of Nail Patella Syndrome (NPS), a distinct disorder associated with patellar aplasia/hypoplasia, but also characteristic nail and elbow anomalies and iliac horns, and a greatly increased risk of glaucoma and nephropathy. NPS was ruled out clinically and by mutation testing of LMX1B. X-ray revealed hypoplastic ischio-pubic synchondroses and bilateral hypoplastic patellae. Physical exam revealed wide space between toes 1 and 2, pes planus, and short 4th and 5th metatarsals. The clinical diagnosis of SPS was assigned and subsequently confirmed via mutation testing of TBX4 with identification of a previously described frameshift mutation. The patient also had a history of depression, anxiety, ADHD and executive dysfunction. Her ophthalmic history is significant for recurrent strabismus, severe myopia, bilateral congenital cataracts and astigmatism. The proband's sister (28 yrs) and niece (3 yrs) also have hypoplastic patellae, an increased gap between toes 1 and 2 and pes planus. Dyslexia, anxiety and a learning disability were also present in the sister. Knee and hip problems, ADHD and other learning disorders were reported in family members unavailable for physical examination. TBX4 is broadly expressed in the developing hindlimb, and is required for normal development of the hindlimb and allantois. Whether the ocular and neuropsychiatric findings observed in the proband described here are coincidental, or represent an extension of the SPS phenotype, remains to be determined.

Discriminant analysis of metacarpophalangeal patterns in multiple genetic conditions. *F.J. Meaney*¹, *M.G. Butler*^{2,3}, *M.F. Davis*¹. 1) Dept of Pediatrics, Univ of Arizona, Tucson, AZ; 2) Section of Medical Genetics & Molecular Medicine, Children's Mercy Hospitals & Clinics, Kansas City, MO; 3) Dept of Pediatrics, Univ of Missouri-Kansas City Sch of Med, Kansas City, MO.

The evaluation of metacarpophalangeal (MCP) patterns in genetic conditions applies a standard anthropometric technique to quantify the amount and direction of abnormal growth in the hand skeleton. The aim of this research was to identify specific multivariate patterns that distinguish several genetic conditions through the application of stepwise discriminant analysis. Measurements of the hand bones were made from radiographs on 96 individuals who had one of five conditions and forty-one healthy controls. The five conditions included Fragile X syndrome (n = 18), Noonan syndrome (n = 15), Prader-Willi syndrome (n = 31), Sotos syndrome (n = 16) and Diastrophic dwarfism (n = 16). More than one clinical geneticist diagnosed each affected individual. The age range of the total sample was from less than 1 month to 40 years, with a mean of 11.5 years (SD 8.4). Z score values were computed for the nineteen hand bones in each individual using published bone length standards. The Z score data and age were used in the stepwise discriminant analysis. Eleven of the 19 MCP variables, but not age, were included in the four functions that differentiated the groups. The analysis produced a correct classification rate of 88%. The first two functions accounted for almost 84% of the variance among groups. The first function describes overall hand bone size, and separates individuals with Diastrophic dwarfism and Sotos syndrome at the extremes. The second function separates individuals with Prader-Willi syndrome from the other five groups, with distal and middle phalanges of the 4th and 5th fingers producing the highest correlations with scores on this function. These data demonstrate the utility of discriminant analysis in the description of specific patterns in hand bone growth among several genetic conditions and its continuing application as a diagnostic tool using the MCP data.

Targeted Molecular Testing Reveals a Microdeletion in a Child with Classic Genetic Disorder and Additional Multi-System Involvement. *L. Medne¹, J.D. Hoffman¹, I. Krantz¹, R. Mendoza-Londono², D. Napierala^{2,3}, P. Stankiewicz², B. Lee^{2,3}, E.H. Zackai¹.* 1) Division of Human Genetics, Children's Hospital of Philadelphia; 2) Department of Human and Molecular Genetics, Baylor College of Medicine; 3) Howard Hughes Medical Institute.

We report a 10 y/o male with intra uterine growth retardation, microcephaly, cardiac ventricular septal defect, severe short stature, micropenis, hypospadias, and moderate MR. He had had very large fontanelles, hypertelorism, flat nasal bridge, brachydactyly, and delayed eruption of teeth. Chest X-rays showed hypoplastic clavicles, abnormal ribs and lack of sternal ossification, strongly suggesting a diagnosis of cleidocranial dysplasia (CCD). Chromosome analysis was normal. Molecular analysis of the coding region and the promoter region of the RUNX2 gene did not reveal any mutations. We predicted that this child with classic CCD findings, MR and multi-system involvement could have a microdeletion. FISH analysis with three BACs, which contain segments of the RUNX2 gene and map to 6p21, confirmed the presence of a microdeletion encompassing the RUNX2 gene. Preliminary studies suggest that the deletion is approximately 3Mb in length. Breakpoints of the deleted segment are being defined. Mundlos et al (1997) and Lee et al. (1997) showed that heterozygous mutations in the RUNX2 gene cause CCD and that most affected individuals have an intragenic mutation. Visible chromosomal translocations/inversions led to the identification of the gene but are a rare cause of CCD, with 4 reported cases in the literature. There are 2 cases of classic CCD with a cryptic microdeletion of 1.5 Mb in one family (Mundlos et al., 1997), and of unknown length in another (Zhang, 2002). A similar approach has been used in the past to explain other expanded phenotypes such as the NF1 plussyndrome with 17q11.2 deletions encompassing NF1 gene (Leppig et al., 1997) and Saethre-Chotzen plus phenotype with 7p21.1 deletions encompassing TWIST gene (Johnson et al., 1998). We recommend, that in a patient with a classic syndrome and additional systemic findings, a cryptic microdeletion should be looked for with targeted molecular testing.

RADIOLOGIC MANIFESTATIONS OF 5 BRAZILIAN CASES OF MUCOPOLYSACCHARIDOSIS VI (MAROTEAU-X-LAMY SYNDROME). *A.C. Paula¹, A.C.G.M. Santos¹, T.P. Delboni¹, D.R. Bertola¹, L.M.J. Albano¹, L.A.N. Oliveira², R. Giugliani³, C.A. Kim¹.* 1) Pediatrics, Instituto da Crianca- HCFM-USP, So Paulo, Sao Paulo, Brazil; 2) Radiology, Instituto da Crianca- HCFM-USP, So Paulo, Sao Paulo, Brazil; 3) Servico Genetica de Porto Alegre- HC-UFRGS, Brazil.

Mucopolysaccharidosis type VI (MPS VI), also known as Maroteaux-Lamy syndrome, is an autosomal recessive lysosomal storage disorder caused by a hydrolase deficiency - the N-acetylgalactosamine-4-sulfatase - formerly known as arylsulfatase B, that is responsible for dermatan sulfate degradation. There are three recognized clinical entities: mild, moderate and severe. The course is progressive involving multiple systems, specially skeletal, cardiac and pulmonary ones. We report on 5 Brazilian patients with MPS VI. Radiologic findings were: 1) Skull: macrocephaly and premature closure of the sutures (100%); olympic forehead (80%); thick calvaria, underdevelopment of mastoid cells, vascular impressions, large omega-shaped sella turcica(60%); 2) Thorax: canoe paddle appearance of the ribs and hypoplastic glenoid fossae (100%); thick clavicles and elevated scapulae (80%); 3) Vertebrae: platyspondyly (80%); 4) Long bones: hatchet-shaped proximal portions of the humeri (100%), tilt of the distal parts of the radius and ulna toward, thickened cortex with prominent bone trabeculation epiphyseal (80%) and metaphyseal (60%) irregularities, enlarged diaphyses, and lacunar lesions (60%); 5) Pelvis and hips: irregularity and underdevelopment of the acetabular roofs (100%), flared small iliac wings, thick ischial and small femoral heads, fragmentation of the femoral head (80%); 6) Hands and feet: small and irregular carpal bones (100%); shortened phalanges (80%); widening of of metacarpal diaphyses (60%). Conclusion: Radiographic findings were consistent of a multiplex dysostosis, typical of MPS type VI, and the more severe skeletal abnormalities were observed in older patients.

Reduced bone mineral content in Marfan syndrome patients. *K. Phan¹, N. Brunetti-Pierri¹, S. Carter^{1,2}, J.W. Belmont¹, J.A. Towbin³, K.J. Ellis⁴, B. Lee^{1,2}.* 1) Department of Mol & Hum Genet, Baylor College of Medicine, Houston, TX; 2) Howard Hughes Medical Institute, Baylor College of Medicine, Houston, TX; 3) Department of Pediatrics, Section of Cardiology, Baylor College of Medicine, Houston, TX; 4) Children's Nutrition Research Center, Department of Pediatrics, Baylor College of Medicine, Houston, TX.

Marfan syndrome is an autosomal dominant disorder of connective tissue characterized by defects of cardiovascular systems, eye, and skeleton. Skeletal findings include tall stature, arachnodactyly, and vertebral defects. The presence of osteoporosis/osteopenia in Marfan syndrome is uncertain and its occurrence is still debated, especially in pediatric patients. In Marfan syndrome the bone mineral content (BMC) provide a more accurate measurement of bone status than bone mineral density (BMD). In a cross-sectional study we have assessed bone mineral status of children and adolescents with Marfan syndrome by dual energy X-ray absorbiometry (DXA). The cohort included 14 males and 5 females [mean age: 9.54.8 yrs] seen in a cardiology clinic. The mean whole body BMC z-score was significantly reduced [-1.691.41] ($p < .001$), while the BMD z score at lumbar spine and other regional sites resulted to be normal. 47% (9/19) of the patients had a z-score in the osteopenia/osteoporosis range with 21% (4/19) of patients in the osteopenic range (z-score < -1.5), and 26% (5/19) in the osteoporosis range (z-score < -2.5). Because individuals gain much of their peak bone mass by the end of adolescence, those not attaining optimal amounts during growth are at risk for the development of osteoporosis and fractures later in life. Therefore the early detection of Marfan syndrome children with low BMC is clinically important for prevention program designed to improve bone status and prevent long term consequence of osteoporosis. Marfan syndrome is caused by loss-of-function mutations in the gene encoding fibrillin-1, which has recently been shown to regulate TGF- activation. Interestingly, TGF- is an important regulator of both skeletal development and homeostasis of bone metabolism and polymorphisms in TGF- gene are a risk factor for osteoporosis.

Severe spondyloepimetaphyseal dysplasia with profound mental retardation : a new autosomal recessive

MCA/MR syndrome. *P. Sarda¹, N. Bigi¹, J. Puechberty¹, C. Coubes¹, G. Lefort², P. Blanchet¹.* 1) Department of Medical Genetics, Hopital Arnaud de Villeneuve, CHU de Montpellier, 34295 Montpellier, France; 2) Department of Medical Genetics, Cytogenetics Laboratory, Hopital Arnaud de Villeneuve, CHU de Montpellier, 34295 Montpellier, France.

We report four sibs born of non consanguinous parents and presenting an unusual syndrome including severe spondyloepimetaphyseal dysplasia and profound mental retardation. After the birth of a normal boy, the couple's second pregnancy with monozygotic female twins was terminated at 34WG because hydrocephaly and cerebral calcifications were detected in both fetuses. One fetus presented flat dysplastic acetabulae on skeletal X-rays. Subsequently, the third pregnancy was also terminated at 25WG because of corpus callosum agenesis and ventriculomegaly in a male fetus. Flat dysplastic acetabulae were also present on skeletal X-rays. The couple's fourth pregnancy was normal. At birth, the apparently healthy boy had a normal cerebral ultrasound. Hypotonia and psychomotor retardation developed at 7 months. Chromosome studies and metabolic tests were normal. The child presented severe osteochondrodysplasia evidenced on X-rays which showed platyspondyly, dysplastic iliae with a lacey border of iliac crests, irregular metaphysis, extreme brachydactyly and highly dysplastic carpal and tarsal bones. Cerebral MRI revealed cerebral atrophy with ventriculomegaly. At the age of 6 years, there is severe mental retardation with no language and total hypotonia. In addition, the boy has convulsions and required tracheotomy because of major respiratory distress due to impaired swallowing mechanism.

Skeletal abnormalities, dysmorphic features and developmental delay in siblings: A new autosomal recessive syndrome? *R.L. Sparkes, D.R. McLeod.* Medical Genetics, Alberta Children's Hospital, Calgary, Alberta, Canada.

We report a boy and girl born to consanguineous Pakistani parents with skeletal abnormalities, dysmorphic facies, and mild to moderate developmental delays. Both parents and four other siblings were normal. Cranial abnormalities in the affected sibs included sagittal and lambdoidal synostosis with dolichocephaly, frontal bossing and midline defects of the posterior occiput. Skeletal abnormalities included bilateral midclavicular pseudoarthroses and widening of the lumbosacral canal, with normal stature. Dysmorphic facial features included hypertelorism, ptosis, high-arched palate and oligodontia. Other clinical findings were bilateral hearing loss, paresis of the inferior rectus muscles which depress the eyes, unusual fibrotic skin lesions, and recurrent pancreatitis. Genetic and metabolic investigations, including karyotype, transferrin isoelectric focusing, subtelomeric FISH, and plasma and urine amino and organic acids were all normal. Extensive review of the dysmorphology literature failed to reveal any similar phenotypes. Although this syndrome shares some features with cleidocranial dysplasia and Saethre-Chotzen syndrome, the latter are autosomal dominant conditions. It is the authors' opinion that these siblings have a rare autosomal recessive condition that has not been previously described.

Bellini metaphyseal dysplasia: Two unrelated cases highlight variability in extra-skeletal manifestations. *V.R.*

*Sutton*¹, *R. Mendoza-Londono*¹, *M.J. Gambello*², *A.E. Schlesinger*³. 1) Dept of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Dept of Pediatrics, Div of Medical Genetics, UTHSC Medical School, Houston, TX; 3) Dept of Diagnostic Imaging, Texas Children's Hospital, Houston, TX.

Bellini Metaphyseal Dysplasia (BMD), also known as Metaphyseal Acroscyphodysplasia (OMIM 250215), is a rare skeletal dysplasia with unusual cone-shaped metaphyses of the distal femora. Most published cases seem to have a variety of non-skeletal manifestations. We describe two unrelated patients with BMD and various extra-skeletal abnormalities. A 26-month-old Caucasian female was evaluated during the neonatal period because of dysmorphic features; At 18 months she was noted to have bilateral limitation of knee extension. At 26 months her weight was 12.5 kg (25-50%) and height 82 cm (5%); she has hypotelorism, narrow & flat nasal root, shallow orbits, nystagmus and a single upper central incisor. There is bilateral limitation to extension of the knees. Skeletal survey showed deformity of the distal femoral and proximal tibial metaphyses, characteristic of BMD. A brain MRI was normal. Chromosome analysis was normal as was FISH for seven holoprosencephaly loci and other microdeletions. The other is a 9.5-year-old black male seen because of leg length discrepancy, and found to have developmental delay, a seizure disorder and precocious puberty. His weight was 29 kg (25%), and height 120.6 cm (<5%). Extremities showed rhizomelic shortening and an 18 cm leg length discrepancy. Skeletal survey revealed cone-shaped metaphyses of the distal femora bilaterally, but was otherwise normal. Endocrinologic testing indicated a central origin of precocious puberty; a brain MRI was normal. The first case of BMD was described in 1966 and since then only a handful of patients with this autosomal recessive metaphyseal dysplasia have been reported. Common features are short stature, MR, accelerated bone age and a knee metaphyseal dysplasia. Based on the variability in non-skeletal manifestations we hypothesize that BMD is a microdeletion disorder involving a gene for skeletal development - most likely related to chondrocyte differentiation.

Analysis of skeletal phenotype and exclusion of mutation in BMP7 gene in two cases of short rib polydactyly syndrome type Majewski. *C.T. Thiel¹, A. Dimmler², H. Stoess³, M. Zenker¹, E. Beinder⁴, T. Aigner², A. Reis¹, A. Rauch¹.* 1) Institute of Human Genetics, University of Erlangen-Nuremberg, Germany; 2) Institute of Pathology, University of Erlangen-Nuremberg, Germany; 3) Institute of Pathology at St. Johannisstift, Paderborn, Germany; 4) University Hospital of Gynaecology and Obstetrics, University of Erlangen-Nuremberg, Germany.

The short-rib-polydactyly syndromes (SRPSs) are a heterogenous group of skeletal dysplasias characterized by short-limb dysplasia, narrow hypoplastic thorax with short ribs, polydactyly and associated visceral abnormalities, mainly polycystic kidneys. To date a responsible mutation in a defined gene could be identified only for the Ellis-van-Creveld syndrome (EVC). This EVC gene was excluded as causative for other SRPS, as demonstrated by linkage analysis. In order to further elucidate the genetic background of SRPSs we compared phenotypic features of affected individuals with developmental defects of knockout models in mice. Previous studies analyzed the histological changes in endochondral ossification in SRPS, mentioning mainly a disorganization and irregularity of the growth plate in long bones. Our studie showed that changes in endochondral ossification represent a partly arrested orthotopic ossification at the stage of the hypertrophic chondroblast and heterotopic perichondral ossification with accessory ossicles in the lower leg of one case. Impaired renal development is indicated by polycystic kidney disease with dilated collecting tubules and glomerulocystic changes in the other case. Excessive polysyndactyly and median cleft palate was apparent in both cases. Due to apparent phenotypic analogies to the knockout mouse model for BMP-7 we excluded impaired expression or mutation of this morphogen as a causative factor for SRPS in the two clinical cases by immunohistochemical methods and analysis of genomic sequence.

A new syndrome of congenital generalized osteosclerosis and bilateral polymicrogyria. *L. Titomanlio¹, G. Bonyhay², Y. Hutten², J.F. Oury³, E. Vuillard³, C. Garet⁴, P. Terdjman⁴, C. Baumann¹, A. Verloes¹, A.L. Delezöide⁴.* 1) Clinical Genetics Unit; 2) Fetal pathology Unit; 3) Obstetric department; 4) Medical Imaging department, Robert Debré Hospital, Paris, France.

We report on a 29 weeks male fetus born to consanguineous healthy parents. He showed a severe sclerosing bone disorder affecting all skeletal elements (membranous bones, face, long bones, axial skeleton), resulting in insufficient modelling, generalized densification and fragility of the skeleton. The basis of the skull and facial bones were extremely sclerotic and mandibular dental germs were not visible. Long bones (including extremities) and spine were irregularly shaped with insufficient metaphyseal wedging. Diaphyseal bones were extremely dense, with thick cortex and absent medullar canal. The first metacarpal and the distal phalanges were short, the latter with terminal tufting. This skeletal dysplasia was associated with an abnormal craniofacial development, consisting of hypertelorism, severe microretrognathia, cleft palate, absent epiglottis, and reduced number and delayed mineralization of teeth buds. Epiphyseal cartilage and growth plate had a normal architecture and cellularity. Cortical bone was thin and irregularly lined. Endostal canals were unusually narrow. Cancellous bone counted numerous osteoblasts and was less compact than normally seen. The matrix was irregular and insufficiently mineralized. Remodelling activity was reduced, and the medullar cavity was not developed. Neuropathologic examination showed a corpus callosum that lacked genu and splenium and bilateral symmetric fronto-parietal cerebral polymicrogyria. This syndrome of unknown origin appears to represent a new variant within the congenital sclerotic bone disorders family. Autosomal recessive inheritance is possible.

Osteoporosis, severe mental retardation, microcephaly and epilepsy : a new syndrome. C. Vinkler^{1,2}, T. Lermansagie², M. Yanouv-Sharav^{1,2}, M. Ginzberg², N. Watemala², O. Vardi², D. Lev^{1,2}. 1) Inst Medical Genetics, Wolfson Medical Ctr, Holon, Israel; 2) Metabolic Neurogenetic Clinic Wolfson Medical Ctr, Holon, Israel.

Bone fragility has been previously described in some sporadic and rare syndromes. We report a girl with a unique combination of severe osteoporosis, dysmorphic features and neurological symptoms. This 12 years old girl was born to healthy unrelated parents, following an uneventful pregnancy. After her birth, small head circumference and dysmorphic features were noticed. At the age of one month she had tonic seizures. She still has epileptic seizures which are controlled to a large extent by a combined anticonvulsive therapy. Serial brain MRI scans revealed partial agenesis of corpus callosum and progressive brain atrophy. Severe osteopenia was already noticed at the age of nine months with hypercalciuria and nephrolithiasis. Lab tests did not reveal abnormal PTH or Vit D metabolism. Based on skeletal survey, laboratory tests and the early clinical presentation it is less likely that bone fragility is due to disuse, although her complete immobilization along with the long-term use of anticonvulsants added to the severe osteoporosis. She was started on pamidronate treatment for her severe osteopenia. At the age of 12 years she has severe mental retardation. Her weight, height and head circumference were -4 S.D. She is not ambulatory and does not speak. She has good eye contact with her family and her caretakers. Hearing is normal. Extensive evaluation including metabolic work-up, chromosome analysis, telomere screening and molecular studies to rule out fragile X syndrome and Angelmann syndrome were all normal. Differential diagnosis includes: Cole-Carpenter syndrome with craniosynostosis, OI like syndrome with extrapyramidal signs, osteoporosis-pseudoglioma syndrome, bone fragility and retinopathy syndrome, sparse hair and mental retardation, brittle bone and leukodystrophy and in bone fragility, congenital cataract and microcephaly syndrome. However our patients phenotype differs from the previously described syndromes. We suggest that this girl has a previously undescribed syndrome.

Hypophosphatasia and homozygosity for a paternal heterozygous G403S TNSALP mutation due to segmental paternal isodisomy for chromosome 1p. *D. Wand¹, C. Glaeser¹, I. Brun-Heath², H. Thiele¹, A. Herrmann³, A. Musil⁴, I. Hansmann¹, E. Morner².* 1) Inst. of Human Genetics, Univ. Halle, Halle, Germany; 2) Centre d'Etudes de Biologie Prenatale, SESEP, Versailles, France; 3) Klinik und Poliklinik f. Geburtshilfe und Reproduktionsmedizin, Univ. Halle, Germany; 4) Institut f. Pathologie, Univ. Halle, Germany.

Hypophosphatasia is an inherited disorder characterised by defective bone and teeth mineralization and deficiency of serum and bone alkaline phosphatase activity. Symptoms are highly variable; severe perinatal and infantile forms (HOPS, OMIM 241500) are transmitted as an autosomal recessive form while milder forms follow both autosomal recessive and dominant mode of inheritance. A wide spectrum of mutations within the TNSALP gene at 1p36.1 have been described in severe and in mild forms. Compound heterozygous missense mutations account for most of the severe cases. We report about a severe form detected sonographically at week 19. After termination the male fetus showed skeletal anomalies of a metaphyseal type of chondrodysplasia compatible with hypophosphatasia. Direct sequencing of the TNSALP coding sequence including exon-intron borders and untranslated exons using chorionic villus DNA identified a 1258 G to A mutation (G403S). Sequencing exon 11 revealed heterozygosity for G403S in the father with hypomineralisation of teeth but no mutation in the clinically normal mother. Genotyping both parents and fetus for 20 microsatellites spanning a 205.5cM chromosome 1 segment between D1S228 (1p36.21) and D1S439 (1q42.12) uncovered lack of maternal alleles and the presence of only one paternal allele for all 1p loci distal to D1S2753 (1p21.3, 120cM) but heterozygosity and biparental inheritance for all 1q and 1p21 markers. Karyotyping at 450 G-band level and FISH using probe for 1p36 did not reveal any evidence for a deletion. It is concluded that the fetus is homozygous for the paternal G403S mutation due to paternal isodisomy for an at least 32.7Mb 1p-segment.

Further delineation of Majewski/ hydrolethalus syndrome in an Old Order Amish kindred. *S. Bakker², V.M. Siu^{1,2,3}*. 1) Department of Pediatrics; 2) University of Western Ontario; 3) Medical Genetics Program of Southwestern Ontario, London Health Sciences Centre, London, ON, Canada.

Short rib-polydactyly syndrome II (Majewski syndrome) and hydrolethalus are lethal autosomal recessive conditions which share features of polydactyly, shortened limbs, median cleft lip and palate, deep-set eyes and a lobulated tongue. Cardiac anomalies, pulmonary hypoplasia, abnormal genitalia, and polyhydramnios may occur. Hydrolethalus exhibits severe hydrocephalus and agenesis of the corpus callosum. Majewski syndrome characteristically shows shortened, ovoid tibias. Hypoplastic epiglottis has been described in Majewski syndrome but not hydrolethalus. We describe two Old Order Amish brothers and their male first cousin who exhibited features of both syndromes. The elder brother, stillborn at 34 weeks to second cousin parents, exhibited severe progressive hydrocephalus, short limbs, and narrow chest on prenatal ultrasound. Postaxial polydactyly and synbrachydactyly were noted on all limbs. Karyotype was 46, XY but external genitalia appeared female. Median cleft lip and palate were present. The younger brother, induced at 24 weeks due to multiple anomalies on ultrasound, exhibited similar features. Autopsy revealed microphthalmia with cataracts and retinal dysplasia, rudimentary sulcation of the brain, and agenesis of the corpus callosum. There was disordered endochondral ossification. X-rays did not demonstrate short ribs or ovoid tibias. Tongue was lobulated. Hypoplastic epiglottis and small lungs were noted. Adrenals were absent. A paternal first cousin to the brothers was born at 33 weeks with similar features and died at 4 days. The parents were also consanguineous. We believe that these three cases offer further evidence that Majewski syndrome and hydrolethalus may represent entities along a continuum resulting from a single genetic defect, and add absent adrenals and sex reversal as further features.

Longitudinal vestibular schwannoma growth rates in neurofibromatosis 2 (NF2): a combined analysis from three countries. *M.E. Baser*¹, *T. Patankar*², *L. Kluwe*³, *V.-F. Mautner*⁴, *E. Makariou*⁵, *D.M. Parry*⁶, *A.J. Wallace*⁷, *R.T. Ramsden*⁸, *D.G.R. Evans*⁷, *A. Jackson*². 1) Los Angeles, CA, USA; 2) Division of Imaging Science and Biomedical Engineering, University of Manchester, Manchester, UK; 3) Department of Neurosurgery, University Hospital Eppendorf, Hamburg, Germany; 4) Department of Neurology, Klinikum Nord Ochsensoll, Hamburg, Germany; 5) Department of Radiology, Georgetown University School of Medicine, Washington, DC, USA; 6) Genetic Epidemiology Branch, National Cancer Institute, Bethesda, MD, USA; 7) University Department of Medical Genetics, St. Mary's Hospital, Manchester, UK; 8) Department of Otolaryngology, Manchester Royal Infirmary, Manchester, UK.

We previously found that vestibular schwannoma (VS) growth rates in NF2 tended to decrease with increasing age and that genotype-phenotype correlations were not apparent. To more definitively address these questions, we assessed VS growth rates in 84 NF2 patients from the United States, Germany, and the United Kingdom. The median follow-up was 3.9 years (range, 0.2 to 14.8 years). Box models were used to estimate VS volumes and linear regression was used to evaluate the association between tumor doubling time (TDT, in years) and covariates. VS growth rates decreased with increasing age at baseline ($\log_{10} \text{TDT} = .834 + .008 \times \text{age at baseline}$, $\text{SE}_b = .004$); people aged ≤ 15 years at baseline had the highest growth rates. Genotype-phenotype correlations were not apparent. To estimate the effect of volumetric accuracy on growth rates, we used two methods (one- and two-component box models) to estimate TDT for 26 VSs that had intracanalicular and extracanalicular portions; the volumes of tumors with two portions are measured more accurately in the two-component model. One-component model TDTs were less than two-component model TDTs by a median of 12%. These results suggest that different three-dimensional VS volumetric methods have a relatively small effect on average VS growth rates, possibly because the magnitude of long-term longitudinal VS volume change is often far greater than the magnitude of VS volume measurement error.

Oculofaciocardiodental and Lenz microphthalmia syndromes result from mutations in the X-linked transcriptional corepressor, BCOR. *G. Black¹, D. Ng², C. Corcoran³, D. Donnai¹, S. Burgess⁴, N. Thakker¹, V. Bardwell³, L. Biesecker².* 1) Dept Clinical Genetics, St Mary's Hosp, Manchester, United Kingdom; 2) Genetic Disease Research Branch, National Institutes of Health, Bethesda, MD, USA; 3) Department of Genetics, Cell Biology and Development/Cancer Center, University of Minnesota, Minneapolis, MN, USA; 4) Genome Technology Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD, USA.

Lenz microphthalmia syndrome comprises microphthalmia with mental retardation, skeletal and other anomalies. Inherited in an X-linked recessive pattern, there are putative loci at Xq27-q28 (MAA) and Xp11.4-p21.2 (MAA2). After refining the MAA2 locus, sequencing of candidate genes showed a substitution c.254C>T, p.P85L, in BCOR (BCL-6 interacting corepressor) in affected males from a Lenz syndrome family. Oculo-facial-cardio-dental syndrome (OFCD) is inherited in an X-linked dominant pattern with presumed male lethality. It is characterized by microphthalmia, dysmorphic facies, radiculomegaly, cardiac and digital abnormalities. Given their phenotypic overlap, we hypothesized that OFCD and MAA2 were allelic and found different frameshift, deletion and nonsense mutations in BCOR in OFCD families. Functional studies of wild type and p.P85L mutant BCOR suggest that BCOR interacts with other transcription factors and perturbation of this interaction causes these two syndromes. Knock down expression of the zebrafish BCOR ortholog, which shows 40% amino acid identity to the human protein, caused developmental perturbations of the eye, developing skeleton, and CNS, consistent with the human syndrome and confirming that BCOR is a key transcriptional regulator during early embryogenesis.

APLASIA CUTIS CONGENITA, SKULL DEFECT, BRAIN HETEROTOPIA, AND INTESTINAL

LYMPHANGIECTASIA. *E.V. Bonioli¹, R.C. Hennekam², C. Bellini¹*. 1) Pediatrics Department, Gaslini Institute, University, Genoa, Genoa, Italy; 2) Departments of Pediatrics and Clinical Genetics, University of Amsterdam, The Netherlands.

This girl was born at term to healthy, non-consanguineous parents following an uneventful pregnancy. During pregnancy a congenital defect of the scalp involving the underlying bone (aplasia squama frontalis) had been demonstrated. We investigated the patient at the age of 7 months. She presented an oval area (6 cm diameter) of healing non-inflamed, well demarcated, epithelized, with no blister skin covering a bony scalp defect. Irregular hair growth around the scalp lesion was present. She showed a depressed nasal bridge, synophrys, telecanthi, hypertelorism, and long philtrum. Peripheral lymphedema was evident (lower leg). High fecal excretion of alpha-1-antitrypsin suggested intestinal lymphangiectasia. Lymphoscintigraphy (age 7 months) showed initial dermal back-flow in the left foot, indicating an accumulation of the radiocolloid in the dilated channels of the dermis. Inguinal lymph nodes were delayed observed. Three-dimensional CT scan (age 7 months) demonstrated aplasia of the frontal bone, widely patent cranial sutures, and subtotal reconstitution of the frontal bone. Sagittal T2-weighted MR image (age 1 month) showed subcortical frontal heterotopia. A normal psychomotor development and a stationary degree of peripheral lymphedema is evident (age 12 months). In conclusion, we describe a patient with an unusual combination of symptoms including aplasia cutis congenita with underlying skull defect at an unusual locus, cortical dysplasia, congenital peripheral lymphedema, and intestinal lymphangiectasia. Some of the characteristics would fit the OMIM 207731 entity, others fit a RELN mutation (OMIM 600514), and several symptoms are also found in the OMIM 235511. Next to these entities a disruption sequence initiated by a lymph vessel dysplasia and thereafter involving brain and skin might also be an explanation. A last possibility might be the presence of a separate, hitherto undescribed entity. Reports on other cases, and detailed evaluation of cases of aplasia cutis for lymphatic vessel dysplasia are needed to allow a more firm conclusion about the pathogenesis.

Polymorphism within the coding region of the LIS1 gene : implications for diagnostic counselling. C. Cardoso¹, S. Das², F. Moro³, A. Moncla⁴, L. Villard¹, J. Mancini⁵, R. Guerrini³, N. Philip ^{*4}, W.B. Dobyns ^{*2}. 1) INSERM U491, Faculte de Medecine la Timone, Marseille Cedex, France; 2) Department of Human Genetics, The University of Chicago, Chicago, IL; 3) Neurogenetics Laboratory, Institute of Child Neurology and Psychiatry, IRCCS Fondazione Stella Maris, Calambrone, Italy; 4) Departement de Genetique Medicale, Hopital des enfants de la Timone, Marseille, France; 5) Departement de Neurologie pediatrique, Hopital des enfants de la Timone, Marseille, France.

Lissencephaly (LIS) is a neuronal migration disorder resulting in a thickened cortex and reduced gyration usually causing severe mental retardation, intractable epilepsy and cerebral palsy. LIS is one component of the contiguous gene deletion disorder known as Miller-Dieker syndrome (MIM:247200) or may occur as an isolated brain malformation in patients with isolated lissencephaly sequence (ILS). The clinical severity generally correlates with the degree of agyria and cortical thickening. Approximately 70 % of patients show abnormalities of the LIS1 gene on 17p13.3 or of the DCX gene on Xq22.3. A more severe lissencephaly in posterior brain regions is generally observed in patients with LIS1 mutations. To date, among all mutations reported in the LIS1 gene only 6 patients have a missense mutation. In the course of screening for LIS1 mutation in ILS patients, we identified by direct sequencing 8 new missense mutations (L51S, K64N, D129V, C281R, G314V, S355N, V364I, D401H). Our data support the hypothesis that, in most cases, the lissencephaly phenotype associated with LIS1 missense mutations is generally milder. However, among these, one (V364I), identified in a ILS boy, was also found in his mother who is mildly mentally retarded but with a normal MRI scan and his grandfather and aunt who are normal thus ruling out its involvement in the etiology of the phenotype of this patient. DCX was sequenced but no mutation was found in this family .These findings clearly call for a careful consideration of the pathogenicity of the LIS1 missense mutations identified in sporadic ILS patients before genetic counselling or prenatal diagnosis is proposed to the corresponding families.*LIS1*.

Depressive symptoms in Machado-Joseph Disease (SCA3) patients and relatives. *C.R. Cecchin¹, A.P. Pires², C.R.M. Rieder³, T.L. Monte³, M.L. Pereira^{1,5}, I. Silveira⁶, T. Carvalho¹, J. Sequeiros⁶, L.B. Jardim^{1,4}.* 1) Medical Genetics Service, Hospital Clinicas Porto Alegre, Porto Alegre, Brazil; 2) Psychology Service, HCPA, Porto Alegre, Brazil; 3) Neurology Service, HCPA, Brazil; 4) Department of Internal Medicine, Universidade federal do Rio Grande do Sul, Brazil; 5) Biochemistry Department, UFRGS, Brazil; 6) UnIGENE, Instituto de Biologia Molecular e Celular, Porto, Portugal.

Objectives: to determine the depression scores of Machado-Joseph disease (MJD) patients, of their spouses, and of individuals at 50% risk for MJD; and to look for some correlation between depressive manifestations and the degree of motor incapacitation. **Methods:** 246 adult individuals were studied: 79 MJD patients (group 1), 43 spouses (group 2) of MJD patients, 80 individuals at risk for MJD (group 3), and a control group of 44 patients with multiple sclerosis (group 4). Two instruments were applied: Beck Depression Inventory (BDI), to quantify the depressive symptoms, and the Barthel index of physical incapacitation (10), both in an adapted version to Portuguese language. **Results:** in the MJD families, the higher average of BDI scores were found among patients, and showed a linear reduction among other family member: they were of 15.6 in group 1, of 10.5 in group 2, and of 5.6 in group 3 ($p < 0.0001$, Anova). Moderate to severe depressive scores were found in 33.5% of MJD patients, and in 16.2% of their spouses. Depressive scores were also associated with age, with female sex and with poor educational level. A direct correlation between BDI scores and motor incapacitation was found among MJD patients ($r = 0.507$, Pearson correlation, $p < 0.0001$). Although depressive scores among the control group of MS were higher than those found in MJD, in MS they did not correlate with physical incapacitation, or with age, or educational level. **Conclusions:** depressive symptoms were rather common in MJD patients, as well as in their caretakers. We suggest that depression is more reactive than primarily related to disease process, in MJD.

Supported by CNPq, CAPES, FAPERGS), Brazil; and ICCTI, Portugal.

PARTIAL CEREBELLAR HYPOPLASIA IN A PATIENT WITH PRADER-WILLI SYNDROME. *D. De Brasi*¹, *L. Titomanlio*¹, *V. Barletta*¹, *A. Romano*¹, *R. Genesio*², *F. Maio*¹, *D. Melis*¹, *F. Fabbrini*², *A. Conti*², *P. Tedeschi*², *G. Andria*¹, *G. Sebastio*¹, *E. Del Giudice*¹. 1) Dept of Pediatrics, Federico II University, Naples, Italy; 2) Dept of Cellular and Molecular Biology and Pathology, Federico II University, Naples, Italy.

Prader-Willi syndrome (PWS) is a recognized genetic condition due to an imprinting defect of the PWS critical region on 15q11-13. The pathogenetic mechanism is represented by *de novo* interstitial deletion of 15q11-q13 of paternal origin. We recently observed a 2-year-old male infant because of craniosynostosis. Antenatal reduced fetal movements were noted. Moderate hypotonia and feeding problems occurred in the first months. Physical examination at 2.6 years revealed: height 89.5 cm (10-25th centile), weight 17.500 g (>95th centile), OFC 47.5 cm (25-50th centile); facial dysmorphism (overfolding auricle, pointed nose, strabismus), scoliosis and bilateral cryptorchidism. Brain MRI disclosed a right cerebellar hemisphere hypoplasia. His general development quotient was 74 (Griffiths Mental Development Scales). HRB (650 bands) unraveled a 15q interstitial deletion. FISH analysis by using polymorphic 15q microsatellites (D15S63, D15S674 in 15q11) and specific 15q markers (RP11-20B10 and RP11-570N16 in 15q12, and RP11-37J3 and RP11-25D7 in 15q13.1) allowed to restrict the deleted region to 15q11-q12. This cytogenetic aberration was not present in both parents. The PWS methylation test disclosed the absence of paternal contribution. Our patient represent one of the few reported cases of PWS with structural CNS abnormality. Particularly, in some autopsy cases of PWS, cerebellar lesions have been reported (Hayashi et al, 1992)¹. So, it is possible that cerebellar hemisphere hypoplasia is consequential to the deletion. Among the genes mapping to PWS critical region, NECDIN (a paternally imprinted gene, strongly involved in CNS development) could be considered to contribute to the pathogenesis of this cerebellar malformation. Accurate study of the genes localized within the deleted region could help us to unravel this peculiar issue.¹[Brain Dev 1992 14(1):58-62].

Clinical and molecular studies in Spanish Autistic patients. *B. Gener¹, I. Cusco¹, M. Del Campo¹, E. Gonzalez², L. Sumoy², M. Vilella³, A. Infante³, J.A. Munoz⁴, M. Salido⁴, O. Villa⁴, L.A. Perez Jurado¹.* 1) Genetics Unit, Dept. of Experimental Sciences, Universitat Pompeu Fabra, Barcelona, Spain; 2) Microarray Laboratory, Center for Genomic Regulation, Barcelona, Spain; 3) Group Pere Mata, Reus, Spain; 4) Cytogenetics laboratory and Pediatrics Department, Hospital del Mar, Barcelona, Spain.

Autistic disorder (AD) is a complex neuropsychiatric disorder of unknown etiology, although 10-15% of cases have known genetic disorders or chromosomal anomalies. Epidemiological, sibling pair and family studies suggest that autism is a heritable oligogenic disorder, although recurrent genomic mutations might underlie a significant proportion of cases. Genome-wide scans show that several chromosomal regions are involved in the etiology of AD. We are studying patients with AD from two different sources: 22 children followed in Neurology clinic and 59 institutionalized adults. A full clinical characterization aimed at identifying comorbid clinical conditions and a thorough battery of neuropsychological tests are being performed. Major or minor congenital anomalies are present in at least 12 patients, including VATER defects, Down syndrome and Tuberous Sclerosis. Undiagnosed PKU and SCID are present in two patients. G-banding karyotypes and Fragile X studies are indicated based on clinical findings. A 47, XY, +mar. ish invdup (15)(q10;q13) [15] karyotype was found in a classical patient with AD and mild dysmorphic features. is being to all patients. We have developed several new molecular tools aimed at identifying recurrent genomic mutations: 1) A multiplex quantitative real time PCR assay with TaqMan probes to simultaneously detect potential duplications at 15q11.2, 17p11, and 22q11.2 regions; 2) a microarray-based Comparative Genomic Hybridation (aCGH) assay containing 216 BAC for single copy regions flanked by SDs and subtelomeric regions, and 3) quantitative PCR-based assays focused on chromosome 7. In conclusion, we have evaluated a large number of patients with AD with a 3 step approach that includes clinical characterization, cytogenetic and molecular studies and new screening assays in search of unknown genome-wide rearrangements.

Joubert Syndrome(JS) and Meckel-Gruber syndrome(MGS) are the same disorder in the Hutterite Brethren.

A.M. Innes¹, J. Parboosingh¹, D. Roccamatysi¹, S. Flavelle¹, D.R. McLeod¹, F.P. Bernier¹, C.R. Greenberg², J. Midgley³, J. Scott⁴, K.M. Boycott¹. 1) Department of Medical Genetics, University of Calgary, Calgary, Canada; 2) Depts of Pediatrics & Child Health and Biochemistry & Medical Genetics, University of Manitoba; 3) Dept of Pediatrics, U of Calgary; 4) Dept of Radiology, U of Calgary.

JS is an autosomal recessive disorder characterized by hypotonia, ataxia, mental retardation (MR) and a molar tooth sign (MTS) on MRI. JS related disorders (JSRDs) combine features of JS plus variable ocular, renal, hepatic and limb involvement. Three loci for JS/JSRDS have been mapped but no genes have been identified. A small number of patients with a JSRD have been reported with homozygous deletions of the gene NPHP1 associated with juvenile nephronophthisis. MGS is characterized by encephalocele, renal cysts and polydactyly. Three loci for MGS have been mapped, but no genes have been identified. MGS has been reported in the Hutterites, a genetic isolate living on the Canadian prairies. Most cases are lethal, making clinical/genetic studies difficult.

We have seen 7 Hutterite patients who have a characteristic dysmorphic face, severe MR, oculomotor apraxia and a MTS (or cerebellar vermis hypoplasia on CT) suggestive of a JSRD. Three of these patients had previously been diagnosed with MGS on the basis of encephalocele and enlarged cystic kidneys (2 patients) or Dandy-Walker malformation and cystic kidneys in one sibling. The remaining four patients have facial and oculomotor features, MR and MTS, consistent with a diagnosis of JS. All 7 patients are closely related and have the same facial phenotype with MTS. We believe they have the same disorder. In this population a mutation in a single gene likely causes the JSRD/MGS phenotype, which highlights the overlap between these conditions, and suggests a common genetic pathway. Genetic modifiers may be responsible for the variability. Using homozygosity mapping, we expect to identify a novel gene responsible for this phenotype. Thus far we have excluded the 3 known JS loci and the three MGS loci. We have also excluded a homozygous NPHP1 deletion.

Shwachman Diamond Syndrome: A behavioral phenotype? *E.N. Kerr¹, A. Dupuis¹, E. Krane¹, L. Ellis¹, S. Hoosen-Shakeel¹, S. Newton^{1,2}, J.M. Rommens^{1,2}, P.R. Durie^{1,2}.* 1) Hospital for Sick Children, Toronto, ON; 2) University of Toronto, ON.

Shwachman Diamond Syndrome (SDS) is a rare recessive disease caused by disruptions to 7p12-q11 (SBDS gene). RNA analyses revealed that SBDS is expressed in all organs. Published data on cognition in SDS are limited by small numbers and poorly defined phenotype and were completed before identification of the gene. **AIM:** To determine if a behavioral phenotype is evident in SDS. Neuropsychological testing was completed with 31 children (ages 6.3-16.9 yrs) who met the diagnostic criteria for SDS (exocrine pancreatic and bone marrow dysfunction) and whose genotype was defined. **RESULTS:** Cognitive functioning of children with SDS was significantly lower than normative samples ($p < .01$) across most domains. 51.6% performed Below Average (< 25th percentile) in intellectual functioning; 19.4% performed below the 2nd percentile while only 9.7% performed Above Average (> 75th percentile). One or no child performed Above Average on higher order language, speed of mental flexibility, sustained and dual attention, and visual-motor integration. Cluster analyses revealed 5 primary classifications ranging from low to high overall performance and differentiated children with the two most common mutations 258+2T>C/183_184TA>CT (n=14) and those with 183_184TA>CT +258+2T>C/258+2T>C (n= 3) from those with 258+2T>C/rare mutation (n=9) and 258+2T>C/ 258+2T>C (n=1). Subjects with 258+2T>C/unknown mutation (n=4) were represented in each cluster. Controlling for family environment, paired analyses between unaffected siblings (n=12) and children with SDS revealed significant deficits in reasoning, problem solving, mental control, dual attention, language, academics, and visual-motor integration. Parents reported that children with SDS display significantly more problems with cognition, hyperactivity, internalizing and externalizing behaviors as well as significantly lower adaptive living skills (e.g., motor, social /communication, community and broad independence) than siblings. Although intra-group variability in performance was evident, the results do suggest probable cognitive consequences of SBDS dysfunction.

H63D homozygous mutation in a patient with hereditary hemochromatosis and Parkinson's disease. R.G.

Malkani¹, S. Cooperman², T. Rouault², A. Crawley³, K. Gwinn-Hardy³. 1) Laboratory of Neurogenetics, National Institute on Aging, National Institutes of Health, Bethesda, MD; 2) Cell Biology and Metabolism Branch, National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD; 3) National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, MD.

Hereditary hemochromatosis (HH) is a genetic disease of iron deposition in various organs of the body, including the brain. Classic medical teaching states that HH does not impact the brain symptomatically; however, several groups have anecdotally reported patients with HH and Parkinson's disease (PD) or parkinsonism; additionally, MRI findings suggest excess iron deposition in the basal ganglia in patients with HH and PD. However, very little risk information is available regarding particular genotypes and Parkinsonian phenotypes. In the limited reports where genotype data are available, the genotype for these patients was homozygous for the Cys282Tyr (C282Y) variant. We present a case of a patient who is homozygous for His63Asp (H63D) and has HH and PD, the first known report for this association.

Möbius sequence : clinical and pathogenic analysis of 68 patients. *M.J. Marques-Dias¹, J.A. Paz¹, D.R. Bertola², L.M.J. Albano², M.B. Moreira², C.H. Gonzalez³, E. Kuczyński⁴, M. Valente², C.A. Kim².* 1) Neurology, University of Sao Paulo Medical School, Sao Paulo, SP, Brazil; 2) Genetics and Radiology Units, Dept. of Pediatrics, Inst. da Crianca, Sao Paulo, SP, Brazil; 3) Department of Biology, Institute of Biosciences, University of So Paulo, So Paulo, Brazil; 4) Psychiatry Institute, Hospital das Clinicas, Sao Paulo, SP, Brazil.

Möbius sequence (MS) is a rare entity related to genetic or environmental etiologies, acting between 4-6 post conception weeks. A vascular disruption in the territory of the subclavian artery and/or its ramifications has been proposed as the main pathogenic mechanism in cases of ambient etiologies such as drug exposition and maternal traumatism. In Brazil a large number of MS patients have been recently reported in relation with misoprostol misuse in the first trimester of pregnancy. The authors present the main abnormalities in 68 patients with MS evaluated between 1991 and 2004. The 68 patients (36 female/32 male) have been submitted to clinical examination in a multidisciplinary basis in order to know the main etiologic factors, the complete clinical spectrum of abnormalities and the possible pathogenic factors. MS has been diagnosed in the presence of uni or bilateral VI and VII cranial nerve palsies. Forty-four children (65%) have been exposed to misoprostol in utero, and in 5 children a traumatic maternal event in the 1st trimester has been referred; 75% of the mothers presented bleeding at the same period (30 in the group with misoprostol and 21 without misoprostol). Besides the VI/VII nerve palsies in all patients, the XII nerve was affected in 44%. In 53 patients MS was associated with extremity defects and in 19 with hydrocephaly. Autism was diagnosed in 12.5% of the patients. Brain stem calcification was detected by CT in 28% and in 3 other cases through neuropathology study. The authors believe that MS associated to extremity defects and hydrocephaly is due to a vascular disruption between 4-6th post conception caused by misoprostol or by other traumatic event. Autistic behavior recently reported in other series of MS should add evidence to the potential structural and functional sequelae of early brain stem lesions.

Apolipoprotein E 4 is associated with risk of dementia in Inclusion Body Myopathy-Paget Bone Disease-Frontotemporal Dementia syndrome. *S.G. Mehta¹, S. Xiong², G.D.J. Watts¹, G. Umberger², M. Lovell², C.D. Smith², V.E. Kimonis¹.* 1) Division of Genetics, Children's Hospital, Boston, Boston, MA; 2) Sanders-Brown Center on Aging, University of Kentucky, Lexington, KY.

Valosin Containing Protein (VCP) is an AAA (ATPase Associated with a variety of Activities) protein. Recently, mutations in the VCP gene were identified as the cause of a rare complex syndrome combining limb-girdle/inclusion body myopathy, Paget disease of bone and frontotemporal dementia (IBMPFD; Watts et al, 2004). We have demonstrated that VCP mutants affect the ubiquitin proteasome degradation pathways in the pathogenesis of the inclusion bodies seen in muscle and bone disease. Since IBMPFD is only 30% penetrant for the frontotemporal dementia (FTD) phenotype at average age 53 years (Watts et al 2004), additional genetic factors may be involved in FTD pathogenesis or age of clinical expression when associated with VCP mutations. We chose APOE as a putative modifier gene, as it is known to be a risk factor for Alzheimers disease, diffuse Lewy body disease and vascular dementia. APOE is not a proven risk factor for sporadic FTD, however. Clinical, biochemical and mutation analysis was carried out on 174 individuals including 61 affected, 28 carriers and 85 control patients followed by genotyping for APOE. Several of the patients have had detailed neuropsychological evaluations or neuropathological examinations to document the presence or absence of FTD. Comparisons were made between affected individuals with FTD, affected without FTD and normal controls. There was a significant difference in frequency of APO 4 alleles in affected patients with FTD ($p=0.0001$). Seven patients with FTD and IBMPFD had at least 1 APOE 4 allele ($p=0.05$). Homozygosity for APO 4 allele was further associated with FTD (3/5, 60%, $p=0.001$). One autopsied individual with VCP mutation, clinical FTD phenotype, and APO 4 allele had many neuritic plaques identified in the brain. These data suggest APOE 4 genotype may modify FTD pathogenesis or age of onset when associated with VCP mutations. This may provide clues to the pathogenesis of sporadic FTD and be helpful for counseling.

Intracranial Anomalies detected by Imaging Studies in 37 Cases of Apert Syndrome. *J.B. Mulliken*^{1,3}, *F. Quintero-Rivera*^{2,3}, *C. Robson*^{1,3}, *V. Kimonis*^{1,3}. 1) Children's Hospital, Boston, MA; 2) Massachusetts General Hospital Center for Human Genetic Research, Boston, MA; 3) Harvard Medical School, Boston, MA.

This study was undertaken to determine the frequency of agenesis of the corpus callosum (ACC) in Apert syndrome. It was prompted by the prenatal detection of ACC and hypertelorism at 19 weeks gestation in a male who was found to have Apert syndrome associated with the common S252W (934C>G) FGFR2 mutation. We report brain imaging in 37 cases of Apert syndrome evaluated at Children's Hospital, Boston. The sample included 27 males and 10 females with an age range of 2 months to 42 years. The findings reported in 14 MRI and 31 CT (8 patients had both) studies in these 37 patients included ACC in 2 (5%), hydrocephalus in 6 (16%), ventriculomegaly in 28 (76%), absence of the septum pellucidum in 7 (19%), and encephalocele in 4 (11%). Chiari I malformation was detected in 7/14 (50%) cases who had an MRI. Less common features included gyral abnormalities and undermyelination of white matter in 2 patients respectively (5%), and heterotopia of the gray matter, and interhemispheric cyst in 1 patient. Complete agenesis of the corpus was found in another male who was diagnosed at birth with Apert syndrome (S252W mutation) after a prenatal history of ACC and ventriculomegaly. In conclusion, a wide range of neuroimaging abnormalities are present in Apert syndrome suggesting that the FGFR2 gene is important in the development of the brain. Also in view of the association of ACC seen in 5% cases, we suggest that prenatal finding of ACC should lead to consideration of Apert syndrome as a possible diagnosis. A careful search by 3D ultrasound imaging for symphalangism and the associated craniofacial findings including brachycephaly, exorbitism and open metopic sutures may aid in accurate prenatal diagnosis.

Abnormal brain structure in children with nonsyndromic clefts of the lip and/or palate (NSCLP). *P.C. Nopoulos, J. Murray, J. Canady, L. Richman, L. Lehn.* Psychiatry, University of Iowa Carver College of Medicine, Iowa City, IA.

In a previous study on brain structure in adult males with nonsyndromic clefts of the lip and/palate (NSCLP), subjects with clefts were found to have abnormally enlarged anterior regions of the cerebrum, smaller than normal posterior regions of the cerebrum, and smaller than normal cerebellum volumes. To better understand the early manifestations of these abnormalities, this study is a preliminary report on the brain structure of CHILDREN (ages 7-12) with NSCLP using Magnetic Resonance Imaging (MRI).

Subjects: To date, 40 children with NSCLP have been collected and are compared to 40 healthy control children. Brain scans are processed by sophisticated software to obtain automated measures of the cerebrum, its four lobes, and the volume of the cerebellum. ANCOVA is used, controlling for the effects of age and gender.

Results: Like the previous sample of adults, children with NSCLP have significantly altered brain structure compared to controls. However, the pattern in childhood has both similarities and differences to the pattern seen in adults. For example, like adults, children with NSCLP have abnormally small volume of the cerebellum. However, unlike the adults who had larger than normal volumes of the frontal lobe, children in this study had significantly smaller than normal volumes of the frontal lobes. In contrast, posterior regions of the cerebrum were significantly larger than healthy controls.

Discussion: Children with NSCLP have significant alterations in the structure of their brain compared with controls. With the exception of smaller than normal cerebellum volumes, the pattern of cerebral brain structure is strikingly different compared to adults with NSCLP. This dichotomy between the brain structure of children with NSCLP and that of adults with NSCLP, suggests an abnormality of normal brain development, in particular late maturational processes that occur from childhood through the second decade of life.

Holoprosencephaly studies in France : mutation review and genotype-phenotype correlation. *S. Odent*¹, *C. Dubourg*², *L. Pasquier*¹, *L. Lazaro*¹, *M. Blayau*², *M.R. Durou*², *C. Bendavid*², *V. David*². 1) Genetique Medicale, Hopital SUD, Rennes, France; 2) Genetique Moleculaire, Hopital Pontchaillou, Rennes, France.

Holoprosencephaly (HPE ; 1/16.000 live births ; 1/250 conceptuses) is a common development defect affecting both the forebrain and the face. Clinical expressivity is variable, ranging from a single cerebral ventricle and cyclopia to clinically unaffected obligated carriers in familial HPE. The disease is genetically heterogeneous but additional environmental agents also contribute to the etiology of HPE. In our cohort of 250 non chromosomal HPE families, the probands were classified in 3 groups : typical HPE (49 per cent with 54 fetuses and 68 children), atypical forms or HPE spectrum (25 per cent), and polymalformative HPE (26 per cent). We studied SHH, ZIC2, SIX3, TGIF genes by D-HPLC and direct sequencing and found 38 heterozygous mutations and 1 deletion (16 per cent of all probands and 24 per cent of typical HPE), 27 of them being novel ones : 20 in SHH, 8 in ZIC2, 8 in SIX3 and 3 in TGIF. There were 17 familial cases and 22 sporadic cases; a mutation was identified in 23 per cent of familial cases. The most original and various phenotypes were associated with a mutation in SHH: hypoplasia in the pituitary gland, colobomatous microphthalmia, cerebellar hypoplasia, choanal or nasal pyriform aperture stenosis, solitary medial maxillary incisor. With a ZIC2 mutation, face was normal; one case was associated with a syntelencephaly, 2 cases with a neural tube defect. With a SIX3 mutation, ophtalmologic findings were frequent; the first case with atelencephaly was described and no other associated malformations were found. With TGIF, a cleft lip was present in the 3 families, in parents and children. This study confirms the extremely variable phenotypes in HPE families and the genetic heterogeneity of the disease. We are just starting to perceive a certain degree of genotype-phenotype correlation.

First occurrence of Aprosencephaly/Atelencephaly and Holoprosencephaly in a family with a SIX3 gene mutation. *L. PASQUIER*^{1,3}, *C. DUBOURG*³, *M. GONZALES*⁴, *L. LAZARO*¹, *V. DAVID*³, *S. ODENT*¹, *F. ENCHARAZAVI*². 1) Clinical Genetics, Rennes University Hospital, France; 2) Service d'Histo-Embryologie et Cytogénétique, Necker University Hospital, Paris, France; 3) Laboratoire de Génétique Moléculaire, Rennes University Hospital, France; 4) Laboratoire de Foetopathologie, Saint-Antoine University Hospital, Paris, France.

Aprosencephaly/Atelencephaly (AP/AT) refers to a spectrum of rare severe forebrain malformations, characterized by absent or rudimentary prosencephalon or its derivatives, leading to extreme microcephaly. The question whether AP/AT is the consequence of a destructive process, or due as Holoprosencephaly (HPE) to an abnormal patterning of the neural tube is still open. However, the occurrence of AP/AT and HPE in the same family nor a common causing gene have never been documented. This is the first report on the occurrence of AP/AT and HPE in a family with three affected sibs carrying a maternally inherited mutation of SIX3. In our panel of 210 unrelated HPE patients, mutational analysis led to the identification of seven SIX3 mutations (representing 3.3%). Phenotype/genotype correlation in this series of SIX3 mutations found a preferential association of HPE with eyes abnormalities, but no other case with AP/AT. Our neuropathological and mutational analysis with genotype phenotype evaluation bring strong evidences on the link between AP/AT and HPE and the role of SIX3 gene in the genesis of AP/AT. Furthermore, we conclude on the essential role of SIX3 in the patterning of the anterior fate of neuroectoderm and in craniofacial and visual field development. In term of timing, AP/AT may be considered as an early defect of posterior-to-anterior patterning of neural tube, affecting the differentiation of the prosencephalon into diencephalon and telencephalon and their derivatives. Further studies and specially the timing and pattern of SIX3 gene expression during early human development should help to understand the mechanism of AP/AT and associated malformations.

Megalencephalic Leukodystrophy with Subcortical Cysts: A report of two siblings and a review of the literature.

A.L. Pettigrew^{1,2}, *R.M.S. Romero*², *C.D. Smith*². 1) Dept Pathology, Univ Kentucky Medical Ctr, Lexington, KY; 2) Dept Neurology, Univ Kentucky Medical Ctr, Lexington, KY.

Megalencephalic leukodystrophy with subcortical cysts (MLC) is a rare autosomal recessive disorder characterized by macrocephaly, slowly progressive spasticity and ataxia, an unusually late onset of cognitive decline, and distinctive white matter changes on MRI. We present two siblings, ages 15 and 12 years, in whom a pair of novel mutations in the MLC1 gene were identified and review 120 previously reported cases in the literature. The 15 year old sister initially presented at age 5 months with macrocephaly and normal development except for a lag in head control. A CT scan identified lucency of the white matter. By age 3 years her FOC was 54 cm. At age 12 she had a generalized tonic-clonic seizure. She was doing well in a regular classes. Her exam showed mild hypertonicity in the lower extremities and unsustained clonus. At age 15, she was strikingly macrocephalic (FOC 64 cm). Her exam was normal except for mild bilateral clonus. She had been held back one year in school and was presently in regular classes with some tutoring. Her brother first presented at age 6 months with macrocephaly (FOC 49 cm) and normal development. He had two seizures at age 37 months and a third several months after minimal head trauma. Hyperactivity and oppositional behavior were reported. After being seizure free and off anticonvulsant medication for several years, he had a recurrence at age 8 after trivial head trauma. By age 9, his FOC was 61.5 cm, and he had difficulty walking. His exam showed spasticity, hyperreflexia, clonus and poor tandem gait. He required special education classes. Their MRIs at ages 15 and 12, respectively, were nearly identical and showed decreased T1 signal and increased T2 signal throughout the supratentorial white matter with sparing of the corpus callosum and geniculocalcarine tracts. Cysts were present in both anterior temporal lobes. Sequencing of the MLC1 gene showed one allele to have a R84H mutation resulting in substitution of a histidine for arginine at position 84 and the other allele to have a canonical splice site mutation following exon 5 (538 + 1ga).

Further delineation of the clinical phenotype associated with mutations in *OPHNI* gene: a clinically recognizable syndrome. *N. Philip*¹, *B. Chabrol*¹, *C. Raybaud*¹, *C. Moraine*², *M.F. Croquette*³, *V. Layet*⁴, *A. Moncla*¹, *L. Villard*⁵. 1) Depts de Génétique Médicale, Neuropédiatrie et Neuroimagerie, Hôpital d'Enfants de la Timone, Marseille, France; 2) Hôpital Bretonneau, Tours, France; 3) Hôpital Saint-Antoine, Lille, France; 4) Hôpital Charles Nicolle, Rouen, France; 5) Inserm U491, Faculté de Médecine Timone, Marseille, France.

A mutation in the *OPHNI* gene, encoding Oligophrenin, has been reported for the first time in a family of non-specific XLMR. Since then, it has been demonstrated that mutations in *OPHNI* were associated with syndromic mental retardation with cerebellar hypoplasia in two families and a sporadic case (Philip et al, 2003; Bergmann et al, 2003). These findings were confirmed by the reappraisal of the first family, demonstrating similar MRI findings. We report here a new family with the same phenotype. We made a review of the literature in order to propose a better definition of the clinical phenotype. Neuroradiological findings were identical in all male patients: cerebellar hypoplasia predominating on the lower vermis, cortical atrophy and variable ventricular dilatation requiring ventriculo-peritoneal shunting in two cases. Mental retardation was constant, usually moderate (IQ around 50), predominating on language. In all cases tested, verbal IQ was significantly lower than performance IQ, and all had rather conserved visuo-spatial abilities. There was no associated ataxia, except in one family. Strabismus was present in three families, epilepsy in two. In addition, we demonstrated that all male patients exhibit a characteristic facial appearance. Heterozygous females exhibit mild mental retardation and slight facial dysmorphism. All five mutations are non-sens mutations or small frameshift deletions. No recurrent mutation or hot-spot was observed, demonstrating that a complete mutation screening of the gene is mandatory in suspected cases.

Cerebellar anomalies: review of a series of 83 children. *S. ROMANO*¹, *N. BODDAERT*², *I. DESGUERRE*¹, *F. BRUNELLE*², *A. MUNNICH*¹, *P. de LONLAY*¹. 1) Department of Medical Genetics, Hopital Necker-Enfants Malades, Paris; 2) Department of Radiology, Hopital Necker-Enfants Malades, Paris.

We report extensive clinical, radiological and biochemical investigation in a series of 83 children with congenital cerebellar abnormally MRI evidence of. All patients but five had isolated cerebellar abnormalities. A classification of patients was made based on the clinical and radiological aspects of the cerebellum in order to obtain homogeneous groups despite the well known variability of cerebellar findings. Five groups were identified: i) cerebellar hypoplasia without cerebellar atrophy ii) cerebellar atrophy without hypoplasia iii) cerebellar atrophy combined to hypoplasia, iv) isolated cerebellar dysplasia v) partial vermian agenesis associated (group A) with a posterior fossa cyst or not (group B). In the group B, 10 children with cerebellar vermian agenesis consistent with Jouberts syndrome presented with partial agenesis of median and inferior vermis and superior vermian dysplasia. Retinopathy was present in all patients while no renal anomalies were associated. Two sisters have an Oro-Facio-Digital syndrome (type VI) with sus-tentorial anomalies including bilateral ventricular dilatation. Apart from these two sisters, 7 patients were born to consanguineous parents. Loci of Joubert syndrome in chromosomes 9q34.1 (CORS 1), 11p12-q13.3 (CORS 2) and 6q23 (COR 3) are now tested in these inbred families.

Variability of expression of neurofibromatosis 1 in monozygotic twins. *E.K. Schorry, B.T. Tinkle.* Cincinnati Childrens Hosp, Cincinnati, OH.

Twin studies have historically been a valuable tool in studying genetic traits and disorders. We present a study of monozygotic (MZ) twins with neurofibromatosis 1 (NF1) in an attempt to better understand which of the variable complications of NF1 are genetic in origin (either due to NF1 mutation or modifying genes) and which are due to non-genetic events. We reviewed medical records and examined 6 sets of MZ twins followed at our NF clinic. All twins met diagnostic criteria for NF1; zygosity was determined by testing of 9 polymorphic markers from blood samples. Features evaluated included: presence or absence of each of the 7 diagnostic criteria of NF1; osseous complications; learning disabilities (LD) or mental retardation (MR); severity score; and MRI findings. The twins ranged in age from 1 to 15 years at time of last examination. We found a high degree of concordance in skin manifestations, including numbers of cafe-au-lait spots. Two sets of twins were concordant for specific LD, and one pair concordant for mild MR. Orthopedic complications were surprisingly concordant in the twins: 2 pairs were concordant for pectus excavatum and 2 pairs concordant for scoliosis. MRI findings of T2 hyperintensities were concordant in 2/3 pairs of twins tested. Specific tumors were generally discordant among twins. One set of twins was discordant for optic nerve glioma, and two pairs were discordant for plexiform neurofibroma. Data from twins was also compared to data from same-gender siblings with NF1. In reviewing our data and comparing to other twin sets published in the literature, we conclude that NF1 complications such as cutaneous manifestations, LD, and orthopedic abnormalities were highly likely to be concordant, implying potential importance of modifying genes. Tumors, including optic nerve gliomas and plexiform neurofibromas, which likely require a second hit mutational event, were generally discordant among the twins, implying that random factors play a role in these tumors. Study of larger numbers of twins may be valuable in further elucidating these factors.

Overgrowth, developmental delay and refractory seizures- a variant of Sotos syndrome? P. Shah¹, D. Chitayat². 1) Dept Pediatrics and; 2) The Prenatal Diagnosis Program, Mount Sinai Hospital, University of Toronto, Toronto, Ontario, Canada.

We saw a 3.5 years old first child of healthy, non-consanguineous parents aged 34 (height 160 cm) and 35 years (height 160 cm) at the time of birth. Pregnancy was following an ICSI procedure. There is family history of open spina bifida (maternal side), hydrocephalus in paternal sister and developmental delay and seizures in a child of another paternal sister. There was no history of alcohol, cigarette smoking or illicit drug exposure. After an elective C/S, infant required minimal resuscitation and cried at 30 sec. Apgar scores were 6 and 10. The BW was 3.75 kg (50th-75th cent), other parameters are not available. Infant was found to be unusually quiet during initial period. Excessive weight gain was noticed from 2-3 month onwards (exclusively breast fed) with all recording 97th centile. Currently, his weight is 28.7 kg, length is 111 cm and skull circumference is 53.5 cm (all 97th centile). He is currently bottle fed and does not receive any solids. Physical examination revealed high forehead, frontal bossing, bushy eyebrows, long eyelashes, depressed nasal bridge, anteverted nostrils, left undescended testis, three caf au lait spots, bilateral club feet, pes cavus, hourglass toe nails and tapering phalanges. He had first seizure at the age of 3 months following DPT immunization. He has multiple recurrent seizures requiring multiple antiepileptics. He is severely delayed (functioning at 2-3 month level) in all aspect of development. He startles to noise and does not make eye contact. He has normal metabolic screen, bone age, chromosomes, echocardiogram and Hb electrophoresis. He had negative screen for genetic markers of fragile X, SNRNP, Prader Willi, CGD, NSD1, Soto syndrome, ATR-X gene. He is on thyroxine supplement for hypothyroidism. MRI revealed delayed myelination, generalized cerebral atrophy, moderately dilated ventricles, thin and stretched corpus callosum. In summary, we present a case similar to the reported case series of variant of Sotos syndrome (1) with an additional feature being refractory seizures. 1. Amiel J. J Med Genet 2002;39:148-52.

Screening for HPE associated deletions in a child with pseudotrisonomy 13. A. Shanske¹, D. Cordero¹, C. Bendavid^{2,3}, B.R. Haddad³, M. Muencke². 1) Ctr for Craniofacial Disorders, Children's Hosp. at Montefiore, Albert Einstein College of Medicine, Bronx, NY; 2) Medical Genetics Branch, National Human Genome Research Institute, NIH, Bethesda, MD; 3) Inst. for Molecular and Human Genetics/Lombardi Comprehensive Cancer Center, and Depts. of Oncology and Obstetrics and Gynecology, Georgetown University Medical Ctr., Washington, DC.

Holoprosencephaly (HPE) is the most common structural anomaly of the forebrain. The underlying etiology is extremely heterogeneous with known teratogens and genetic factors such as visible cytogenetic anomalies, including trisomy 13, in 25-50% of newborns and gene mutations in 20-25% of chromosomally normal infants. Cytogenetic deletions and translocations have helped define HPE minimal critical regions and identify several HPE genes. Cohen and Gorlin (1991) proposed the term pseudotrisonomy 13 syndrome to designate cases that clinically resemble trisomy 13 syndrome but had normal chromosomes. There have been 26 cases reported in the literature with several cases where consanguinity suggests autosomal recessive inheritance. Genetic heterogeneity including an undetected microdeletion or dominant new mutations have been suggested. We utilized a panel of 6 BAC FISH probes to search for microdeletions in a child with pseudotrisonomy 13. JA was the 3655 gm product of a term pregnancy born to unrelated parents. A brain anomaly was identified prenatally. Postnatally, an MRI revealed semilobar HPE with multiple large extra-axial interhemispheric loculated cysts. A VP shunt was placed at 3 months because of increasing head size. His physical examination at 14 months revealed a dysmorphic severely developmentally delayed youngster with macrocephaly, bilateral epicanthal folds, hypoplastic ala nasae, and a prominent capillary hemangioma over the forehead. Polysyndactyly (pre- and post-axial) involved all 4 extremities. Laboratory investigation included a normal male GTG-banded karyotype and cholesterol. Our multicolor FISH probe panel (containing BAC probes for 6 HPE candidate genes: SHH, TGIF, ZIC2, SIX3, DISPATCHED, HNF3, Zic2) revealed no microdeletions. This study represents the first attempt to screen a patient with pseudotrisonomy 13 for a deletion of an HPE candidate gene.

A newly described type of lissencephaly in an extended consanguineous Israeli Arab family. *R. Shenhav¹, M. Mahajna², G. Halpern¹, S. Shalev³, M. Shohat^{1,4}.* 1) Medical Genetics, Rabin Medical Center Beilinson Campus, Petah Tikva, Israel; 2) Pediatric Neurology, Schneider Children's Medical Center of Israel, Petah Tikva, Israel; 3) Genetics Unit, Ha'emek Medical Center, Afula, Israel; 4) Sackler Faculty of Medicine, Tel Aviv University, Israel.

We report 2 related consanguineous Israeli Arab families who have together 5 boys with severe microcephaly. This appears to represent a new type of lissencephaly that is transmitted by autosomal recessive inheritance. All 4 parents are healthy. In one family the parents are second cousins - they have one healthy daughter as well as 2 affected children. In the second family the parents are first cousins. They have 3 affected sons, 2 of them twins, but no healthy children. The wife in the first family and husband in the second family are siblings, and the husband in the first family and the wife in the second family are second cousins. In all the affected boys the clinical picture and the course of the illness were similar. One child was still alive aged 11 months, but all the other affected children died between 2.5 and 8 months of age. Ultrasound examination in the third trimester revealed microcephaly, IUGR and limb abnormalities. Birth weight was <5th percentile. Clinical characteristics included severe microcephaly (-4.5SD), dysmorphic facial features with a low sloping forehead, micrognathia, prominent nasal bridge, prominent helices, bilateral simian crease, flexion contractures of both hands with overriding fingers, partial syndactyly of the fingers and dorsiflexion of both feet with overriding of the toes. Other features were arthrogryposis, rigidity of the lower limbs, convulsions, choanal atresia and bilateral polar congenital cataracts. MRI of the brain showed microcephaly, a small brain, pachygyria and a thin corpus callosum. The younger boy of the first family had a normal karyotype, 46,XY, and FISH showed no deletions in 17p13.3. Histology revealed lissencephaly, with a thick cortex, reduced white matter, and abnormal lamination with 4 layers instead of 6. Cerebellar histology was normal. Linkage studies are being undertaken.

Association of HOXD1 and GBX2 allelic variants with autism spectrum disorders. *C.J Stodgell¹, M. O'Bara¹, S.L. Hyman², S. Bryson³, P.M. Rodier¹*. 1) OB/GYN, Univ. of Rochester, Rochester, NY; 2) Pediatrics, Univ. of Rochester, Rochester, NY; 3) Pediatrics, IWK Health Centre, Dalhousie Univ., Halifax, Nova Scotia, Canada.

Autism spectrum disorders (ASDs) are developmental disorders with an estimated prevalence of 3-6/1,000. Genome scans have suggested linkage to Chr. 2q. We tested two candidates located on Chr. 2q for their association with ASDs in. HOXD1 (2q31.1) is important in the formation of the abducens nerve, and has been linked to Duane syndrome, a congenital abnormality of eye muscle innervation that has been reported in autism was genotyped in. We identified two SNPs in noncoding regions of HOXD1 of 188 unrelated cases of ASD and 144 unrelated controls. The first SNP is a G>C SNP 391 bases upstream of the start codon and the second SNP (T>C) is located at base 125 of the intron; both met allele frequency expectations and there was no significant difference between the cases and controls. Of 322 cases and controls where genotypes for both SNPs were available the G allele of the 3' SNP and the T allele of the intronic SNP were linked 94% of the time. GBX2 (2q37), is also a transcription factor important in maintenance of the isthmic organizer (the mid/hindbrain division) and formation cerebellar vermis. Analysis of GBX2 upstream of the start codon revealed 2 alleles that differed by 12 bases (ACAGACGGCGGG). The frequency of the short allele was .75 in 206 unrelated cases and .54 in 200 controls. Comparisons of the short allele between cases and control indicated that significant difference with the short allele being more common in cases than in controls, OR=5.09 (95% CI, 3.58-8.01); p=.00009. We also calculated that the short allele was in transmission disequilibrium (Z=5.02). These data further support the hypothesis that genes responsible for brainstem and cerebellar formation are important candidates for the etiology of ASDs. (Supported by grants to PMR 1PO1HD35466, a Collaborative Program for Excellence in Autism, and 1RO1HD34969.).

Subset of Individuals with Autism and Macrocephaly Associated with Germline PTEN Tumour Suppressor Gene Mutations. *Z. Talebizadeh¹, M.G. Butler¹, M.J. Dasouki¹, X.P. Zhou², M. Brown¹, T.N. Takahashi³, J.H. Miles³, C.H. Wang⁴, R. Stratton⁵, R. Pilarski², C. Eng^{2,6}.* 1) Dept Genetics, Children's Mercy Hosp, Kansas City, MO; 2) Clinical Cancer Genetics Program, Human Cancer Genetics Program, Comprehensive Cancer Center, Division of Human Genetics, Department of Internal Medicine, The Ohio State University, Columbus, OH; 3) Department of Pediatrics, University of Missouri, Columbia, MO; 4) Department of Neurology, Stanford University Medical Center, Stanford, CA; 5) Southwest Genetics, San Antonio, TX; 6) Cancer Research UK Human Cancer Genetics Research Group, University of Cambridge, UK.

Autism is an early onset neurodevelopmental disorder defined by significant impairment in communication and social interaction accompanied by a pattern of repetitive or stereotypical behaviors and interests. Macrocephaly is also seen in 20% of autistic patients. Autism is genetically and phenotypically heterogeneous and several genome-wide linkage analyses have shown the involvement of at least 15 genes from different chromosomes including chromosome 10. However, the genetic etiology of autism remains elusive. Individuals with Cowden syndrome and other related disorders are characterized by germline PTEN mutations and occasionally have neurobehavioral features resembling autism and also macrocephaly. The PTEN gene is localized to chromosome 10q23. We hypothesize an association between macrocephaly and autism and PTEN gene mutations. Therefore, we undertook PTEN gene mutation analysis in 18 subjects with autism spectrum disorder and macrocephaly. Of these 18 autistic subjects (13 males and 5 females; ages 3.1 to 18.4 years) with a head circumference range from +2.5 to +8.0 SD, 3 males (17%) carried germline PTEN mutations. These 3 probands had previously undescribed PTEN mutations, H93R (exon 4), D252G (exon 7) and F241S (exon 7). These three residues were highly evolutionarily conserved. We suggest that PTEN gene testing be performed on patients with autistic behavior and macrocephaly. The gene findings may impact on recurrence risks as well as medical management for the patient.

Principal signs and symptoms of NF1 patients attended at the CNNF Brazil. *G. Carakushansky^{1, 2}, M. Geller^{1, 2}, K. Higino^{1, 2}, D.R. Azulay¹, G. Coutinho², M. Coutinho², J.G. Rangel Goncalves¹, A. Bonalumi Filho², M. Suchmacher², E. Kahn¹.* 1) Dept Pediatrics, Federal Univ Rio de Janeiro, Rio de Janeiro, Brazil; 2) Teresopolis Medical School, Rio de Janeiro, Brazil.

Introduction: Neurofibromatosis type 1 (NF1) or von Recklinghausen disease is an autosomal dominant disorder caused by mutations in the 17q11.2 gene. It presents complete penetrance and a large variation in the expression of the occurrence of manifestations both intra and interfamilyally, as well as in an individual at different stages in life, as it is age-dependent. Diagnosis is based on the establishment of clinical criteria. Men and women are equally affected.

Material and Methods: Descriptive, observational, transversal study consulting the Centro Nacional de Neurofibromatose (CNNF) database, located at Instituto de Dermatologia da Santa Casa de Misericórdia in Rio de Janeiro and at the Instituto de Pediatria e Puericultura Martago Gesteira of the Federal University of Rio de Janeiro, from 1998 to 2004.

Results: 166 NF1 patients were attended, 93 females and 73 males, and plexiform neurofibromas were observed in 33%; subcutaneous neurofibromas in 56%; cutaneous neurofibromas in 60%; café-au-lait spots between 05 and 15mm in 80%; café-au-lait spots larger than 15mm in 74.69%; axillary freckling and other folding regions in 40%; Lisch nodules in 15%; and sensorineural auditive loss in 7%.

Conclusions: The majority of patients are female, predominance of cutaneous neurofibromas and café-au-lait spots between 05 and 15mm, a large proportion present freckling, Lisch nodules and sensorineural auditive loss are present in a minority of NF1 patients in Brazil.

Prevalence of Plexiform Neurofibromas at the CNNF Brazil. *M.G. Ribeiro¹, M. Geller^{1, 2}, K.S. Higino^{1, 2}, G.P. Coutinho², M.P. Coutinho², L.G.J. Darrigo², G. Carakushansky^{1, 2}.* 1) Genetics Department, Federal University of Rio de Janeiro, Rio de Janeiro, Brazil; 2) Teresopolis Medical School, Rio de Janeiro, Brazil.

Introduction: Neurofibromatosis 1 (NF1) is an autosomal dominant disorder caused by mutations to the 17q11.2 gene. The NF1 gene is a tumor suppressor, and is related to the appearance of specific lesions, such as cutaneous, subcutaneous, or plexiform neurofibromas, freckling, optic gliomas, Lisch nodules, and bone dysplasias. The plexiform neurofibroma constitutes one of the significant complications of NF1 that may occur in childhood, rarely developing after adolescence. Studies relate a prevalence of 15%, however there are divergences, with other studies relating a prevalence of 16 to 40% in NF1 patients.

Materials and Methods: Descriptive, observational, transversal study consulting the Centro Nacional de Neurofibromatose (CNNF) database, located at Hospital Geral da Santa Casa de Misericórdia do Rio de Janeiro and at the and at the Instituto de Pediatria e Puericultura Martagão Gesteira of the Federal University of Rio de Janeiro from 1998 to 2004.

Results: 166 NF1 patients were attended, 93 female and 73, male and 33% (55 cases) of plexiform neurofibromas were observed. The distribution of the plexiform neurofibromas by sex was 60% (33 cases) for females and 40% (22 cases) for males; while the age distribution was 7.27% (4) from 0 to 5 years of age; 16.36 (9) from 6 to 12; 18.8% (10) from 13 to 21 years; 47.27% (26) from 22 to 49 years, and 10.91(6) in patients older than 50.

Conclusion: In Brazilian patients, plexiform neurofibromas are predominant in female patients above 20 years of age.

Hemizyosity at the NCF1 gene in Williams-Beuren syndrome patients decreases their risk of hypertension. A. Antonell, M. Del Campo, L.F. Magano, F.J. Munoz, R. Flores, M. Bayes, L.A. Perez Jurado. Genetics and Cell signaling Units, Dept of Experimental Sciences, Universitat Pompeu Fabra, Barcelona, Spain.

Williams-Beuren syndrome is a neurodevelopmental disorder with multisystemic manifestations due to a segmental aneusomy at chromosomal band 7q11.23. Hemizyosity at the elastin gene is known to be the cause of the vascular stenoses and thought to predispose to the hypertension present in about 50% of patients. The most common ~1,55 Mb deletion is mediated by non-allelic homologous recombination between large blocks of segmental duplications. These blocks contain functional genes and pseudogenes, specifically several copies of two genes (NCF1 and GTF2IRD2), the number of which varies depending on the location of the deletion breakpoints. Fine mapping of these deletions analyzing several paralogous sequence variants was performed in order to investigate potential associations with some of the phenotypic differences present in these patients. The sample included 84 sporadic patients with an identical size deletion at 7q11.23. Significant associations were found among clinical features and molecular deletion subtypes. Particularly, high blood pressure, which was not correlated with the severity of cardiovascular disease, was more common in patients with no deletion of the NCF1 gene ($p < 0.005$). NCF1 encodes a cytosolic subunit of the leukocyte NADPH oxidase (p47phox), an enzymatic complex that catalyzes the production of superoxide (O_2^-) from NADPH and oxygen. To gain insight in the molecular mechanism by which NCF1 gene dosage correlates with blood pressure, we compared the activation of the respiratory burst (nitroblue tetrazolium test) by phorbol myristate acetate treatment (1M) in Williams-Beuren syndrome cell lines with and without NCF1 gene deletion. As expected, patients hemizygous at NCF1 gene showed less activity of the NADPH oxidase activity and thus less production of superoxide ($p < 0.005$). However, it is still unknown whether or not the decreased production of superoxide contributes to increased vascular nitric oxide bioactivity. Therefore, our findings highly suggest that deletion of NCF1 protects against high blood pressure in patients of Williams-Beuren syndrome.

Neurofibromatosis-Noonan syndrome: molecular evidence of the concurrence of both disorders in a patient. D.

*Bertola*¹, *A.C. Pereira*², *P.S.L. Oliveira*², *L. Messiaen*³, *B.D. Gelb*⁴, *C.A. Kim*¹, *J.E. Krieger*². 1) Genetics Unit, Instituto da Crianca, Sao Paulo, SP, Brazil; 2) Laboratrio de Genetica e Cardiologia Molecular, InCor, University of Sao Paulo, SP, Brazil; 3) Medical Genomics Laboratory, Department of Genetics, University of Alabama, Birmingham, AL, USA; 4) Department of Pediatrics and Human Genetics, Mount Sinai School of Medicine, New York, NY, USA.

Noonan syndrome (NS) is an autosomal dominant disorder characterized by short stature, dysmorphic facial features, webbed neck, sternal deformity, heart defect, cryptorchidism in males and bleeding diathesis. The gene responsible for NS (PTPN11) was recently identified. Neurofibromatosis type 1 (NF1) is another autosomal dominant disorder characterized by café-au-lait spots, neurofibromas, Lisch nodules, axillary and inguinal freckling. The NF1 gene encodes a GAP-related protein, which acts as a negative regulator of the Ras-mediated signal transduction pathway. A clinical overlap between both syndromes named neurofibromatosis-Noonan syndrome (NFNS) is unequivocal. Four possible explanations for this combination were proposed: chance concurrence of NS and NF1; NFNS is just an unusual variant of the NS; NFNS is a somewhat unusual type of NF1; NFNS is a new entity. So far, a molecular study of the NF1 and PTPN11 genes in NFNS patients showed mutations only in the NF1 gene. We studied a 14-year-old patient with typical findings of NF1 and NS for mutations in the PTPN11 and NF1 genes. Her father was considered clinically affected by NS, with mild features. Mutational analysis for the PTPN11 gene showed an arginine to glutamine substitution at position 510 of the protein (R510Q) in the proband and her father. In the NF1 gene, a missense mutation in exon 16 was identified changing a leucine for an arginine at position 844 of the protein (L844R). This mutation was not present in her parents. The patient here reported inherited a PTPN11 gene mutation from the father and also has a de novo mutation in the NF1 gene, showing, for the first time, molecular evidence for the concurrence of both disorders in an individual, suggesting genetic heterogeneity in NFNS.

Genotype-phenotype correlation in Marfan syndrome. *A.H. Child, J. Aragon-Martin, P. Comeglio.* Cardiological Sciences, St George's Hospital Medical School, London, United Kingdom.

Purpose : To look for genotype-phenotype correlation in Marfan syndrome spectrum of disorders (fibrillin-1 deficiency).

Method: Over 600 mutations are reported in fibrillin-1 gene, 123 discovered in our clinic population. Screening for 347 consecutive patients was carried out using SSCA and /or dHPLC. Twenty-two patients were analysed using both techniques. Abnormal fragments were sequenced. One hundred chromosomes from control individuals established whether mutations were polymorphisms.

Results: One hundred and twenty three FBN-1 mutations were identified, 10 of which recurred, 32 had already been described and 91 were novel. One hundred and thirty three relatives of 60 probands were tested for carrier status, including 5 newborns (4 proven unaffected). Classic Marfan syndrome cases yielded a detection rate of 52/72 (72.2%) while a lower yield was observed from marfanoid phenotype (58/206 or 28.2%). No mutations were detected in 36 patients with isolated aortic aneurysm. In predominant ectopia lentis the mutation yield was 13/33 (39.4%).

Conclusion: FBN-1 mutation detection in the Marfan syndrome spectrum aids diagnosis, prognosis and management. Mutations in exons 24-32 are linked with neonatal Marfan syndrome, mutations at calcium-binding sites usually cause major disruption in fibrillin-1 function as do cysteine substitutions. In ectopia lentis, mutations are most often found in the first 15 exons and do not involve cysteine substitutions.

The genetic epidemiology of familial arrhythmogenic right ventricular cardiomyopathy/ dilated cardiomyopathy in Newfoundland. *G.G. Cook¹, K.A. Hodgkinson¹, S. Connors², L. Thierfelder³, A.S. Bassett⁴, P.S. Parfrey¹.* 1) Patient Research Centre, Memorial University, St. John's, Newfoundland, Canada; 2) Division of Cardiology, Health Sciences Centre, St. John's, Newfoundland, Canada; 3) Max-Delbrück Centrum für Molekulare Medizin, Berlin, Germany; 4) Clinical Genetics Research Program, Centre for Addiction and Mental Health, University of Toronto, Ontario, Canada.

We have previously shown that Newfoundland families with arrhythmogenic right ventricular cardiomyopathy (ARVC) linked to a founder haplotype at 3p25 (ARVD5) have a significantly increased mortality in males, with an overlap between an ARVC and dilated cardiomyopathy (DCM) phenotype. To determine its contribution to familial ARVC/DCM we studied 46 families referred to the Newfoundland provincial genetics clinic with ARVC, DCM or sudden cardiac death (SCD) under 50 years who had at least 2 family members with manifestations of cardiomyopathy. Of these, 25 families had at least 3 affected members in 2 successive generations and at least 2 in one sibship. 17 (68%) families were linked to ARVD5 and 8 (32%) families had ARVC/DCM/SCD not linked to 3p25. Age to death, or last follow up, was determined in family members with an a priori 50% risk of inheriting ARVC/DCM. Mortality was significantly greater in male subjects from ARVD5 families compared to families not linked to 3p25: Median age to death was 52y (95% CI 47-57; n=266) vs. 65y (95% CI 58-72; n=90): relative risk (RR) 2.2 (95% CI 1.4-3.4), p=0.0004. Results were not significantly different for female subjects: median age to death 75y (95% CI 69-81; n=206 ARVD5) vs. 90y (95% CI 67-113; n=77 not linked to 3p25): RR 1.4 (95% CI 0.7-2.7). Irrespective of linkage to 3p25, in densely affected ARVC/DCM/SCD families, males at 50% risk die significantly earlier than females (p=0.0405; non-3p25 linked, p=0.0001; 3p25 linked). We conclude that ARVD5 is a major genetic cause of familial cardiomyopathy in Newfoundland with a significantly worse mortality in male family members of probands to that for familial cardiomyopathy unlinked to 3p25.

Assymmetric septal Hypertrophy. Report of a family case. *N. Davalos¹, V. Sanchez-Barba¹, I.P. Davalos^{2,3}, L.E. Figuera^{2,3}.* 1) Hospital Regional Dr.Valentin Gomez Farias, ISSSTE; 2) Doctorado en Genetica Humana, CUCS, U de G; 3) Division de Genetica,CIBO, IMSS. Guadalajara, Jalisco Mexico.

The first demonstration of Asymmetric Septal Hypertrophy (ASH) or Cardiomyopathy Familial Hypertrophic (HC) was described by Teare in 1958, reported the autopsy findings of sudden death in 9 young subjects. ASH in early stages produces a presystolic gallop due to an atrial heart sound, and EKG changes of ventricular hypertrophy. Ventricular tachycardia or fibrillation is thought to be the principal mechanism of sudden death in patients with hypertrophic cardiomyopathy (HC). Genetic heterogeneity for ASH has been postulated with involved genes in 20q13.3, 15q14, 14q12, 3p21.3-p14.3. CASE REPORT: The propositus 33 male years-old. Clinically he presented chest pain and dyspnea with periodicity of twice a week. Familial history of sudden death. Physical examination show: high 170 cm; weight 74 Kg; blood pressure 100/60mm Hg; at cardiac area FC 70x and an aortic systolic ejection murmur. Study of proband with the full-blown condition shows that an atrial heart sound ('presystolic gallop') and EKG changes of septal hypertrophy. The echocardiographic study revealed: 1) ASH of septum without SAM. 2) septum hypokinesia. 3) diastolic disfunction. 4) FE 75%. The purpose of this paper is to describe a familial case with ASH. This family shows at least 10 affected members in 5 generations with a sex ratio F:3; M:7. Although this case revealed an association with strenuous physical exertion or sports (Spirito 1997, Maron 2003) and more males than females were affected (Greaves 1987). The pattern of inheritance was consistent with autosomal dominant inheritance, few cases with an autosomal recessive and X-linked recessive inheritance was described. Spirito in 1997 reviewed heterogeneity of clinical and genetic features and stated that the diverse clinical and genetic features of ASH make it impossible to define precise guidelines for management (OMIM 192600). Although studies have found specific mutations associated with the various forms of this condition, genotype-phenotype studies are needed to learn more about the changes in the gene and the mode of inheritance.

In frame deletion in the fibrillin1 gene in a patient presenting a Weill-Marchesani phenotype with aortic aneurysm: extending the spectrum of fibrillinopathies? *J. De Backer¹, M. Godfrey^{1, 2}, P. Van Akker¹, P. Coucke¹, A. De Paepe¹*. 1) Medical Genetics Department, University Hospital Ghent, Belgium; 2) Department of Paediatrics, Univ of Nebraska Medical Center, Omaha, NE.

In frame deletions of more than one codon of the fibrillin1 gene (FBN1) are infrequently encountered Marfan syndrome (MFS). One 9nt and one 66nt deletion have been described in 2 patients with neonatal MFS. One 48nt deletion has been described in a patient with classical MFS. Recently, an in frame deletion of 24nt has been described in a family with autosomal dominant Weill-Marchesani syndrome (WMS). We present a 62 year old male patient with an ascending aortic aneurysm for which surgery was performed. Ten years earlier he underwent surgery on both eyes for acute glaucoma, and subsequently for cataract. Ocular examination showed very shallow anterior eye chambers. Lens dislocation was not seen. On physical examination he presented a stocky stature, a round face, stiff joints and short fingers. The patients brother and sister both died suddenly at the ages of 63 and 45 years respectively. Furthermore, both his mother and maternal uncle as well as his eldest son, suffered from bilateral glaucoma. Mutational analysis of the FBN1 gene in the patient revealed a 12nt deletion in exon 20 (c2502-2513delTGAAAGTACTTT). The patient represents an unusual, so far unique, condition combining clinical features of MFS (aortic dilatation) and WMS(ocular and skeletal features). Probably the disease segregates in the family as an autosomal dominant trait. The underlying FBN1 mutation has not been reported previously neither in MFS nor in WMS. The 12nt deletion is located in exon 20, encoding the 9th cb- EGF like domain of the FBN1 gene. It is in close vicinity to a conserved cystein residue and as such likely interferes with normal calcium binding essential for functional integrity of the FBN1 gene. This observation confirms that intragenic deletions of the FBN1 gene can cause the WMS phenotype, that the clinical definition of WMS should be expanded to include cardiovascular manifestations of MFS and nicely illustrates the continuum of clinical phenotypes associated with mutations in the FBN1 gene.

Characteristics, associations, and outcome of Absent Pulmonary Valve syndrome in the fetus. *M. Gentile*^{1,2}, *P. Volpe*², *D. Paladini*³, *M. Marasini*⁴, *A.L. Buonadonna*¹, *P. Arciprete*⁵, *F.M. Boscia*². 1) Dept Med Genet, IRCCS de Bellis, Castellana(BA); 2) Dept Obstet Gynecol, AUSLBA/04 Bari; 3) Dept Obstet Gynecol, University Federico II of Naples; 4) Dept Pediatr Cardiol, Giannina Gaslini Institute, Genova; 5) Dept Cardiac Surg, AUSLBA/04, Bari, Italy.

Objectives. To assess: A) the accuracy of prenatal diagnosis; B) the incidence of extra-cardiac and chromosomal anomalies; C) the perinatal outcome in a population of 21 fetuses diagnosed with Absent Pulmonary Valve Syndrome (APVS).

Methods. The following variables of 21 fetuses with APVS were retrieved from databases: indication for referral, gestational age at diagnosis, cardiomegaly, branch pulmonary dilatation, associated anomalies, FGR, fetal/neonatal outcome. Karyotyping was performed in 20/21 cases, with FISH analysis to detect the 22q11 microdeletion performed in 16/21 cases.

Results Prenatal diagnosis of APVS proved correct in all cases, with only 3 cases occurring not in association with TOF. Additional cardiovascular anomalies were present in 5 cases (24%). Extra-cardiac anomalies were found in 9 cases (42.8%), and were associated with chromosomal anomalies in 5. The 22q11 microdeletion was present in 4/16 cases (25%). Fetal/neonatal outcome was as follows: 9 terminations of pregnancy, 3 intrauterine deaths, 6 post-natal deaths, and 3 (14.3%) neonates alive after surgery. Cardiomegaly and marked branch pulmonary dilatation was present in 16 and 15 cases, respectively, and was associated with bronchomalacia in virtually all cases.

Conclusions. APVS can be reliably diagnosed and characterized in prenatal life. The association with major chromosomal anomalies (5/20, 25%) or 22q11 microdeletion (4/16, 25%) is consistent. The relatively poor survival rate (14.3%) is due to the high rate of terminations, associated genetic anomalies, and bronchomalacia.

Nonsyndromic familial Tetralogy of Fallot (TOF) in two families with 3- terminal frame shift mutations of JAG1.

C. Glaeser¹, D. Kotzot², A. Caliebe³, S. Schulz¹, U. Schweigmann⁴, I. Hansmann¹. 1) Inst Human Genetics, Univ Halle, Halle, Germany; 2) Dep. of Med. Biol. & Human Genet., Medical Univ., Innsbruck, Austria; 3) Inst. of Human Genet., Univ. Kiel, Germany; 4) Dep. of Pediatric Cardiol., Medical Univ., Innsbruck, Austria.

Tetralogy of Fallot (TOF) is the most common cyanotic conotruncal heart malformation. Genes involved and molecular pathogenesis are largely unknown. Syndromic TOF has been observed with various chromosomal disorders (trisomy 21, microdeletions 22q11.2, e.g.). Few isolated nonsyndromic sporadic or familial TOFs have been found to be associated with single gene mutations (ZFPM2/FOG2 and NKX2.5). In addition, recent observations identified the JAG1 gene mutated in Alagille syndrome (AGS) as a candidate for TOF. We report about two families of European Caucasian origin with several individuals showing TOF and being affected by truncating frame shift mutations within the 3- terminal coding region of JAG1. In family A with 3 sisters with TOF a segregating maternal frame shift mutation within exon 24 (3021-3022insGC) was detected. None of the sisters demonstrated features characteristic for AGS with exception of butterfly vertebrae and an additional rib reported for the oldest sister. The mother carrying the mutation is clinically normal and even does not show any evidence for heart malformation. In family B with 3 out of 6 sibs with TOF (1 sister, 2 brothers) and one affected son a truncating frame shift mutation within exon 26 (3599-3600insG) was detected. Also in this family none of the individuals met the diagnostic criteria for AGS. Our data indicate that even truncating mutations within the 3- coding region of JAG1 may be causally related with familial nonsyndromic TOF. Further studies in sporadic and familial cases have to reveal whether JAG1 has a significant impact on TOF. Due to the asymptomatic mother carrying the mutation and the observation of low penetrance in the large kindred with TOF and a missense mutation within exon 6 of JAG1 (Eldadah ZA et al. 2001) it would be interesting how the penetrance is being modulated by the normal JAG1 allele and/or by other genes e.g. that of the NOTCH signalling pathway.

Noonan-like phenotype and PTPN11 gene: study of 15 patients. *C. Kim¹, A.C. Pereira², J.E. Krieger², L.M.J. Albano¹, D.R. Bertola¹.* 1) Genetics Clinic Unit, Dept Pediatrics, Inst da Crianca, Sao Paulo, Sao Paulo, Brazil; 2) Laboratorio de Genetica e Cardiologia Molecular, Heart Institute (InCor), University of Sao Paulo, Sao Paulo, Brazil.

Noonan syndrome (NS) is an autosomal dominant disorder comprising short stature, facial dysmorphisms, short and/or webbed neck, cardiac defect (mainly pulmonary stenosis and hypertrophic cardiomyopathy), cryptorchidism in males and bleeding diathesis. The gene responsible for this disease (PTPN11) was recently identified and accounts for 30 to 50% of the cases diagnosed clinically as NS. A few other conditions (cardiofaciocutaneous - CFC syndrome, Leopard syndrome, Noonan-like/multiple giant cell lesion syndrome, Noonan-neurofibromatosis, Costello syndrome) share several of the clinical findings present in NS. The gene PTPN11 has been tested for as the possible responsible for these disorders and this was the case for Leopard syndrome and Noonan-like/multiple giant cell lesion syndrome. On the other hand, CFC syndrome and Costello syndrome are not caused by mutations in this gene. We studied 15 patients with a Noonan-like phenotype: 10 with CFC syndrome, 3 with Leopard syndrome and 2 with Noonan-like/multiple giant cell lesion syndrome. Mutational analysis of the PTPN11 gene was performed using DHPLC and amplicons with an aberrant elution profile were subsequently sequenced. No mutations in the coding region of the gene were found in any patients. These results reinforce that CFC syndrome is not caused by mutations in the coding region of the PTPN11 gene and the Leopard syndrome is, as NS, an heterogeneous disorder. For Noonan-like/multiple giant cell lesion syndrome, so far there is only one family studied and the mutation found in the PTPN11 (Asn308Ser) was also present in another patient with NS and apparently no history of multiple giant cell lesions, indicating that Noonan-like/multiple giant cell lesion syndrome is part of the spectrum of NS. The absence of mutations in the coding region of the PTPN11 gene in our 2 patients with Noonan-like/multiple giant cell lesion syndrome, indicates that this is also an heterogeneous disorder.

Congenital cardiac disease in 2 patients with Cranio-osteoarthropathy. *S. O'Connell*¹, *M. Suri*², *C. Hall*³, *W. Reardon*¹. 1) National Centre of Medical Gen, Our Lady's Hospital for Sick C, Dublin, Dublin, Ireland; 2) Clinical Genetics Service, City Hospital, Nottingham, UK; 3) Great Ormond Street Hospital for Children, London, UK.

Cranio-osteoarthropathy is a rare condition. Classically, signs are identifiable in infancy with clubbing of fingers, and delayed closure of the clinically enlarged cranial sutures, followed by periosteal new bone formation on x-rays of the long bones. Ultimately, joint swelling and stiffness follow, typically involving the large joints. We report two unrelated patients with features of cranio-osteoarthropathy, both of whom also had a history of congenital heart disease. Moreover, the cases reported here, manifesting significant differences in radiological features, emphasise the variability of radiological findings which can attend this condition.

Familial aplasia cutis congenita, left-sided cardiac obstructive defects, and balanced 2;19 chromosome translocation. *M.E. Pierpont*^{1,2}, *J.A. Baker*¹, *K.E. Bloom*^{2,3}, *R.R. Higgins*⁴, *A. Singh*⁵. 1) Children's Hosp, Mpls/St Paul, MN; 2) Univ Minnesota, Mpls, MN; 3) Dermatology Center For Children and Young Adults, Mpls, MN; 4) Allina Cytogenetics, Mpls, MN; 5) Children's Heart Clinic, Mpls, MN.

Aplasia cutis congenita (ACC) has been described in association with congenital cardiac abnormalities. We report two families with members affected by ACC and left-sided cardiac obstructive defects. In family 1, a 15-month-old boy has ACC and complex cardiac disease (bicuspid aortic valve, aortic stenosis, coarctation of the aorta, mitral stenosis, hypoplasia of the transverse aortic arch). His 30-month-old sister has ACC and a normal echocardiogram. An older brother died at 3 months from aortic atresia and hypoplastic left ventricle. He had no ACC. The parents have no ACC and normal echocardiograms. The maternal grandmother has mild scalp vertex alopecia. Chromosomal analyses have revealed a balanced translocation $t(2;19)(p23.3;p13.11)$ in the proband, his sister, and the mother. In family 2, an 11-year-old male proband has ACC and multiple left-sided cardiac defects (bicuspid aortic valve, coarctation of the aorta, parachute mitral valve, subaortic muscular ridge, supravalvular mitral ring). A younger male sibling died at 7 weeks from hypoplastic left heart. There is an older sister with no ACC and normal echocardiogram. The father has ACC and a normal echocardiogram. The paternal grandmother has mild ACC. The proband has a normal karyotype. These two families illustrate that investigation for the presence of variable congenital heart defects should be considered for each person with ACC. In these two families, no one has a limb defect, so confirmation of Adams Oliver syndrome (AO) is not possible. However, individuals with AO have previously been described with various forms of left-sided obstructive cardiac defects, suggesting a contiguous gene disorder. The presence of a balanced translocation in family 1 provides new information for possible localization of the gene(s) responsible for ACC, AO and left heart development at 2p23.3 or 19p13.11.

A family exhibiting arterial tortuosity syndrome displays homozygosity of microsatellite markers associated with the arterial tortuosity locus. *S.H.E. Zaidi¹, V. Peltekova⁵, S. Meyer², A. Lindinger², A.D. Paterson³, L-C. Tsui^{3, 4}, A.S. Teebi³, M.F. Ul Haque³.* 1) Dept of Medicine, Toronto General Hosp, Toronto, Ontario, M5G 2C4, Canada; 2) Universitätskliniken des Saarlandes, Kirrberger Strae, Homburg, Germany; 3) Program in Genetics and Genomic Biology, Hospital for Sick Children, Toronto, ON, M5G 1X8, Canada; 4) The University of Hong Kong, Pokfulam Road, Hong Kong; 5) Mount Sinai Hospital, Samuel Lunenfeld Research Institute, Toronto.

Arterial tortuosity syndrome is a rare autosomal recessive disorder, which is characterized by severe tortuosity and lengthening of systemic and large arteries in the affected individuals. In addition patients also exhibit hyperextensible skin and hypermobility of joints, features that are characteristics of Ehlers-Danlos syndromes. This rare syndrome has been described in several ethnically diverse families and an arterial tortuosity locus on chromosome 20q13 has recently been discovered. Here we report a family with an affected child and seven unaffected individuals. The affected girl manifests elongation and severe tortuosity of the aorta, carotid and other arteries. Additional clinical symptoms include loose skin, hypermobile joints, hernias and facial features that resemble Ehlers-Danlos syndromes. This phenotype is similar to the clinical appearance of patients, for whom the arterial tortuosity locus has been mapped. We therefore performed genotyping using the microsatellite markers that are located at the arterial tortuosity locus, for the affected child, her parents and all unaffected siblings. The affected child was homozygous for these markers, while parents and three of the five siblings were found heterozygous. Genotyping using additional markers defined the genomic interval to a 37cM region flanked by D20S885 and D20S893 microsatellite markers, within which the arterial tortuosity locus is located. No mutations were identified in the coding regions of three functional candidate genes that resided at this locus. This is the second only report of the involvement of arterial tortuosity locus in an ethnically distinct family.

Stereotypy and serotonin in children with Autistic Disorder. *R.K. Abramson*¹, *A.V. Hall*², *S.A. Ravan*², *H. Cope*³, *M.L. Cuccaro*³, *M. Pericak-Vance*³, *H.H. Wright*². 1) Dept Neuropsychiatry & Behav, Wm S Hall Psychiatric Inst, Columbia, SC; 2) Dept Neuropsychiatry, Univ. South Carolina Sch. Med., Columbia, SC; 3) Center for Human Genetics, Duke University, Durham, NC.

Stereotypy is a repetitive behavior in children with Autistic Disorder(AD). In children with AD, stereotypies may be 1)environmentally mediated (Kennedy et al,2000;Militeri et al,2003), 2)persistent and independent of environment suggesting a biologically-based etiology(Kennedy et al,2000) or 3)both environmental and biologically based. Selective serotonin reuptake inhibitors treat biologically based repetitive behaviors in AD. The purpose of this study was to evaluate whether whole blood serotonin levels (5HT) in children with AD contribute to severity of stereotypy. Diagnoses of 71 probands(average age 8.54.1yrs) from the Duke/USC molecular studies of AD, were confirmed using the Autism Diagnostic Interview-Revised. Stereotypy was measured by the Aberrant Behavior Checklist stereotypy score(ABC-S). 5HT was determined by HPLC. Children were free of medication affecting 5HT. Controlling for race[17 African Americans (AA), 54 Caucasians (C)], a trend existed towards a negative correlation between the ABC-S and 5HT, $r=-.226, df=68, p=0.060$. 5HT for AA probands($X=322.948.7SE$) was higher($t=2.215, p=0.039, df=69$) than for C probands($X=210.414.4SE$). With race appropriate means, proband 5HT was high(2SD above the mean) in 24%($n=17$) and low(2SD below the mean) in 11.3%($n=8$). In the combined subgroup, AA probands had lower ABC-S scores($X=3.5831.271SE, n=5$) than C probands($X=7.2260.679, n=20$)($F=6.388, p=0.02, df=23$). C probands with low 5HT ($X=9.6671.137$) had the highest ABC-S scores. In this small race controlled sample, a trend existed for higher 5HT and lower ABC-S scores. A larger sample is necessary to evaluate the relationship between 5HT level and severity of stereotypies in AD. In a group of children the biological contribution to the severity of stereotypy may be larger than the environmental contribution, and may point the way to targeted pharmacologic intervention. High 5HT with decreased stereotypy may point to a sub-phenotype relevant to select genes to dissect the complex etiology of AD.

Severe and Progressive Osteolysis of the Toes, Feet and Legs (Acrotarsotibial Osteolysis): A Novel Disorder or a Variant of Torg Syndrome ? *D. Aktas¹, O. Akan², M. Ozates³, N. Akarsu⁴, A. Zankl⁵, A. Superti-Furga⁵, E.*

Tuncbilek¹. 1) Department of Genetics, Hacettepe University Medical School, Ankara, Turkey; 2) Department of Radiology, Hacettepe University Medical School, Ankara, Turkey; 3) Department of Radiology, Dicle University Medical School, Diyarbakir, Turkey; 4) Department of Pediatrics Hematology, Hacettepe University Medical School, Ankara, Turkey; 5) Molecular Pediatrics, University of Lausanne, Switzerland.

We report a family with three adults sibs affected by a distinct form of osteolysis restricted to the lower limbs. The onset of disease is insidious, first changes having been noticed in early adulthood. Osteolytic changes begin at the phalangeal and metatarsal bones of the foot and not progresses proximally to involve tarsal bones, tibia and fibula. In the most severely affected of the three sibs, only a small, proximally broad and distally pointed fragment each of the tibia and fibula are left. Radiographically, the changes resemble those seen in the Torg and Winchester syndromes with but are strictly limited to the lower extremities. Notably, the hands and upper extremities are not affected. There are additional findings, such as bilateral cervical ribs and increased aeration in cranial sinuses, of doubtful significance. Skin, hair, nails and teeth were unremarkable; neuromuscular signs were not noticed. Renal function was normal. During a follow-up of five years, the osseous changes, and the resulting clinical deformation and motor disability, showed a clear progression. The parents and three sibs are clinically unaffected and no radiological abnormality on their hands was found. There is no known consanguinity and the most striking feature of this condition is its limitation to the lower extremities, although it cannot be excluded that the hands will become affected later in the course of disease. The lack of ectodermal, neuromuscular and renal changes exclude a series of syndromes associated with osteolysis. We are currently testing the hypothesis that this disorder may be allelic to the Torg/Winchester syndrome, but pending molecular results, we propose the name of acrotarsotibial osteolysis syndrome to reflect the site and progression of lesions.

Three cases with limb anomalies. *N. Almadani, F. Afroozan, Y. Shafeghati, M.H. Kariminejad.* PO Box 14665/154, Pathology & Genetics Ctr, Tehran, Iran.

Three cases with limb anomalies Two patients with Tibial aplasia-Ectrodactyly syndrome , This pattern of malformation are included : split-hand/split foot, absence of Arms&Legs. Ours patient is 18 month old male with unrelated parents that suffered from Hypoplastic /absent tibia, split hands, Hypoplastic/absent carpus, Absent metacarpus, metatarsus, phalanges & toes, Oligodactyly, bilateral patellar hypoplasia and contracted knee joints. The second case is two years old male from unknown parents that suffered from Acromelia of upper limbs, Reduction deformity of arms, Absent hand, Hypoplastic/absent carpus, Absent fingers/toes or oligodactyly, Absent metacarpus & metatarsus, Hypoplastic or absent Tibia. The second syndrome is Fibular aplasia- oligodactyly-camptomelia that reported by Hecht& Scott (1981) is included absent hands, absent foot. Our case was one years old male from unrelated parents that suffered from Reduction deformity of arm, Absent hands, Oligodactyly, absent lower limb, Bowed and hypoplastic femur, Hypoplastic/absent fibula and tibia, Absent feet& toes, Syndactyly of toes . Our two cases with tibial aplasia- Ectrodactyly are similar to patients that reported with this syndrome in references, but our case with fibular aplasia- oligodactyly- camptomelia may be similar to the femur- fibula- ulna complex (FFU syndrome) but ulna deficiency not seen in our case, And the otherhand in fibular- oligodactyly- camptomelia not seen any kind of femoral deficiency.

Umbilical cord deformation sequence in an infant with arthrogryposis multiplex congenita. *J.R. Corona-Rivera^{1,2}, M.C. Abreu-Fernández², A. Corona-Rivera¹.* 1) Laboratorio de Genética Humana, CUCS, Universidad de Guadalajara; 2) Servicio de Genética, División de Pediatría, Hospital Civil de Guadalajara Dr. Juan I. Menchaca, Guadalajara, Jal., México.

Arthrogryposis multiplex congenita (AMC), also referred to as amyoplasia, is sporadic in occurrence. The current report identifies a newborn female with AMC and umbilical cord deformational sequence (UCDS). The correlations among the clinical findings are discussed. The proposita was born to a 25 y-year-old G3, P2 mother. Threatened abortion at 4th month and decreased fetal movements were noted by the mother. The delivery was normal vaginal vertex at 40.3 weeks gestation. Birth weight was 2525 g, length was 49 cm, and OFC was 34 cm. Apgar scores were 7 and 8, at 1 and 5 minutes, respectively. Length of umbilical cord was not available. Physical examination showed symmetric contractures of the four extremities, round face, small upturned nose, and midline capillary hemangioma; shoulders were internally rotated and adducted with decreased muscle mass, elbows were fixed and extended, wrist and fingers were flexed, and also showed talipes deformity. On the left lower limb, two deep grooves were observed, as well as a mild mark of constriction on the left wrist. Radiographs showed gracile ribs and thin long bones. Karyotype and renal ultrasound were normal. Electromyography reported myopathic arthrogryposis. UCDS result from constrictive umbilical cord loops around a fetal part producing deep grooves and significant structural deformation in the underlying fetal tissues. Fetal hyperkinesia is a key theory for UCDS occurrence, since increased fetal activity is believed to determine long cords. No other causative factors related to long cords like polyhydramnios, abdominal pregnancy or fetal hypertension were noted in this case. To our knowledge, cord wrapping around a limb is occasionally seen on arthrogryposis cases, although non related to UCDS. Fetal hypokinesia-AMC associated to UCDS is an unexpected event suggesting that other unknown causative factors are needed for UCDS occurrence in this patient.

Male children with sporadic form of neurofibromatosis type-1 (NF1) are at risk for learning impairment. *F.X. Coude*^{1,2}, *C. Mignot*², *S. Lyonnet*¹, *A. Munnich*¹. 1) Departement de Genetique, Hopital Necker, Paris, France; 2) Centre de Pediatrie, Aix-en-Provence, France.

Neurofibromatosis Type-1 (NF1) is a common genetic disorder associated with a variety of medical complications, cognitive impairments, and behavioral problems.

One hundred and sixteen patients with NF1 (62 males, 54 females; mean age 11.3 years, SD 2.3) were studied in terms of learning impairment (one or more grade repetitions or school exclusions).

Seventy of 132 patients had significant learning impairment which was more frequent in male than in female patients (46 vs 24, $P=0.01$) and in sporadic than in inherited forms (47 vs 23, $P=0.01$) of the disease. In male patients with the sporadic form of NF1 the incidence of learning impairment was 83%.

The incidence of learning impairment was clearly dependent upon the mode of inheritance of NF1 and the sex of the patient. These both parameters may be taken into account in order to discriminate young children with NF1 at risk for learning problems.

A novel SOX2 mutation associated with bilateral anophthalmia. *L. de Sanctis¹, U. de Sanctis², L. Tornetta³, L. Razzano², F. Cresi¹, K. Williamson⁴, D.R. Fitzpatrick⁴*. 1) Dept. of Pediatrics, Torino, Italy; 2) Dept. of Clinical Physiopathology, Ophthalmic Clinic, Univ. of Torino, Italy; 3) Dept. of Infant Neuropsychiatry, Regina Margherita Children Hospital, Torino, Italy; 4) MRC Human Genetics Unit, Edinburgh EH4 2XU, UK.

SOX2 is a transcription factor with site- and stage-specific expression in the developing eye and nervous system. Four SOX2 mutations have been described in subjects with bilateral anophthalmia and anophthalmia/microphthalmia, the rarest and most severe structural eye defect. SOX2 mutations account for 10-15% of these disorders and other genetic and environmental factors have been implicated. EYY was born at 41 weeks of gestation from unrelated healthy parents after an uneventful pregnancy, weighing 3260g and with a head circumference of 34 cm. At birth he was found to have bilateral anophthalmia with small palpebral fissures, confirmed at 3 months by MRI scan, which also showed rudimentary optic nerves and hippocampal and parahippocampal malformation. No significant craniofacial dysmorphism were present, apart from a prominent antehelix bilaterally. At 16 months of age he had hyperextensible joints with axial hypotonia. His cognitive development was apparently normal. He has had one grand mal seizure associated with fever, but normal EEG. SOX2 mutation analysis, performed on genomic DNA, as previously described (Fantes et al.2003), identified a frameshift mutation c.628delA in the activation domain of SOX2. Direct sequencing both parental samples showed that this was a de novo mutation. We report the first point deletion in SOX2 gene associated with bilateral anophthalmia, thus confirming the essential role of this transcription factor in eye development. Clinical detailed study in the other SOX2 mutated subjects could clarify whether the here described craniofacial dysmorphisms, neuropsychomotor impairment and brain MRI malformations are specific.

An heterozygous mutation of the lamin A/C gene leading to a complex phenotype : acro-osteolysis, atrial fibrillation, hypertriglyceridaemia and autoimmune thyroiditis. V. Drouin¹, J. Senant², L. Maréchal^{1, 2}, P. Richard³, R. Ben Yaou³, T. Frebourg^{1,2}, G. Bonne³. 1) Department of Medical Genetics, Rouen University Hospital, 76031 Rouen, France; 2) Department of Neurology, Rouen University Hospital, 76031 Rouen, France; 3) Inserm U523, Institut de Myologie, Groupe Hospitalier Salpêtrière, Paris, France.

The *LMNA* gene encodes A and C lamins which are intermediate filament proteins of the nuclear lamina. *LMNA* mutations have been shown to be responsible for distinct autosomal dominant or recessive pathologic conditions primarily affecting striated muscle, adipocytes, or peripheral nerves or causing premature aging. Complex phenotypes have recently been described. We report in a family a new complex phenotype with dominant transmission resulting from an heterozygous *LMNA* mutation. The proband is a 50 year old women. At 35 years she developed atrial fibrillation and, at 45 years, a Hashimoto thyroiditis and hypertriglyceridaemia. Clinical examination revealed acro-osteolysis of the upper limbs, proximal muscular weakness, slight excess of subcutaneous fat in the neck and truncal region, curly hairs but her teeth and skin were normal. Radiological examination of clavicles was normal. She has two sons : one of them presented clinical isolated muscular weakness and the older one has a normal clinical examination. The proband's brother has distal acro-osteolysis, atrial fibrillation and hypertriglyceridaemia and the proband's mother, deceased, had distal acro-osteolysis, atrial fibrillation and conduction defect. Molecular analysis of the *LMNA* gene revealed an heterozygous mutation (R335W) in the proband and her two sons. Acro-osteolysis is one of the skeletal abnormalities described in mandibulo-acral dysplasia, an autosomal recessive disorder caused by homozygous mutations of the *LMNA* gene, associated in some cases with partial lipodystrophy. This feature has not been described so far in patients with *LMNA* heterozygous mutations. This case emphasizes the importance of complete clinical and biological evaluation in patients with laminopathy.

Hypercalciuria and nephrocalcinosis in infants with Osteogenesis Imperfecta. *E.R. Elias¹, P. Zeitler²*. 1) Dept Genetics & Pediatrics, Children's Hosp, Denver, CO; 2) Department of Endocrinology Children's Hosp, Denver, CO.

Excessive urinary calcium excretion and nephrocalcinosis have been reported in patients with OI. However, little is known about how the bisphosphonate pamidronate, now widely used to treat OI patients, may effect urinary calcium excretion in this patient population. We examined nephrocalcinosis and urinary calcium excretion in a population of infants with OI treated with pamidronate.

Methods: Nine young children with OI were studied between 1/01 and 6/04. The patients included 2 females with very severe OI (biochemically Type II/III), 5 female patients with severe phenotype (biochemically Type III or III/IV), and 2 patients (one female, one male) with mild phenotype (Type I). The patients received IV pamidronate every 2 months, starting at age 2 months, at a dose of 0.5 mg/kg/d for three days. A random urinary Ca/Cr ratio was determined. Renal ultrasounds were obtained at baseline and every 6 months. Serum calcium and renal function were also assessed.

Results: All patients with severe or very severe phenotype developed hypercalciuria by 6 months of age, defined as Ca/Cr 0.2. The Ca/Cr ranged from 0.75-1.44 by one year of age. After one year, with continued pamidronate therapy, the Ca/Cr ratio fell in all patients, and reached normal range in three patients by age 2 years. Both patients with Type II/III OI developed nephrocalcinosis by age 1 year, as did one phenotypically severe patient with Type III OI. The nephrocalcinosis resolved by age 2 years in two patients, and improved in the third. The two patients with mild OI had normal Ca/Cr and normal renal ultrasounds. All patients maintained normal serum calcium and renal function.

Conclusions: Hypercalciuria was present in all seven patients with severe OI phenotypes and nephrocalcinosis developed in three of these patients. The elevated calcium excretion and renal calcium improved over time with pamidronate use. Further study is warranted to determine if these findings can be replicated in a larger number of patients, and if this apparent effect of pamidronate is dose or age dependent.

Two brothers with findings resembling Pseudo-TORCH syndrome: Further widening of the phenotype. C.

Gardiner¹, L.H. Keane², C.S. Smith³, G.K. Brown⁴, T.J. Vulliamy⁵, P. Lebon⁶, C.J. Padfield⁷. 1) Clinical Genetics Service, Nottingham City Hosp, Nottingham United Kingdom; 2) Department of Obstetrics and Gynaecology, Nottingham City Hospital, Nottingham; 3) Department of Paediatrics, Nottingham City Hospital, Nottingham,; 4) Department of Biochemistry, University of Oxford, Oxford; 5) Department of Haematology, Hammersmith Hospital, London; 6) Service de Virologie, Hopital Saint Vincent de Paul, Paris; 7) Department of Pathology, Queens Medical Centre. Nottingham.

Intracranial calcification and microcephaly are frequently associated conditions with a heterogeneous pathogenesis. Two brothers of non-consanguineous parents are reported who presented with microcephaly at 20 weeks gestation. Post-delivery both brothers developed hyperbilirubinemia, disseminated intravascular coagulation, renal failure and died in the neonatal period. At post mortem there was periventricular calcification. Skeletal survey and microscopy of the psoas muscle was normal. Congenital infection screen, chromosome analysis and interferon-alpha levels in the CSF were normal. Blood lactate was raised but there was no evidence of systemic cytochrome oxidase deficiency on testing. Prenatal presentation of microcephaly with hyperbilirubinemia and thrombocytopenia and normal CSF interferon-alpha, may make Aicardi- Goutieres (AGS) less likely. Hoyeraal-Hreidarsson syndrome is associated with thrombocytopenia and microcephaly. Mutations in the DKC1 gene have been identified in this condition. Mutation analysis was performed in the second brother, but was negative. The brothers would fulfil the diagnostic criteria for pseudo-TORCH syndrome, but only two previously described families have had children who died either shortly after birth or in utero. Only approximately half of the AGS families show linkage to chromosome 3 and the recent description of three AGS-like patients with normal interferon-alpha and high CSF neopterin and biopterin suggests genetic and phenotypic heterogeneity. AGS and pseudo-TORCH may be allelic and identification of genes associated with these conditions will allow the elucidation of the underlying molecular and biochemical mechanisms in these diseases.

Neurofibromatosis 1 or isolated Lisch nodules? Case report. *M. Geller*^{1, 3}, *K.S. Higino*^{1, 3}, *S. Kac*², *G. Carakushansky*^{1, 3}, *M.G. Ribeiro*³. 1) Teresopolis Medical School, Rio de Janeiro, Brazil; 2) Hospital dos Servidores do Estado do Rio de Janeiro, Brazil; 3) Federal University of Rio de Janeiro, Brazil.

Introduction: Neurofibromatosis 1 (NF1) is an autosomal dominant condition caused by mutations on the NF1 (17q11.2) gene, presenting complete penetrance and a wide variety of manifestations. Diagnosis is based on two or more NIH criteria: six or more café-au-lait spots; two or more neurofibromas of any kind or plexiform neurofibroma; axillary or inguinal freckling; optic glioma; two or more Lisch nodules; distinct bone lesion (long bone pseudoarthrosis or sphenoid wing dysplasia); first degree relation with NF.

Lisch nodules represent the most frequent ophthalmologic alteration in NF1 patients. In the presence of other NF1 diagnostic criteria or a positive family history, their presence confirms NF1 diagnosis. In the absence of other signs, their presence is highly suggestive of NF1. Lisch nodules are extremely rare in the general population, and as such they are practically a pathognomonic sign of NF1.

Case Report: RSG, female, age 14 years 9 months, first pregnancy of young, non-consanguineous parents, no family history of NF1. Was referred to the CNNFUF RJ due to three café-au-lait spots larger than 15mm, two smaller than 05mm, numerous bilateral Lisch nodules, marfanoid phenotype, ocular hypertelorism, psychomotor agitation alternated with periods of tranquility, and learning disability. Born with congenital crooked foot, surgically corrected at 9 months. Presented neuropsychomotor development delays (walked at 14 months, talked at 18 months), menarche at 12 years, convulsive febrile crises in early childhood. Currently in high school, presents karyotype 46, XX and negative innate metabolism errors.

Conclusion: Strong suspicion of NF1, although not meeting the NIH criteria. We highlight that this may be an atypical or late onset case of NF1, in which many of the classic manifestations of NF1 are not present until the end of the third decade of life; requires clinical follow-up.

Parry Romberg Syndrome. Two report cases in different mexican families. *C.N. Gil^{1,4}, J.M.R. Aparicio^{2,4}, W.B. San Martin³, N.C. Hernandez¹, E.M. Huitzil⁴, F.C. Salinas⁵*. 1) Estomatology; 2) Genetics; 3) Maxilar Surgery, Hospital Para el Nino Poblano Puebla, Mexico; 4) Estomatology Benemerita Universidad Autonoma de Puebla; 5) Oral Genetics Medical University, South Carolina, USA.

Introduction. Parry-Romberg Syndrome is a rare disorder characterized by slowly progressive degeneration or atrophy of the soft tissues of half of the face with changes of the eyes and hair; and neurological abnormalities including episodes of seizures and severe pain in tissues supplied by the fifth cranial nerve including the mouth, cheek, nose, and/or other facial tissues (trigeminal neuralgia). In individuals with the disorder, initial facial changes usually the tissues above the upper maxilla and progress to involve the angle of the mouth, the areas around the eye, the brow and the ear. In addition, the skin overlying affected areas may become hyperpigmented or with vitiligo. Many individuals also experience atrophy of half of the upper lip and tongue as well as abnormal exposure. Clinical cases. Two male patients were evaluated at the department of genetics, a 9 and 16 years old males with the clinical manifestations mentioned above. Apparently, there is not medical background in their families and both are de novo genetic affected. In most cases, appears to occur randomly for unknown reasons (sporadically). However, several familial cases have been reported, which suggest that the disorder may be inherited as an autosomal dominant trait. In some cases, prior trauma in the affected area may play some role in predisposing certain individuals to the disorder. moreover, Parry-Romberg Syndrome appears to affect more females than males. There is no cure and there are no treatments that can stop the progression of Parry-Romberg syndrome. Reconstructive or microvascular surgery may be needed to repair wasted tissue. The timing of surgical intervention is generally agreed to be the best following exhaustion of the disease course and completion of facial growth. Most surgeons will recommend a waiting period of one or two years before proceeding with reconstruction. Muscle or bone grafts may also be helpful. Other treatment is symptomatic and supportive.

Clinical characterization of esophageal atresia with/without tracheoesophageal fistula in newborn infants. H.

Kawame¹, K. Shimizu², T. Nakamura², Y. Momose³, S. Ishizone³, Y. Fukushima⁴. 1) Medical Genetics; 2) Neonatology; 3) Surgery, Nagano Children's Hospital, Nagano; 4) Div Clin & Molecular Genetics, Shinshu Univ of Schl of Med, Nagano, Japan.

Esophageal atresia with/without tracheoesophageal fistula (EA/TEF) is a life-threatening malformation that occurs in 1/3,000 newborns. This condition occurs as an isolated anomaly, or occurs frequently, with other malformations and as a part of recognized syndromes. The molecular and genetic pathogenesis of EA/TEF remains unknown. In clinical setting, infants with EA/TEF are still associated with significant morbidity and mortality. In order to describe the clinical picture of newborn infants with EA/TEF, we reviewed the findings of 37 patients with EA/TEF that were treated at Nagano Children's Hospital (NCH) over a 10-year period. Polyhydramnios recognized in 68% of cases. The mean birth weight was 2227 g (range, 1017-3360 g). Gross Type C was most common (76%). Eleven newborns (30%) were isolated cases; 26 (70%) had associated malformations. Among 26 infants with associated anomalies, 14 were diagnosed: Trisomy 18 (8), VACTERL association (3), other chromosomal abnormalities (2), and hemifacial microsomia (1). Cardiac (67%), tracheo-broncho-pulmonary (33%), skeletal (33%), and gastrointestinal anomalies (17%) were identified in undiagnosed patients with associated anomalies. Besides of Type H patients, gastrostomy was performed in all patients and 30 patients had subsequently end-to-end primary repair. All isolated cases survived, but survival rate was 46% in patients with associated anomalies. Among those, Trisomy 18 accounted for 70%. Late complications were found in 80% of survival patients. Those included postoperative leakage, stenosis, gastroesophageal reflux, and feeding difficulties. Family history was negative in all cases. The prognosis and mortality largely depend on presence of other associated anomalies and systemic syndrome. A precise diagnosis is crucial for the prognostic information and management. Dysmorphological evaluation by clinical geneticists for other associated malformations including VACTERLs features together with appropriate chromosomal analysis is essential.

Exclusion of Fras1 gene mutation in patients with MOTA Syndrome and report of 8 new cases in Manitoba aboriginal and a Dutch Patient. C. Li^{1,4}, A. Slavotinek², J. van de Kamp³, S. Marles¹, C. Greenberg¹, B. Chodirker¹, A. Chudley¹. 1) Sect Genetics & Metabolism, Univ Manitoba, Winnipeg, MB, Canada; 2) Div Clinical Genetics, Univ California, San Francisco; 3) Dept Clinical Genetics, Leiden University, The Netherlands; 4) Genetics Program, University Health Network, Univ Toronto.

The Manitoba Oculotrichoanal (MOTA) Syndrome is characterized by the presence of an aberrant anterior wedge-shaped hairline, unilateral upper eyelid coloboma or cryptophthalmos, hyper-telorism, broad or notched nasal tip and anal anomalies. The condition is particularly prevalent in the Aboriginal of Island Lake region of Northern Manitoba. Since the first report of 6 children [Marles et al., 1992], 7 more patients of Cree/Ojibway background have been identified. Ocular, anal and hair anomalies are not always observed. Omphalocele, a feature previously not identified, is present in 3 of them. Furthermore, two of the patients have bilateral, instead of unilateral, abnormal anterior hairline and eye anomalies. Development is essentially normal in these patients. A Dutch girl was recently identified as probably having this condition. She has bilateral coloboma of the upper eyelids, absent upper fornix of the left eye, broad nasal tip with palpable groove. All patients examined to date have normal karyotypes. The fact that these patients have hypertelorism, grooved nasal tips, anal anomalies and omphalocele suggests a midline developmental defect. There is some clinical overlap, but major differences to Fraser syndrome, an autosomal recessive condition with classical features of cryptophthalmos, syndactyly, ambiguous genitalia, laryngeal and genito-urinary malformations, and mental retardation. Mutations in FRAS1 gene have been demonstrated to cause Fraser syndrome. We screened two patients with MOTA syndrome for mutations in the FRAS1 gene by sequencing and no mutations were identified. Recently, a large Turkish kindred with individuals having features consistent with MOTA syndrome were identified. Linkage analysis using this family excluded the involvement of FRAS1 gene in these patients. (personal comm, A. Tukun, Ankara Univ, Turkey).

The Role of a Genetics Evaluation in the Patient with Craniosynostosis. *M.J. Lyons, K.M. Chen, A. Kwan, L. Hudgins.* Pediatrics/Medical Genetics, Stanford University, Stanford, CA.

Craniosynostosis is common with an incidence of 1 in 2000 births. The cause is unknown in the majority of cases with approximately 10-20% attributed to genetic syndromes. The purpose of our study is to determine the utility of a genetics evaluation for patients referred with a diagnosis of craniosynostosis. Patients referred over a 7 year span who had possible craniosynostosis were assessed. The results for 62 patients were included. A total of 23 individuals were referred with a presumptive diagnosis of a craniosynostosis syndrome. A genetics evaluation led to a change in the diagnosis in 43% of these patients, including 50% of cases referred with a diagnosis of Crouzon syndrome (n=10), Pfeiffer syndrome (n=4), and Saethre-Chotzen syndrome (n=2). Even in Apert syndrome, the diagnosis was changed based on a genetics evaluation in 2 of 7 patients. Overall, a genetics evaluation led to a definitive diagnosis for 33 (53.2%) patient referrals. The most common clinical diagnosis was Crouzon syndrome with confirmatory testing in 6 of 8 cases. A clinical diagnosis of Apert syndrome was made for 6 patients with confirmatory testing in 2 of 2 tests performed. Pfeiffer syndrome was clinically diagnosed in 3 cases with confirmatory testing in 1 of 2 tests performed. A clinical diagnosis of Saethre-Chotzen syndrome was made for 3 patients with confirmatory testing in 2 of 3 tests performed. Jackson-Weiss syndrome was suspected in 2 cases. The diagnosis was changed to Pfeiffer syndrome in one case after testing. A chromosomal abnormality was detected in 3 cases. The 8 remaining diagnoses included craniofrontonasal dysplasia (n=3), Antley-Bixler syndrome (n=2), craniodiaphyseal dysplasia (n=1), hemifacial microsomia (n=1), and Costello syndrome (n=1). Our study demonstrates a relatively high yield for a genetics evaluation with a genetic diagnosis made in over half of the referrals. The genetics evaluation allowed for the selection of appropriate diagnostic testing, leading to a more accurate diagnosis with the best use of available resources. An accurate diagnosis is critical for accurate recurrence risk counseling and prenatal diagnosis.

Cartilage-Hair Hypoplasia in the Geauga County Amish settlement of Ohio. *L. Nye¹, E. Puffenberger², M. Johnson³, A. Zinn³, H. Morton², H. Wang¹.* 1) Das Deutsch Center (DDC) Clinic for Special Needs Children, Middlefield, OH; 2) The Clinic for Special Children, Strasburg, PA; 3) Center for Human Genetics, and Departments of Genetics and Pediatrics, University Hospitals of Cleveland and Case Western Reserve University, Cleveland, OH.

Cartilage-hair hypoplasia (CHH) is an autosomal recessive form of short-limbed dwarfism caused by errors in the RMRP gene. It was first recognized as a distinct entity in the Old Order Amish, and later reported in non-Amish groups as well. However, it has not previously been found in the Geauga County Amish settlement of Ohio, the fourth largest Amish community in North America. Here we report the first case of CHH in this community and describe his unusual presentation, as well as a first report of suspected Leri-Weill dyschondrosteosis (LWD) in his maternal line. The proband was the product of a marital union between fourth cousins. Genealogic analysis showed that both maternal and paternal ancestors mostly originated from Holmes County, Ohio. The proband was a full term male with birth weight of 2840 gm and length of 39 cm. He presented with bilious emesis. Hirschsprung disease was later confirmed via laparotomy. With classical signs of CHH including skeletal features, sparse and light-colored hair, and lymphopenia, along with his ethnic origin, diagnosis of CHH was easily made. Mutational analysis of the RMRP gene established that he was homozygous for the 70AG mutation, common in the Amish. However, this family's pedigree was further complicated by maternal short stature associated with the Madelung deformity and cleft lip, and cleft lip in two of the proband's three siblings. Mutational analysis showed that the mother was heterozygous for the 70AG mutation. Her radiographic findings are suggestive of a different skeletal dysplasia, Leri-Weill dyschondrosteosis (LWD). We think it most likely that she has LWD plus an unrelated cleft lip rather than an atypical form of CHH. To our knowledge, no cases of LWD have been described in the Old Order Amish community. Further studies, including evaluation of maternal relatives and mutational analysis of the SHOX gene, which is associated with LWD, are being considered.

Novel mutations of PTPN11 in Korean patients with Noonan syndrome. *J.Y. Park¹, S.S. Kim¹, G. Kim¹, S. Park¹, J.H. Choi², I.S. Park^{1,2}, H.W. Yoo^{1,2}, Y. Kim^{1,2,3}.* 1) Genome Research Center for Birth Defects and Genetic Disease; 2) Department of Pediatrics, Asan Medical center; 3) Asan Institute for Life Sciences, University of Ulsan College of Medicine, Seoul, Korea.

Noonan syndrome (NS; OMIM 163950) is an autosomal dominant developmental disorder with incidence of 1 in 1,0002,500 live births. Clinical characteristics of NS are proportionate short stature, facial dysmorphism, skeletal anomalies, and cardiac defects. Multiple minor anomalies such as hypertelorism, downward slanting palpebral fissures, malrotated ears, webbed neck, low posterior hairline and cubitus valgus are also presented with NS. The protein-tyrosine phosphatase nonreceptor-type 11 gene (PTPN11) was as the gene mutated in this patients with NS. PTPN11 is a cytoplasmic protein with two tandemly repeated Src homology 2 (SH2) domains in the amino-terminus and a protein-tyrosine phosphatase (PTP) domain in the carboxyl-terminus. The SH2 domains are known to function as mediators for the interaction of the PTP domain with phospho-tyrosine substrates. PTPN11 is widely expressed in the most tissues and functions as a signaling molecule in regulation of variety of cellular processes such as mitogenic activation, metabolic control, transcription regulation, and cell migration. Using PCR-direct sequencing of the exonic regions of PTPN11, we identified eight heterozygous missense mutations of PTPN11 in 24 Korea NS patients, including two novel mutations, T59A and A461T, and six reported mutation, Y62D, Q79R, E139D, F285S, Y279C, and N308D. To further confirm the association of T59A and A461T mutations with NS, we tested 100 alleles of non-patients for the presence of T59A and A461T, and consequently verified that T59A and A461T are present only in the NS patients. These mutations were found in the SH2 domain or the PTP domain. These results further support that haploinsufficiency of PTPN11 is responsible for the phenotypic features of NS across different ethnics.

Congenital diaphragmatic hernia: clues to genetic causes. *B. Pober^{1,2}, A.E. Lin^{1,3}, B. Strauss¹, M. Mullen², S. Chakravorty², MN. Westgate³, J. Wilson², P.K. Donahoe¹, L.B. Holmes^{1,3}.* 1) MassGeneral Hospital for Children, Boston, MA; 2) Dept Surgery, Children's Hospital, Boston, MA; 3) Brigham and Women's Hospital, Boston, MA.

Congenital diaphragmatic hernia (CDH) is a common, often lethal birth defect. Improved treatment will likely stem from understanding the genetic causes of CDH. We analyzed all CDH cases ascertained by a single surveillance system to identify clues to genetic causation. **Methods:** Cases consisted of all infants >20 weeks gestation who delivered over a 30 year period at Brigham & Women's Hospital. Records were reviewed for classifying CDH type (Bochdalek vs. non-Bochdalek), presence or absence of associated anomalies (focusing on associated cardiovascular malformations, CVMs), and apparent etiology of CDH. Family history was also reviewed. **Results:** We identified 223 cases with CDH. Since many cases are referred to our hospital, we calculated a nonreferred CDH birth prevalence of ~2.2/10000. Among all 223 babies with CDH, 90% had a Bochdalek hernia. Half had CDH associated with other birth defects, syndromes or chromosome abnormalities, while the other half had isolated CDH. In most cases we could not identify an etiology for the CDH. Detailed analysis of CVMs showed no significant increase in any type but we classified 4/5 conotruncal defects as double outlet right ventricle. Preliminary analysis of precurrence risk showed it to be low; among 163 nonsyndromic Bochdalek hernia cases only 1/145 prior siblings had CDH. We found 9 twin pairs discordant for CDH but only one was a nonreferred case. On initial examination, we found no evidence of advanced paternal age among fathers of CDH cases. **Discussion:** These findings do not identify a specific genetic etiology for CDH. However, our low frequency of familial clustering, similar to the work of Czeizel (*AJMG*;21:1985), as well as the presence of discordantly affected twin pairs, many of whom are MZ, suggest multifactorial inheritance or de novo dominant mutations. If CVM analyses on larger cohorts confirm homogeneity among, or show an excess of, conotruncal defects then genes important for conotruncal formation might be involved in diaphragm development.

Malignant hyperthermia and genetic disorders in Brazilian families. A. Santa Rosa¹, R. Sudo², J. Cabral de Almeida³, J. Llerena³. 1) Serviço de Pediatria, Hosp. Geral de Bonsucesso, Ministério da Saúde, Rio de Janeiro, Brasil; 2) Centro de Hipertermia Maligna, Depto. Farmacologia, Universidade Federal do Rio de Janeiro; 3) Centro de Genética Médica, IFF, FIOCRUZ, Rio de Janeiro.

Malignant hyperthermia (MH) is an autosomal dominant condition affecting skeletal muscle in susceptible patients undergoing general anesthesia. Triggered by commonly used halogenate inhalatory anesthetic agents and succinylcholine, MH remains one of the major causes of anesthetic death, despite the availability of presymptomatic testing and specific pharmacologic treatment. MH susceptibility is genetically heterogeneous. The ryanodine receptor (RYR) gene, mapped on 19q13.1-13.2 (Maclennan, 1990, McCarthy, 1990) represents an important candidate gene but only about 50% of the families shows linkage to this region.

Since 1993, the Malignant Hyperthermia Center has received 121 patients from the whole country to perform the *in vitro* caffeine/halothane contracture test, the only reliable method of predicting MH susceptibility (Larach, 1989). 32 of them (26,44%) were referred due to personal history of MH crisis, 78 (64,46%) because of positive familial history, and 11 (9,4%) for having clinical/genetic conditions associated to a greater risk of developing MH, including a case of central core disease. The 66 positive patients (54,54%) were arranged in 25 families. After thorough clinical examination including complete pedigrees, the authors have found 2 families with King-Denborough syndrome, one with Noonan-like phenotype, a probable myotonic dystrophy patient, mother of two affected siblings, and a patient with Kabuki make-up syndrome, a previously undescribed association.

Knowledge of MH susceptibility status before undergoing surgery is of utmost importance. That is why we consider that clinical geneticists working together with pharmacologists can surely be of great help in diagnosing previously unnoticed genetic conditions in families with known pharmacogenetic diseases like MH, reporting new associations, and selecting within those families the best subjects for further mutation studies on the RYR1 gene and others involved on the MH phenotype.

Pacman dysplasia is a prenatal form of mucopolipidosis type II (I-cell disease). *R. Saul¹, V. Proud², H. Taylor¹, J. Leroy¹, J. Spranger¹.* 1) Greenwood Genetic Ctr, Greenwood, SC; 2) Children's Hospital of the King's Daughters, Norfolk, VA.

Mucopolipidosis type II (ML-II) or I-cell disease is a lysosomal enzyme transport disorder in cells of mesenchymal origin. Patients with ML-II have an unremitting course, usually leading to death before ten years of age. Pacman dysplasia has been previously reported to be a lethal skeletal dysplasia with epiphyseal stippling and osteoclastic overactivity. All 4 cases of Pacman dysplasia have been recognized prior to 30 weeks gestation. We report a sibling of a fetus with Pacman dysplasia. The affected patient at 7 months of age had dysmorphic craniofacial features (prominent forehead, midface hypoplasia, depressed nasal bridge, upturned nares and slightly posteriorly rotated ears), clear corneae and scoliosis. Radiographs were consistent with dysostosis multiplex. Plasma lysosomal enzyme activities were grossly elevated for arylsulfatase-A, beta-galactosidase, and beta-glucuronidase. Fibroblast lysosomal enzyme activities were markedly reduced for alpha-mannosidase, beta-mannosidase, beta-galactosidase, and beta-glucuronidase. Lysosomal enzymes in leucocytes were normal. Intracytoplasmic inclusions were present in fibroblasts. The diagnosis of mucopolipidosis type II (I-cell disease) was firmly established. Her previous male fetus sibling had been electively terminated at 24 weeks gestation for a suspected lethal short-limbed dwarfism. Radiographs confirmed widespread stippling, femoral periosteal cloaking and osteopenia. This sibling was reported by Miller et al. (2003) as the fourth case of Pacman dysplasia. We suggest that this fetus has prenatal expression of ML-II. This wide spectrum of expression is consistent with other lysosomal storage disorders, many of which are known to cause abnormalities ranging from severe prenatal expression (lethal non-immune hydrops fetalis) to a more typical postnatal course. This prenatal form appears to expand the phenotypic spectrum of ML-II and suggests that Pacman dysplasia is not a separate entity.

A case of trisomy 13 with unusual longevity and autoimmune dysfunction. *R.E. Schnur, S. Ennis, S.N. Moore, J. Keenan.* Pediatrics/Genetics Division, Cooper University Hospital, Camden, NJ.

Long term survival beyond infancy is quite rare in trisomy 13 and there is limited data on the natural history of this disorder in long-term survivors. We describe a case of non-mosaic trisomy 13 in a 24 year-old African-American female, one of only 3 reported adult patients with this disorder. She had typical features, including unilateral cleft lip and palate, rocker bottom feet and minor cardiac defects, but no life-threatening anomalies. Menarche occurred at 13 years of age. She has had regular periods with premenstrual behavior changes, but her periods are now becoming shorter and lighter. Developmentally, she is extremely delayed. She drinks from a cup and she hand scoops her food, but is unable to use utensils. She is largely non-verbal, but says mama non-specifically and uses other sounds that seem specific to her situation. She is partially able to walk with support. She has favorite toys and responds positively to her caregivers. She has a well-controlled seizure disorder with demyelination on MRI scan. Cytogenetic analysis of two separate peripheral lymphocyte specimens (ages 3 and 17) showed a 47, XX, +13 karyotype in 20 metaphases for each screen. At age 20, she developed increased fatigue and was diagnosed and treated for hypothyroidism. Raynaud's phenomenon was noted at age 21. She has recently had difficulty maintaining her weight. She also has had numerous infections of the skin and oral mucosa, particularly with *Candida*. She now has anti-Sjögren, anti-double stranded DNA, anti-cardiolipin, and anti-Smith antibodies, and a low C4 component of complement, consistent with systemic or subacute lupus. She has also had proteinuria. Patients with trisomy 13, as with other aneuploid disorders (e.g., trisomy 21, 45,X, and 47,XXY), may be at risk for the development of autoimmune diseases.

18q Deletion Syndrome: Mimicking Non-Classical Congenital Adrenal Hyperplasia. *C.D. Trevors, D. Chitayat, M. Nezarati.* Clinical & Metabolic Genetics, The Hospital For Sick Children, Toronto, Ontario, Canada.

18q deletion syndrome consists of facial dysmorphism, mental deficiency, short stature and hypoplasia of the external genitalia in both sexes. This is a relatively rare condition with approximately 100 cases previously reported. The clinical manifestations vary according to the extent of the deletion. The condition was reported to be associated with 17,20-lyase deficiency, which results in elevated 17(OH) progesterone. A false diagnosis of non-classical congenital adrenal hyperplasia thus has been repeatedly made and treatment with corticosteroid initiated. We report a male patient, born to a 34 year-old primigravida woman of French Canadian descent and a 39 year-old father of Italian descent. The couple is healthy, non-consanguineous and their karyotypes were normal. The patient presented with a micropenis and elevated 17-hydroxyprogesterone. He was thus diagnosed as having non-classical congenital adrenal hyperplasia and was placed on cortef. No decrease in cortisol levels was noted and there were no signs of virilization or premature sexual development observed. The results of the molecular testing for congenital adrenal hyperplasia are pending. Seven cases of isolated 17,20-lyase deficiency have, however, been reported previously in children with 18q Deletion Syndrome. They had elevated 17-hydroxyprogesterone and decreased androgen levels. An isolated 17, 20-lyase deficiency should not result in a decrease in cortisol levels. There have been very few cases reported of isolated 17, 20-lyase deficiency. The validity of its existence has been questioned due to the fact that cytochrome P450c17 catalyzes both 17-hydroxylase and 17, 20-lyase activities. Mutations in the genes encoding both cytochrome P450c17 (CYP17) and 21-hydroxylase (CYP21A2) are known causes of non-classical congenital adrenal hyperplasia. Although rare, based on previous reports, the possibility of an isolated 17, 20-lyase deficiency should be explored in all individuals with 18q Deletion Syndrome prior to treatment with corticosteroids.

Adults with VATER association: long term prognosis. *P.G. Wheeler¹, D.D. Weaver²*. 1) Div. of Genetics, Nemours Children's Clinic, Orlando, FL; 2) Dept. of Medical and Molecular Genetics, IU School of Medicine, Indianapolis, IN.

VATER association is an extensively used diagnosis typically based on a constellation of congenital anomalies. Since reported long-term follow-up information on VATER association is limited, it is difficult to prognosticate the future of infants with this condition. There are some data on growth failure and mental retardation but these data are minimal [Bull et al., 1985; Mapstone et al., 1986; Weaver et al., 1986]. Since first described, the findings associated with VATER association have been expanded greatly, and now overlap syndromes such as Feingold syndrome [Feingold et al., 1997], Fanconi anemia [Perel et al., 1997], and the 22q11.2 deletion [McDonald-McGinn DM, et al., 1999]. We have undertaken a long-term follow-up of individuals reported originally by Weaver et al in 1986 or diagnosed with VATER association by his associates and him after 1986. Out of 50 potential interviewees, we were able to contact 19 individuals or families. Two of the 19 individuals had died from their birth defects: one at 3 d/o with cardiac failure due to a truncus arteriosus and one at 4 y/o, cause unknown. One was unwilling to participate. Of the rest, we interviewed and examined 7 persons, and interviewed another 9 over the phone. Of the 16, 5 had had some degree of cognitive impairment. These individuals were more likely to have congenital anomalies outside of the typical scope of VATER association, such as prune belly syndrome or features of CHARGE association. Of nine individuals with a history of imperforate anus; 5 had partial or complete incontinence as adults, which has led to difficulties in maintaining employment. Height was 5th%ile or less in 6 of 16 patients. Three of 4 patients who were trying to have children had difficulties with infertility. In 2 of the women, the infertility was thought to be related to a history of congenital anomalies of the GU system and multiple pelvic surgeries. We will further review the long-term medical and neurologic problems in these individuals, discuss the differential diagnoses associated with VATER association, and recommend a protocol for evaluating individuals suspected of having VATER association.

Non-mosaic isochromosome Yp in a male with hypogonadism and mild cognitive disability. *P.L. Wilson, S.E. Palmer, P.R. Blackett, J.Y. Lee, H. Overcash, S. Li.* University of Oklahoma HSC, Department of Pediatrics, Sections of Genetics and Endocrinology, Oklahoma City, OK.

Isochromosome Yp and Yq have been reported in a small number of patients with female, ambiguous, or abnormal male phenotypes, almost all mosaic for 45,X. We report a rare case of non-mosaic isochromosome Yp in a 16-year-old male with delayed puberty. Physical examination revealed a male phenotype with hypogonadism (small penis, mild gynecomastia, and eunuchoid appearance). The remainder of the phenotype was unremarkable with normal stature. Early development was reportedly normal. He had mild cognitive deficits and ADHD with immature behavior. Endocrine evaluation revealed a delayed bone age, normal thyroid studies, low testosterone, and low growth hormone, LH, and FSH unresponsive to GnRH stimulation. Chromosomal analysis revealed 46 chromosomes including one X and a small metacentric marker chromosome, resulting in a karyotype of 46,X,i(Y)(p10). To confirm the findings we performed FISH analysis using an SRY probe mapped to Yp11.3. Signals for the SRY gene were present on both ends of the marker chromosome, confirming isochromosome Yp. The father and three fertile paternal half-brothers were unavailable for evaluation. The young man's full brother had no reported delays in puberty or development; his karyotype was 46,XY. Certain phenotypic features of this case may reveal effects of presence, absence, or dosage of certain Y genes. One other case of i(Yp) was reported in a fetus with slight facial and foot dysmorphism. Those features are absent in this patient, and the endocrine abnormalities cannot be compared. Abnormalities of the Y chromosome in the presence of 45,X mosaicism usually results in a female or an ambiguous phenotype. The absence of mosaicism in this patient may account for his male phenotype. The dosage effect of two copies of SRY, in the absence of 45,X mosaicism, has unclear phenotypic effects. Absence of DAZ and AZF genes on Yq would predict isolated azospermia, with normal or elevated FSH. Therefore, the exact roles of the duplicated Yp and absent Yq genes of this karyotype responsible for this young man's cognitive and endocrine deficiencies are unclear.

Trigonocephaly, Polysyndactyly, Brachydactyly, Cutis Laxa and Developmental Delay: A New Autosomal Recessive Syndrome. *N. Al-Sanna'a*¹, *M. Al-Khunaizi*¹, *A.S. Teebi*². 1) Pediatrics Specialty, Dhahran Health Center, Dhahran, Saudi Arabia; 2) Division of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, ON.

Trigonocephaly with metopic syntosis is genetically heterogeneous. Syndromic and non-syndromic forms exist. Among the syndromic forms, an increasing number of rare autosomal recessive syndromes are being characterized together with a number of rare chromosomal syndromes. Developmental delay is relatively common. Here we report on two brothers born to a phenotypically normal first cousin parents from Saudi Arabia with another unique presumably autosomal recessive trigonocephaly syndrome. Both displayed a characteristic constellation of features that include trigonocephaly with metopic syntosis, narrowing of coronal structures, peculiar facial appearance, redundant skin with features of cutis laxa, variable limb anomalies that include polydactyly, cutaneous syndactyly and brachydactyly and mild developmental delay. Chromosomal analysis in the older brother showed a balanced translocation 46,XY,t(2;6)(12q23) while chromosomes were normal in the other. We believe that the constellation of manifestations represents a previously unrecognized autosomal recessive syndrome.

Congenital Hypertrichosis Lanuginosa. A report case in a Mexican Family. *J.M.R. Aparicio^{1,8}, C.N. Gil^{2,8}, M.P. Barrientos³, W.B. SanMartin⁴, E.R. Balbuena⁵, L.H. Hurtado⁶, M.A. Gutierrez⁶, J.L. Penaloza y Senties⁷, F.C. Salinas⁹.*
1) Genetics; 2) Estomatology; 3) Endocrinology; 4) Maxilofacial Surgery; 5) Dermatology; 6) Citogenetics and Clinical Laboratory; 7) Pediatrics Hosp para el Nino Poblano, Puebla, Mexico; 8) Dept estomatology, Benemerita Universidad Autonoma de Puebla, Mexico; 9) Dept Oral Genetics, Medical University South Carolina, USA.

Introduction. Disorders of hypertrichosis are distinguished by the distribution of hair, as well as by the temporal pattern of growth, the possible associated congenital anomalies, and the possible inheritance pattern. An X-linked syndrome of hypertrichosis associated with gingival hyperplasia has been described. Patients develop excessive body hair, but the abnormal hair is of the terminal type. In 1648, Aldrovandus first documented a family with hypertrichosis. Over the next 300 years, more than 50 reports were described, and 34 patients with congenital hypertrichosis were identified. In 1993, Baumeister et al raised the possibility that 9 of the patients with hypertrichosis had a defining clinical presentation, which he called Ambras syndrome. In 1 of the 9 patients, a specific genetic abnormality was found on chromosome 8, and the remaining 8 patients were proposed to have shared this defect. In 1998, Balducci described a patient with CHL who had a different genetic defect on chromosome 8. Clinical case. A 45 days new born patient with congenital hypertrichosis lanuginosa, was evaluated where, most of the body is covered with fine, blond or unpigmented hair at birth. There was not found abnormalities of other organ systems, although single case reports note abnormalities such as supernumerary teeth, glaucoma, aortic and cardiac valve abnormalities, and macromastia. is 1 case per 10 billion. No racial nor sex predilection exists. The pathogenesis is unknown. However, it has been refered to be inherited in an autosomal dominant manner; most cases involve a familial component. A paracentric inversion on bands 8q12 and 8q22 in one patient was reported by Balducci in 1998. No known hormonal or endocrinologic abnormalities have been identified.

The Hunter-MacDonald syndrome is associated with risk of meningioma. *L. Armstrong¹, G.E. Graham², R.N. Schimke³, D.J. Kirse⁴, F. Costello², H.H. Ardinger⁵.* 1) University of BC, Vancouver, BC, Canada; 2) University of Ottawa, Ottawa, ON, Canada; 3) University of Kansas, Kansas City, KS; 4) Wake Forest University, Winston-Salem, NC; 5) Prairie Village, KS.

The Hunter-MacDonald syndrome (HMS) has been described as an autosomal dominant pattern of congenital malformations. To date, four people in two unrelated families have been diagnosed and two other family members seem to have the condition on record review. Follow-up of these families has shown that predisposition to brain tumor is also a feature of HMS.

In HMS there is short stature, scoliosis, epiphyseal dysplasia, camptodactyly of the fingers, thumb subluxation, and malformed feet. Craniofacial features include normal head circumference, tall forehead, bitemporal narrowing, ptosis, short palpebral fissures, short philtrum, and a columella extending below the alae nasi. Decreased hearing acuity and congenital heart defects are present in most. Intelligence is normal. High resolution chromosome analysis is normal. The father of Proband 1 and the grandmother of Proband 2 died at the ages of 35 and 55 years with brain tumors. Proband 1 was diagnosed with a brain tumor at age 36 years. The asymptomatic 42 year old mother of Proband 2 was found to have a brain tumor on screening MRI. Thus, four of the six known individuals with HMS have had tumors clinically and/or pathologically diagnosed as meningiomas. The remaining two have not been screened.

Individuals with the pattern of congenital malformations of HMS should be screened for meningiomas. The diagnosis should be considered in people who develop a meningioma and have any of the typical skeletal, craniofacial, hearing, or cardiac features. Candidate genes include those associated with the multiple epiphyseal dysplasias, with signaling pathways regulating osteogenesis and tumor suppression, and with familial meningioma.

Connective tissue dysplasia in two new patients with NF1 microdeletions: further expansion of phenotype. D.

Babovic-Vuksanovic¹, K. Mensink¹, B. Heese¹, R.J. Spinner², R.P. Ketterling³, R.A. Knudson³, H.F. Gilmer³, N.M. Lindor¹. 1) Dept Medical Genetics, Mayo College of Medicine, Rochester, MN, USA; 2) Department of Neurosurgery, Mayo College of Medicine, Rochester, MN, USA; 3) Department of Pathology and Laboratory Medicine, Mayo College of Medicine, Rochester, MN, USA.

Abstract Deletions of the entire gene have been found in approximately 5-10% patients with neurofibromatosis type 1 (NF1). The phenotype of these patients usually includes early onset and large number of neurofibromas, presence of congenital anomalies, cognitive deficiency and variable dysmorphic characteristics and growth abnormalities. Previous reports include mitral valve prolapse, joint laxity and soft skin of palms in a few patients, but connective tissue abnormalities are not generally recognized as a part of NF1 microdeletion syndrome. We describe clinical findings in two newly diagnosed patients with NF1 microdeletions (not visible by standard chromosome analysis), with presenting symptomatology of connective tissue abnormalities and typical NF1 features only appearing later. We suspect that connective tissue dysplasia is common in patients with NF1 microdeletions, and screening for associated cardiac manifestation may be warranted. Despite a large number of known patients with NF1 microdeletions, the phenotype is still incompletely defined. By reviewing available literature, we conclude that skeletal anomalies are common in this population of NF1 patients as well. More detailed clinical information and molecular studies in other individuals with large deletions involving NF1 locus may shed a light on possible genotype/phenotype correlation or may lead to identification of new genes responsible for connective tissue disorder in proximity to the NF1 gene.

The Adult Phenotype of 22q11 Deletion Syndrome (22qDS). *A.S. Bassett^{1, 2}, O. Caluseriu^{1, 4}, V. Wong^{1, 2}, M. Gatzoulis³, G. Webb^{2, 3}, R. Weksberg^{2, 4}, E.W.C. Chow^{1, 2}.* 1) Centre for Addiction and Mental Health (CAMH), Toronto, ON, Canada; 2) University of Toronto, Toronto, ON, Canada; 3) Toronto Congenital Cardiac Clinic for Adults, Toronto, ON, Canada; 4) Hospital for Sick Children, Toronto, ON, Canada.

Initial reports of clinical features in microdeletion syndromes such as 22qDS rely on paediatric data. Adults reported are most commonly transmitting parents with milder phenotypes. We systematically assessed the clinical features of 77 adults with 22qDS, ascertained through a cardiac clinic (n=32), psychiatric (n=36), genetic (n=13), or other sources (n=6) including three as transmitting parents. Subjects (36 male; 41 female), mean age 31.5 (SD 9.6) years, had 22q11.2 deletions confirmed with FISH. 59 (77.6%) were diagnosed with 22qDS as adults and variable levels of learning difficulties, dysmorphic facial features and hypernasal speech were found in most subjects. Only 33.5% had a history of palatal surgery (3.9% with overt cleft palate); 7.8% had hypoplastic thymus. Common later onset features included (% , 95% CI): hypocalcemia (55.8%, 44.5-67.2), hypothyroidism (20.8%, 11.5-30.1), thrombocytopenia (27.3%, 17.1-37.5), hearing deficit (27.3%, 17.1-37.5), severe acne (23.4%, 13.7-33), cholelithiasis (18.2%, 9.4-27), asthma (18.2%, 9.4-27), epilepsy (15.6%, 7.3-23.9), renal failure (9.1%, 2.5-15.7), and pilonidal sinus/cyst (6.5%, 0.8-12.1). The most common psychiatric disorder was schizophrenia, present in 22.6% (7-38.2) of subjects ascertained with tetralogy of Fallot. Of 22qDS subjects ascertained with schizophrenia, 33.3% (17.2-49.8) had a major CHD. Three subjects died, aged 18, 25, and 69 years; only one had a CHD. The CHD rate in adults with 22qDS is lower than previously reported when ascertainment bias is taken into account, despite using CHD as a clinical criterion for deletion testing. Understanding the adult phenotype is essential for determining rates of congenital and later onset features. More accurate frequency estimates will be important for genetic counselling and planning long term follow-up of multi-system genetic syndromes.

Three new Cases of duplication 22Q11.2 with neuropsychological problems, learning disability and subtle dysmorphic features. *S. Beiraghi¹, A. DeMarco¹, R. Lutz², K. Conway¹, K. Moller¹.* 1) University of Minnesota, Minneapolis, MN; 2) University of Nebraska Medical Center, Omaha, NE.

Duplication of 22Q11.2 region is a rare condition with a subtle physical phenotype, yet significant speech and neuropsychological findings.

Here we report on three cases with two De novo and one maternally inherited duplication of (22)(q11.2)(q11.2) with hypernasal speech, learning disabilities, Attention Deficit Hyperactivity Disorder (ADHD), visual impairments, and mild craniofacial anomalies.

Case 1 is the product of a second pregnancy to healthy nonconsanguineous parents. At age of 9 years, she was referred for concerns of hypernasal speech. Clinical examination revealed subtle dysmorphic features including hypertelorism, learning disabilities, ADHD, and significant velopharyngeal inadequacy for speech.

Case 2 is a 13 year old white female with maternally inherited dup22q11.2. Clinical examination revealed subtle dysmorphic facies, visual impairment, hypernasal speech, ADHD, and depression.

Case 3 is a 14 year old male with physical findings including hypospadias, inguinal hernia, and urthero diverticulum. His history is significant for ADHD, multiple learning and behavioral problems, hypernasal speech, and suspected schizophrenia.

Based on the subtle phenotype of these cases, 22q11.2 duplications may be rarely identified because of the lack of significant physical findings. However, given the speech disorder and neuropsychological findings associated with this genetic disorder, FISH testing is warranted for identifying these cases..

Laryngotracheal involvement and novel skeletal findings in a patient with probable Rothmund-Thomson

Syndrome: A novel RTS subset? *M.J. Borden¹, L. Armstrong², L.L. Wang³, S.E. Plon³, T. Kovest⁴, A.G.W. Hunter⁴, G.E. Graham⁴.* 1) Human Genetics Department, McGill University, Montreal, QC, Canada; 2) Children's and Women's Hospital of British Columbia and University of British Columbia, Vancouver, BC, Canada; 3) Texas Children's Hospital and Baylor College of Medicine, Houston, TX, USA; 4) Children's Hospital of Eastern Ontario and University of Ottawa, Ottawa, ON, Canada.

Rothmund-Thomson syndrome (RTS) is an autosomal recessive condition characterized by poikiloderma, hypotrichosis, juvenile cataracts, growth retardation, skeletal anomalies and increased risk of malignancy. We describe a 16-year-old French Canadian female who meets the criteria for probable RTS but has novel respiratory and skeletal anomalies. Her characteristic features are poikiloderma, scalp alopecia, generalized hypotrichosis, reduced nasal height, hypodontia, minor nail anomalies, severe feeding difficulties, early failure to thrive, short stature, small hands and feet, osteoporosis, delayed bone age and puberty, and secondary amenorrhea. She did not have the photosensitive rash seen in some RTS patients but had little sun exposure before age 4. She has no radial ray anomalies or history of cataracts, corneal dystrophy or malignancy. She has mild intellectual delay, which has (rarely) been reported in RTS. Her novel respiratory features include severe congenital subglottic stenosis, tracheo-bronchomalacia, recurrent respiratory infections and chronic lung disease. Airway malformations in RTS were first reported in a 4-year-old male with subglottic stenosis, a type I laryngeal cleft, bilateral vocal cord paralysis and recurrent respiratory infections. Skeletal anomalies are recognized in RTS, but our patient's avascular necrosis of the hip, mild leg length discrepancy, L5/S1 spondylolisthesis, anterior vertebral wedging, and hypoplastic medial malleoli are novel. Sequencing of 21 exons and 13 short introns of the *RECQL4* gene did not reveal pathogenic mutations. Southern blotting was negative for large rearrangements. Genetic heterogeneity is recognized so these patients may represent an RTS subset caused by a single gene mutation or contiguous gene deletion.

Adult psychiatric phenotype in 6p25 deletion syndrome. *O. Caluseriu*^{1, 2}, *E.W.C. Chow*^{1, 3}, *R. Weksberg*^{2, 3}, *L. Rosenberg*^{1, 3}, *D.J. MacCrimmon*^{4, 5}, *A.S. Bassett*^{1, 3}. 1) Clinical Genetics Research Program, CAMH, Toronto, ON, Canada; 2) The Hospital for Sick Children, Toronto, ON, Canada; 3) University of Toronto, Toronto, ON, Canada; 4) Hamilton Health Science Centre, Hamilton, ON, Canada; 5) McMaster University, Hamilton, ON, Canada.

Chromosome 6p deletion is a rare finding in patients with developmental delay. Anderlid et al (2003) have proposed distinct phenotypes associated with interstitial (6p22-p24 region) and terminal (6p24-pter) deletions. The terminal deletions are clinically characterized by Axenfeld anomaly, hearing loss and mid-face hypoplasia. We present an adult with clinical features of a 6p terminal deletion and a psychiatric phenotype. We assessed a 36-year-old Caucasian woman with schizophrenia and dysmorphic features. She had a long, asymmetric face, hypertelorism; low set, posteriorly rotated ears, short nose with upturned tip, high-arched palate and difficulties with coordination. The patient had a history of Axenfeld anomaly, bilateral hearing loss and mitral valve incompetence. She also presented delayed developmental milestones, mild mental retardation and articulation difficulties. She had a 7 year history of unstable mood, developed psychotic episodes with delusions and auditory hallucinations at age 33 years and was diagnosed with schizophrenia. She recently had a single generalized seizure. A CT scan showed generalized cortical brain atrophy and extensive bilateral white matter attenuation in the area of the corona radiata. There was no family history of mood disorder or schizophrenia. Diagnosis of 46, XX, del(6)(p25) was made by standard chromosomal studies (G-banding, 500 band resolution). To our knowledge, this is the first report of an adult with del 6p25 and a psychiatric phenotype. Haploinsufficiency of genes including FOXC1 in the 6p25-pter region has been proposed to contribute to the developmental delay in 6p25 deletions. Linkage studies have previously suggested the presence of susceptibility genes for schizophrenia in 6p25-p24. Patients with 6p25 deletion may be at increased risk of developing a psychiatric illness in adulthood. 6p25-pter may contain genes for susceptibility to schizophrenia.

Abdominal Visceral Findings in the Marfan Syndrome. *K. Chow, L.J. Kessler, J.E. Bavaria, H.I. Litt, R.E. Pyeritz.*
Univ Pennsylvania Sch Med, Philadelphia, PA.

Marfan syndrome (MFS) is a connective tissue disorder with well-characterized features in the ocular, cardiovascular, respiratory and musculoskeletal systems. Managing the aortic complications involves computed tomographic (CT) or magnetic resonance (MR) imaging. Cysts in the liver and kidneys and stones in the gall bladder were frequent and apparently incidental findings on these radiological studies. Accordingly, we reviewed CT and MR exams from an unselected cohort of patients (pts) with MFS to determine the prevalence of abdominal visceral findings and compare the findings to both published population values and exams of people being considered as renal and hepatic donors at our institution. Imaging records for 69 pts (mean age 43 yrs, range 17-75 yrs; F=28, M=41) meeting strict diagnostic criteria for MFS seen in 1998-2004 were reviewed. The presence and number of abdominal visceral findings were noted, particularly renal and hepatic masses and cholelithiasis. Dedicated abdominal CT or MR scans were available in 41 pts, while chest scans with imaging of the upper abdomen were reviewed in 28. Renal cysts were present in 41 pts (59.4%) vs 9/29 controls (31%) and 41% reported in the general population ($p=0.01$ for controls and $p=0.004$ vs population). 27.5% of pts had one cyst, while 31.9% of pts had 2 or more. The mean number of renal cysts was 4.1 in pts vs 1.0 in controls. Hepatic cysts were present in 24 pts (34.8%) vs 5/29 controls (17.2%) and 18% in the general population ($p=0.08$ vs. controls and $p=0.001$ for population). The mean number of hepatic cysts was 2.6 in pts and 0.24 in controls. Cysts were more frequent the older the pt. Cholelithiasis was present in 14 pts (20.2%) vs none in controls ($p=0.009$) and 13.8% in the general population ($p=0.116$); those with previous cholecystectomy were not included. Patients with MFS have an increased prevalence of renal and hepatic cysts, and they develop these cysts at earlier ages compared to the general population. There is a trend towards increased prevalence of gall stones. Further studies will evaluate the rate of appearance and growth in cysts and explore the pathogenesis of these visceral features.

Features of Wolfram Syndrome Without Detectable Molecular Change in WFS1. *K. Crow¹, P. Himes², L. Linck¹, R. Weleber², K. Trzupke², J. Reiss¹, R.J.H. Smith³.* 1) Dept Medical Genetics, Kaiser Permanente Northwest, Portland, OR; 2) Casey Eye Institute, Oregon Health & Sciences University, Portland, OR; 3) Molecular Otolaryngology Research Laboratories, University of Iowa Hospitals & Clinics, Iowa City, IA.

Wolfram syndrome (WS or DIDMOAD: Diabetes Insipidus & Mellitus with Optic Atrophy and Deafness) is a rare autosomal recessive condition with estimated incidence of 1/770,000. Minimum diagnostic criteria are juvenile-onset diabetes and optic atrophy by age 15 years. In addition to diabetes insipidus and high-frequency hearing loss, other features may include seizures, psychiatric illness, cognitive decline and urinary tract abnormalities. Two loci, WFS1 and WFS2, have been identified in this genetically heterogeneous condition. We report two cases with clinical diagnosis of Wolfram syndrome but without detectable pathological changes in WFS1. Case 1 is a 14-year-old girl diagnosed with diabetes mellitus at age 3, and progressive optic atrophy and bilateral high-frequency sensorineural hearing loss at 12 years. She is treated for depression and has heat intolerance due to autonomic dysfunction. Case 2 is a 28-year-old woman diagnosed with profound congenital sensorineural hearing loss in her first year, insulin-dependent diabetes at 4 years, and optic atrophy at 8 years. She developed a seizure disorder at age 12 followed by cognitive decline and mental illness. Both cases had molecular analysis of WFS1: Case 1 carried several benign single nucleotide polymorphisms (SNPs). Case 2 was heterozygous for H323R, a novel conservative amino acid change of unclear significance, and several benign SNPs. In addition, mitochondrial screening in Case 2 was negative for changes associated with MERRF, NARP, and MELAS; Friedrichs ataxia analysis established heterozygosity for this condition. While both cases meet the clinical criteria for WS, Case 1 represents a classic presentation. Case 2 exhibits unusual congenital profound hearing loss rather than typical high-frequency hearing loss diagnosed in the second decade. Interactions with other loci may contribute to the severity of hearing impairment in the second patient.

Identification of a behavioral phenotype in mouse models of Bardet-Biedl syndrome. *R.E. Davis¹, M. Fath^{1,2}, D.Y. Nishimura¹, C.C. Searby^{1,2}, M. Andrews^{1,2}, K. Wang¹, B. Yang¹, E.M. Stone^{1,2}, V.C. Sheffield^{1,2}.* 1) University of Iowa, Iowa City, IA; 2) Howard Hughes Medical Institute, Iowa City, IA.

Bardet-Biedl syndrome (BBS) is a genetically heterogeneous disorder characterized by obesity, retinopathy, polydactyly, hypogenitalism, renal abnormalities and cognitive impairment. Eight BBS genes have been identified. Our lab has developed mouse models for BBS2 (*Bbs2^{-/-}*) and BBS4 (*Bbs4^{-/-}*). Although developmental delay and learning disabilities are often stated features of BBS, there is a paucity of details regarding neurological and behavioral deficits in human BBS patients. Therefore, we carried out detailed neurological characterizations of knockout mice strains using a battery of behavioral tests (SHIRPA). Thirty-eight separate observational measurements were compared between *Bbs2* and *Bbs4* knockout, heterozygous, and wild type mice. There was no significant difference in the observations that assess muscle and lower motor neuron functions such as body position, balance and coordination, gait, positional passivity, tail elevation, grip strength, body tone or various reflexes. However, *Bbs2^{-/-}* and *Bbs4^{-/-}* mice showed deficits compared to littermate control mice in visual placement, olfaction, vocalization and touch escape. Notably, the knockout mice of both genotypes were significantly more docile during handling. The observed docility was further evaluated using a face-to-face social dominance tube test. This testing demonstrated social subordination of homozygous *Bbs2* and *Bbs4* knockout mice to heterozygote and wild type mice.

Quantification and analysis of craniofacial disorders using morphometric analysis of 3-dimension laser surface scans. *B. Dawson*^{1,2}, *S. Carter*^{1,2}, *G. Milne*¹, *A. Tran*¹, *C. Shaw*¹, *C. Bacino*¹, *B. Lee*^{1,2}. 1) Dept. of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Howard Hughes Medical Institute.

Craniofacial malformations are present in a significant portion of human birth defects. To facilitate both the speed of diagnosis and to create a quantitative and reproducible method of analyzing variation in craniofacial size and shape, we are developing Cyberware 3-dimensional laser surface scanning to gather morphometric data on affected populations with Cleidocranial Dysplasia (CCD), and control groups, and individuals with Achondroplasia. We demonstrate high reproducibility of the scanning process through using standard operating procedure.

We have developed a method to quantify the variation between CCD (N=8), Achondroplasia (N=8), and control populations (N=20), by first performing a fast 3d laser scan and subsequently marking and measuring the linear distances between a set of carefully chosen facial landmarks based on existing human craniofacial indexes. Using methodology based on 25 landmarks, over 300 unique linear distances are generated. By utilizing Euclidean Distance Matrix Analysis (EDMA), an invariant form of statistical form analysis, we generated a matrix containing every permutation of linear distance between landmarks, and measure the variance of each set of distances in comparison to each other and the norm. Data from this cohort show that statistical morphology software can differentiate between populations with and without CCD, as well as separating two separate conditions with distinct craniofacial phenotypes from each other (CCD and Achondroplasia). These data form the basis for developing new tools to quantify dysmorphology in humans.

Program Nr: 669 from the 2004 ASHG Annual Meeting

Meier-Gorlin Syndrome (Ear-Patella-Short Stature Syndrome): Growth Hormone Deficiency and Previously Unrecognized Findings. *E. Faqeih, N. Sakati, A.S. Teebi.* Department of Medical Genetics, King Faisal Specialist Hosp., Riyadh, Saudi Arabia.

Meier-Gorlin syndrome (MGS) is a rare, well-characterized autosomal recessive syndrome, associating pre and post natal growth retardation with bilateral microtia, patellar aplasia/hypoplasia, and other anomalies. Intelligence is usually normal or borderline. We report a Saudi Arabian female patient of consanguineous parents, with typical features of this syndrome in addition to respiratory difficulties including emphysematous lung changes and isolated growth hormone deficiency. Her intelligence was above average. Literature pertaining to MGS has been reviewed and the importance of growth hormone deficiency as a factor contributing to the severity of growth retardation in some cases is discussed.

Sensorineural Hearing Loss (SNHL) in a patient with Beckwith-Wiedemann Syndrome(BWS). *Y.P. Geng¹, E. Godoy¹, S. Ramanathan², L. Mehta².* 1) Queens Long Island Medical Group, Flushing, NY; 2) Schneider Childrens Hospital, Manhasset, NY.

Hearing loss in patients with BWS is rare. Several cases of conductive hearing loss due to stapedial and/or malleus fixation have been described. Here we report a 9 year old male with BWS and bilateral severe to profound SNHL. The patient presented with typical BWS features, including macrosomia, omphalocele, macroglossia, hypoglycemia in early infancy, and hemihypertrophy. Diagnosis was confirmed by molecular genetic testing, which showed abnormal methylation of H19 and LIT1 genes, consistent with uniparental disomy of paternal chromosome 11p15 (patUPD). High resolution chromosome karyotyping and EKG were normal. The boy was found to have SNHL at age of 3 years. Parents and a brother are healthy. There is no family history of consanguinity, BWS, deafness or long QT syndrome. The etiologies of SNHL considered included: 1) congenital anomaly of inner ears; 2) connexin 26 mutation(s); 3) aminoglycoside induced ototoxicity due to MTRNR1A1555G mutation; 4) kernicterus or CNS infection; and 5) involvement of KCNQ1 gene. The first three possibilities were ruled out because of normal CT scan of temporal bone and inner ears, and normal connexin 26 sequencing and A1555G mutation analysis. The patient had a history of neonatal jaundice, but not CNS infection. Information regarding the severity of hyperbilirubinemia is not available. Of interest is that the KCNQ1 gene is located in the BWS region, and is maternally expressed in most tissues excluding the heart, where there is biallelic expression. Homozygous mutations of this gene cause Jervell and Lange-Nielsen syndrome (JLNS), a long QT syndrome characterized by SNHL. Recent studies indicate that defective subunit assembly may be responsible for the phenotype of JLNS. Given this mechanism and the lack of reports of SNHL in BWS, it appears that reduced expression of KCNQ1 alone, as expected with patUPD, is unlikely to cause SNHL. Hence the SNHL in our patient could be multifactorial or contributed to by significant neonatal jaundice.

Christians adducted thumbs syndrome with rod-shaped nemaline inclusions. *K. Godbole¹, S. Unger², S. Keating³, W. Halliday^{3, 4}, L. Steele⁴, D. Chitayat^{1,5,6}.* 1) Dept Clinical Genetics, Hosp Sick Children, Toronto, ON, Canada; 2) Department of Pediatrics, Mount Sinai Hospital, Toronto, Ontario, Canada; 3) Laboratory Medicine and Pathobiology Mount Sinai Hospital, Toronto, Ontario, Canada; 4) Department of Pediatric Laboratory Medicine, Hospital for Sick Children, Toronto, ON, Canada; 5) Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto, Ontario, Canada; 6) U of T, Toronto, Canada.

Christian syndrome is an autosomal recessive condition consisting of adducted thumbs, camptodactyly, facial dysmorphism, hypotonia, cleft palate and in some craniosynostosis (OMIM #201550).

We present a hypotonic newborn adducted thumbs who was prenatally diagnosed to have isolated, bilateral club feet and 46, XY karyotype. He required resuscitation at birth and remained ventilator dependent until death on the 10th day of life. His weight and length were below the 3rd percentile. He had a myopathic face, overriding cranial sutures with sloping forehead, hypertrichosis, short palpebral fissures with epicanthic folds, long curly eyelashes, simple low set and posteriorly rotated ears, micrognathia with cleft palate and sloping shoulders. He had proximally inserted adducted thumbs, camptodactyly, bilateral club feet with clinodactyly of 5th toes, restricted joint movements and undescended testes with hypoplastic scrotum. There was hypotonia with areflexia. CT scan of his brain was normal. The autopsy showed rod-shaped nemaline inclusions in striated muscles.

This clinical presentation best fits Christians adducted thumbs syndrome. Previously reported muscle biopsy studies in patients with Christians syndrome do not mention this finding except for a couple of reports with myopathic EMG. The finding of nemaline rods can be primary- and Christian syndrome may be one of the clinical manifestations of NRD or secondary and part of Christian syndrome. It is also possible that this patient had two conditions, NRD and Christian syndrome. Further cases may answer these questions.

GOMEZ-LOPEZ-HERNANDEZ SYNDROME: DESCRIPTION OF TWO MORE BRAZILIAN CASES. IS THERE ANY COINCIDENCE? I. GOMY¹, B. HECK¹, C. MARTINELLI², JM. DE PINA-NETO¹, LM. BATISTA¹, MP. CESCATO³, VE. FERRAZ¹. 1) MEDICAL GENETICS, UNIVERSITY OF SÃO PAULO, RIBEIRÃO PRETO, SÃO PAULO, Brazil; 2) ENDOCRINOLOGY PEDIATRICS, UNIVERSITY OF SÃO PAULO, RIBEIRÃO PRETO, SÃO PAULO, BRAZIL; 3) PSYCHIATRY PEDIATRICS, UNIVERSITY OF SÃO PAULO, RIBEIRÃO PRETO, SÃO PAULO, BRAZIL.

Gomez-Lopez-Hernandez syndrome or cerebellotrigeminal dermal dysplasia (MIM#601853) is a recurrent pattern syndrome characterized by neurocutaneous findings that include cerebellar ataxia, parietal alopecia, corneal and facial trigeminal anesthesia, and mental deficiency. All cases reported were sporadic and the etiology remains unknown. However the recurrent-pattern among unrelated patients suggests a common pathogenesis. Brocks et al (2000) reported the eighth case which had been identified as the oldest case and presented psychiatric findings as bipolar disorder and growth hormone deficiency. We now report two more unrelated Brazilian patients, who one of them at the age of 26 years is the new oldest case identified to date. These are the fourth and fifth Brazilian cases of a total of ten that had been reported in the literature since 1979 (Gomez, 1979; Lopez-Hernandez, 1982). Both cases have cranial asymmetry, midface hypoplasia, rhombencephalosynapsis in MRI, biparietal alopecia and mental retardation. The older patient presents findings that had not been described yet such as macrocephaly secondary to obstructive hydrocephalus, spastic paraparesis, seizures, esophageal stenosis secondary to esophageal reflux. Moreover he has growth hormone deficiency but has no trigeminal anesthesia or corneal opacities. Psychiatric evaluation was normal. He was born of consanguineous parents but his ten siblings are normal. The younger patient has corneal opacities and anesthesia, presents bipolar disorder, but has no growth hormone deficiency. Parents are not consanguineous and there are no similar cases in his family. We think that this is not such a rare syndrome and may be likely underdiagnosed, as we identified half of the cases reported to date. The etiology is still not known but the validity of a recurrent-pattern syndrome increases with the more abnormalities found in the condition and the more patients recognized as having the syndrome.

Mosaic trisomy 13: report of one case with abnormal skin pigmentation. *A. Gonzalez-del Angel¹, R. Avendano¹, L.M. Velasco¹, B. Blanco¹, C. Salas¹, R. Ruiz-Maldonado², V. del Castillo¹.* 1) Department of Human Genetics; 2) Department of Dermatology. Instituto Nacional de Pediatría, Mexico City, Mexico.

Mosaic trisomy 13 is a rare entity and as in other cases of chromosomal mosaicism the clinical manifestations are usually milder, although the correlation between phenotype and percentage of trisomic cells has not been established. We report a case of mosaic trisomy 13 with minor dysmorphism, borderline mental development and abnormal skin pigmentary pattern. The patient is a female, 3 years old, pregnancy was uneventful, obtained by spontaneous delivery at 36 weeks of gestation, with a birth weight of 3000g, she remained one month in the intensive care unit with episodes of hypoglycemia and neonatal hyperbilirubinemia. Gesell test was performed, reporting 80% of development in the motor area, 75% in the adaptive area, and 70% in language. At physical examination, weight and height were at 25th centile, cephalic circumference in third centile, bilateral epicanthic folds, strabismus, small ears, normal palate and clinodactyly fifth finger of hands; she had an abnormal pigmentary pattern consisting of hyperpigmented linear and whorly lines, disseminated at trunk and limbs, without midline involvement. Cerebral CT scan, renal US and echocardiography were normal. Blood cytogenetic analysis showed 46, XX/47,XX+13 mosaicism with the abnormal cell line in 36% of analyzed cells, karyotype of light and dark skin showed 9% and 92% of trisomic cells respectively. At least five reports of mosaic trisomy 13 and abnormal pigmentary pattern have been documented and mental retardation is a constant feature; our patient is unique because she has an almost normal development and minimal clinical manifestations, despite the degree of trisomy 13 cell line, which is higher than in previously reported patients. The mosaic trisomy 13 cases described in the literature have a pigmentary cutaneous mosaicism different than the observed Ito's hypomelanosis. This pattern is called phylloid, which resembles an art nouveau picture and oblong macules, that do not follow Blaschko's lines, our patient seems to have this dermatologic manifestation.

Bohring-Opitz syndrome: A new case and review of the literature. *D.K. Grange¹, F.S. Cole²*. 1) Division of Medical Genetics; 2) Newborn Medicine, Department of Pediatrics, Washington University School of Medicine, St Louis, MO.

We report a new case of Bohring-Opitz syndrome, a rare malformation syndrome of unknown etiology. The first patient was reported as a case of Opitz trigonocephaly (C) syndrome. Four strikingly similar cases were described by Bohring (1999), and it was proposed that this could represent the severe end of the spectrum of C syndrome or a distinct disorder. Overlapping features with C syndrome include trigonocephaly, glabellar nevus flammeus, upslanting palpebral fissures, wide alveolar ridges with frenulae, cerebral anomalies, and polydactyly. However, in Bohring-Opitz syndrome, there are more severe anomalies, including exophthalmos, retinal abnormalities, cleft lip and/or palate, flexion deformities of the upper limbs, radial head dislocation, hirsutism, intestinal malrotation, and feeding problems. Many patients died in infancy and had severe developmental disabilities. Our patient was born at 35 wks gestation. She had trigonocephaly with metopic suture synostosis, glabellar nevus flammeus, abundant scalp hair, synophrys, upslanting palpebral fissures, proptotic eyes with ankyloblepharon, small mouth with thick alveolar ridges and prominent midline frenulum, retrognathia, preaxial polydactyly with digitalized thumb, flexion contractures, ulnar deviation of the hands and marked hirsutism. Chromosome analysis and subtelomeric FISH studies were normal. She had a dysplastic pulmonary valve. Brain MRI showed dysplastic, asymmetrically enlarged lateral ventricles. She had malrotation of the intestine. Severe feeding difficulties required gastrostomy tube feedings. Development was delayed. She died at 5 months of age. A total of 11 other patients with Bohring-Opitz syndrome have been reported. In addition, McGaughan (2000) described a similarly affected patient with a duplication of 3p26.3 to 3pter detected by subtelomeric FISH analysis. Greenhalgh (2003) reported two affected siblings, but all other cases have been sporadic. Autosomal recessive inheritance, a new dominant mutation with gonadal mosaicism as the cause of the familial cases, or a cryptic chromosomal rearrangement have all been proposed as potential genetic etiologies for Bohring-Opitz syndrome.

Program Nr: 675 from the 2004 ASHG Annual Meeting

Malpuech syndrome and ocular-skeletal-abdominal abnormalities (OSA syndrome) are the same: Case Report.
B. Hall. University of Kentucky Lexington, KY.

Mingarelli et al (1996) reported 2 sisters with typical facial features including high arched eyebrows, prominent eyes, ptosis, and malar hypoplasia, diastasis recti secondary to abdominal muscle weakness, lumbosacral spina bifida, scoliosis and radioulnar synostosis. Both were of normal intelligence and stature. Malpuech et al (1983) reported a brother and sister with similar findings plus having heart defects (coarctation, VSD, PDA), cleft lip/palate (Case 1), and caudal appendage. Subsequent reports by Guion-Almeida (1995), Crisponi et al (1999), and Galen-Gomez et al (2004) have confirmed the Malpuech syndrome. I report a 14 year old male who clearly has Malpuech syndrome even including the caudal appendage and PDA, but who also has radioulnar synostosis. Mingarelli's OSA syndrome and Malpuech syndrome are identical facially and share many unique non-facial features, enough in fact to consider them the same autosomal recessive disorder.

Profound Hypertelorism, Midface Prominence, Dental/Enamel Hypoplasia, Prominent/Simple Ears, Osteopenia with Repeated Fractures and Borderline Intelligence in Two Brothers: New Syndrome or An Association of Two Distinct Syndromes? *H. Hamamy*¹, *K. Ajlouni*¹, *A. Teebi*². 1) Genetics, The Jordanian University, Amman, Amman, Jordan; 2) Division of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, Ontario.

Profound hypertelorism is very occasionally encountered among patients attending the genetic clinic. The differential diagnosis includes few syndromes namely craniofrontonasal dysplasia and Teebi Hypertelorism Syndrome. We report on two brothers (8 and 10 years old) of first cousin Jordanian Arab parents with the constellation of profound hypertelorism with upslanted eyes on a plane significantly exceeding 180°, midface prominence, peculiar facial appearance, prominent simple ears, dental enamel hypoplasia, osteopenia with repeated fractures and sloping shoulders. Both have mild to moderate sensori-neural hearing loss and both are of borderline intelligence with school difficulties. The father has mild hypertelorism and the family history is negative for severe hypertelorism or repeated fractures. Skeletal survey showed generalized osteopenia. Chromosomes were normal as well as FISH for subtelomeric rearrangements. We think that the constellation of anomalies represent a previously unrecognized syndrome or less likely the association of a unique hypertelorism syndrome and a connective tissue disorder. The inheritance is likely autosomal recessive.

ADOS-G profiles in males with fragile X syndrome. *S.W. Harris¹, B. Goodlin-Jones^{1,2}, S. Nowicki¹, S. Beran¹, D. Hessl^{1,2}, F. Tassone^{1,3}, S. Rogers^{1,2}, R.J. Hagerman^{1,4}.* 1) M.I.N.D. Institute, UC Davis Health System, Sacramento, CA; 2) Department of Psychiatry and Behavioral Sciences, UC Davis Health System, Sacramento, CA; 3) Department of Biochemistry and Molecular Medicine, UC Davis School of Medicine, Davis, CA; 4) Department of Pediatrics, UC Davis Health System, Sacramento, CA.

Stereotypic behaviors associated with autism, including hand flapping and poor eye gaze, have often been described in children with fragile X syndrome (FXS), and some children with FXS are co-morbidly diagnosed with autism. The Autism Diagnostic Observation Schedule Generic (ADOS-G) is a useful tool for assessing autistic features in children and adults with FXS. Each of the four ADOS-G modules includes "presses" designed to elicit behaviors that are associated with autism.

We were interested in looking more closely at the pattern of ADOS classification in boys with FXS, and the specific behaviors that are encompassed in the ADOS algorithm. We assessed 69 males with the full mutation ranging in age from 2 to 18 years (mean=6.8 years, SD 3.7), with an IQ range of 25 to 91 (mean=57, SD=13). The resulting ADOS classifications were no autism 55% (n=38), ASD 16% (n=11), Autism 29% (n=20).

We found that variables such as age at exam and Full Scale IQ (FSIQ) score did not correlate with the overall ADOS classification. FSIQ did, however, have a significant negative correlation with the ADOS classification of the communication domain of the scoring algorithm ($p=.007$). We also found that the rates of the classifications of no autism, ASD, and autism varied by module used for assessment. This may be due to the fact that many of the patients who had lower expressive language skills, and were therefore assessed using module one or two, were those that had autism.

We hope to further investigate specific behaviors captured by the ADOS, as well as the possibility of a specific ADOS profile for individuals with FXS.

Prader-Willi syndrome with multi-suture craniosynostosis: Report of two cases. *R. Klatt¹, L. Velsher², S. Dyack³, P. Ray⁴, L. Steele⁴, T. Barozzino⁵, M. Sgro⁵, A. Teebi¹, D. Chitayat^{1,6}.* 1) Division of Clinical & Metabolic Genetics, Dept. of Paediatrics, The Hospital for Sick Children, Toronto, ON, Canada; 2) Genetics Program, North York General Hospital, Toronto, ON, Canada; 3) Division of Medical Genetics, Dept. of Paediatrics, IWK Health Centre, Halifax, NS, Canada; 4) Division of Molecular Genetics, Dept. of Paediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, ON, Canada; 5) St. Michael's Hospital, Toronto, ON, Canada; 6) Prenatal Diagnosis & Medical Genetics Program, Mount Sinai Hospital, Toronto, ON, Canada.

Prader-Willi syndrome (PWS) is a genetic condition that presents early in life with hypotonia, feeding difficulties, failure to thrive, and characteristic facial features. In early childhood, the condition typically involves obesity and developmental delay as well. The PWS critical region is 15q11-13. We report on two unrelated patients with PWS and craniosynostosis confirmed by imaging studies. Patient 1 was born to healthy non-consanguineous parents of Pakistani descent. The pregnancy was complicated by poor fetal movements. Severe hypotonia and dysmorphic features, including abnormal head shape, were noted at birth. Chromosome analysis showed 46, XX and FISH analysis using probes for SNRPN and D15S10 showed a deletion of 15q11-13. Abnormal methylation was demonstrated. DNA analysis for FGFR2, FGFR3, and TWIST was negative. A skull x-ray and CT scan confirmed bicoronal synostosis. Patient 2 was born to healthy consanguineous parents of Sri Lankan descent. Poor feeding and hypotonia were noted neonatally. Chromosome analysis was 46,XX and there was abnormal methylation of the SNRPN gene. DNA analysis for FGFR3 was negative. Abnormal head shape was initially noticed at 5 months of age. A CT scan confirmed bicoronal and metopic synostosis. Review of the literature revealed one prior case of PWS with craniosynostosis, but this was not confirmed by CT scan or x-ray. Therefore, these are the first two cases of documented craniosynostosis in association with PWS. We hypothesize that dysfunction of the PWS critical region can result in the disturbance of one or more genes associated with craniosynostosis.

OEIS complex with del(3)(q13.2.q21). *R. Kosaki¹, T. Okuyama¹, N. Kawashima², T. Honna², K. Ueoka³, K. Kosaki⁴.*
1) Dept of Strategic Medicine; 2) Dept of Pediatric Surgery; 3) Dept Urology National Center for Child Health and Development, Tokyo, Japan; 4) Dept Pediatrics, Keio Univ, Tokyo, Japan.

Most cases of cloacal extrophy occur sporadically, but there have been several reports of recurrence in siblings, including monozygotic twins, suggesting a genetic contribution to the pathogenesis of this condition. A case of cloacal extrophy with a de novo 9q34.1-qter deletion was recently reported. The case represented the first report of cloacal extrophy accompanied by an unbalanced chromosomal defect. Here, we report a patient with cloacal extrophy who exhibited a de novo deletion at another chromosomal location, 3q13.2.-3q21. [Case report] The male patient was born at 41 weeks to a non-consanguineous Japanese couple after an uneventful pregnancy without teratogen exposure. The boy, who weighed 3018 g, exhibited cloacal extrophy with omphalocele, ileal atresia, and an imperforate anus. A scrotal fold was present, but no penile structure was visible. Dysmorphic features included low-set ears, midface hypoplasia, hypertelorism with epicanthal folds, a high arched palate, and a pointed chin. X-ray studies revealed symphysis pubis diastasis, a malformed sacrum, spina bifida, and butterfly vertebrae of the lower thoracic region. He also exhibited tethered cords and skin-covered lipomyeloceles. The patient was diagnosed as having (omphalocele-exstrophy-imperforate anus-spinal defects (OEIS) complex. On the second day after birth, the omphalocele and anterior wall of the bladder were surgically repaired. At the age of two months, the cloaca was divided into a colon and a bladder, and the anterior wall of the bladder and the abdominal wall were repaired. G-banding chromosome analysis revealed a 46,XY,del(3)(q13.2.q21) karyotype. The parents had normal karyotype. The present description of a 3q interstitial deletion and the report describing a 9q terminal deletion give further credence to the concept that genetic defects may be responsible for the pathogenesis of cloacal extrophy / OEIS complex and indicate potential loci for the putative genes.

Textbook Features of Saethre-Chotzen Syndrome in Six Members of a Previously Undiagnosed Family: An Exciting Day in the Office, a Reason to TWIST and Shout. *D. Kostiner¹, K. Crow¹, C. Miranda¹, M. Brock², J. Israel².* 1) Dept Genetics, Kaiser Permanente, Portland, OR; 2) Dept ENT.

Saethre-Chotzen syndrome (SCS) is an autosomal dominant condition that affects ~1/37,000. No single feature is obligatory, but typical features include craniosynostosis, low frontal hairline, hypertelorism, ptosis, lacrimal duct defects, small ears, deviated septum, maxillary hypoplasia, narrow palate, partial 2/3-finger syndactyly, and brachydactyly. We present 6 relatives with unmistakable features of SCS to illustrate the consistency of features within the family and to explore the possible genotype-phenotype correlation of the causative mutation. TWIST1 gene analysis is currently pending in the proband. 1) LH, age 18, has hypertelorism, dacryostenosis, small ears, recurrent otitis, surgeries for broad nose and deviated septum, high/narrow palate, partial 2/3-finger syndactyly, transverse palmar creases, and brachydactyly. 2) Her brother, 11, has ear tubes, deviated septum, high/narrow palate, speech problems, and partial 2/3-finger syndactyly. 3) Her father, 43, had surgeries for ptosis, deviated septum, and dental crowding, partial 2/3-finger syndactyly, and premature graying. 4) Her uncle, 46, had surgery for ptosis and deviated septum. 5) Her grandfather, 70s, has severe L-sided ptosis, prominent nose, and partial 2/3-finger syndactyly. 6) Her great grandmother, deceased at 80, had short stature, exophthalmos, hypertelorism, and possible craniosynostosis. Most cases of SCS are due to changes in the TWIST1 gene on chromosome locus 7p21. TWIST1 is a basic helix-loop-helix (bHLH) transcription factor that apparently helps specify and maintain cell identity. Genotype-phenotype correlations for different mutations within exon 1 have not been observed, i.e. any mutation that alters the sequence seems to cause loss of functional TWIST1 protein. Complete TWIST1 deletions, translocations, inversions, and ring 7 may additionally cause atypical features and delay. Some patients with SCS-like features have the FGFR3 P250R mutation associated with Muenke syndrome. Confirming a mutation in this family might help contribute to the understanding of the Saethre-Chotzen phenotype.

Natural history of Sotos syndrome with submicroscopic deletion of 5q35 including NSD1. *K. Kurosawa¹, T. Yamamoto¹, M. Masuno², K. Imaizumi¹, Y. Kuroki².* 1) Clinical Research Institute, Kanagawa Children's Med Ctr, Yokohama, Japan; 2) Kawasaki University of Medical Welfare, Kurashiki, Japan.

Sotos syndrome is an autosomal dominant overgrowth syndrome with characteristic craniofacial dysmorphic features and various degrees of mental retardation. Two thirds of Japanese patients with Sotos syndrome had a common 2.2 Mb deletion involving the entire NSD1 gene, and subset of of patients had NSD1 point mutations. The clinical features are classified according to the dosage effects of NSD1 gene. The patients with submicroscopic deletion of 5q35 including NSD1 gene show more severe phenotype than those of point mutation type. We have evaluated 14 (10 boys and 4 girls) individuals with Sotos syndrome of submicroscopic deletion. We review the clinical features, the spectrum of associated abnormalities, and management of complications according to medical records. The diagnosis is based on the clinical features and cytogenetic analysis including the standard GTG and FISH analysis with RP1-118M12 PAC clone, involving the NSD1 gene. The mean birth weight was 3310 g, length 49.5 cm. Overgrowth became less remarkable at later age, but macrocephay was prominent according to growth. 8 cases (57%) had seizures and 6 were medicated with antiepileptic drugs. CNS abnormalities such as ventricular dilatation, hypoplastic corpus callosum, and multiple ependymoma was noed in 9 cases. Infantile hypotonia and feeding difficulty was the major problems in the neonatal period. Delayed developmental milestones were evident from infantile periods in all cases. Most cases had moderate to severe mental retardation. Congenital heart disease occurred in 6 cases and was important determinant of survival. The patterns of CHD was complex with pulmonary valve atresia and tetralogy of Fallot. Urogenital problems including vesicouretero-reflux, hydroenephrosis, and hypospadias occurred in 8 (57%). The information of natural history of Sotos syndrome with NSD1 deletion was suggested to be important for management and caring the disorder.

Two cases of chromosome 8p23 deletion with different clinical presentation. *L. L. Fishman¹, G. Maegawa¹, R. Babul-Hirji¹, D. Chitayat^{1,2}, A. Teebi¹.* 1) Div of Clin & Metab. Genetics, Hospital for Sick Children, Toronto, ON, Canada; 2) Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, U of T, Toronto, Ontario, Canada.

We report the clinical findings of two patients with a terminal deletion of the short arm of chromosome 8. Case 1: 14 year-old boy with moderate developmental delay and some aggressiveness outburst. He was born to healthy parents with a non-contributory family history. Pregnancy was unremarkable and delivery was normal without any perinatal complication. Physical examination showed microcephaly, mild scoliosis and dysmorphic features such as a low nuchal hair line and two hair-whorls close to vertex. He had a dysphonic voice. His neurological exam was normal except from his cognitive dysfunction. The chromosome showed 46, XY, del(8)(p23.1). Parents karyotypes were normal. Case 2: 11 year-old boy who presented with developmental delay and congenital heart disease. Parents were healthy and family history was unremarkable. Pregnancy was uncomplicated and he was born by induced vaginal delivery at 32 weeks gestation. He had some cyanotic spells soon after birth and an echocardiography revealed small VSD, ASD and pulmonary stenosis. He presented delay in achieving his developmental milestones. On physical examination, his OFC was 51.7 cm (- 1SD). He had dysmorphic features such as brachycephaly, flat occiput, low nuchal hairline with webbed neck, bitemporal narrowing, droopy eyelids and hypoplasia of malar areas. He had bilateral inverted nipples, systolic ejection murmur. He had digitalized thumbs and pes planovalgus bilaterally. His neurological exam showed a decreased muscle bulk and tone. His chromosome showed 46, XY, del(8)(p23.1). The parents chromosomes were normal. These two cases represent the clinical variability of the 8p23 deletion syndrome. The cardiac malformations are present in up to 2/3 of patients. The typical destructive and aggressive behavior is also characteristic of this syndrome. However the facial dysmorphic features could be mild or even absent which could delay the diagnosis of a chromosomal abnormality on the differential work-up.

Mosaic Duplication of 9q11qter: A case report and review of published cases for the dup(9q) syndrome. *A.H.M. Lai¹, M.H. Yong², L. Knight², S.H. Teo¹, I.S.L. Ng¹.* 1) Genetics Service, Department of Paediatric Medicine, KK Women's and Children's Hospital, Singapore; 2) Cytogenetics, KK Women's and Children's Hospital, Singapore.

Partial trisomy 9q is a rare chromosomal abnormality that results in a variable clinical phenotype. Clinical features reported include deep-set eyes, microdolichocephaly, a beaked nose, and microretrognathia. We present a female infant with an unbalanced mosaic karyotype: 46,XX,der(14)t(9;14)(q11;p11.1)[3]/46,XX[57] resulting in duplication of 9q11 to 9qter in 3 of the 60 cells analysed. She has a high forehead, short palpebral fissures, bilateral ptosis, a small mouth, microretrognathia, a right single palmar crease, a ventricular septal defect, laryngomalacia, hypothyroidism, hearing impairment, bilateral visual impairment and severe global developmental delay. This patient is compared with reported cases with pure partial dup(9q). Some features described in almost all the reported cases, such as deep-set eyes, beaked nose, long fingers and stiff joints, are not observed in our patient.

Possible autosomal recessive inheritance of Cornelia de Lange -like syndrome. *A.F. Lewanda, M.E. Nunes.* Inova Fairfax Hosp Children, Fairfax, VA.

Cornelia de Lange syndrome (CdLS) is a dominant disorder characterized by facial dysmorphism and micromelia, recently found to be caused by *NIPBL* gene mutations. We report three patients from two unrelated, consanguineous families who have CdLS features. This may represent recessive inheritance. Parents in family 1 are second cousins from Somalia. Their first child was seen as a newborn with microcephaly, synophrys, deep set eyes, downturned mouth, hypoplastic nipples, small distal phalanges, 2-3 toe syndactyly, hypertonicity and irritability. By two years of age, she was at the 5th percentile for height and weight, and remained microcephalic. She had also developed GE reflux, long curly eyelashes, bilateral radial head dislocation, and hypoplastic proximal radii. Her hand length was average for a 6 month-old, and foot length for a 1 year-old. Karyotype and methylation studies for PWS were normal. Their next child was SGA and microcephalic, hirsute, with synophrys, long eyelashes, anteverted nares, and tapered fingers without gross reduction. Cardiac evaluation revealed a dysplastic pulmonary valve with stenosis. Karyotype was normal. Parents in family 2 are first cousins from the Middle East. Their newborn (patient 3) had microcephaly, hoarse cry, and unilateral clubfoot with limb atrophy. By four months, she developed microbrachycephaly, and severe GE reflux requiring Nissen fundoplication. Examination revealed growth parameters at the fifth percentile (head notably smaller), synophrys, long eyelashes, prominent columella, anteverted nares, retrognathia, hypoplastic nipples, short metacarpals with single palmar crease, atrophy of the right leg, and hirsutism. Cry remained low-pitched. Karyotype was normal. In both families, parents did not show features of CdLS. Features of patients 1 and 3 became more obvious with time. While only dominant or sporadic inheritance have previously been ascribed to CdL or CdL-like syndromes, our patients suggest the possibility of a recessive CdL-like syndrome. This would be distinct from published cases in which the mutation identified in multiple affected siblings has not been found in parents. We are pursuing *NIPBL* mutation testing in these families to distinguish between these hypotheses.

FURTHER DELINEATION OF THE GUADALAJARA CAMPTODACTYLY TYPE II (GSTII). *G. Lopez-Cardona*^{1,6}, *D. Garcia-Cruz*^{2,6}, *N.O. Davalos*^{2,6}, *B. Patio-Garcia*^{2,6}, *L.X. Rodriguez-Rojas*^{2,6}, *M.X. Ruiz*⁷, *M.O. Garcia-Cruz*⁵, *Z. Nazar*³, *I.P. Davalos*^{2,6}, *W.E. Bitar-Alatorre*⁴, *J. Sanchez-Corona*^{1,6}, *J.M. Cantu*^{2,6}. 1) Division de Medicina Molecular, Centro de Investigacion biomedica, Guadalajara, Jalisco, Mexico; 2) Division de Genetica, Centro de Investigacion Biomedica, Guadalajara, Jalisco, Mexico; 3) Servicio de Radiologia, Hospital de Especialidades, CMNO, IMSS, Guadalajara, Mexico; 4) Servicio de Ortopedia, Hospital de Especialidades, CMNO, IMSS, Guadalajara, Mexico; 5) Servicio de Labio y Paladar Hendido HGR46, IMSS, Guadalajara, Mexico; 6) Doctorado en Genetica Humana, Universidad de Guadalajara; Guadalajara, Jalisco; Mexico; 7) Servicio de Genetica, Hospital Metropolitano, Quito; Ecuador.

Our purpose is to describe the clinical and radiological features in a new case of GCSTII and to propose a further delineation of this syndrome. We describe a 38 years old woman with low-set hair, unusual facies, small pinnae with ample conchae, short and wide neck with limited lateral and flexion movements; camptodactyly, limitation of flexion movements at the knees and extension at the ankles, skin syndactyly and clinodactyly of the 4 and 5 toes. X-ray findings: brachycephaly, scoliosis, cuboid-shaped vertebral bodies, camptodactyly of 4 and 5 fingers with subdislocation of the 1 finger in right hand; flexion contracture of the 3 to 5 prominent metacarpophalangeal joint of the 1 finger in the left and dysplastic distal epiphysis of the proximal phalanx, compacted carpal bones on both hands. Congenital hip dislocation, acetabular hypoplasia, hypoplastic iliac bones and ischiopubic branches, hypoplasia of left femoral neck and slender femoral, tibial and fibular bones; bilateral hypoplasia and upper dislocation of patellae. Feet: bilateral hypertrophy of 1st rays and prominent talus. The propositas parents are healthy and consanguineous in accordance with autosomal recessive inheritance suggested for GCSTII (MIM211920) by Cantu et al 1985.

Trisomy 17p10-p12 due to mosaic supernumerary marker chromosome: delineation of molecular breakpoints and clinical phenotype and comparison to other proximal 17p segmental duplications. *J.R. Lupski^{1,2,5,6}, S.A. Yatsenko^{1,5}, D. Treadwell-Deering^{2,3,5,6}, K. Krull^{2,3,5,6}, D. Glaze^{2,4,5,6}, M. Horz^{1,5}, P. Stankiewicz^{1,5}, L. Potocki^{1,5,6}.*
1) Departments of Molecular & Human Genetics; 2) Pediatrics; 3) Psychiatry and Behavioral Sciences; 4) Neurology; 5) Baylor College of Medicine, Houston, TX; 6) Texas Children's Hospital, Houston.

The unstable, gene-rich 17p11.2p12 region is associated with a wide variety of structural chromosomal aberrations. Supernumerary marker chromosome 17 (SMC17) comprises a subset of these, and the majority of SMC17s often utilize the same substrates for recombination as the common 17p11.2 and 17p12 rearrangements. We report a 9-year-old girl with a *de novo* mosaic SMC17. The der(17) encompasses genetic material from 17p10-p11.2 and is present in 97% of peripheral blood lymphocytes and 78% of buccal cells. The patient has few features similar to individuals with duplication 17p11.2 including mental retardation, language impairment and sleep disturbances but has normal growth, and no structural abnormalities of the heart, kidneys or brain. She has no significant behavioral abnormalities or dysmorphic features. Molecular analyses determined that the der(17) contains *RAI1* but not *PMP22*. One breakpoint was identified within the centromere and the second breakpoint maps within the distal SMS-REP (Smith-Magenis syndrome low-copy repeat, LCR). We have recently characterized the breakpoints of three other marker chromosomes originating from the proximal short arm of chromosome 17. In all three cases, one breakpoint maps within the centromere and in two cases the second breakpoint maps within a LCR, suggesting that genome architecture may play a significant role in the formation of marker chromosomes. Herein, we present the cytogenetic, molecular, and clinical data of this patient and compare our results with those of patients with dup(17)(p11.2p11.2) syndrome and other SMC17 patients.

Deletion 2q37.1 - an emerging phenotype. *J.J. MacKenzie^{1,3}, G. Davies², K. Harrison^{1,3}*. 1) Department of Pediatrics, Queen's University, Kingston, ON, Canada; 2) Department of Obstetrics and Gynecology, Queen's University, Kingston, ON, Canada; 3) Department of Pathology, Queen's University, Kingston, ON, Canada.

We report a new case of an individual with the karyotype 46,XX,del(2)(q37.1)[20]/46,XX[10] initially detected at an amniocentesis prompted by a large pleural effusion identified on ultrasound at 18 weeks gestation. We now have 6.5 years of follow up data on this child and have compared her findings with other cases in the literature. Our patient's clinical features include: dolicocephaly, fine hair, short forehead, frontal bossing, hypertelorism, short nose with an overturned tip, a hypoplastic malar area, long philtrum, thin upper lip, arched palate, low set ears with small attached lobules, short neck, broad chest, arachnodactyly with transverse palmar creases, gibbus deformity, lax joints and mild hypotonia. She is also affected with developmental delay and carries a formal diagnosis of autism.

A review of other cases has allowed us to determine similarities in the phenotype which are starting to emerge including: sparse hair, frontal bossing, hypertelorism, low set ears, arched or cleft palate, long philtrum, thin upper lip, short neck, arachnodactyly, and psychomotor retardation. Recently, two cases have been reported in a series of individuals with autism and a review of the literature describes perseverative behavior in other cases which is consistent with the diagnosis in our patient.

At the time of prenatal diagnosis, limited information was available, regarding this deletion, to provide to the family. Further delineation of the phenotype in persons with a 2q37.1 deletion has the potential to improve detection using molecular cytogenetic techniques in those who do not have a microscopically visible change. This will provide us the opportunity to further define the phenotype and to correlate the clinical features with specific genes in this region. We suggest that a 2q37.1 deletion should be considered in individuals with the described features and a careful clinical exam for these should be done in patients presenting with signs of autism.

Cutis marmorata telangiectatica congenita and gastroschisis: an unusual association. *L. Martelli, I. Gomy, C. Lourenco, L. Batista, SE. Hansing, DRD. Carvalho, J. Souza, JM. Pina-Neto.* Dept Genetics-FMRP, Univ Sao Paulo, Ribeirao Preto SP, SP, Brazil.

Cutis marmorata telangiectatica congenita (CMTC) is a localized or widespread vascular anomaly, usually present at birth, and characterized by a persistent reticular vascular pattern with a marble-like bluish or deep purple appearance. Atrophy or hypertrophy of the underlying tissue are commonly reported features. In addition, CMTC is often reported in association with a variety of other congenital anomalies, including but not limited to undergrowth or overgrowth of an involved extremity. The first report of CMTC occurred in 1922 by Van Lohuizen who described a child with livedo reticularis, telangiectases, and superficial ulceration. The pathogenesis of CMTC remains unclear, and the cause may be multifactorial. Most cases occur sporadically, although rare cases occur in families. We report a case of a neonate, born at 39 weeks, the first child of non consanguineous marriage, whose obstetric ultrasound has revealed gastroschisis. At birth, physical examination showed gastroschisis, criptorchidia and slightly bluish red, flat, reticulated pattern over the trunk and legs, more marked on the left side than the right side. The differential diagnosis included Adams-Oliver syndrome. To our knowledge, this is the first description of CMTC and gastroschisis in the same patient. Sponsored by: FAEPA.

Lobodontia - further characterization of a rare dominantly inherited disorder of dental morphogenesis. *F.A. McKenzie¹, E. Mahoney²*. 1) Hunter Genetics, Newcastle, NSW, Australia; 2) Department of Paediatric Dentistry, Westmead Hospital, Sydney, Australia.

Lobodontia is a rare autosomal dominant disorder of dental morphogenesis. It is characterized by delayed eruption and prolonged retention of the primary dentition and generalised morphological abnormalities, including multitubercular molar crowns and conical molar roots, small crown size, pointed buccal cusps of premolars and canines and peg- or shovel-shaped incisors. Hypodontia and tooth invagination is also described. There are only three cases previously reported in the medical literature. We present a fourth family with this disorder and further delineate the associated features. The molecular basis for this disorder is not known but it is postulated that an abnormality of dental development occurs after tooth type has been determined, but at an early stage of morphological differentiation that affects all tooth types of the permanent dentition.

Bilateral microtia, absent external auditory meati, Mondini type malformation, duodenal atresia, thyroid hemiplasia and biliary atresia. A New syndrome. *P. McNamara¹, G. Maegawa², H. White¹, M. Thomas⁵, G. Taylor³, J. Kim¹, P. Kim⁴, D. Chitayat^{2,5}.* 1) Neonatology; 2) Div of Clinical and Metabol. Genetics; 3) Dept of Pathology; 4) Div of Paediatric Surgery, Hosp. for Sick Children; 5) Prenatal Diagnosis and Medical Genetics Prog., MSH, U of T, Toronto, Ontario, Canada.

We present a previously apparently undescribed syndrome with a unique pattern of malformations. A female was born at 36 wks GA with multiple abnormalities including IUGR, coarse facial features, bilateral microtia with absence external auditory meati, duodenal atresia (DA), intestinal malrotation and anterior displacement of the anus. Parents were healthy and non-consanguineous. The 1st pregnancy was terminated for sirenomelia and the 2nd resulted in a healthy son. The pregnancy was initially uncomplicated. MSS was done at 20.3 weeks and showed an increased risk for Down syndrome (1:356). Amniocentesis showed 46, XX. A 3rd trimester U/S showed IUGR and double bubble indicative of DA. Her bwt was 1550 g (<3rd), blt was 45 cm (10th) and OFC was 30.5 cm (<2nd). At birth, microcephaly and bilateral microtia with absence of the external auditory meati were noted. A lt. eye esotropia was evident. There was an asymmetric crying with the mouth deviating to the rt. side, micrognathia and anterior displacement of the anus. Surgery showed complete DA with blind-ended jejunum in lt.-lower quadrant with a long pedicle and intestinal malrotation with Ladd's bands. Cholescintigraphy revealed no evidence of bile drainage suggesting biliary atresia. The TSH was elevated and the thyroid scintigraphy revealed poor lt. lobe uptake. The neck U/S confirmed the hemiplasia of the left thyroid lobe. The brain MRI/MRS were normal. The CT-scan for petrous bone showed bilateral Mondini type deformity, bilateral absence of external auditory canals and internal fused ossicles. The association of DA with intra and extra-hepatic biliary atresia has been reported in the past. However, the association with ear anomalies, thyroid and gastrointestinal malformations has not been reported. We thus suggest that this constellation is a hitherto previously undescribed new syndrome.

Hermansky Pudlak Syndrome in two African-American brothers. *M.A. Merideth^{1,2}, S.E. Sparks¹, K.J. O'Brien^{1,2}, W.A. Gahl¹.* 1) Section on Human Biochemical Genetics, Medical Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, Maryland; 2) Intramural Office of Rare Diseases, Office of the Director, National Institutes of Health, Bethesda, Maryland.

Hermansky Pudlak Syndrome (HPS) is an autosomal recessive disorder characterized by oculocutaneous albinism, a bleeding disorder secondary to a platelet storage pool deficiency, and in some patients, lysosomal accumulation of ceroid lipofuscin. A subset of patients develops fatal pulmonary fibrosis and granulomatous colitis. There exist seven subtypes of HPS, each due to mutations in one of seven different genes, whose functions are thought to involve vesicle formation and trafficking. HPS has been identified primarily in patients of Puerto Rican, Northern European and Japanese descent, although affected individuals have been ascertained in nearly all ethnic groups. We report HPS in two African-American brothers, diagnosed at ages twelve and thirteen years by electron microscopy showing absence of platelet dense bodies. Both boys had been diagnosed with oculocutaneous albinism at birth. They also had excessive bruising that was apparent in the two years prior to diagnosis of HPS. The younger brother had a gastrointestinal bleeding episode immediately prior to his diagnosis of HPS at the age of twelve years. The elder brother has nystagmus, iris transillumination and a visual acuity of 20/160 bilaterally. The younger brother also has nystagmus and iris transillumination, and a visual acuity of 20/160 on the right and 20/125 on the left. Laboratory evaluations are currently underway to determine the HPS subtypes of these two patients. To our knowledge this is the first diagnosis of HPS in African-American patients. The diagnosis of HPS should be looked for in this and all ethnic groups with oculocutaneous albinism, and not just among Puerto Ricans.

A New Association with Ectrodactyly-Synechia of the Labia Minora-Coloboma Parpebral and Palsy Facial. J.

Montoya¹, J.C. Prieto^{1,2}, O.L. Gutierrez². 1) Instituto de Genetica Humana, Universidad Javeriana, Bogota, Cundinamarca, Colombia; 2) Hospital la Victoria, SDS, Bogota, Colombia.

Ectrodactyly, is a congenital limb malformation, characterized by a deep median cleft of the hand and/or foot due to the absence of the central rays and may occur as an isolated entity or as part of a syndrome. More than 50 syndromes and associations are distinguished. The ectrodactyly can be seen with associated malformations, cleft lip/palate, polydactyly, triphalangeal thumbs, ectodermal dysplasia, keratosis, urinary tract malformations, cutis aplasia congenita, macular dystrophy, sensorineural hearing loss, microcephaly, microphthalmia, sagittal craniostenosis, mental retardation, spina bifida, diaphragm defects, congenital heart disease, tibial hypoplasia, fibular hypoplasia, holoprosencephaly, micropenis, cryptorchidism and transverse vaginal septum. A large number of human gene defects can cause ectrodactyly. The most common mode of inheritance is autosomal-dominant, the autosomal-recessive and X-linked forms occur more rarely and other cases of ectrodactyly are caused by chromosomal deletions and duplications. We report on a female infant 3 years old, product of the fifty pregnancy. She was delivered vaginally at 37 weeks of gestation without complications. Her parents are not consanguineous. The positive findings found on the physical examination were: prominent forehead, coloboma parpebral, anteverted nostrils, wide spaced central incisors, facial palsy, hypopigmented skin, ectrodactyly right of the hand and foot, clinodactyly of fifth finger bilateral, syndactyly and synechia of the labia minora. R-banded chromosomes in peripheral lymphocytes were normal with no evidence of chromosome instability or other anomalies. The result of the karyotype was 46, XX. Here we report a case with additional phenotypic manifestations mainly in genitalia, limbs and eyes. This report supports the existence of a new association of ectrodactyly with malformations in genitalia and eyes.

Cornelia de Lange syndrome and congenital glaucoma: a case report and review of the literature. *S. Nallasamy*¹, *T.L. Young*¹, *D. Yaeger*², *J. McCallum*², *M. Kaur*², *I.D. Krantz*². 1) Ophthalmology and Genetics, Children's Hospital of Philadelphia and University of Pennsylvania School of Medicine, Philadelphia, PA; 2) Human Genetics and Molecular Biology, Children's Hospital of Philadelphia and University of Pennsylvania School of Medicine, Philadelphia, PA.

Cornelia de Lange syndrome (CdLS) is a multi-system congenital disorder that is characterized by dysmorphic facial features, hirsutism, limb abnormalities, mental retardation, growth retardation, gastroesophageal dysfunction, cardiac, ophthalmologic and genitourinary anomalies. Recently, it was discovered that mutations in the *NIPBL* gene on chromosome 5p13 cause CdLS. The most common eye findings in CdLS include: hypertrichosis of the eyebrows; synophrys; long, arcuate eyelashes; telecanthus; myopia; ptosis; nystagmus; and chronic conjunctivitis - often due to nasolacrimal duct obstruction (NLDO). To our knowledge, there has been one reported case of CdLS with glaucoma in a newborn with aniridia presenting with profound buphthalmos. Herein, we present a new case of a male infant with CdLS and congenital glaucoma. The patient was diagnosed with CdLS as a neonate, at which time his eyes were unremarkable. His first complete ophthalmologic exam at 13 months of age demonstrated bilateral NLDO, ptosis, significant myopia, elevated intra-ocular pressures and bilateral optic nerve cupping indicative of glaucoma, and longer than average axial eye lengths. The patient underwent a trabeculotomy in both eyes for congenital glaucoma. Probing and irrigation for NLDO was unsuccessfully attempted and the patient will likely require creation of new nasolacrimal duct conduits. This case illustrates the severity of the eye findings that may be associated with CdLS, and reports a novel presentation of congenital glaucoma without apparent anterior segment structural defects. Interestingly, this patient has a previously unreported deletion, 5721delTGAAA, in exon 31 of *NIPBL*. Towards a better etiologic understanding of the extensive and variable ophthalmologic involvement in CdLS, we are currently gathering ophthalmologic and genotypic data from a large cohort of individuals with CdLS to evaluate for genotype-phenotype correlations.

AXIAL MESODERMAL DYSPLASIA COMPLEX (AMCD). REPORT OF A FIRST CASE IN MEXICO AND REVIEW OF THE LITERATURE. *J. Nastasi, JM. Mantilla, LE. Becerra, M. Díaz, ML. Ramírez, LE. Figuera.* Genética, CIBO-IMSS, Guadalajara, Jalisco, México.

Classically, it has been suggested that Goldenhar spectrum or related syndromes, and caudal regression syndrome are included within axial mesodermal dysplasia complex. Characteristics finding of this condition are: craniofacial abnormalities such as asymmetrical face, preauricular tags, dysplastic ears, congenital heart defects, as well as spinal, gastrointestinal and urogenital malformations. AMCD results from failure of mesodermal cell migration, at early blastogenesis. The defect pattern in this developmental field depends on the time when the causal agent was present, for instance gestational diabetes. The proposita, 11 month old, was born from unrelated parents, 35 years old both. There is no family history of congenital malformations. Three healthy sibs and the mother had two miscarriages. During the pregnancy the mother had gestational diabetes, the child was born after 38 weeks of gestation, she was obtained by vaginal delivery. At birth, her weight was 2.075 g, height 35 cm, and occipital-frontal circumference 31 cm. Multiples malformations were noted at birth and physical examination revealed: abundant hair with frontal low hairline, slant up palpebral fissures, high and wide nasal bridge, anteverted nares, short filtrum, microretrognathia, bilateral multiple preauricular tags in the trago-oral line, short neck, thorax, and abdomen without alterations, genitalia with hipoplastic mayor labia. Spine with an excrescence of dorso-lumbar column. Upper limb without apparent malformations. Lower limbs hipoplastics, bilateral tags on the acetabular region, pterigium popliteal, and club foot bilateral. RX: It was observed lumbosacra spine agenesis, and pelvis fused and hipoplastic. Abdominal ultrasonograms normal. Karyotype was 46,XX. This is the first reported case in Mexico, in the present case, the gestational diabetes could be the agent causing this complex. It has been proposed that AMDC is compound by a spectrum of diverse entities, including Goldenhar syndrome, VACTERL association, caudal regression syndrome and Klippel Feil syndrome. All of them display overlapping signs, then they can be manifestations of the same complex.

COACH syndrome: description of 3 new cases and proposed minimal diagnostic criteria. *M.A. Parisi¹, M. Gentile², L. Finn³, I.A. Glass¹, W.B. Dobyns⁴.* 1) Dept Ped/Div Gen & Develop, Children's Hosp & Reg Med Ctr, Seattle, WA; 2) Dept Med Genet, IRCCS, Castellana Grotte, Italy; 3) Dept Pathology, Children's Hosp & Reg Med Ctr, Seattle, WA; 4) Dept Human Genet, Univ of Chicago, Chicago, IL.

COACH syndrome is a rare autosomal recessive condition characterized by Cerebellar vermis hypoplasia (CVH), Oligophrenia (mental retardation), Ataxia, Colobomas, and Hepatic fibrosis. Renal involvement may include juvenile nephronophthisis. In some cases, the molar tooth sign (MTS) has been identified on MRI; this hindbrain malformation consists of CVH, a deep interpeduncular fossa, and elongated superior cerebellar peduncles. The MTS is a key radiologic sign for Joubert syndrome (JS; hypotonia, developmental delay, breathing abnormalities, oculomotor apraxia, and variable features such as renal disease and colobomas). Here we describe three new cases of COACH syndrome and propose minimal diagnostic criteria. Two of the subjects have colobomas, and two exhibit a classic MTS. A total of 30 cases are now reported, including 9 sets of affected siblings. Thirteen were male (47%). The MTS was identified in 10 subjects with suitable imaging. Colobomas were present in 63%, and renal involvement in 60%. The age of onset of hepatic involvement was variable, ranging from 6 months to 46 years. For 14 subjects, hepatic enlargement was the first indication of liver dysfunction; 4 had abnormal liver function tests, and 4 presented with acute gastrointestinal bleeding. Several children responded to ursodeoxycholic acid, and three received liver transplants. Because of the significant clinical overlap between COACH and Joubert syndromes, COACH can be considered a JS-related disorder. We propose minimal diagnostic criteria for COACH syndrome: CVH (particularly the MTS), mental retardation, and hepatic fibrosis. Ocular colobomas are not necessary for the diagnosis, and renal involvement is variable. Because of the difficulty in predicting which children with JS will develop hepatic fibrosis or renal cystic disease, we recommend routine screening for these complications in children with JS, as early identification and treatment of liver and kidney disease may slow their progression.

Autism in Angelman Syndrome. *S.U. Peters¹, A.L. Beauder², N.S. Madduri¹, T. Sahoo², C.A. Bacino².* 1) Depts. of Pediatrics & 2) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX. 77030.

Angelman syndrome (AS) is a neurodevelopmental disorder characterized by severe mental retardation, ataxia, and a happy/sociable disposition. Maternally inherited chromosome 15q abnormalities, such as duplications, within the AS critical region result in autistic symptomatology, implying a role for the UBE3A gene in autism etiology. This study examined the prevalence of autism in AS in 19 children representing three known molecular classes of AS (deletion positive, UPD, and UBE3A mutations). Children were studied over the course of 1 year. Eight of 19 children (42%) met criteria for autism according to the Autism Diagnostic Observation Schedule. Seven of 16 children who were deletion positive met criteria for autism, and 1 of 2 children with UPD met criteria for autism. The one child with a UBE3A gene mutation did not meet criteria for autism. There were no differences in autism diagnosis as a result of chronological age. Parents of children who were diagnosed with autism according to the ADOS-G were administered the Autism Diagnostic Interview Revised. Data from the ADI-R were convergent with data from the ADOS-G in all cases. Children with co-morbid autism and AS scored significantly lower on measures of language ($p < .01$), adaptive behavior (socialization skills; $p < .05$), and cognition ($p < .01$), and demonstrated a slower rate of improvement over the course of the study. All 8 children who initially met criteria for autism continued to meet criteria for autism after an additional year of follow-up, suggesting that the diagnosis of co-morbid autism could not be solely attributable to developmental delays because symptoms of autism did not decrease in severity over time. Children with co-morbid autism specifically demonstrated deficits in communication and socialization that mirror those observed in children with idiopathic autism. Further analyses are underway to determine how 15q11-q13 deletion size and location are related to a diagnosis of autism within our group of deletion positive patients. This study highlights the phenotypic overlap between autism and AS and further suggests that dysregulation of UBE3A may play a role in the causation of autism.

Probable new syndrome with Hypomelanosis of Ito-triphalangeal thumb, peculiar facies, cutis gyrata, dental anomalies, and normal intelligence. *E.J. Ramirez-Lizardo^{1,2}, S.E. Totsuka-Sutto¹, J.R. Corona-Rivera^{1,3}.* 1) Laboratorio de Genetica Humana, Universidad de Guadalajara CUCS; 2) Departamento de Genética, IJCR Secretaria de Salud Jalisco; 3) OPD H Civil Juan I Menchaca. Guadalajara, Jalisco México. elizardo@cucs.udg.mx.

Hypomelanosis of Ito (HI) is characterized by unilateral or bilateral macular hypopigmented whorls, streaks, and patches. Abnormalities of the eyes, musculoskeletal, and central nervous systems occur in some cases. Triphalangeal thumb (TT) has been reported in two previous cases of HI. We report a male patient with HI-TT associated to peculiar facies, cutis gyrata on forehead, dental anomalies, and normal intelligence proposed as a probable new mendelian syndrome. The propositus was born at term after an uncomplicated pregnancy and normal vaginal delivery to a 43-year-old G10, P7, A3 mother and 48-year-old father. TT was noticed at birth, and ridged forehead at 2-month-old. Psychomotor development and scholastic achievements were normal. First dentition was referred at age of 6-month-old and permanent dentition at age of 7-year-old. The patient reported a third permanent supernumerary complete ectopic dentition at age of 10-year-old. At 20-year-old showed weight 67 kg (0.2 SD), height 167 (0.8 SD), and OFC 52 cm (-2.1 SD); peculiar facies, striking ridged forehead, synophrys, mild bilateral ptosis, apparent hypertelorism, broad nose, localized hypoplastic amelogenesis imperfecta, 2nd premolar and 1st molar were bilaterally supernumerary on upper archade and were located on the palatal aspect. The skin showed many depigmented areas in linear and whorls patterns with a localized hypertrichosis area over a hypopigmented patch on back. TT on left hand and bilateral pes cavus were also observed. Histologically, ridged forehead was compatible with cutis gyrata. We included differential diagnosis with other syndromes with HI, TT, cutis gyrata and dental anomalies. We failed to find an entity for this pattern of defects and may thus represent new syndrome with skin (HI, cutis gyrata) and skeletal anomalies (dental and thumb anomalies), with possible autosomal dominant inheritance, based on observed advanced paternal age.

A case of neonatal progeria with findings suggestive of a connective tissue disorder. *D.L. Skidmore¹, W. Halliday², S. Viero², V. Edwards², G. Somers², K. Liu³, A. Hinek³, K. Chong^{1,4}, D. Chitayat^{1,4}.* 1) Clinical Genetics and Metabolics, Hospital for Sick Children, Toronto, Ont., Canada; 2) Division of Pathology and Laboratory Medicine, Hospital for Sick Children, Toronto, Canada; 3) Division of Cardiovascular Research, Hospital for Sick Children, Toronto, Canada; 4) Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto, Canada.

Neonatal progeroid syndromes are recognisable at birth with a wizened face, wrinkled skin, reduced subcutaneous fat and low birthweight. Subsequent growth is poor and most patients have developmental delay. We report a case of neonatal progeria with a strong similarity to either Megarbane-Loiselet or DeBarsy Syndromes. As has been previously proposed, findings were suggestive of a connective tissue disorder. This male child was born to a consanguineous couple following a pregnancy complicated by oligohydramnios and decreased fetal movement. At birth, he was noted to have a wizened facial appearance, pinched nose and prominent jowls. His entire skin was thin, with prominent vessels and decreased turgor. There were progressive flexion contractures of the fingers, elbows and knees. MRI showed tortuous cerebral vessels and several areas of brain parenchymal haemorrhage, subsequently confirmed on autopsy. The child perished at 6 months of age for unclear reasons. Histological examination of his congenital corneal opacities revealed an epithelium of varied thickness and an absence of Bowman's membrane, as has been previously reported in DeBarsy Syndrome. Immunohistochemistry demonstrated the presence of Collagen types I, II, III, IV. The amount Collagen type I and elastin were decreased on skin biopsy. On electron microscopy, the collagen filaments were normal, however the elastin fibres appeared moth-eaten. Procollagen I and III electrophoresis was normal. In culture, the production of elastin and collagen type I were normal and fibronectin was increased. There appeared to be an intracellular accumulation of procollagen. This case again suggests that some forms of neonatal progeria syndromes fall with the spectrum of connective tissue disorders.

Program Nr: 699 from the 2004 ASHG Annual Meeting

Concomitant Partial Trisomy 16q and Partial Monosomy 14q: A case report. *L.D. Smith¹, J.E. Sampson¹, S.A. Smith².* 1) Dept Molecular and Medical Genetics, Oregon Health and Sci Univ, Portland, OR; 2) Department of Pediatrics, Oregon Health and Science University, Portland, OR.

Partial trisomy 16q and partial monosomy 14q are rare genetic anomalies with identifiable phenotypes. We present the first patient in the literature to have an unbalanced translocation between chromosomes 14 and 16 resulting in simultaneous occurrence of both of these rare genetic conditions. There is overlap in the reported phenotypes for each of these aneuploidies and our patient exhibited features consistent with both syndromes. Features of trisomy 16q were dominant, manifesting as intestinal and pulmonary vascular abnormalities. Comparing the genotype and phenotype of this patient with previously reported cases provides further refinement of the phenotype-genotype map of 16q proposed by Brisset et. al. (2002).

Growth Assessment of Smith-Magenis Syndrome (SMS). *A.C.M. Smith^{1,2}, A.K. Leonard¹, A. Gropman^{1,2}, D. Krasnewich¹.* 1) MGB/NHGRI/NIH, Bethesda, MD; 2) Georgetown Univ. Med Ctr, Washington, DC.

Smith-Magenis syndrome (SMS) is a well-described, clinically recognizable syndrome associated with an interstitial deletion of chromosome 17p11.2; however, the natural history remains less defined. Over two thirds exhibit short stature, and failure to thrive is frequently seen in infancy. An assessment of anthropometric standards [weight (kg), length/height (cm), head circumference (cm), body mass index (BMI)] was performed on 54 children (22M/32F) with a confirmed deletion diagnosis of SMS and born between 1980-2002. A combination of longitudinal and cross sectional data was collected during evaluation and record review. Data were arranged using mathematical methods to construct gender-based growth curves by age (0-24 months & 2-14 years). Curves were compared to normative data derived from the CDC-National Health & Nutrition Examination Survey (NHANES 2000). BMI was calculated (kg/m^2) in cases where height and weight were simultaneously available. Results: Birth parameters are within the normal range for both sexes. Mean birth length is 49.50cm (50%) for males and 48.77cm (25-50%) for females. Mean birth weight is 3.11 kg (5-10%) for males and 3.05 kg (25%) for females. Mean birth head circumference (HC) is 34.9cm (25%) for males and 33.6cm (25%) for females. Poor growth (5%) is noted within the first 6 months of age and may persist into early childhood. HEIGHT: Males track at 5% through 3 yr, increasing to 25% by 14 yr. Females are at 5% until age 3 yr, then track between 5-25% from 3-7 yr, followed by a decline to <3% by age 12 yr. WEIGHT: Males decline after birth to 5% by age 5 months, then steadily increase to 25% by 6 yr and are at 90% by 14 yr. Females exhibit a brief decline in weight before age 6 months, then track at 25-50% from 1-7 yr with the majority reaching >90% by age 12 yr. HC is normocephalic in the majority. BMI values are variable across ages. This study represents the first systematic assessment of growth in SMS and offers clinicians a means to identify clinically significant growth problems in this rare syndrome.

High cognitive functioning in Pallister-Killian syndrome. *H. Stalker*^{1,2, 3}, *R. Zori*^{1,3}, *B. Gray*^{1,3}, *A. Bent-Williams*^{1,3}, *F. Dolwick*², *C. Williams*^{1,3}. 1) Div Genetics, Dept Pediatrics, Univ Florida, Gainesville, FL; 2) Craniofacial Center, Univ Florida, Gainesville, FL; 3) Raymond C. Philips Unit, Univ Florida, Gainesville, FL.

Pallister-Killian syndrome (PKS) is a rare syndrome of multiple congenital anomalies attributable to the presence of a supernumerary isochromosome 12p. The syndrome presents with characteristic features including: pigmentary skin changes, facial dysmorphia (sparse anterior scalp hair, flattened midface, macrostomia, and coarsening of facial features) and developmental delay. The developmental phenotype of PKS is quite variable; but most are considered to fall into the profound range of developmental functioning. We report on an individual with classical features of PKS with development significantly better than that reported in the literature. As an infant, the patient was hypotonic with sparse anterior scalp hair and distinctive facial features. Chromosome studies performed in childhood revealed an isochromosome 12p in 15 of 52 cells examined in skin fibroblasts, following a normal peripheral blood study. At 14 years of age, she presented to the craniofacial center at the University of Florida for evaluation for midface distraction surgery due to severe midface hypoplasia. FISH studies on buccal mucosa using the D12Z3 probe revealed the presence of the isochromosome 12p in 34 of 150 cells examined. She was noted to have streaky skin hyperpigmentation and has had progressive coarsening of facial features consistent with PKS. Her developmental course has been noteworthy in that a Stanford Binet study at age 4 years revealed a full scale IQ of 83 and at 13 years revealed an IQ of 93. At age 14, the Kaufman Test of Educational Achievement (K-TEA) test also revealed a normal level of functioning with age equivalent scores ranging from 9 years 9 months to 18 years 3 months with relative weaknesses in mathematics and relative strengths in reading and decoding. This child demonstrates a milder developmental course of PKS and highlights the need to consider chromosomal analysis for this condition in individuals with normal intelligence if other physical phenotypic features are present.

ICF syndrome with no mutation in DNMT3B. *M. Suzuki¹, T. Iwai¹, M. Sone¹, K. Miyamoto², H. Yamagata², I. Kondo².* 1) Department of Pediatrics, Kagawa Childrens Hospital, Zentuuji, Kagawa, Japan; 2) Department of Medical Genetics, Ehime University School of Medicine, Ehime, Japan.

The immunodeficiency-centromeric instability-facial anomalies (ICF) syndrome is a rare autosomal recessive disorder characterized by recurrent infections with defective cellular immunity, mild facial dysmorphism and developmental delay. The most diagnostic feature is the pericentromeric instability of chromosomes 1, 9 and 16. An impaired function of DNA methyltransferase 3B (DNMT3B) is causal of this disease. DNA mutations in the DNMT3B gene have been identified in at least 30 patients with the ICF syndrome, but some patients with the ICF syndrome did not have any mutations in the literature, suggesting genetic heterogeneity for the clinical conditions.

We have experienced a case of a female patient with ICF syndrome who suffered of recurrent respiratory infections after three months of age. She was born at term, weighing 1,770g, to no consanguineous healthy parents. When she was hospitalized at 4months of age ; immunodeficiency (IgG 23 mg/dl, IgM 5 mg/dl, IgA 6 mg/dl) was noted. The subsets of T cells and B cells were 86.5% and 5.6%, respectively. She had a typical ICF face and growth and developmental delay. Chromosome analysis showed multiradial configurations involved the heterochromatin regions on chromosomes 1 and 16 in cells examined (16%). She died of Pneumocystis Carinii pneumonia when she was 16months old. DNA analysis were performed in the entire coding and promoter regions of DNMT3B using ABI310 direct sequencer. However, no mutations were detected in DNMT3B.

Clinical features in this patient were identical to most cases with DNMT3B mutations. However, pre- and postnatal growth and development were severely retarded in our case compared to those in patients with DNMT3B mutations. These results suggest that the second gene responsible for the ICF syndrome might have important role in development and growth in addition to immunity.

Teebi-Shaltout Syndrome: A Report of Further Arab Patients. *A.S. Teebi^{1,2}, I. Haroun¹, I. Ahmed³, M.S. Al-Mureikhi⁴, M.S.Z. Salem⁴, G. Al-Thani⁴.* 1) Div'n Clin & Metab Genetics, Hosp Sick Children, Toronto, ON, Canada; 2) University of Toronto, Toronto, ON Canada; 3) Department of Pediatrics, Um-Alqura University, Makkah, Saudi Arabia; 4) Department of Pediatrics, Hamad Medical Corporation, Doha, Qatar.

Teebi-Shaltout syndrome (TSS) was originally described in 1989 in a patient of consanguineous Arab parents from Kuwait. Another Arab family was reported to have 3 affected children. The parents were first cousin of Tunisian origin living in Germany. Manifestations included slow growing hair, hypertelorism, mild ptosis, absent primary teeth, small mouth, mild micrognathia, camptodactyly and caudal appendage. Additional features included blepharophimosis, microphthalmia, and renal anomalies. Inheritance is likely autosomal recessive.

Here we report on 4 patients from 3 consanguineous Arab families with features suggestive of TSS and some previously unrecognized findings thus expanding its spectrum. The first family with a 5-year old male and a 7-year old female sibling from Saudi Arabia. Manifestations included unusual hair, mild hypertelorism, blepharophimosis, small mouth with normal primary teeth, camptodactyly of the 3rd and 4th fingers, and a caudal appendage in one. Intelligence was within normal range.

The other two families are distantly related but from the same large Qatari tribe each with one affected child (a male and a female). Manifestations included a triangular face, blepharophimosis, small mouth with thick lips, long fingers with camptodactyly of 3rd and 4th fingers, sacrococcygeal dimple with a small caudal appendage in one, long big toes, and syndactyly between 2nd and 3rd, and 4th and 5th toes in both feet. Psychomotor development in the 4 patients was within normal.

Based on this report and the previous 2 reports of Arab patients, it appears that TSS is probably not very rare among Arabs and that its pattern of anomalies should be considered when evaluating patients with camptodactyly and/or caudal appendage.

Beckwith-Wiedemann syndrome in a child with subtle phenotype conceived by intracytoplasmic sperm injection: case report and review. *L.N. Teed, A. Ahmad.* Genetics and Metabolism, Children's Hosp of Michigan, Detroit, MI.

Beckwith-Wiedemann syndrome (BWS) is characterized by macrosomia, hemihypertrophy, macroglossia, visceromegaly, omphalocele, ear creases and pits, and an increased risk of embryonal tumors. BWS can result from a number of different genetic mechanisms involving chromosome 11p15: chromosome rearrangements; paternal UPD for chromosome 11; methylation abnormalities of the genes *KCNQ1OT1/LIT1* and *H19*; and mutations in the *CDKN1C* gene. Recent reports have noted an increased frequency of conception via in vitro fertilization (IVF) and intracytoplasmic sperm injection (ICSI) in children with BWS.

We report a case of BWS in a girl conceived by ICSI, who presented for evaluation at 2 years 9 months of age. The pregnancy was uncomplicated with a normal ultrasound examination. She was born at 35 weeks gestation by spontaneous vaginal delivery. Birth weight and birth length were both greater than the 90th percentile for gestational age. There was no known history of neonatal hypoglycemia. Macroglossia and an umbilical hernia were noted in the newborn period but a diagnosis of Beckwith-Weidemann syndrome was not considered. At presentation to genetics clinic at 2 years and 9 months, her height was 97 cm (90th percentile) and weight was 15 kg (75-90th percentile). On physical examination, she had mild macroglossia with a tendency to hold her mouth open and a small umbilical hernia. The physical exam was otherwise completely normal with no ear creases or pits, hemihypertrophy, or visceromegaly. Family history was unremarkable. Review of photographs confirmed the macroglossia was more apparent at younger ages. Peripheral blood karyotype was normal. Molecular analysis detected hypomethylation of the *KCNQ1OT1/LIT1* gene.

This report adds to the previously reported cases of BWS in the medical literature (about 20 total cases) associating assisted reproductive technologies with epigenetic alterations. We suggest that conception via IVF or ICSI be considered a supportive finding in children with features, albeit subtle, of BWS.

Familial Sotos syndrome with unusual clinical manifestations. *D.H. Tegay, J. Weiss-Burns, P. Galvin-Parton.* Stony Brook University Hospital, Stony Brook, NY.

Sotos syndrome is characterized by childhood overgrowth, advanced bone age, macrocephaly, distinctive facial features and developmental delay. Mutations or deletions involving NSD1 are causative and follow autosomal dominant inheritance. Frequently reported associated features include hypotonia, congenital heart disease, seizures, scoliosis, strabismus, and cancer. Rare familial cases have been reported and decreased fertility has been implied.

Here we report a case of a 5 year-old Caucasian female with typical features of Sotos syndrome ascertained during evaluation for severe glomerulonephritis secondary to systemic lupus erythematosus. NSD1 DNA sequence analysis revealed a novel single base pair deletion predicted to be pathologic for Sotos syndrome (6291delG) due to the frameshift creation of a downstream premature stop codon. Due to large stature, learning disability and distinctive facial features, testing was carried out on the 44 year-old mother of the proband and also revealed the causative 6291delG NSD1 mutation, confirming familial Sotos syndrome.

NSD1 is expressed in a variety of tissues including brain, kidney, muscle, spleen, thymus and lung, where it appears to be involved in chromatin regulation and interacts with a variety of nuclear receptors. Systemic lupus erythematosus has not previously been reported in association with Sotos syndrome. The severity of this patient's lupus glomerulonephritis (WHO class IV) together with a prior case report describing increased severity of familial ADPKD in an individual with concomitant Sotos syndrome suggests the possibility of a deleterious effect of NSD1 mutations on the kidneys.

Tricho-Hepato-Enteric Syndrome: a report of 2 further cases with a novel pattern of iron accumulation and abnormal platelets. *R.E. Teitelbaum¹, D.L. Skidmore^{1,4}, R. Moodie³, W. Kahr⁵, N. Martin¹, J. Kingdom², N. Okun², Y. Diambomba^{3,6}, S. Viero⁵, S. Unger⁴, N. Querica⁴, D. Chitayat^{1,4}.* 1) Prenatal Diagnosis & Medical Genetics, Mount Sinai Hospital, Toronto, ON, Canada; 2) The Department of Obstetrics and Gynecology, MSH, Toronto, Canada; 3) Department of Neonatology, Hospital for Sick Children, Toronto, Canada; 4) Clinical and Metabolic Genetics, HSC, Toronto, Canada; 5) Department of Pediatric Laboratory Medicine, HSC, Toronto, Canada; 6) The Department of Neonatology, MSH, Toronto, Canada.

Tricho-Hepato-Enteric syndrome (THES) is a disorder which consists of: abnormal hair, liver dysfunction, abnormal hepatic iron storage and intractable diarrhea. The condition was first reported by Stankler et al(1982) and further delineated by Verloes et al(1997). We report sisters affected with this condition and further delineate the clinical manifestations. The first child died at 6 month of age due to sepsis, intractable diarrhea and liver dysfunction. She was noted to have FTT, congenital hyperbilirubinemia, thrombocytopenia, possible immunodeficiency, VSD, mild facial dysmorphism, "woolly" hair and liver fibrosis. Histology showed iron deposition in the Kupffer Cells of the liver and at the apical end of the thyroid follicles. Bowel biopsies were non- diagnostic. Platelet microscopy revealed giant platelets with canalicular dilatation, vacuolation and abnormal content. Her karyotype was 46,XX. The second pregnancy was complicated by mild IUGR and transiently distended bowel loops at a gestational age of 30 weeks. Postnatal examination showed a female child with woolly hair and similar dysmorphisms. At two weeks of life, she developed intractable diarrhea. An MRI inferred the presence of metal in the liver and thyroid, but not the pancreas, spleen or heart. Like her sibling, her ferritin was elevated and her platelets had similar abnormalities. Furthermore, some of the platelets had an almost complete absence of microtubules. It appears that in addition to previously reported findings that THES has a distinct pattern of iron deposition and novel hematological findings.

Rare case of median cleft of the upper lip with pedunculated skin-covered mass presented through nostril. M.

*Tolarova*¹, *A. Capozzi*². 1) Craniofacial Genetics, Department of Orthodontics, Univ of the Pacific, Sch Dent, San Francisco, CA; 2) Shriners Hospital for Children, Sacramento, CA.

A median cleft of the upper lip occurs either as an isolated anomaly or as a part of well-recognized syndromes (Majewski, OFD, Ellis-van Creveld, holoprosencephaly, etc). In a frontonasal dysplasia sequence, a midline cleft of the upper lip may continue through the nose (a bifid nose) up to widely spaced eyes (hypertelorism). However, only approximately 25 authors have described patients with a median cleft of the upper lip, double frenum, hamartomas, and a nasal mass extending from columella. Our patient was a 6 months old baby girl who presented with a slight facial asymmetry, midline defect of the upper lip with a small midline defect of the alveolar maxillary ridge, and a pedunculated skin-covered club-shaped cylindrical mass protruding through a left nostril. The face was asymmetrical with a wide nasal bridge. The left palpebral fissure and the left eye were smaller. The girl was born as a second child to a 20 years old mother and to a 36 years old father. Mother had a first child from her previous marriage and father had three healthy children from his previous marriage. Birth weight was 6 lbs 2 oz. The mother had a cold in the third month of pregnancy. The younger brother of the mother was born with cleft lip and palate. A CT scan revealed that there is no communication with nasal or frontonasal sinuses. It also excluded a frontonasal encephalocele. The girl underwent surgery under general anesthesia. A pedunculated mass that was attached to the nasal septum was successfully removed. The nasal airway was clear after excision of the nasal mass and the girl could easily breathe through her nose. As the mass involved a margin of the left ala nasi, a defect of the left nostril occurred after the excision. It could be corrected later. Histological examination showed that the mass consisted of skin, fibrous connective tissue, and adipose tissue. The child was released from the hospital the following morning and recovered successfully. The study of this case, as well as the surgery, was supported by the Rotaplast International, Inc.

A New Syndrome of Congenital Extraocular Muscle Fibrosis and Ulnar Hand Anomalies Maps To Chromosome

21qter. *T. Tükel^{1,4,5}, A. Uzumcu⁵, A. Gezer⁶, H. Kayserili⁵, M. Yuksel-Apak⁵, O. Uyguner⁵, S.H. Gultekin³, H.C. Hennies⁷, P. Nurnberg^{7,8}, R.J. Desnick^{1,2}, B. Wollnik⁵.* 1) Department of Human Genetics, Mount Sinai School of Medicine, New York, NY; 2) Department of Pediatrics, Mount Sinai School of Medicine, New York, NY; 3) Department of Pathology, Mount Sinai School of Medicine, New York, NY; 4) Department of Genetics, Institute for Experimental Medicine (DETAE), Istanbul University, Istanbul, Turkey; 5) Division of Medical Genetics, Child Health Institute, Istanbul University, Istanbul, Turkey; 6) Department of Ophthalmology, Istanbul Faculty of Medicine, Istanbul University, Istanbul, Turkey; 7) Gene Mapping Center and Department of Molecular Genetics, Max Delbrück Center for Molecular Medicine, Berlin, Germany; 8) Institute of Medical Genetics, Charité, Humboldt University Berlin, Berlin, Germany.

We report a new autosomal recessive syndrome of congenital fibrosis of extraocular muscles (CFEOM) with notable ulnar hand abnormalities. All six affected patients from a large consanguineous Turkish family, aged 2 to 29, had 1) nonprogressive restrictive ophthalmoplegia with blepharoptosis primarily of the right eye and 2) postaxial oligodactyly/oligosyndactyly of varying severity in both hands, but always more severe on the right. A genome scan at a marker density of about 7 cM established linkage of the disease locus to chromosome 21qter. The multipoint LOD score was 4.53 at 55cM on chromosome 21 and recombinations defined the critical region as ~1.5 cM between microsatellite D21S1897 and the telomere of the long arm. This region contains about 15 genes and 10 open reading frames but no obvious candidate genes. Clinical findings of the patients and fine mapping of the locus are presented in detail. Identification and functional studies of the syndrome-causing gene may provide insights into the development of the extraocular muscles and the cranial motor nuclei, as well as anteroposterior limb development.

Cytogenetic and clinical description of the 9p deletion syndrome. *H. Vance¹, C. Crowe², L. Christ¹, M. Eichenmiller¹, M. Graf¹, A. Matthews¹, T. Hassold¹, S. Schwartz¹.* 1) Case Western Reserve Univ, Cleveland, OH; 2) MetroHealth Med Ctr, Cleveland, OH.

The 9p deletion syndrome (9p-) is characterized by trigonocephaly, typical facial features, long middle phalanges, umbilical and inguinal hernias, abnormal genitalia, cardiac abnormalities, and hypotonia. All patients have some degree of cognitive impairment. The critical region for 9p- has been localized to a region between 9p22.3-p23. To better define the cytogenetic and clinical manifestations resulting from a deletion of the critical region, 35 patients were identified with cytologically terminal deletions of chromosome 9p proximal to this critical region. High-resolution chromosome analysis, microsatellite analysis, and BAC analysis were utilized to define breakpoints, deletion sizes, and parental origins of the deletions. Clinical data on each patient was obtained by physical examination and review of medical history. Cytogenetic and molecular analysis revealed that: 1) breakpoints are heterogeneous, with deletions in this group ranging in size from 14.1 to 19.6 Mb; and 2) paternally derived deletions occur significantly more frequently than maternally derived deletions. Clinical data analysis demonstrated that: 1) all patients with deletions proximal to the 9p-critical region have phenotypic manifestations characteristic of 9p-; 2) there is great variability in the frequency and severity of phenotypic expression; 3) several trends suggestive of karyotype/phenotype correlations were observed; and 4) certain findings were noted only in specific subgroups of patients with larger deletions, including tapered fingers, sandal toe gap, nystagmus, and rockerbottom feet, suggesting more proximal localization of these traits. These observed trends may partially contribute to the clinical variability of 9p-. However, results from this study indicate that breakpoint analysis alone cannot predict phenotype. Thus, following the prenatal or postnatal identification of a deletion of the 9p critical region, genetic professionals should continue to emphasize the clinical variability of 9p- to parents and families and provide a thorough evaluation and appropriate management.

The mute Elfin : Williams syndrome and autism. Report of 5 patients. A. Verloes¹, P. Blanchet², A. Toutain³, R. Touraine⁴, D. Héron⁵, O. Dupuy¹, C. Baumann¹, P. Saugier-veber⁶, E. Excoffier⁷, D. Cohen⁸, S. Tordjman⁹. 1) Clinical Genetics Depts, Robert Debré Hosp, Paris; 2) Montpellier University Hosp; 3) Tours University Hosp; 4) Saint-Etienne University Hosp; 5) La Pitié-Salpêtrière Hosp, Paris; 6) Rouen University Hosp; 7) Child Psychiatry Depts, Robert Debré Hosp, Paris; 8) La Pitié Salpêtrière Hosp, Paris; 9) Rennes University Hosp, France.

Williams syndrome (WS) is a rare genetic condition whose clinical manifestations include a distinct facial appearance, CHD, neonatal hypercalcemia, and a cognitive and behavioral phenotype characterized by a relative preservation of linguistic and social-affective skills ("cocktail party" personality with expansive and expressive speech) and musical ability in the face of profound impairment of visuo-spatial abilities and numeric processing. Domains of socialization and communication are considered to be relative strengths, whereas daily living and motor skills are relative weaknesses in WS. We report 5 WS patients with MR and pervasive developmental disorder (PDD) of the autistic type (according to DSM IV criteria) resulting in e.a. in total absence of language. Evaluations of the 5 patients by ADI and CARS confirmed the clinical diagnosis of PDD. All patients were deleted by FISH in 7q11.23. At time of submission, investigation by QMPSF for 9 exonic amplicons within 7 different genes inside the common 1.5 deletion and 2 genes at the boundaries confirmed the presence of the common deletion in 2/5. Only 2 previous reports mention coexistence of WS and PDD in the literature. Causal relationship between WS and PDD will be discussed. Despite verbal fluency, it appears that WS patients exhibit PDD-related behaviors, such as hyperacusis, obsessive interests, global spatial perception deficit, Asperger-like verbal prosody, inflexibility, ritualism, obsessiveness, and perseverating attitudes. More severe PDD behavior may be more common in WS than reflected by literature scan. A possible hypothesis would be a mutation in the second allele of a gene involved in neuropsychological functions in WS genomic interval leading to total inactivation of the gene expression.

Obesity and Stature in Adults with 22q11 Deletion Syndrome. *V.W.Y. Wong^{1, 2}, E.W.C. Chow^{1, 2}, O. Caluseriu^{1, 3}, R. Weksberg^{2, 3}, A.S. Bassett^{1, 2}.* 1) Clinical Genetics Research Program, Centre for Addiction and Mental Health (CAMH), Toronto, ON, Canada; 2) University of Toronto, Toronto, ON, Canada.; 3) Hospital for Sick Children, Toronto, ON, Canada.

Background: 22q11 Deletion Syndrome (22qDS) is a common microdeletion syndrome. Up to 30% of adults may develop schizophrenia (SZ). While children with 22qDS have been reported to have short stature and failure to thrive, there is limited information on adult parameters. Method: Height (Ht) and Weight (Wt) of 72 adults (age >17 y) with 22qDS confirmed using standard FISH methods (age > 17) were measured. There were 38 female and 34 male subjects assessed at mean age 28.8 y (SD = 10.1 y). 35 subjects (48.6%) had psychotic illnesses treated with medications that can cause weight gain; 16 subjects had a history of hypothyroidism. Adult body mass index (BMI), Ht and Wt percentiles were calculated using US Centre for Disease Control Growth Charts, which account for age and sex. Results: There is a significant difference in Ht between Male and Female as expected ($p = <0.0001$) and Wt ($p = 0.0028$), but not in BMI ($p = 0.9597$). There was no significant difference on any measure between subjects who had or did not have a psychotic illness, or those with or without hypothyroidism. Comparing the 22qDS sample with general population (age and sex corrected) percentile norms, significantly greater proportions of subjects with 22qDS had short stature: height <3%ile ($n = 13$; 18.31%; $\chi^2 = 11.47$; $df = 1$; $p = 0.0007$), <10%ile ($n = 30$; 42.25%; $\chi^2 = 24.10$; $df = 1$; $p = <0.0001$), and obesity: BMI >90%ile ($n = 31$; 43.66%; $\chi^2 = 25.81$; $df = 1$; $p = <0.0001$). BMI ranged from 20.4 - 38.1 for men and 17.2 - 48.3 for women. Only 4 subjects (5.6 %) were underweight. Conclusions: Overall, adults with 22qDS are shorter in stature and have more obesity than the general population. Weight gain in 22qDS is not primarily associated with anti-psychotic medications or thyroid disease, and represents a major health issue for these patients.

Schizophrenia as the presenting feature of Velo-cardio-facial-syndrome: effect of targeted therapy. *H. Yonath, C.W. Brown.* Dept Molecular & Human Gen, Baylor College of Medicine, Houston, TX.

The clinical presentation of the 22q11.2 deletion syndrome (22q11.2 DS) can be quite variable, and the characteristic features may include congenital heart disease, palatal abnormalities, immune deficiency, facial dysmorphism, learning disabilities, and psychiatric illness. Hypocalcemia, feeding difficulties, renal anomalies, and hearing loss are also common. Although patients with 22q11.2 DS are usually diagnosed during early childhood, we report a case in which the syndrome was diagnosed in an 18-year old female referred to our Genetics clinic due to acute psychosis that had responded poorly to medical therapy. Physical examination revealed a long face, bulbous nose, prominent upper lip, protuberant asymmetric ears, nasal voice, webbed neck, and tapering fingers. Cardiac exam and stature were normal. Echocardiogram and renal sonogram showed no structural abnormalities. Fluorescence in situ hybridization identified a characteristic 3 Mb 22q11.2 deletion. The gene encoding catechol-o-methyltransferase, an important enzyme for dopamine metabolism, lies within the deletion interval and may be relevant to the formulation of a more targeted treatment plan for these patients. Some 22q11.2 DS patients who are refractory to conventional forms of therapy for schizophrenia improve when treated with Metyrosine, an inhibitor of tyrosine hydroxylase. Although our patient showed a good initial response to Metyrosine, her psychiatric status worsened within a few weeks as the dose of the drug was increased. L--methyldopa, which inhibits the decarboxylation of dopa to dopamine, is currently being considered. This patient represents an example of the wide variability of 22q11.2 DS, and manifests the need for increased awareness of this disorder when evaluating schizophrenic patients.

Another Ptosis Loci? Distal 3q beyond BPES. *D. Zand, K. Rosenbaum.* Dept Genetics and Metabolism, CNMC, Washington, DC.

With the recent commercial utilization of fluorescence in situ hybridization (FISH) technology, diagnoses of cryptic subtelomeric deletions have been more common. Some subtelomeric deletions are reported frequently, and good description is available within the literature (J Med Genet 2003:40:385-398). The chromosome 1p subtelomeric deletion has become to have a recognizable phenotype. Children with other deletions have not yet been as well delineated. For example, subtelomeric deletion of 3q is much less common, with only one report (J Med Genet 2001:38:417-20) in the literature. That report noted facial dysmorphism and moderate mental retardation in a two-year old child, but no further elaboration was available. We present a nine-year old pre-pubertal Caucasian male with a de novo subtelomeric deletion on chromosome 3q. He presented with a history of multiple surgeries to correct bilateral ptosis, and mild developmental delay accompanied by behavioral outbursts. On physical exam his growth parameters were on the growth chart, but he had very mild dysmorphism which included ptosis. He had an elevated palate, simple ears, malar flattening, and camptodactyly of his DIP joints. Additionally he had diffuse eczema and a monotone, hoarse voice. By comparison, a two-year old patient with an interstitial deletion of 3q28-3q29, and the subtelomere FISH for 3q present did not have ptosis or other eye findings on clinical exam. Ptosis is a relatively non-specific dysmorphism, and has been associated with many syndromes. FOXL2, the gene mutated in blepharophimosis, ptosis, and epicanthus inversus syndrome (BPES, OMIM 110100) is located on chromosome 3q23, proximal to the subtelomere. There are also reports of ptosis in ring chromosome 3 (Am J Med Genet 39:2:130-2), and distal deletions on chromosome 3p. The paucity of reports of patients with subtelomere 3q deletions raises the possibility for different loci important in eyelid development. Additionally there may be a cis-acting element within the region deleted that may interact with other known loci, such as FOXL2. Comparison of additional patients, and molecular evaluation of their individual deletions will be essential.

A contiguous gene syndrome involving both Elastin gene and ABCB4 gene due to interstitial 7q11.22-q21.2

deletion. *M. Aminah*¹, *Y.S. Choy*², *S.K. Tan*¹, *A. Ruziana*³, *C.B. Lim*³, *N.L. Lim*⁴. 1) Cytogenetic Lab. , Kuala Lumpur Hospital, Kuala Lumpur, Malaysia; 2) Genetics & Metabolism Unit, Pediatric Institute, Kuala Lumpur Hospital, Malaysia; 3) Hepatology Unit, Pediatric Institute, Kuala Lumpur Hospital, Malaysia; 4) Pediatric Department, Selayang Hospital, Malaysia.

The loss of a segment of adjacent/contiguous genes due to the deletion of a segment of chromosome is an important cause to explain an array of apparently clinically unrelated problems in a patient. We reported here a patient who had a normal routine karyotype reported earlier in another center referred to us for further evaluation of dysmorphism associated with chronic cholestatic hepatitis and multiple problems including hypothyroidism, failure to thrive, multiple birth defects, pulmonary stenosis and mitral insufficiency, cutaneous hyperelasticity and hypermobility of joints as well as bladder diverticulum. In addition, he had mild hypercalcemia, hypertension and developmental delay. Biochemical and pathological assessment confirmed intrahepatic cholestasis without biliary atresia. His facies was typical to that of William syndrome. High resolution karyotyping revealed an interstitial deletion of one of the 7q11.22 to q21.1 segment. This deletion encompassed the Elastin gene responsible for William syndrome at 7q11.23 and ABCB4 gene causing Familial Intrahepatic Cholestasis Syndrome explaining the myriad of clinical signs and symptoms in this patient. Other genes potentially involved in this deletion due to haploinsufficiency include CCM1 gene which causes cerebral cavernous malformation, MHS3 gene that predisposes to malignant hypertension and PTPN12 gene that predisposes to colonic cancer later in life. Detection of the deletion provided invaluable information in counseling and management of the patient.

Chromosome 19 q12.q13.3 deletion is associated with severe developmental delay, autism, and anesthesia and sedative sensitivity. *P. Benke, M. Rodriguez, V. Karamanian, M. Floyd.* Div. Genetics, Dept. Pediatrics, Univ. Miami Sch. Medicine, Miami, FL.

Only one patient with a 19 q12.q13.3 deletion has been reported to date. We report here the subsequent course of this patient, interesting because of the progression of her CNS behaviors and delay to an autism-like state, and important because of her severe sensitivity to anesthetic agents and sedatives. The patient is a 9.5 year old girl with chromosome 19 q12.q13.3 deletion previously described as dysmorphic, SGA, and delayed (Kulharya et al; *Amer. J. Med. Genet.* 77:391, 1998). Dysmorphic features, including small head, small size, minor facial anomalies (low set ears, epicanthic folds), oral dysphagia, deafness, brain atrophy, heart anomalies, kidney anomalies and severe developmental delays were observed. She progressed to autistic-like behaviors as she became older, with poor eye focus and interactions, repetitive utterances and hand motions/hand flapping, and self-mutilation and self-stimulation activities. She could stand but not walk, she did not talk, she had poor sleep, and she understood very little. She indicated hunger with increased irritability. Severe drug-sedative sensitivity was observed when she received 30 mg. chloral hydrate for a CNS scan, and then required resuscitation/intubation followed by emergency intervention for a cardiopulmonary arrest 6 hours later. Chronic reflux and poor weight gain led to a fundoplication and G-tube placement. Prolonged recovery time from anesthesia/ketamine and a second arrest followed this procedure. Enzymes that metabolize drugs, including cytochrome oxidase and p450 enzymes are located on chromosome 19q13.1-13.2, and it is likely that their function was compromised by the chromosome deletion. Deletion mapping using microsatellite markers revealed that the deleted region was between Markers DS 19S425 and DS19S412, which contains genes for P450 and cytochrome oxidase. A 19q locus for autism has been suggested. Chromosome 19 q12.q13.3 deletion is a severe MR-dysmorphic-autism-like disorder and is associated with increased anesthesia and sedative drug sensitivity.

Survival to age 40 months in a 69,XXY infant. *R. Best¹, L. D'Souza¹, K. Brooks¹, K. Corning², K. Clarkson².* 1) Dept Obstetrics/Gynecology, Univ South Carolina Sch Med, Columbia, SC; 2) Greenwood Genetic Center, Columbia, SC.

Triploidy, the presence of a complete extra set of chromosomes, is a chromosomal abnormality where the conceptus receives a double chromosomal contribution from one parent. Triploidy accounts for 6% of spontaneous abortions, while only 1% of triploid conceptions survive to term. Triploid fetuses can be classified either as a Type I triploid of paternal (diandric) origin with mild to moderate intrauterine growth retardation (IUGR) and a partial hydatidiform mole, or as a Type II triploid of maternal (digynic) origin having severe, asymmetrical IUGR. Survival of live born triploids is higher for those of digynic origin, and thus far no triploid has been reported to survive beyond 312 days. We report here a triploid male who survived 40 months. The infant was born to a 29-year old healthy female at 30 weeks gestation and required NICU admission for respiratory distress. At birth, the infant weighed 1102 g and presented with several physical abnormalities. Physical examination showed bitemporal narrowing, flat nasal bridge, small mouth, wide alveolar ridge, narrow high palate, patent ductus arteriosus, primary hypospadias, bilateral scrotal hydroceles, hypoplastic nipples, bilateral inguinal hernias, bilateral transverse palmar creases and bilateral syndactyly of the toes. Congenital optic nerve atrophy, macular scarring, and absence of the gallbladder were noted. Lab studies were initiated to exclude Smith-Lemli-Opitz syndrome and cytogenetic abnormalities. 17-dihydrocholesterol values were within normal limits. Cytogenetic analysis of 50 metaphase cells from mitogen-stimulated peripheral blood cultures revealed a 69, XXY karyotype without evidence of mosaicism. The family declined study of skin fibroblasts for further study of mosaicism as well as molecular studies to confirm parental origin. Clinical findings and the extraordinary survival of this child are suggestive of digynic origin.

Hypomelanosis of Ito associated with de novo Extra Structurally Abnormal Chromosomes. *Y.S Choy¹, A. Ruziana², S.K. Tan², L.H. Ngu¹, W.T. Keng¹, I.H.M. Hussain¹.* 1) Genetics & Metabolism Unit, Pediatric Institute, Kuala Lumpur Hospital, Kuala Lumpur, Malaysia; 2) Cytogenetic Laboratory, Kuala Lumpur Hospital, Malaysia.

Hypomelanosis of Ito is a neurocutaneous phenotype with skin hypopigmentation along the lines of Blascko associated with multiple extracutaneous manifestations, mostly of central nervous and musculoskeletal origin. The pathogenic etiologies are heterogeneous but chromosomal mosaicism has been found in about 50% of individuals. Juxtaposition of normal and abnormal neural cells in the brain parallels the cutaneous findings. Here we report 3 patients with hypomelanosis of Ito having mental, psychomotor and speech retardation, hypotonia and behavioral problems associated with de novo extra structurally abnormal chromosomes (ESAC). One of them has a karyotype of 47, XX, +r(X) detected uniformly in all the amniocytes and all the lymphocytes tested. She also has severe bilateral vesicoureteric reflux, dysgenetic corpus callosum and coarse facies. Functional mosaicism of Xp disomy due to the ring lacking in the XIST locus is probably the cause of the disorder as demonstrated in previous studies. The other 2 unrelated patients, a boy and a girl, have an extra bisatellited isodicentric 15 marker chromosome in all the lymphocytes tested. FISH using SNRPN probes confirmed trisomic or tetrasomic dosage of the segment. Apart from the neurobehavioral and cutaneous abnormalities both of them have dysmorphic facies and short stature. Their phenotype is similar to another patient with 46, XY, r(15). Unlike the latter whose hypomelanosis probably due to haploinsufficiency of P genes depending on the size of the ring in different cells, the exact mechanism of hypomelanosis in these two patients is yet to be elucidated.

Program Nr: 718 from the 2004 ASHG Annual Meeting

Chromosome 6 In The Genetic Clinic. *J. Claus, B.G. Kousseff.* Dept Pediatrics, Genetics Div, USF Regional Genetics Program, Tampa, FL.

Between 1/2/81 and 12/31/02 through busy (2002 patient volume 2,797) pediatric and prenatal clinics at the University of South Florida, 42,795 probands/families were evaluated. Thirty-two had anomalous chromosome 6. There were fifteen translocations; t(1;6) was encountered three times, all with different breakpoints. One of them had FISH positive test for DiGeorge syndrome and t(1;6) in his sister. t(3;6) and t(6;9) were encountered twice each, all with different breakpoints, and t(4;6), t(5;6), t(6;7), t(6;12), t(6;14), t(6;15) and t(6;18) were evaluated as singular proband/families each. t(6;6) was a mosaic. Five were maternal, 2 paternal, 3 de novo, 2 had family history of affected individuals and 3 were without complete parental studies. Two probands had complex chromosome rearrangements (CCR) with 4 and 8 breakpoints respectively. The six inversions were 4 pericentric, 1 each maternal, paternal, de novo and 1 with incomplete parental study. The latter had familial Hay-Wells ectodermal dysplasia as well. The two paracentrics were 1 de novo and 1 maternal with X/XX/XXX mosaicism? There were 2 del6q, both de novo (AM J Med Genet 62:105). One dup6q was de novo. There were 4 del6p: 2 de novo and 2 with incomplete parental studies. Among them, 1 de novo and 1 with incomplete study had the same breakpoint, 6p23. Trisomy 6 was encountered in 2 unrelated products of conception as a part of family studies. One of them had a mother with t(10;16), trisomy 16 and triploidy in additional miscarried fetuses. All together 17 proband/families were evaluated through the pediatric clinic, 10 as prenatal patients and 5 as having family history of anomalous chromosome 6. Twenty-five were Caucasians, 3 Hispanic, 1 Afro-American and 3 were biracial. The study emphasized that karyotype/phenotype correlations will be meaningful only if based on large number of patients with completed parental studies. This requires clinical and cytogenetic expertise within the university based genetic programs.

Unsuspected Klinefelter Syndrome diagnosed during oncologic evaluation: a case series. *M.M. Eberl^{1, 2}, M.R. Baer³, L. Fitzpatrick⁴, M.C. Mahoney^{1, 2, 5}, S.N.J. Sait⁶, S. Kakati⁶, A.W. Block⁶, C.D. Farrell⁷.* 1) Division of Cancer Prevention and Population Sciences, Roswell Park Cancer Institute (RPCI), Buffalo, NY; 2) Department of Social and Preventive Medicine, School of Public Health, SUNY Buffalo, Buffalo, NY; 3) Leukemia Section, Department of Medicine, RPCI, Buffalo, NY; 4) Department of Pediatrics, RPCI, Buffalo, NY; 5) Department of Family Medicine, SUNY Buffalo, Buffalo, NY; 6) Clinical Cytogenetics Laboratory, Department of Pathology and Laboratory Medicine, RPCI, Buffalo, NY; 7) Department of Cancer Genetics, Clinical Genetics Service, RPCI, Buffalo, NY.

Klinefelter Syndrome (KS) has significant implications for health and for medical management, however, it remains widely underdiagnosed. Contributing to this lack of recognition is the variable phenotypic expression of KS and the tendency of primary care clinicians to underestimate the prevalence of KS in their patient populations. It is not unusual for KS to elude diagnosis until problems with infertility arise or karyotyping is performed for other reasons, such as the work-up of a malignancy. This report presents one pediatric and five adult male patients with previously undiagnosed KS ascertained as a result of cytogenetic testing for suspected hematologic malignancies. The presenting medical problem, as well as the karyotypic and phenotypic presentations in these cases, will be discussed. Clinical features span the spectrum of classic to subtle phenotypic findings, with age at diagnosis ranging from 7 years old in the pediatric case to 48-67 years in the adult cases. The medical, genetic and psychosocial implications of the KS diagnosis will be explored. Screening and prevention considerations, such as bone density testing in the untreated adult males and timely testosterone supplementation in pediatric cases, will be outlined. Family physicians must become familiar with the more common genetic conditions and their varied presentations. This case series highlights the importance of maintaining a comprehensive and holistic approach to medical care, including regular communications with, and education of, community practitioners.

A locus for Nasal Glioma on chromosome on Chromosome 7p21.1. *S. Ennis*^{1,2}, *K. Ryan*², *P. Carthy*², *A. Dunlop*², *K. Dunne*³, *A.J. Green*^{1,2}. 1) Department of Medical Genetics / Conway Institute of Biomolecular and Biomedical Research, University College Dublin, Crumlin, Dublin 12, Ireland; 2) National Centre for Medical Genetics, Our Ladys Hospital for Sick Children, Crumlin, Dublin 12, Ireland; 3) Dept. of Paediatrics, University College Hospital, Galway, Ireland.

A 2 year old girl was seen in the genetics clinic. She was the second child of healthy unrelated parents, and was referred because of a de novo balanced reciprocal chromosome translocation 46,XX, t(3;7)(p13;p21). Karyotyping had been carried out because of concern over dysmorphic features. The patient was developmentally appropriate, and did not in fact show any dysmorphic features. She had a 1 cm raised lesion on the bridge of her nose, which had been present from birth. MRI scan of her brain did not show any connection between this lesion and the intracranial contents. The lesion was removed, and showed on histology to contain heterotopic glial and neuronal tissue, giving a diagnosis of a nasal glioma. Nasal gliomas are rare usually isolated developmental anomalies, whereby neuronal and glial tissue develops on the bridge of the nose, in the absence of a frontal encephalocele. This individual had a cytogenetically visible de novo apparently balanced reciprocal translocation 46,XX, t(3;7)(p13-p12.3;p21.1). Fine mapping of the 3p and 7p regions was carried out using FISH mapped BACs to establish the location of the break points. FISH analysis indicated a break point between the chromosome 3p clones RP11-90H15 and RP11-79O5 and within the chromosome 7p clone RP11-123E5. Analysis of the break point surrounding regions identified AGR 2 (anterior gradient 2 homolog) a *Xenopus* gene (XAG2), which is critically involved in forebrain development and the most dorsally expressed gene in frog brain development, in close proximity and distal to the 7p break point as a possible candidate gene. A second patient with nasal glioma which occurred as part of a rare genetic disorder, Knobloch syndrome was identified. Sequence analysis of the AGR 2 gene revealed no mutations. We are now recruiting a larger series of patients with non-syndromic nasal gliomas, to look for alterations in the AGR2 gene.

Program Nr: 721 from the 2004 ASHG Annual Meeting

Chromosome 8 In The Genetic Clinic. *G. Jervis*¹, *B.G. Kousseff*², *University of South Florida, Regional Genetics Program.* 1) Clinical, Genzyme Genetics, Tampa, FL; 2) University of South Florida, Regional Genetics Program, Tampa FL.

Between 1/2/81 and 12/31/02 through busy (2002 patient volume 2,797) pediatric and prenatal clinics at the University of South Florida, 42,795 probands/families were evaluated. Forty-nine had anomalous chromosome 8. There were sixteen translocations; t(8;13) was encountered three times, all with different breakpoints. Two had t(5;8) and one each t(1;8), t(2;8), t(3;8), t(4;8), t(6;8), t(7;8), t(8;15), t(8;17), t(8;18), t(8;22) and t(X;8). Six were maternal, 2 paternal, 6 de novo, 1 was with a family history and another with incomplete parental study. One had de novo CCR with 3 breakpoints. There were 11 trisomies, 10 mosaics and 1 trisomy in a POC. The 4 inversions were 2 maternal, 1 paternal and 1 de novo. There were 10 dup 8p; 1 maternal, 6 de novo, and 3 with incomplete parental studies. One of these 3 also had inversion. The 4 del 4p were 2 de novo and 2 with incomplete parental studies. The 3 dup8q were 1 with incomplete parental study and 2 de novo. One of these had also inversion. Thirty probands/families were pediatric, 16 were prenatal, and 3 had family history of anomalous chromosome 8. Thirty-five were Caucasians, 7 Hispanic, 6 Afro-American and 1 was biracial. The study emphasized that karyotype/phenotype correlations will be meaningful only if based on large number of patients with completed parental studies. This requires clinical and cytogenetic expertise within the university based genetic programs.

Program Nr: 722 from the 2004 ASHG Annual Meeting

CHROMOSOME 5 IN THE GENETIC CLINIC. *M. Jodah, B.G. Kousseff.* Dept Pediatrics, USF Regional Genetics Program, Tampa, FL.

Between 1/2/81 and 12/31/02 through busy (2002 patient volume 2,797) prenatal and pediatric genetics clinics at the University of South Florida 42,795 probands/families were evaluated. Fifty-two had anomalous chromosome 5. Twenty three had translocations; 4 had t(5;7) with different breakpoints. Three each had t(3;5) and t(5;19) respectively. Two each showed t(5;9), t(5;18), t(1;5), t(5;8) and t(2;5) respectively; all with different breakpoints. One each had t(4;5), t(5;6), and t(5;15), respectively. Six were maternal with one showing 47,XXY as well. Three were paternal and 5 denovo. Among the latter there was one with Trisomy 21. Five had complex chromosome rearrangement (CCR) all denovo. Two had 3 breaks each and one each had 6, 8, and 10 breaks respectively. There were 18 probands with del 5p; 9 were denovo with 1 of them having a father with 46,XY/47,XXY. A male with del 5p had a mosaic mother and a female had a mother who also had del 5p. A family was studied for del 5p in a first cousin. A prenatal study showed mosaic del 5p in chorionic villi sampling and 46, XX in amniocytes, pseudomosaicism. The remaining 5 had incomplete parental studies. The 4 inversions were 1 paracentric and 3 pericentric. Two of the 3 pericentric were maternal. The 2 del 5q were interstitial in one and a terminal in another, both denovo. Seventeen were prenatal, 1 had family history of del 5p and 34 were evaluated through the pediatric clinic. Thirty-eight were Caucasians, 8 Hispanic, 5 African-Americans, and 1 of mixed race. This study demonstrates the wealth of information available in busy genetics clinics having cytogenetics laboratory as part of the genetic program.

Disruption of the gene Euchromatin Histone Methyl Transferase1 (Eu-HMTase1) is associated with the 9q34 subtelomeric deletion syndrome. *T. Kleefstra¹, M.J.G. Banning¹, H. van Esch², W. Nillesen¹, A.R. Oudakker¹, A. de Brouwer¹, H.G. Yntema¹, N. de Leeuw¹, B.C.J. Hamel¹, E.A. Sistermans¹, C. van Ravenswaay¹, M. Smidt³, H.G. Brunner¹, B.B.A. de Vries¹, H. van Bokhoven¹.* 1) Human Genetics, UMC ST Radboud, Nijmegen, Netherlands; 2) Centre for Human Genetics, University Hospital Leuven, Belgium; 3) Rudolf Magnus Institute of Neuroscience, University Medical Center Utrecht, The Netherlands.

Submicroscopic subtelomeric deletions have recently been reported to account for ~ 5% of the total population of mental retardation. Some submicroscopic telomeric deletions are rather common which allow recognition of a specific phenotype. Recently, several patients have been reported with a terminal submicroscopic deletion of chromosome 9q. Common features seen in these patients are severe mental retardation, hypotonia, brachycephaly, flat face with hypertelorism, synophrys, anteverted nares, thickened lower lip and carp mouth with macroglossia and conotruncal heart defects. The minimal critical region responsible for this 9q subtelomeric deletion phenotype (9q-), has been previously estimated to be ~1 MB. We have detected an interstitial deletion 9q34.3 in a patient with a phenotype that is clearly different from the 9q- deletion phenotype. The distal endpoint of this interstitial deletion seems to be close or overlapping with the common breakpoint region in 9q- deletion patients, suggesting a more distal localization of the causative gene(s) for the 9q- phenotype. In a second patient, we characterized the breakpoints of a de novo balanced translocation t(X;9)(p11.23;q34.3). This patient is a mentally retarded female patient with features similar to those seen in the 9q- phenotype. Molecular investigations revealed that the chromosome 9 breakpoint disrupted the gene Euchromatin Histone Methyl Transferase 1 (Eu-HMTase1), situated in the refined critical region at the telomeric end of chromosome 9q. Expression data suggest that Eu-HMTase1 is highly abundant in brain and heart tissue and is likely to play an essential role in early embryonic development. These data strongly suggest that haploinsufficiency of Eu-HMTase1 is responsible for the 9q- phenotype.

Interstitial deletion of 13q associated with polymicrogyria. *J.M. Kogan¹, J.C. Egelhoff², H.M. Saal¹*. 1) Division of Human Genetics, Cincinnati Childrens Hospital Medical Center, Cincinnati, OH; 2) Department of Radiology, Cincinnati Childrens Hospital Medical Center, Cincinnati, OH.

Deletion of the long arm of chromosome 13 is a rare condition characterized by a range of clinical findings. We report a male dizygotic twin with a karyotype of 46,XY,del(13)(q14.1q31.2). His clinical findings include failure to thrive, hypotonia, polymicrogyria, bilateral foci of retinoblastoma, a mild hearing deficit, bilateral inguinal hernias, a submucous cleft palate, and dysmorphic features including a triangular shaped face, a small chin, protuberant eyes, downslanting palpebral fissures, and a downturned mouth. Chromosome analysis revealed an interstitial deletion of chromosome 13 which was confirmed by FISH analysis to include the Rb locus, but spare the 13q subtelomeric region. The karyotype was 46,XY,del(13)(q14.1q31.2).ish del(13)(RB1-,D13S327+) *de novo*. The parents karyotypes were normal. Retinoblastoma tumors are a well known complication of deletion of the retinoblastoma susceptibility gene, located at chromosome 13q14.2. Growth retardation is another common feature that has been described in other patients with a deletion of 13q. At 4 months of age this patient had brain findings on MRI consistent with bilateral frontal polymicrogyria. Another MRI at 13 months of age revealed additional involvement of the temporal lobes and left parieto-occipital cortex, as well as prominent infratentorial and supratentorial vasculature. Polymicrogyria is a disorder of neuronal migration resulting in cortical malformation characterized by numerous and shallow sulci. There are a variety of polymicrogyria syndromes that are distinguished by the cortical location of the abnormal folding. Several of the subtypes have known genetic loci associated with them. To our knowledge, this is the only published case of polymicrogyria in association with a deletion of chromosome 13. Additional studies need to be done to further characterize the relationship between chromosome 13q and polymicrogyria. Nevertheless, these findings reinforce the need for chromosome analysis in any patient with polymicrogyria.

Questionnaire-based comprehensive study of infants with trisomy 18 in Japan. *T. Kosho*¹, *H. Kuniba*², *Y. Tanikawa*³, *Y. Hashimoto*⁴, *H. Sakurai*⁵, *Y. Fukushima*¹. 1) Dept Medical Genetics, Shinshu Univ Sch Medicine, Nagano, Japan; 2) Department of Pediatrics, St.Barnabas' Hospital, Osaka, Japan; 3) Kobe City College of Nursing, Hyogo, Japan; 4) Sanno Institute of Psychology, Tokyo, Japan; 5) Trisomy 18 Support Group in Japan, Nagano, Japan.

Management of infants with trisomy 18 has been controversial, though it is the second most common autosomal trisomy in liveborn infants. Insufficient data about the natural history are one of the most important factors. We conducted a questionnaire-based comprehensive study of infants with trisomy 18 in Japan to help delineate the natural history. We collected data about pregnancy, delivery, complications, interventions, growth, development, and parental narratives from 88 families (the response rate was 70%) in Trisomy 18 Support Group in Japan. 58 % of the babies were delivered by C-section. Mean gestational age was 38 weeks and 5 days and mean birth weight was 1869g. Survival rate was 80 % at 1 month and 31 % at 1 year. Major cause of death was heart failure due to congenital heart diseases (53%). Convulsion, observed in 20 % of the infants, disappeared or improved in 35 %, was stable in 50 %, and worsened in 15 %. In 5 long-term survivors over 10 years old, 4 accomplished fully oral feeding and 3 walking alone. 54 % could go home. In those receiving respiratory supports (50 %), 45 % could withdraw them. 18 operations including 5 cardiac surgeries were performed. While 32 % of the families were presented by medical staffs the principle that the babies would be treated as intensively as possible, 39 % were offered some limitations of the therapies. From parental narratives, many felt happy with the babies birth and existence themselves. They also felt dissatisfaction with the stereotyped opinions from many medical staffs that any aggressive treatments would not be recommended without any sufficient informations about daily lives of the survivors and activities of the support group. Though considering inevitable ascertainment bias and inaccuracy in collecting data, the results will provide informations useful in counseling families of fetuses and infants with trisomy 18.

CHROMOSOME 4 IN THE GENETIC CLINIC. *B. Kousseff.* Pediatrics & Genetics, USF Regional Genetics Prog, Tampa, FL.

Between 1/2/81 and 12/31/02 through busy (2002 patient volume 2,797) prenatal and pediatric genetics clinics at the University of South Florida 42,795 probands/families were evaluated. Forty-nine had anomalous chromosome 4. Nineteen had translocations; 3 each had t(1;4) and t(4;11); all with different break points. One t(4;11) was mosaic. Two each had t(3;4), t(4;5),t(4;9),and t(4;12); all with different breakpoints. One each had t(2;4), t(4;6), t(4;8), t(4;10), and t(4;16). Four were maternal, 3 were paternal, 4 were denovo and 8 were with incomplete parental studies. Four had complex chromosome rearrangement (CCR): two each had 4 and 3 breakpoints. Two were with paternal translocations, 1 with t(4;7), and t(13;18), and another with t(1;4) and ins(4). There were 10 probands with del 4p; 3 denovo and 7 with incomplete parental studies. They demonstrated the varied phenotype of Wolf-Hirschhorn syndrome based on the size of the deleted segment of 4p. The 5 inversions were 3 paracentric and 2 pericentric. Among the paracentric there was 1 denovo and 2 with incomplete parental studies. The 2 pericentric were 1 maternal and 1 paternal. There were 3 dup 4p all denovo with breakpoint at p16. The 3 del 4q were one denovo, del 4q32 and 2 interstitial with incomplete parental studies. Both dup 4q were interstitial and without parental studies. There were 2 denovo ring (4) and 1 trisomy 4 that resulted in a miscarriage. Thirteen probands were prenatal and 36 were evaluated through the pediatric clinic. Thirty-nine were Caucasians, 5 Hispanic, 4 African-Americans, and 1 Chinese. This study demonstrates the wealth of information available in busy genetics clinics having cytogenetics laboratory as part of the genetic program.

A case of 20p trisomy syndrome resulting from a tandem duplication of whole short arm of chromosome 20. *H. Maruyama, T. Satoh, M. Shinozuka, S. Ninomiya, Y. Yokoyama, T. Morishima.* Department of Pediatrics, Okayama University Graduate School of Medicine and Dentistry, Okayama, Okayama, Japan.

(Introduction) Trisomy 20p is rare and 54 cases were reported in our knowledge. Major parts of trisomy 20p are the product of reciprocal translocations. A few cases are caused by parental chromosomal inversions. We report the first case of 20p trisomy syndrome resulting from tandem duplication of whole short arm of chromosome 20. (Clinical features) The proband, a 1-year-and-4-month-old girl, was referred to us for the evaluation of multiple congenital malformations. The infant was born at 40 weeks of gestation. The birth weight was 3949g. Physical examination showed flat occiput, coarse hair, round face, upslanted palpebral fissure, hypertelorism, prominent anteverted nose, low set ear, simian crease, webbed neck, thorax deformity, cubitus valgus, hypotonia, delayed dental eruption and developmental delay. Echocardiogram showed ventricular septal defect. The computed tomography of the brain revealed agenesis of corpus callosum. (Cytogenetic analysis) Peripheral blood lymphocytes were cultured from the patient and both parents. GTG banding of the patient showed that an unknown origin chromosome was added to the short arm of chromosome 20. Spectral karyotyping showed the extra material to be of chromosome 20 origin. So we diagnosed that the karyotype of this patient was 46, XX dup(20)(p11.2p13). The parents had normal chromosomes. (Conclusion) A trisomy 20p syndrome has been difficult to describe as many cases involve only partial trisomy, often with partial monosomy of the partner chromosome. As our patient is an example of pure trisomy 20p, the features are important in helping to delineate the syndrome. In our case, agenesis of corpus callosum was found. So it might be a new feature of trisomy 20p.

Multiple congenital anomalies in a mexican patient with trisomy X syndrome. *P. Medina, S. Monroy, V. del Castillo, R. Cruz, L. Gomez, A. Gonzalez del Angel.* Department of Human Genetics, Instituto Nacional de Pediatría, Mexico city, Mexico.

The trisomy X syndrome is caused by nondisjunction at maternal meiosis I. It is observed in approximately 1 in 1000 newborn females. Women with 47,XXX karyotype often have a normal phenotype with relatively tall stature and normal pubertal development, hormone levels, and reproductive competency. In some patients multiple congenital anomalies have been described as malformations of the urogenital tract, brain, skeleton, heart, pulmonary hypoplasia and craniofacial dysmorphisms such as short palpebral fissures, midface hypoplasia, long philtrum, square chin and abnormal ears but without a consistent phenotype. They are at risk for developmental delay, including language and learning impairment, mild global intellectual deficits and psychiatric disturbances as schizophrenia. We report an 8 year old female, her parents were healthy without history of consanguinity, and she had 3 healthy sisters and a healthy brother. She had mild global intellectual deficits, minor dysmorphisms such as short palpebral fissures, retrognathia and a broad nose. By echocardiogram a displasic pulmonary valve, persistent arterial conduct and tricuspid deficiency were detected. Abdominal ultrasonography showed right ectopic kidney and extensive collector system. Ophthalmologic evaluation detected a left iris colobome and bilateral dacryostenosis. Karyotype analysis of lymphocyte and fibroblast cells showed 47, XXX in all metaphases examined. The ophtalmologic abnormalities seen in our patient have not been previously described in trisomy X syndrome. In fact, the congenital anomalies that have been reported in patients with 47, XXX karyotype may be coincidental or they can be etiologically related to the aneuploidy. Establishing genetic counseling and a direct relationship between congenital anomalies and 47.XXX remains difficult, as in the present case, especially because of the lack of a distinct phenotype. Further clinical data are needed to resolve this question.

Platelet dysfunction in a patient with 11q24.2 monosomy. *D. Melis¹, L. Pecoraro¹, F. Majo¹, R. Genesio², A. Conti², M. Tardi¹, D. De Brasi¹, V. Barletta¹, F. Fabbrini², R. Della Casa¹, G. Andria¹, G. Sebastio¹.* 1) Dept Pediatrics, Federico II Univ, Naples, Italy; 2) Dept Biology, Molecular and Cellular Pathology, Federico II Univ, Naples, Italy.

Jacobsen syndrome is characterized by psychomotor and growth retardation, microcephaly, trigonocephaly, facial dysmorphism, thrombocytopenia, eye and heart anomalies. We describe a patient with 11q24.2 deletion. At birth, thrombocytopenia was observed; percentage of chromatide breaks and bone marrow analysis were normal. She was admitted every 6 months until she was 5 years old. Physical examination showed mild mental retardation, short stature, clinodactyly and dysmorphic features including relative macrocephaly, downslanting palpebral fissures, hypertelorism, broad flat nasal bridge, short nose, carpe-shaped mouth, short neck. The mean platelet volume and the platelet count were checked periodically during the follow-up and a cyclic pattern was observed. A low platelet count with normal mean platelet volume was observed in the first year of life; mean platelet volume was found to be increased afterward. Direct and indirect test for platelet antibodies were negative. Peripheral blood smear, performed at the latest control, showed few giant platelets. A reduced platelet aggregation after exposure to ADP and collagene was scored. A low-normal aggregation capacity was also observed after exposure to ristocetin and arachidonic acid. The phenotype of the six patients with 11q24.2 deletion described in the literature is characterized by short stature, macrocephaly, mild mental retardation, hypertelorism, carpe-shaped mouth, broad flat nasal bridge, short nose, short neck and clinodactyly, not including trigonocephaly, microcephaly, severe mental retardation, ocular and cardiac malformation, which are typical of Jacobsen syndrome. By analyzing the phenotype of these patients it is possible to hypothesize a typical phenotype for the monosomy 11q24.2. No systematic study of thrombocytopenia and platelet function has ever been performed in the patients with 11q24.2 deletion. The detection of platelet dysfunction could suggest that a gene involved in platelet function is present at 11q24.2.

Alagille syndrome resulting from an apparently balanced de novo translocation: 46,XX,t(1;20)(p22.1;p11.2). R. Segel¹, J.M. Cowan¹, R.P. Spiro², L.A. Demmer¹. 1) Pediatrics, Tufts Univ. School of Medicine, Boston, MA; 2) National Birth Defects Center, Waltham, MA.

Alagille syndrome (AGS; McKusick no. 118540) is an autosomal dominant developmental disorder affecting multiple organ systems with variable expressivity. Alagille syndrome was mapped to 20p11.2-p12.2 and subsequently *JAG1* mutations and gene deletions were demonstrated in AGS. Although it has been suggested that AGS patients with large deletions may be more prone to developmental delay and hearing loss, no clear genotype-phenotype correlation has been identified for AGS gene mutation or deletion carriers. To date, two cases of AGS associated with reciprocal translocations have been reported. The first patient was found to have a 2-3Mb deletion at the chromosome 20 breakpoint and had the typical facial, liver, cardiac, skeletal and eye findings described in AGS, as well as FTT and microcephaly, but no developmental delay. Her father and sister also carried the translocation but were less severely affected. The second patient was found to have a >3Mb deletion which included *JAG1* and presented with typical dysmorphic features and liver disease, complex congenital heart disease, heart failure, and poor weight gain. We present a new case of AGS arising as a result of a de novo translocation. Our patient has the typical facial features of Alagille syndrome, VSD, PDA, direct hyperbilirubinemia, elevated liver enzymes, posterior embryotoxon, and a butterfly vertebra. Hearing screen was normal, as was renal ultrasound. Growth and development are normal at 8 months. The pregnancy was achieved via IVF/ICSI with fresh sperm 18 months after the father had completed chemo/radiotherapy to the groin for non-Hodgkin's lymphoma. Parental karyotypes were normal.

Future counseling for this couple presents several challenges. There is an accumulating literature suggesting an increased frequency of chromosome anomalies in offspring conceived via ICSI. In addition this father's lymphoma treatment increases his risk of producing chromosomally abnormal sperm. This couple should be offered prenatal diagnosis in all future pregnancies.

Tandem duplication of chromosome 7q11.22-q21.11 in a patient with developmental delay. *E. Seo¹, N.E. Lanphear², S.W. Scherer³, L.R. Osborne⁴.* 1) Medical Genetics Clinic & Lab, University of Ulsan, Asan Medical Centre, Seoul, Korea; 2) Pediatrics, Cincinnati Childrens Hospital Medical Center, Cincinnati, OH; 3) Genetics and Genomic Biology, Hospital for Sick Children, Toronto, Ontario, Canada; 4) Medicine, University of Toronto, Toronto, Ontario, Canada.

Duplication of the long arm of chromosome 7 is very rare and the clinical presentation is extremely heterogeneous, depending on extent and composition of chromosome bands included within the duplication. We present the first patient to be reported with a confirmed duplication of the chromosome region 7q11.22-q21.11 including the interval commonly deleted in Williams-Beuren syndrome (WBS). This male patient presented at the genetics clinic at the age of 7 months with hypotonia and dysmorphic features. The patient is now 18 months old and is at 50th centile for weight and height with a head circumference in the 10-25th centile. Echocardiogram was normal and there was no evidence of involvement of the eyes or kidneys. He has developmental delay, with greatest deficits in gross motor skills and oral motor skills, including expressive language. His facial features are not typical of WBS with low set ears and a very small mouth, and he has no vocalization pattern and has not yet been weaned from the bottle. Karyotyping revealed a tandem duplication of 7q11.23-q21.2 that was confirmed by fluorescence in situ hybridization with probes spanning the region. The duplication was shown to extend approximately 16.5 Mb from RP11-325K1 to RP11-665O4. Both his parents had normal karyotypes and FISH analysis did not show a duplication. The clinical characteristics of this patient are different from those of WBS and suggest that individuals presenting with WBS-like features are unlikely to carry a duplication of 7q11.23. This study provides new information for the clinical characterization of duplications of chromosome 7q11.22-q21.11.

Familial tandem duplication of chromosome 20p. A. Shanmugham¹, S. Gupta², P. Koduru², A. Yenamandra³, L. Mehta¹. 1) Schneider Children's Hospital at North Shore; 2) Cytogenetics Laboratory, North Shore University Hospital, Manhasset, NY; 3) Vanderbilt University, School of Medicine.

Duplication of chromosome 20p is a rare abnormality described in association with developmental disabilities and birth defects. We present an 8 year old girl with a history of learning disabilities, strabismus and bifocal vision abnormalities, short stature, relative macrocephaly and subtle facial dysmorphisms, including a round face with micrognathia and prominent forehead. She is classified as learning disabled with global delays, most marked in fine motor performance and visual motor skills. Chromosome analysis identified a chromosome 20p duplication [46,XX,dup(20)(p11.2p12)]. Parental blood chromosome analysis identified the father of the patient to have the same duplication [46,XY,dup(20)(p11.2p12)]. Proband's father also reported learning disabilities and short stature. He also has minor facial dysmorphisms and no medical problems. Chromosome 20p duplication is mainly reported in association with unbalanced chromosome translocations where there is aneuploidy for other chromosome segments. This patient and her father carry a rare tandem duplication. To our knowledge, only one other familial tandem duplication of chromosome 20p has been reported (Moog et al, 1996). Reported findings of partial 20p trisomy are moderate mental retardation with speech delays and poor motor coordination. Heart, renal and vertebral defects have also been reported. A recognizable facial phenotype has been suggested with a round face, prominent cheeks, short nose, dental abnormalities, and coarse hair. Our patients present with a milder phenotype with regard to cognitive abilities and birth defects. This may be due to the lack of other associated chromosome imbalances as found in unbalanced translocation outcomes. Further cases of tandem 20p duplications are required to establish a more definitive phenotype.

A new microdeletion syndrome associated with congenital diaphragmatic hernia at chromosome 15q26. *A.M. Slavotinek¹, M. dela Cruz², S.S. Lee¹, R. Davis³, A. Shrit⁴, E. Carlson², D. Albertson³, D. Pinkel³.* 1) Dept Pediatrics, UCSF, San Francisco, CA; 2) Genome Core Facility, UCSF, San Francisco, CA; 3) Comprehensive Cancer Center, UCSF, San Francisco, CA; 4) Dept. Pathology, Miami Valley Hospital, Dayton, OH.

Congenital diaphragmatic hernia (CDH) occurs in 1 in 2500 live births and is associated with a high perinatal mortality. The genetic etiology of this sporadic malformation remains unknown. Chromosome abnormalities have been reported in 10-33% of patients and these cases frequently have additional anomalies. We are currently using array comparative genome hybridization (array CGH) to detect submicroscopic chromosome rearrangements in CDH with malformations suggestive of Fryns syndrome. In a deceased female infant who was small for gestational age and had CDH, pulmonary hypoplasia, cleft palate, hypoplastic left heart syndrome, a single umbilical artery and talipes, we found reduced copy number for two BAC clones at chromosome 15q26.2. Microsatellite marker analysis showed a deletion of the maternal allele for D15S1014 mapped to 15q26.2, confirming an interstitial deletion estimated to be between 4 and 10 Mb in size. A karyotype at 400-band resolution had shown an apparently normal female karyotype (46, XX). There are 4 previous reports of CDH and pure monosomy for chromosome 15q24 to 15qter and the critical region for a gene involved in diaphragm formation has been hypothesized to be between chromosome 15q26.1 and 15q26.2. Clinical findings besides the hernia have included reduced growth parameters, minor craniofacial dysmorphism, congenital heart disease, pulmonary hypoplasia, renal hypoplasia, fifth finger brachydactyly and clinodactyly, talipes equinovarus and a single umbilical artery. We consider that these anomalies constitute a new and recognizable contiguous gene deletion syndrome associated with CDH at chromosome 15q26. Our case is the first report of CDH associated with a submicroscopic deletion and we consider that testing for deletions of band 15q26 is indicated for CDH with additional malformations consistent with 15q26 deletion syndrome.

A new case of terminal deletion of the long arm of chromosome 13 revealed by subtelomeric FISH-analysis. *M.I. Soller¹, G. Blennow²*. 1) Clinical Genetics, Lund University Hospital, Lund, Sweden; 2) Pediatrics, Lund University Hospital, Lund, Sweden.

We report on a 1-year-old boy with mild to moderate mental retardation with speech retardation, microcephaly, mild hypertelorism, short philtrum and malformed ears. The high-resolution G-band karyotype was normal. Fluorescence in situ Hybridization (FISH) with specific probes of chromosomal telomeric regions (ToTelVysion Probe Panel) to metaphase spreads were then used and showed a terminal deletion of the long arm of chromosome 13, band q34 ((VIJ yRM2002, D13S327). The parents showed normal chromosomes. Several cases with deletions of distal parts of the long arm of chromosome 13 have been published, but only one previous case revealed an identical sole subtelomeric terminal deletion of 13q34. In both patients the phenotype was characterized by mild to moderate mental retardation, mild facial dysmorphism, microcephaly, low birth weight, and hypertelorism. The mild phenotype might explain why only two patients with this deletion have been described so far.

Characterisation of chromosomal deletions involving 3q26->3q28 using a novel method for Multiplex Ligation-Dependent Probe Amplification, and relation of deletion position to clinical phenotype. *R. Stern¹, C. Mackie Ogilvie¹, A. Male¹, D. Bonneau², A. Guichet², R. Roberts¹, J. Berg^{1,3}.* 1) Medical and Molecular Genetics, Guy's Hospital, London, United Kingdom; 2) Service de Gentique Medicale, CHU Angers, France; 3) Department of Molecular and Cellular Pathology, Ninewells Hospital and Medical School, Dundee, DD1 9SY, U.K.

A number of patients have been reported with a complex clinical phenotype caused by deletions involving chromosome 3q26 ->q28. The phenotypic features reported include anophthalmia/severe microphthalmia which is presumed to be due to deletion of SOX2. Additional features are seen, including microcephaly, a hypoplastic pituitary, intrauterine growth retardation (IUGR), midline brain defects, abnormal neuronal migration and unilateral absence of the first cranial nerve, which may be caused by contiguous deletion of other genes in the region. Multiplex ligation-dependent probe amplification (MLPA) is a technique for determining copy number changes at multiple target loci. We wished to use this technique to assess copy number changes in this region. This technique utilises two sequence tagged half-probes corresponding to the target loci, which are ligated together and then amplified by universal primers complementary to the sequence tags. However, the probe sets need to be generated by cloning in single-stranded bacteriophage vectors. To circumvent this time-consuming process, we successfully developed a novel approach using synthetic oligonucleotide probes to analyse these patients by MLPA. Our data from the analysis of two patients suggests that the minimum candidate interval for the genes causing microcephaly, IUGR and a small pituitary is approximately between 178.8 and 189.1MB (ensembl build v22), including the genes *chordin* and *dishevelled*, implicated in neuronal and eye development. The interval for absence of the corpus callosum, unilateral absence of the first nerve and abnormal neuronal migration is wider at 12.5 MB between 178.9 and 191.4MB, but may be restricted to the interval between 189.1 and 191.4MB. This region contains *claudin 1*, an integral membrane protein involved in tight junctions and expressed in the occipital lobe.

Costovertebral dysplasia caused by dup22(pter->q11.2). *V.S. Tonk¹, G. Wilson^{1,3,4}, R. Schutt², G. Wood¹, H. Wyandt⁵, M. Ito⁵.* 1) Department of Pediatrics, Texas Tech University, Lubbock, TX; 2) Department of Orthopedics, Texas Tech University, Lubbock, TX; 3) Cook Children's Hospital, Fort Worth, TX; 4) Texas Child Neurology, Plano, TX; 5) Center for Human Genetics and Department of Pediatrics, Boston University School of Medicine, Boston, MA.

Here, we report a female infant affected with costovertebral dysplasia (CVD) presented with subtle facial anomalies and neonatal respiratory distress. The child has had severe growth and developmental delay due to pulmonary insufficiency and hypoxia during 11 months of her life. Two prior reports (before banding technology) of D/G and D/D translocations associated with costovertebral dysplasia suggest that imbalance of a peri-centromeric region common to chromosomes 14 and 22 may cause this anomaly. Her karyotype demonstrated an extra NOR-positive fragment, and subsequently it was identified as chromosome 22 (pterq11.2pat) by fluorescent and DNA microsatellite marker studies. Our study strongly indicates a partial trisomy of chromosome 22 is a cause of CVD in this case.

Unbalanced subtelomeric rearrangement involving the terminal ends of chromosome 4 and 7: Case report, review of the literature and discussion of 4q deletion phenotype. *P. van Galen¹, M. Innes¹, J. Chernos², K. Bowser².*
1) Dept of Medical Genetics, Alberta Children's Hosp, Calgary, AB, Canada; 2) Cytogenetics Laboratory, Alberta Children's Hosp Calgary, AB Canada.

We report on a boy with a subtle chromosome 4q35-qter deletion initially detected by G band analysis at the 625-650 band level previously missed at 550-600 band level. Subsequent subtelomere FISH with a multi-telomere probe panel (ToTelvysion) showed the abnormal chromosome 4 to be derived from an unbalanced translocation between the distal long arm of chromosome 4 and chromosome 7 resulting in deletion of 4q35-4qter and duplication of 7q36-7qter. Parental chromosomes by G banding analysis were normal indicating a de novo event. Clinical findings include: mild developmental delay, ADHD, macrocephaly, hypotonia, V shaped cleft palate, small VSD, bilateral optic nerve hypoplasia, short palpebral fissures, epicanthal folds, short upturned nose, long simple philtrum, and small simple posterior rotated ears. Given the combination of cleft palate and VSD he had been previously diagnosed clinically with VCFS despite normal 22q11 FISH. We are aware of only one similar case of a familial cryptic translocation resulting in two brothers with deletion of 4q33-4qter and duplication 7q34-7qter. Similar features are limited to macrocephaly and ADHD suggesting limited involvement of the single band 7q36 duplication in our patient. Instead our case supports previous observations of a distinct phenotype associated with terminal deletion of chromosome 4 and validates a correlation between the severity of phenotype and amount of deleted chromosome. Common features of 4q terminal deletion syndrome include short nose with abnormal bridge, cleft palate, congenital heart defects, poor postnatal growth, hypotonia and moderate to severe MR. This case emphasizes the role of subtle subtelomeric rearrangements in the etiology of mild MR and the importance of preceding subtelomere FISH with high resolution G band analysis.

Speech and language impairment and oromotor dyspraxia due to deletion of 7q31 which involves FOXP2. S.

Zeesman^{1,2}, *M.J.M. Nowaczyk*^{1,2,3}, *I. Teshima*^{4,5}, *W. Roberts*⁵, *J. Oram Cardy*⁶, *J. Brian*⁵, *L. Senman*⁵, *S. Choufani*⁷, *L.R. Osborne*^{8,9}, *S.W. Scherer*^{7,8,9}. 1) Dept of Pediatrics, McMaster University Medical Center, Hamilton, ON, Canada; 2) Hamilton Regional Lab Medicine Program, Hamilton Health Sciences, Hamilton, ON; 3) Dept of Pathology and Molecular Medicine, McMaster University, Hamilton, ON; 4) Dept of Pediatric Lab Medicine, Hospital for Sick Children, Toronto, ON; 5) Dept of Pediatrics, University of Toronto and Hospital for Sick Children, Toronto, ON; 6) Dept of Medical Imaging, University of Toronto and Hospital for Sick Children, Toronto, ON; 7) Dept of Genetics and Genomic Biology, Hospital for Sick Children, Toronto, ON; 8) Dept of Medicine, University of Toronto, Toronto, ON; 9) Dept of Molecular and Medical Genetics, University of Toronto, Toronto, ON, Canada.

We report the clinical, cytogenetic and molecular findings in a girl with a deletion of chromosome 7q31-q32. This child has a severe communication disorder with evidence of oromotor dyspraxia, dysmorphic features and mild developmental delay. Notably, she is unable to cough, sneeze or laugh spontaneously. Her deletion includes the FOXP2 gene, which has recently been associated with speech and language impairment and a similar form of oromotor dyspraxia in at least two other unrelated families. We suggest that the probands communication disorder and oromotor deficiency are due to haploinsufficiency for FOXP2 and that her dysmorphism and developmental delay are a consequence of the absence of the other genes involved in the microdeletion. Taken together with results from the literature, our findings suggest that the child's presentation may define a new contiguous gene deletion syndrome encompassing the 7q31-FOXP2 region. Cytogenetic and molecular analysis of this region should be considered for other individuals displaying similar characteristics.

13q critical region for anorectal and urogenital anomalies. *A.R. Zinn¹, L.J. Santos¹, R.A. Schultz², N.M. Garcia³, L.A. Baker⁴.* 1) McDermott Center for Human Growth & Development, UT Southwestern Med School, Dallas, TX; 2) Dept. of Pathology, UT Southwestern Med School, Dallas, TX; 3) Dept. of Surgery, UT Southwestern Med School, Dallas, TX; 4) Dept. of Urology, UT Southwestern Med School, Dallas, TX.

Introduction: The 13q-deletion syndrome includes severe genitourinary and anorectal birth defects. Bartsch et al. (Am J Med Genet 65:218, 1996) have suggested a critical region for these anomalies in the interval of 13q32.2-34. We sought to narrow this critical region, thereby delineating the causal gene(s) mediating these anomalies.

Methods: Nine patients with known deletions around 13q32-qter were ascertained. Peripheral blood was obtained from patients and available parents. Deletions were mapped by loss of heterozygosity of microsatellite markers and/or by fluorescence in situ hybridization (FISH) on patient lymphoblastoid metaphase preps. The data were synthesized and a deletion map defining the critical region was generated.

Results: The patients fell into three groups: 1) four patients with anorectal and/or genitourinary anomalies (hypospadias and/or penoscrotal transposition), 2) three male patients with developmental delay but no anorectal or genitourinary anomalies, and 3) two XY patients with ambiguous genitalia without anorectal anomalies. The proximal boundary of the critical region was delimited by marker D13S280 in 13q33.1.

Conclusions: The critical region of chromosome 13q mediating genitourinary/anorectal anomalies has been mapped to an 11 Mb interval. Haploinsufficiency of 13q shows incomplete penetrance for anorectal and genitourinary anomalies. There may be a second locus in 13q31.3 mediating ambiguous genitalia. Mapping additional deletions will narrow the critical region. Identification of the gene(s) mediating these syndromic genitourinary defects will likely further our knowledge of molecular mediators of nonsyndromic hypospadias, penoscrotal transposition and anorectal malformations.

Expanded phenotype of the 22q duplication syndrome. *S. Hassed, S.A. Vaz, J. Lee, J.J. Mulvihill, S. Li.* Dept Pediatrics/Genetics, Univ Oklahoma Medical Ctr, Oklahoma City, OK.

The velocardiofacial, DiGeorge, and Sphrintzen syndromes result from microdeletions in a critical region on chromosome 22q and, hence, are collectively termed the 22q deletion syndrome. Like other microdeletion syndromes with a paired condition due to duplication of the same genomic region, the 22q deletion syndrome has a complementary 22q duplication syndrome, represented by xx published cases with mild craniofacial anomalies and slight developmental or cognitive delay. To add to the spectrum of the 22q duplication phenotype, we report an 18-year-old female with chronic aortic regurgitation, mild mitral and tricuspid regurgitation, recurrent renal infections, kidney stones, and pyelonephritis resulting in surgery to remove scar tissue and reimplant ureters,, hypernasal speech, normal intelligence, and features of Asperger syndrome. Family history revealed her mother had hypernasal speech and no other health problems. A brother had severe strokes in his 20s, due to cerebrovascular hemorrhage. The patient had 46,XX karyotype in all blood cells, and FISH studies with TUPLE2 showed duplication of 22q identified on interphase cells. The 22q duplication syndrome may not be so benign a condition as previously described and may share features with 22q deletion syndrome. Again, it is suggested that, in all FISH studies, interphase cells be scanned along with the metaphase cells, since duplications are much more obvious in interphase cells than in metaphase cells.

Y chromosome sequences in two patients with true hermaphroditism. *J. Toscano-Flores^{1,2}, M. Diaz-Rodriguez^{1,2}, J.R. Padilla^{1,2}, F. Rivas¹, M.L. Ramirez-Duenas¹.* 1) Western Biomedical Research Center, Instituto Mexicano del Seguro Social; 2) Graduate Studies Program in Human Genetics, Universidad de Guadalajara, Guadalajara, Mexico.

True hermaphroditism (TH, OMIM #235600) is a rare dysfunction (1:20,000 newborns) of sex differentiation, in which ovarian and testicular tissues coexist in one or both gonads. The most common karyotype is 46, XX, and few cases are familial. Two newborn patients from healthy and non-consanguineous parents with TH are presented here. Both cases had a 46, XX karyotype (>16 cells analyzed per case) on cytogenetic analysis. The first patient was evaluated at two months of age for ambiguous genitalia. In addition, physical examination showed asymmetric gonads (only one palpable in scrotum), small penis, and urogenital sinus. The second, a 6 month-old patient presented with a 2.5 cm phallus with an open urethral fossa, perineo-scrotal hypospadias, and no palpable gonads in the scrotum. Histopathologic studies revealed the presence of normal left ovary and right ovotestis in patient 1, and bilateral ovotestis in patient 2. Y chromosome sequences (STR markers: DYS390, DYS391, DYS392, DYS393 and DYS19), detected by PCR PAGE, were positive in both patients. Ambiguous genitalia in a newborn is a situation of social urgency, that requires immediate intervention. In the present cases, in addition to contributing to precise diagnosis and surgical treatment, positive Y sequences allow for a better classification of TH cases. Since these Y STRs span throughout the Y chromosome, the presence of hidden mosaicism is concluded. This approach can prove useful in the practice of clinical genetics.

Chromosome 1p36 deletion: A case with multiple anomalies overlapping VATER association. *M.G. Bialer¹, S. Race¹, R. Schiff¹, R. Smith¹, D. LaGrave², J. Neidich², B. White², A. Anguiano².* 1) Dept Pediatrics, North Shore LIJ Health System, Manhasset, NY; 2) Quest Diagnostics-Nichols Institute, San Juan Capistrano, CA.

The 1p36 deletion syndrome is the most common chromosome abnormality detected by subtelomeric FISH screening, with estimates of prevalence as high as 1 in 5,000. Cases typically have cognitive delay, dysmorphic features and congenital anomalies, most commonly congenital heart disease and cleft lip (CL)/palate. We present a case of 1p36 deletion with several previously unreported anomalies resulting in overlap with VATER association. Comprehensive U/S during the pregnancy revealed bilateral choroid plexus cysts (CPC) and a unilateral CL. Amniocentesis chromosomes, AFP, 22q11 FISH and fetal echo were reported to be nl. However, after birth, Ped. Cardiology evaluation revealed fenestrated foramen ovale and multiple muscular VSD's (swiss cheese septum) with large LR shunt. Genetics evaluation at 27 days revealed left thumb hypoplasia, complete left CL and alveolus, large anterior and posterior fontanelle and shawl scrotum. Renal U/S was nl. Vertebral X-rays revealed a butterfly vertebra at T7. Hand X-rays revealed hypoplastic 1st metacarpals and phalanges bilaterally. At this time the diagnosis of VATER association was considered, as there were 3 typical anomalies and other features were compatible. A blood chromosome analysis and DEB-stimulated chromosome breakage study were nl. When the patient developed seizures at 2 mo and was diagnosed with a mixed hearing loss, the diagnosis was reconsidered. Subtelomeric FISH screening was sent and revealed del(1)(p36.3). Parental subtelomeric FISH testing was nl. This case has 3 anomalies that we believe are previously unreported in 1p36 deletion syndrome: CPC, butterfly vertebra and thumb hypoplasia. Although the usual indication for subtelomeric FISH screening has been cognitive delay, this case was ascertained because of multiple congenital anomalies, seizures and hearing deficit. Subtelomeric FISH screening should be contemplated if a diagnosis of exclusion is being considered, e.g. VATER or CHARGE association, especially if there are atypical features.

Down Syndrome: twenty eight mexican patients from a second level Childrens Hospital. *L. Cornejo^{1,2}, E. Medecigo¹, L. Islas¹, R. Perez¹.* 1) Genetics, Hospital del Niño DIF, Pachuca de Soto, Hidalgo, Mexico; 2) Area Academica de Medicina, Instituto de Ciencias de la Salud, Universidad Autonoma del Estado de Hidalgo, Pachuca de Soto, Hidalgo, Mexico.

Introduction. There has been multiple reports about Down Syndrome from divers populations as the most frequent chromosomal alteration but from Hidalgo State, Mexico. These disease is the most frequently seen in our Genetic Department. Objective: To report the first large series of Down Syndrome patients from our Hospital focus in: medical demand attention timing, maternal and paternal age at the conception time, karyotyping results, and associated malformations. Material: Twenty eight patients attended at the Hospital from April 2003 to March 2004. The patients were clinically and karyotyping tested. They were attendent also at least in the Cardiac and Endocrinology departments. Results: Twenty seven patients were isolated cases (96%); sixteen patients were females (57%), and twelve patients were males (42%). Eighteen patients (64%) has been assisted at the hospital in their first year of life, the mean for this group was 2.8 months old; for those patients assisted after, the mean was 6 years old, two years old the youngest and 15 years old the oldest. October was the mode of the month to be born with six cases. The mean for maternal age was 30 years old, 19 years old the youngest and 42 years old the oldest; the mean for paternal age was 34 years old, 19 years old the youngest and 64 years old the oldest. Second gestation was the mode for gravity with six cases. We found fifteen cases out of eighteen (83%) with cardiac anomaly, and the PCA as the most common alteration. All isolated cases showed a regular 21 trisomy. All patients were normal for thyroid function. Two cases (7.17%) had imperforate anus, one of these was born from a diabetic mother; one patient (3.57%) had bilateral hearing loss; and, one patient (3.57%) had seizures. Conclusion: Maternal age as risk factor starts earlier than general population, cardiac (but malformation type)malformations are higher and endocrinology function is lower than the generally reported. We will look for a cross-sectional study in near future.

Implications of dup(8)(q24.1qter) and/or del(15)(q26.1qter) in Fryns syndrome. *C. Higgins, G.B. Schaefer, Z. VanDyke, T. Hempel, D. Pickering, M. Nelson, W.G. Sanger, B.J. Dave.* Univ Nebraska Medical Ctr, Omaha, NE.

We present a case of a deceased newborn male with a der(15)t(8;15)(q24.2;q26.2) and the clinical manifestations suggestive of Fryns syndrome. The infant was the product of a complicated pregnancy of a 38 year old primigravid female. Prenatal assessment revealed IUGR, hypoplastic left heart with a small VSD, hydronephrosis, a two-vessel cord, club feet, oligohydramnios, and a suspected congenital diaphragmatic hernia (CDH). Amniocytes revealed a 46,XY karyotype. The infant was born at term with a low birth weight and poor APGAR scores. Clinical exam shortly after birth confirmed the prenatal findings including CDH. Additionally, the infant had low-set, malformed pinnae, a flat nasal bridge, prominent forehead, anteverted nares, retromicrognathia, a microphallus and no palpable testes. The digits were angulated with hypoplastic nails. These findings were suggestive of Fryns syndrome. Cytogenetics, FISH, CGH, and DNA microarray studies were performed postnatally on blood lymphocytes and skin fibroblasts. A der(15)t(8;15) was cytogenetically detected only on prometaphase chromosomes at a 750 band level. FISH studies on blood and fibroblasts using subtelomeric probes detected a deletion of terminal 15q, which was replaced by an 8q telomere. Subsequent CGH and DNA microarray further delineated the breakpoints. CGH demonstrated the loss of terminal 15q and gain of terminal 8q. However, the DNA microarray studies allowed a delineation of the breakpoints within 8 megabases. The microarray analysis revealed that the genes located in 15q26.1 remained intact whereas those located in 15q26.3 and the 15q telomere were deleted. Thus, a deletion of the genes distal to 15q26.1 and/or the duplication of the region distal to 8q24.1 may be implicated in the congenital abnormalities observed in some cases of Fryns syndrome. A combination of prometaphase analysis, FISH, CGH and DNA microarray investigations in this case with a cryptic chromosomal abnormality facilitated the localization of the breakpoints. This illustrates the importance of an ever-increasing need to use technologies beyond conventional cytogenetics in the diagnosis of congenital abnormality syndromes.

Genetic and molecular analysis of a large cohort of patients with syndromic and non-syndromic trigonocephaly - screening for loss of heterozygosity in 9p and 11q regions. *F.S. Jehee¹, D. Johnson⁴, K. Abe¹, L. Alonso³, N. Alonso², C. Kim², D. Cavalcante⁶, S.A. Wall⁴, S. Boyd⁵, E. Jabs⁵, A.O. Wilkie⁴, M.R. Passos-Bueno¹.* 1) CEGH, IBUSP, Brazil; 2) FMUSP, Brazil; 3) UNIFESP, Brazil; 4) Craniofacial Unit, Oxford, UK; 5) Johns Hopkins University, USA; 6) UNICAMP, Brazil.

Trigonocephaly is mostly caused by craniosynostosis of the metopic suture and is characterized by a triangular forehead. It occurs as an isolated or syndromic malformation and affects more males than females. Little is known about the genetic aetiology of trigonocephaly and different models of inheritance have been proposed. Environmental factors, such as valproic acid, hyperthyroidism and microcephaly can also induce trigonocephaly. Deletions in two chromosomal regions, del(9p22-24) and del(11q23-24), are associated with syndromic phenotypes and include usually trigonocephaly. To contribute to a better understanding of the genetic basis of metopic synostoses we evaluated a large cohort of patients with syndromic and non-syndromic trigonocephaly. Additionally, we performed a loss-of-heterozygosity analysis to detect microdeletions and further restrict the 9p and 11q candidate regions. Our sample consisted of 96 patients, 39 non-syndromic, 35 syndromic, 5 with secondary trigonocephaly and 17 without complete clinical data. Consanguinity and multiplex families were observed in 3.9% and 10.4%, respectively. Male preponderance was higher in syndromic patients (4.2:1) than in non-syndromic (1.8:1). The empirical recurrence risk for non-syndromic and syndromic trigonocephaly were 2.8% and 11.8%. These data suggest that syndromic and non-syndromic cases may have different aetiology. We believe that the main inheritance pattern for non-syndromic trigonocephaly is multifactorial and that there is a greater involvement of genes on the X chromosome in syndromic cases. We found 7 deletions in syndromic patients: 6 in 9p and 1 in 11q, so the detection rate in the syndromic group was 20%. We conclude that microdeletion screening for 9p22-24 and 11q23-24 should be offered to all cases of syndromic trigonocephaly. FAPESP, CEPID (jehee@uol.com.br).

Partial trisomy 16p de novo duplication of p11.2p13.1 in three unrelated patients. *K. Keppler-Noreuil¹, K. Mathews², S. Patil¹.* 1) Dept Pediatrics/Med Genetics; 2) Div. of Ped. Neurology, Univ. of Iowa Hosps & Clinics, Iowa City, IA.

Complete trisomy 16p has been described with a similar pattern of malformations, including low birth weight, severe developmental delay, seizures, characteristic facial features, cleft palate, CHDs, renal and GU anomalies. Partial trisomy 16p may involve different regions with variable clinical findings, but most reported cases involve the entire short arm, and often are associated with other chromosome imbalance in a translocation. We report here the clinical and cytogenetic findings of 3 unrelated cases with de novo duplication of 16p involving p11.2p13.1 and compare the findings with 5 other reported cases.

Case 1, a 6 yr old girl, was diagnosed at 2 years of age with developmental delay (IQ 60-70); microcephaly, short stature and GH deficiency; VSD, coarctation, and mitral stenosis; cerebellar hypoplasia; and craniofacial findings of hypertelorism, epicanthal folds, posteriorly rotated ears, broad nasal bridge with anteverted nares. Her karyotype: 46,XX,dup(16)(p11.2;p12). Case 2 presented at 2 yrs with global developmental delay, small stature, 1 seizure, normal HC, and craniofacial findings of high nasal bridge, up-slanting PFs, and prominent mouth. His karyotype: 46,XY,dup(16)(p11.2;13.1). Case 3, 4 yrs, had seizures, hypotonia, developmental delay, tremor, VUR, anteriorly placed anus, normal growth, and craniofacial findings of mild hypertelorism, and shallow orbits. Her karyotype: 46,XX,dup(16)(p12.2;p13.11).

These cases with similar duplicated regions involving 16p11.2p13.1 had in common mild developmental delay, seizures, short stature and craniofacial abnormalities. However, other anomalies were variable. The 5 other reported cases in the literature also involved 16p11p13, three having involvement of 16p11.2p12. The only consistent finding among the combined 8 cases was developmental delay, and >50% had seizures, hypertelorism, narrow palpebral fissures, large nasal bridge, and low set ears, these being milder, but reminiscent of cases with complete trisomy 16p. All cases lacked life-threatening medical complications.

Bone ossification study in patients with achondroplasia. *M.G. Arteaga-A^{1, 2}, A. Gonzalez-DA², V. DelCastillo², H. Ahumada³, R. Castillo⁴.* 1) Depto. Genetica, Facultad de Medicina, UANL, Monterrey, N.L., Mexico; 2) Depto. Investigacion en Genetica Humana,; 3) Depto. de Radiologia e Imagen,; 4) Subdireccion de Investigacion, Instituto Nacional de Pediatria, Mexico.

Achondroplasia is the most common chondrodysplasia, with a frequency of about 1 in 15,000. It is caused by a mutation of the FGFR3 gene on chromosome 4 (4p16.3), coding for the fibroblast growth factor receptor; the altered FGFR3 is constitutively activated with unregulated signal transduction through the receptor, resulting in an inappropriate cartilage growth plate differentiation and ultimately deficient endochondral growth. Major clinical manifestations are easy to recognize: disproportionate short-limb dwarfism, macrocephaly, midfacial hypoplasia, rhizomelic micromelia, trident hand with relatively short fingers, limitations of elbow extension, kyphosis at thoracolumbar junction in infancy. The clinical diagnosis must be supported by radiological features: large calvaria with prominent frontal; decreased size of the skull and the foramen magnum; decrease in the interpediculate distance from upper to lower lumbar spine; flat, rounded iliac bones; shortening of the tubular bones; square or oval radiolucent areas in proximal femur and humerus in infancy; retarded and irregular ossification in the knee region; disproportionate shortness of the humerus and lengthening of the fibula. After detect disturbance of the bone ossification in a few patients we found that there aren't radiographic standards of skeletal development for patients with bone dysplasias and we consider is necessary to find a better method to detect abnormalities in this process than the visual matching process of the hand. For determinate the possible bone maturation disturbance of these patients, we evaluated bone radiographies of 47 patients from both sexes, with achondroplasia, admitted to the Genetic department of the INP since 1991 to june 2003, using the method of Garn et al, which evaluate in percentiles 19-20 ossification centers, according to sex and age, using three radiographs: hand, foot and knee. After skeletal assessment, we correlated the clinical findings of medical files. We present and discuss the results.

Increased risk of cardiovascular disease in a patient with Marfan Syndrome and a homozygous C677T mutation of the MTHFR gene which has been associated with Homocystinuria. *D. Basel, M.W. Kilpatrick, P. Tsipouras.*
Genetics and Developmental Biology, Univ Connecticut Hlth Ctr, Farmington, CT.

We present a 39-year old man who was diagnosed clinically with Marfan Syndrome based on the Ghent criteria. Subsequent analysis of the Fibrillin gene (FBN1) led to the identification of a C2001T mutation in exon 15 predicting a phenylalanine for cysteine amino acid substitution at residue 623 (C623F). The patient required aortic surgery. Pre-operative testing identified elevated levels of plasma homocysteine leading to molecular analysis of the n(5,10)-methyltetrahydrofolate reductase (MTHFR) gene. A homozygous C677T mutation of the gene was detected. The primary gene involved in homocystinuria is cystathionine beta-synthase (CBS). However, mutations in the MTHFR gene have been implicated as a cause of homocystinuria. The C677T mutation produces a thermolabile enzyme with reduced activity resulting in increased levels of homocysteine. This finding is in keeping with a recent history of 2 thrombo-occlusive episodes in our patient. He has experienced deep vein thromboses and cerebrovascular accidents (CVA) involving his visual cortex bilaterally. The presence of MTHFR homocystinuria is a confounding factor in an individual with Marfan syndrome and it impacts on the cardiovascular management of this patient. The relative frequency of homozygous C677T mutations in the general population warrants screening for the presence of this mutation in patients with Marfan syndrome.

Clinical characteristics of NF2 associated ependymomas. *F. Nunes, J. Harrington, M. MacCollin.* Dept Neurology, Massachusetts General Hosp, Charlestown, MA.

Ependymomas have been reported in approximately 33% of neurofibromatosis 2 (NF2) patients. Because spinal tumors, including ependymomas, schwannomas, and meningiomas, occur in up to 90% of NF2 patients it is imperative to understand the natural history of these tumors before deciding on intervention. Thirty-nine patients meeting diagnostic criteria for NF2 and showing radiographic characteristics of spinal ependymomas were included in this study. Full record review included clinical data, imaging studies, surgical reports, pathology reports and mutational analysis of the *NF2* gene. All tumors showing radiographic characteristics of ependymomas were located in the spinal cord, with no supra-tentorial ependymomas occurring among these patients. Eighty-two percent of the patients showed intramedullary tumors at the level of the cervical cord and cervical medullary junction confirming that this is a site of predilection for these tumors in NF2 patients. Thoracic ependymomas were seen in 44% of the patients. Multiple tumors were seen in 66% of patients with coexisting cervical and thoracic tumors seen in 33%. Only seven of 39 patients (20%) required intervention because of tumor related symptoms, including limb weakness (50%), pain (33%), and gait disturbances (17%). Mutational analysis of the *NF2* gene in genomic DNA was performed in 25 unrelated patients, with frameshift and nonsense mutations present in 40% of the patients. Splice site alterations were found in 20% of the patients, and in 40% mutations could not be found. No missense mutation was seen in this cohort. Interestingly, in a large family with exon 12 splice site mutation cervical ependymomas were seen in 8 members. In conclusion, ependymomas in NF2 patients have the cervical cord and cervical medullary junction as a site of predilection, and seldom require intervention. Further work is needed to define the molecular events in the *NF2* gene or elsewhere which predispose to ependymoma development.

Anthropometric landmarks from 3dMD surface images: a study of accuracy and repeatability. *K. Aldridge¹, S.A. Boyadjiev Boyd², V.B. DeLeon¹, J.T. Richtsmeier¹*. 1) Dept Anthropology, Pennsylvania State Univ, University Park, PA; 2) McKusick-Nathans Institute of Genetic Medicine, Baltimore, MD.

Anthropometric landmarks are a powerful tool for the assessment and characterization of facial dysmorphology. However, the collection of quantitative data from young children, especially those with associated developmental disability, can be challenging. Here, we test the accuracy and repeatability of landmark data collected from 3-dimensional images obtained by 3dMD photogrammetry technology. 3dMD imaging captures surface information in 2 msec., permitting rapid and noninvasive data collection. We obtained two surface images from each of 7 adults and 8 children. 3D landmark coordinate data were collected from 20 precisely-defined facial landmarks by two observers in separate trials. Analysis of interlandmark linear distances calculated from these combined data allowed to test between-scan accuracy and within- and between-observer repeatability. Results indicated between-scan accuracy was good. However, landmarks on the jaw had a relatively high level of between-scan variance, likely explained by movement at the TMJ between scans. Also, trigion, on the ear, had relatively low accuracy and apparent poor resolution of tragus, attributed to the oblique angle at which the surface of the tragus is captured. Within- and between-observer repeatability was acceptable and showed similar results, with the highest repeatability at the canthic and lip folds and on mediolateral placement of midline landmarks. Relatively lower repeatability was observed at gonion and superoinferior placement of midline landmarks, particularly glabella. Low repeatability at these landmarks is comparable to that observed in other modes of anthropometric data collection. These results support the use of surface imaging for analysis of facial phenotypes. Data is captured instantly and provides highly accurate information about surface morphology. However, care should be taken in selecting appropriate landmarks. We demonstrate that precise landmark definition, including detailed instructions for visualizing and collecting landmarks, substantially improves both within- and between-individual repeatability.

The OEIS complex in two brothers born to consanguineous parents. *S. Ala-Mello, H. Laivuori.* HUSLAB
Department of Clinical Genetics, Helsinki University Central Hospital, Helsinki, Finland.

The OEIS complex is a rare combination of malformations comprising omphalocele, exstrophy of the cloaca, imperforate anus, and spinal defects (Carey et al. *Birth Defects Orig Art Ser XIV(6B)* 1978;14:253-263). The etiology is probably heterogeneous. The higher incidence of the OEIS complex in monozygotic twins than in dizygotic twins suggests a possible genetic contribution to the occurrence of these defects. Most cases of the OEIS complex are sporadic, but it has recurred in two children from separate pregnancies born to non-consanguineous parents (Smith et al. *J Med Genet* 1992;29:730-732). Here we report the findings of two brothers with the features of the OEIS complex born to consanguineous Kurdish parents (first cousins). Their third child was born at 30 weeks of gestation weighing 1540g, and died within an hour after delivery. The necropsy showed postaxial polydactyly of fingers and toes, dilated renal pelvices, biliary atresia, anal atresia, short bowel, pulmonary segmentation defects, heart defects (transposition of great arteries, single ventricle), absent tracheal opening, and micrognathia. The karyotype was normal (46,XY). Their fourth child was born at 36 weeks of gestation weighing 2510 g. After delivery several defects were noted: exstrophy of the cloaca with hypoplastic external genitalia, imperforate anus, omphalocele, and club feet. Radiological examination showed defects at the thoracic vertebral bodies (VII, IX and XI). The ultrasound examinations of heart and brain were normal, but the left kidney was not visualised. The karyotype was normal (46,XY). The recent literature has demonstrated the variability in the OEIS complex (Keppler-Noreuil et al. *Am. J Med Genet* 2001;99:271-279). The findings observed in these two brothers have been previously described in the spectrum of the OEIS complex (Oxford Medical Databases). We suggest that autosomal recessive inheritance is likely within this family.

AMNIOTIC BANDS SEQUENCE WITH BILATERAL FACIAL CLEFTS AND ENCEPHALOCELE. LE.
Becerra-Solano, M. Díaz-Rodríguez, ML. Ramírez-Dueñas. CIBO-IMSS, Guadalajara, Jalisco, Mexico.

The amniotic deformity, adhesion, and mutilation (ADAM) sequence is characterized by amputations, limbs are the most commonly involved, but it may be associated with a wide spectrum of congenital anomalies. Its inheritance is not clear. We describe a 13-months-old male, product of the first pregnancy from a young nonconsanguineous couple, without important familial antecedents. Abortion threatening at 4 month of pregnancy because of urinary and vaginal infection. At 8 months the obstetric ultrasound detected encephalocele; labor was induced unsuccessfully. Vaginal delivery at 42 weeks of gestation. Birth weight was 2.4 kg, length not recorded and Apgar score 9-10. Physical examination showed weight 4,2 kg and length 72 cm. Head circumference was not measured, because of a parietal encephalocele of 10-15 cm, with alopecia in the top, narrow bifrontal cranial diameter, prominent metopic. Face with bilateral longitudinal cleft (Tessier: 4 and partial 5-10) through superior lip to nasolacrimal union, as a consequence it was formed a V shaped cleft palate and a communicating cavity between nose and mouth. The disruption continued through parietal bones to posterior fontanelle. Coloboma of eyelids, ulcerous lesion in right cornea and opacity in left cornea. Wide nasal bridge and the premaxilla was separated of the face by the cleft. Pectus excavatum, heart auscultation with holosystolic murmur and sinusal pauses. Hypertonia of extremities, bilateral adducted thumb; right leg had a circumferential constriction. Rest of the exploration was normal. The patient died at 19-months-old by respiratory infection, but autopsy was no performed. Karyotype was 46,XY and cranial computed tomography showed mild cortical atrophy and absent parietal bones. There are few reports of ADAM associated to encephalocele and bilateral symmetrical facial clefts, their affectation degree was not so severe, but with a shorter term survival than our patient. This is the first report, to our knowledge, with such an association; it could be explained by a fortuitous event, but the disruption of ADAM as the basic defect, for both encephalocele and facial clefts, can not be rejected.

Sirenomelia with bilateral absent radii and oligodactyly: a new syndrome or a variant of the VACTERL association? *H. Berger*¹, *S. Keating*², *S. Viero*², *M. Thomas*³, *D. Chitayat*³. 1) Obstetrics and Gynaecology, Mount Sinai Hospital, Toronto, Ontario, Canada; 2) Department of Pathology and Laboratory Medicine, Mount Sinai Hospital, Toronto, Ontario, Canada; 3) Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto, Ontario, Canada.

Sirenomelia is a rare congenital malformation characterized by single or fused lower limbs and other anomalies. Invariably, it is associated with urogenital abnormalities resulting in severe oligohydramnios. The incidence of this disorder is 1:60000 - 1:100,000 births and in most cases the abnormalities are restricted to the lower part of the body. We reviewed all cases with sirenomelia detected at our center and report two cases with similar upper limb abnormalities. There is a debate regarding the etiology of sirenomelia with some suggesting that it is but a variant of the Caudal Regression Syndrome (CRS). Others have noted an association between VACTERL and sirenomelia. The presence of upper limb abnormalities in three of ten cases detected in our center could support this association. However, the finding of two cases, in families of the same ethnic background (Sri-Lankan), with the same pattern of upper limb abnormalities, raises the possibility that this is a previously unidentified syndrome.

Bladder exstrophy-epispadias complex: analysis of 232 families. S.A. Boyadjiev Boyd¹, G.H. Ashrafi¹, C.L. Radford¹, S. South¹, G. Stetten¹, Y. Lakshmanan², J.L. Dodson², J.P. Gearhart². 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Division of Pediatric Urology, The James Buchanan Brady Urological Institute, Johns Hopkins University School of Medicine.

Objective: To identify genetic and non-genetic factors contributing to the risk of bladder exstrophy-epispadias complex (BEEC). **Patients and Methods:** A total of 291 BEEC families were invited to participate in this study and 232 of those were recruited. Epidemiologic information was obtained from 151 families, and a detailed clinical genetic examination was performed on 94 probands. More than 500 DNA samples were collected from 183 families for molecular analysis. **Conclusions:** BEEC is a sporadic isolated birth defect with a recurrence risk well below 1%. Among patients, 95% were Caucasian, and males were more common in both the epispadias group (M/F=2.2, n=29) and the classic bladder exstrophy group (M/F=1.8, n=164). In the cloacal exstrophy group, however the sex ratio was close to unity (M/F=1.1, n=15). A statistically significant association with advanced parental age was observed ($p < 0.001$). Birth weight, gestational age, maternal reproductive history, and exposures to tobacco and alcohol, did not appear significantly different from the general population. Seven affected had anomalies outside of the BEEC spectrum, but none of probands had defined syndromes or developmental delays. A male patient with classic bladder exstrophy and an apparently balanced *de novo* translocation 46,XY,t(8;9)(p11.2;q13) was identified. The chromosome 9 breakpoint was mapped within *CASPR3*. Multiple copies of this gene flanking the heterochromatic region on chromosome 9 were identified by FISH. Molecular analysis of the *HLXB9*, which causes Currarino syndrome, did not detect mutations in the blood or bladder DNA of ten BEEC patients. Expression profiling of developing, normal, and exstrophic human bladder identified a group of 154 potential candidate genes for SNP based association studies of case-parent BEEC trios.

Small head circumference of newborns as a possible Chernobyl aftermath. *G. Lazjuk¹, I. Zatsepin¹, R. Khmel¹, P. Verger², E. Robert-Gnansia³, B. Gagnière⁴.* 1) Belarus Institute for Hereditary Diseases, Minsk, Belarus; 2) Observatoire Régional de la Santé PACA, Marseille, France; 3) Institut Européen des Génomutations, Lyons, France; 4) Institut de Radioprotection et de Sûreté Nucléaire, Paris, France.

It is a well known fact that even relatively small doses of in utero radiation exposure of the fetuses can induce microcephaly and mental retardation (UNSCEAR, 1988; D. Bard et al., 1997). To assess a possible teratogenic impact of Chernobyl accident, we analyzed the anthropometrical sizes of infants, born in 1986 and 1987, whose mothers during the pregnancy were living in the settlements with ¹³⁷Cs soil contamination of at least 555 kbq/m², the information was obtained from medical records on delivery and infants development. The surveyed group contained 912 cases and 1121 cases were taken as the control. The newborns with the disorders that can effect the head size, twins and the cases with incomplete information on newborns were not analyzed. The analyses were performed using parametric (t-test for independent samples) and nonparametric (Mann-Whitney U Test and Kolmogorov-Smirnov test) tests of homogeneity. The rates of infants with small anthropometrical sizes, determined from centile tables for the gestational age, were compared using ² test. To determine head circumference deficiency, the centile tables according to weight were also used. The control group showed no statistically significant differences in the length and weight of the newborns. On the contrary, the mean head circumference of newborns from the exposed group was 1.1 cm smaller than in the control. Moreover, the rate of newborns with small head circumference was twice as high in the exposed group (4.1% versus 2.0%, for their gestational age and 1.2% versus 4.4%, when weight was considered). We tend to relate the finding with radiation exposure of the growing brain of the fetus and to verify, if a deficient head circumference of newborns with other normal anthropometrical sizes is a mild microcephaly.

Unilateral Split Hand/Foot Malformation, Hypogonadotropic Hypogonadism and Anosmia: Variation of Cleft Hand-Absent Tibia, Ectrodactyly-Ectodermal Dysplasia Clefting or Kallmann Syndromes? *J.F. Macayran¹, P. Lee¹, E. Vilain^{1,2}*. 1) Pediatrics, Univ California, Los Angeles, CA; 2) Human Genetics, Univ California, Los Angeles, CA.

We describe an 18-year-old male with unilateral ectrodactyly, developmental delay, hypogonadotropic hypogonadism with bilateral cryptorchidism, hearing loss, myopia, and anosmia.

He was born with a hand deformity and leg length discrepancy. The left hand and foot were normal. The right upper extremity had a split hand malformation with three rays. The distal right tibia was hypoplastic. The right foot was adducted and small but had five toes. He also had: developmental delay, mild mental retardation, hearing loss, myopia, anosmia, micrognathia, patent ductus arteriosus, rib and vertebral anomalies, scoliosis, osteoporosis, bilateral cryptorchidism, and hypogonadotropic hypogonadism. High resolution karyotype was 46,XY.

This constellation of symptoms involving ectrodactyly of the hand and lower limb anomaly falls into the category of cleft hand and absent tibia, also known as split-hand/foot malformation with long bone deficiency, initially described by Roberts in 1967. However, there are also features that fit more in the spectrum of ectrodactyly-ectodermal dysplasia and cleft lip/palate syndrome (EEC) in which hearing loss, vision abnormalities, cryptorchidism, and hypogonadotropic hypogonadism have been described. But this case showed no evidence of ectodermal dysplasia or clefting. In addition, EEC often has bilateral ectrodactyly which is not the case here. Characteristics of anosmia and hypogonadotropic hypogonadism raise the possibility of Kallmann syndrome. Both mental retardation and hearing loss have been seen in Kallmann syndrome; however, ectrodactyly has not been described. The pituitary and olfactory defects may be attributable to a generalized clefting phenomenon occurring in EEC. We characterize this case as cleft hand and absent tibia with some features of EEC syndrome, including hypogonadotropic hypogonadism, cryptorchidism, and hearing loss.

Follow-up of an infant with harlequin ichthyosis. *L. Mehta¹, T. Cavaliere¹, P. Shineman², M. Bialer¹.* 1) Schneider Children's Hospital at North Shore, Manhasset, NY; 2) Huntington Hospital, Huntington, NY.

Harlequin ichthyosis (HI) is a rare, severe, congenital hyperkeratinization disorder. It is considered autosomal recessive. The genetic defect remains unknown. Survival is reported to be limited. A particularly distressing appearance at birth contributes to the impression that HI is lethal. Several survivors are now reported, the oldest being about 9 years. We present follow up on an infant now 2 years old. He was born to healthy non-consanguineous parents at 32 wk. gestation after premature rupture of membranes. Prior to delivery, sonogram findings included an open mouth, protruding tongue and echogenic amniotic fluid. These findings are reported elsewhere (Vohra, et al, 2003). At birth, typical findings of HI were present, with armor-like plaques of thickened, fissured skin over the body and scalp, ectropion, eclabium, small hypoplastic nose, no visible external ears, digit deformities and undescended testes. Chromosomes and TGM1 gene analysis were normal. Research studies on skin confirmed the diagnosis (Dale lab). After 6 weeks of supportive and topical care, most skin plaques had shed. Underlying skin was bright red and shiny, suggestive of ichthyosiform erythroderma. He was eating well and went home. Weight progressed at 5% and height at less than 5%. At age 2, cognitive, social and speech development appear age appropriate. He has no medical problems unrelated to HI. The most persistent plaques are on the scalp and feet. Scalp hair is present, though sparse. Teeth erupted normally. Nails are thick and require frequent cutting. Vision and hearing are normal. Ear canals require frequent clearing. Eyelids, nose and external ears remain hypoplastic. Joint limitations and thumb contractures have resulted in gross and fine motor delays. The parents of this child remain deeply committed to his care and are his main caregivers. The chief components of skin care are baths, emollients and exfoliating lotions. Despite the major psychosocial and economic impact of HI, results of treatment can be gratifying and the condition is not always lethal, as implied in the literature. This information is important for counseling parents at the time of diagnosis.

Malformations in Fetal Carbamazepine Syndrome. A. Rasalam¹, J. Reid², D. Lloyd², J. Little³, D. Shaw³, P. Turnpenny⁴, S. Moore⁵, J. Dean⁶. 1) Dept. of Child Health, University of Aberdeen; 2) Neonatal Unit, NHS Grampian; 3) Dept. of Medicine and Therapeutics, University of Aberdeen; 4) Peninsula Genetics Service, Exeter; 5) Medical Genetics Program, Memorial University, Newfoundland; 6) Dept. of Medical Genetics, NHS Grampian.

Carbamazepine is commonly used to treat epilepsy and bipolar disorder. In a population based cohort study to investigate teratogenic effects of antiepileptic drugs (AEDs) conducted in Aberdeen, Scotland, families were ascertained through maternity records indicating maternal AED use in pregnancies delivering between 1981 and 2001. 626 pregnancies exposed to AEDs were identified from a total birth cohort of 125728 (5 per 1000 livebirths). These children were born to 389 mothers, who were invited to an assessment interview. 159 mothers and their 260 children participated. Case records of those who declined, were audited, to assess any bias. In the participating cohort, 85 children were exposed antenatally to carbamazepine alone. 15 (18%) had developmental delay and 9 (11%) had major malformations. Malformations included inguinal hernia (3), submucous cleft palate (1), VSD(1), pelvi-ureteric junction obstruction (1), pyloric stenosis (2), and 2 male siblings with ambiguous genitalia (androgen receptor defect excluded). Excluding cases with hernia and pyloric stenosis, only 5 children have major malformations (6%). In the case records audit, 48 children were exposed to carbamazepine alone, of whom 4 (8%) have major malformations (2 fused labia, 1 CDH, and 1 inguinal hernia). Overall, 13/133 (9.8%) children exposed to carbamazepine alone have major malformations. In the participating cohort, a further 8 children have major malformations amongst 32 exposed to carbamazepine and other AEDs. Malformations include hernia (2), CDH(1), cleft palate (1), hypospadias (1 also exposed to valproate), neural tube defect (1), talipes equino-varus (1) and ambiguous genitalia (also exposed to lamotrigine). Genital malformations have occurred in 5 children exposed to carbamazepine alone or in combination. This association has not been reported before. We present case studies of these children to contribute to knowledge of carbamazepine teratogenesis.

Multiple congenital anomalies of unknown etiology: A retrospective review. *S.R. Sanders¹, J.A. Evans^{1,2}, A.E. Chudley^{1,2}, S. Phillips^{1,3}, B.N. Chodirker^{1,2}.* 1) Section of Genetics and Metabolism, Department of Pediatrics and Child Health; 2) Department of Biochemistry and Medical Genetics; 3) Department of Pathology, University of Manitoba, Winnipeg, Manitoba, Canada.

Accurate diagnosis of multiple anomaly syndromes is important for a number of reasons including genetic counseling and preventative healthcare. Unfortunately, the diagnosis is often not apparent at the time of the initial assessment. The diagnosis may only become available later when more syndromes are delineated or when newer technologies become available. We therefore hypothesized that a re-evaluation of previously undiagnosed cases using currently available databases would allow for a significant number of diagnoses to be made. We searched our clinic database to identify all patients with at least 2 major anomalies without a specific diagnosis. The charts including photographs were reviewed and evaluated using POSSUM, LDDDB, OMIM and Medline. An attempt was made to contact families where a new diagnostic test was available or recurrence risks were altered significantly. We identified 75 cases for evaluation. A presumptive diagnosis was suggested for 20 cases including : 22q deletion (confirmed on FISH), COFS syndrome (1 mutation identified), Smith-Magenis syndrome, Alagille syndrome, Seckel syndrome, Lambotte syndrome, Goldberg-Shprintzen syndrome, Disorganization syndrome and Holzgreve-Thomas syndrome. We therefore conclude that continued re-evaluation of undiagnosed cases with newer available technologies would often enable a diagnosis to be made.

Gene Expression Variation in Families with Hypodontia. *E. Severin, L. Boboc.* Dept Human Genetics, Carol Davila Univ Med Pharm, Bucharest, Romania.

Hypodontia is a common human anomaly affecting the tooth development of one or both dentitions. More than 200 genes are expressed during tooth development, and mutations in several of these genes cause failure of tooth formation. The isolated form of hypodontia can be sporadic or familial. The affected members within a family often exhibit variable expression of congenitally missing teeth with regard to the tooth class, region, symmetry and number of the teeth involved. Objective of the study: Variation in gene expression was suspected to produce a range of phenotypes within the families with hypodontia. *Subjects and Methods:* The study population consisted of 76 families with non-syndromic hypodontia. Six Caucasian families were selected based on the intrafamilial variability of hypodontia. The diagnosis of hypodontia has been made by clinical and radiographic examinations. The family study method was also performed. *Results:* Gene expression variation was observed in six families with hypodontia in two or three successive generations. Each affected member of the same family had different manifestations of the hypodontia. The permanent teeth most frequently missing were upper lateral incisors followed by lower second premolars and upper second premolars (excluding the third molar). Less frequently, hypodontia occurred unilateral and the left side of the upper arch was more involved. The absence of one upper lateral incisor was often associated with a small peg-shaped contralateral tooth. According to the family pedigrees the hypodontia followed an autosomal-dominant pattern of inheritance with incomplete expression of a gene defect that caused tooth agenesis and reduced penetrance on the side affected. The cases presented had no associated systemic conditions or syndromes involving both jaws. *Conclusions:* Our results provide a more direct link between gene expression variation and phenotypic outcomes. There is variable expressivity both between and within families. Individuals from different families have different mutant alleles, but individuals within the same family would be expected to have the exact same mutant allele. The mutant alleles for the hypodontia of posterior teeth are different from those of anterior teeth.

Program Nr: 761 from the 2004 ASHG Annual Meeting

Genetic and epidemiologic study of congenital eye malformations in 293,923 consecutive births. *C. Stoll, B. Dott, M.P. Roth.* Laboratoire de Genetique Medicale, Faculte de Medecine, Strasbourg, France.

Congenital eye malformations (CEM) were studied in 293,923 consecutive births during the period 1979-2000. The prevalence rate of CEM was 6.8 per 10,000, for microphthalmia 1.7, anophthalmia 0.23, cataract 2.7, and coloboma 1.4, respectively. Sex ratio was 0.79. Prenatal diagnosis was performed in 27 cases and 12 pregnancies were terminated. The more common types of associated malformations in the 108 affected cases (53.2%) were clubfeet, microcephaly, hydrocephaly, cleft lip/palate and facial dysmorphia. At birth infants with CEM and other malformations were smaller, weighed less and their head circumference was lower than in controls. Placental weight was also lower than in controls. Pregnancies with CEM were more often complicated by threatened abortion, oligoamnios, and polyhydramnios. Mothers of children with CEM took more often drugs during pregnancy and fathers were more often exposed to occupational hazard than parents of controls. There was a significant association between CEM and consanguinity of parents. The overall recurrence risk was 8.7%. First degree relatives of probands had more than 3 times the prevalence of non-eye malformations than controls. These results are of relevance for genetic counseling.

Prader-Willi Syndrome (PWS) with congenital hypothyroidism (CH) in a newborn with maternal uniparental disomy (MUPD15). *Y. Wang¹, J.E. Martinez¹, S.K. Bhowmick², X. He¹, C.M. Tuck-Muller¹, T.-J. Chen¹.* 1) Dept Medical.Genetics,; 2) Dept Pediatrics, Univ South Alabama, Mobile, AL 36688.

PWS is a complex genetic disorder characterized by early hypotonia, mental retardation, obesity, small hands and feet, and psychological features. The molecular basis of this disorder has been shown to be loss of genes located on paternal 15q11-13 (deletion) or their functions (MUPD15 or imprinting defect). Some of clinical symptoms suggest that PWS may be associated with hypothalamic dysfunction. However, to our knowledge, no PWS patient with CH has been reported. We report a female newborn, who presented with neonatal hypotonia and poor respiratory effort. Physical examination revealed craniofacial dysmorphism, including narrow bifrontal diameter, periorbital edema, short palpebral fissures, short upturned nose, and thin upper lip, along with low set hypoplastic nipples and long digits with flexion contractures of the PIP joints (camptodactyly). During the first week of life, low free T4 (<0.2ng/dl) and very high TSH (>340 IU/ml) led to the diagnosis of severe CH, perhaps due to dysgenetic thyroid. After thyroid hormone replacement therapy, the persistence of lethargy, universal hypotonia and feeding difficulties suggested the diagnosis of PWS. Karyotyping and FISH analysis of 15q11 were normal. Molecular studies indicated abnormal methylation on the SNRPN gene confirming the diagnosis of PWS. Linkage analysis using 13 STR markers on chromosome 15 showed that the patient inherited only one set of the maternal STR markers establishing MUPD15. The elevated TSH indicates a normal hypothalamic response to the hypo-functioning thyroid, which is not consistent with the previously reported hypothesis of hypothalamic dysfunction in PWS. It is not clear whether the CH in our patient is related to her MUPD15. The overlapping neonatal manifestations of CH and PWS (lethargy, decreased arousal, weak cry and poor suck), and the presence of unusual physical features (long digits with camptodactyly) could confuse the diagnosis and delay the identification of a newborn with PWS.

Ambiguous genitalia in a male with classical Congenital Adrenal Hyperplasia (CAH). *R. Babul-Hirji¹, D. Wherrett¹, W. Farhat¹, M. New², D. Chitayat¹.* 1) The Hospital for Sick Children and University of Toronto, Toronto, Ontario, Canada; 2) Mount Sinai School of Medicine, New York, NY.

Classical congenital adrenal hyperplasia results from an inherited enzyme defect in cortisol synthesis. More than 90% of cases are due to 21-hydroxylase (21-OH) deficiency. The androgen excess with this condition typically results in ambiguous genitalia in affected females. We report a male who presented with ambiguous genitalia and subsequently was diagnosed with 21-OH CAH.

The patient was initially seen for penoscrotal hypospadias with chordee. The phallic length was normal and the testes were palpable in the scrotum. Karyotype was 46,XY and an abdominal ultrasound was normal. At 36 hours of age, he had low LH & FSH with high testosterone and androstenedione with mildly raised 17-hydroxyprogesterone. The normal male chromosomal and gonadal sex raised the possibility of Partial Androgen Insensitivity syndrome (PAIS), although DNA analysis of the AR gene was negative. On day 13, he presented with a salt-wasting crisis with high levels of 17 hydroxyprogesterone at 231 nmol/L (normal <10). He was treated with fluodrocortisone, hydrocortisone and salt supplementation and recovered. DNA analysis of the 21-OH gene revealed an Exon 7 (V281L) mutation inherited from the father. Sequencing of the entire 21-OH gene found no additional mutations.

As ambiguous genitalia in a male is not consistent with classical 21-OH CAH, the likely explanation is this patient has two conditions: i) CAH and PAIS; ii) CAH and multifactorial inheritance of the hypospadias or (iii) CAH and a deficiency in an as yet unknown enzyme involved in the conversion of testosterone to dihydro-testosterone. The latter would result in normal external genitalia in a female with 21-OH classical CAH. This needs to be considered when counseling parents of female babies with classical 21-OH CAH born with normal external genitalia when the mothers were not on dexamethasone. This case presented a challenge not only clinically but also in genetic counseling.

Clinical Features of Familial Aortic Aneurysms and Dissections: Association with Type B Dissections, Variable Expression in Monozygotic Twins and Evidence of a De Novo Mutation Causing Disease. *D. Milewicz¹, D.*

Lemuth¹, V. Tran Fadulu¹, E. Sparks², R. He¹, B. Neichoy¹, J. Coselli³. 1) Div Med Genetics, Int Med, Univ Texas Medical School, Houston, TX; 2) Div Cardiology, Int Med, Ohio St Univ, Columbus, OH; 3) Div of Cardiothoracic Surgery, DeBakey Surg, Baylor College Med, Methodist DeBakey Hrt Ctr, Houston, TX.

Familial thoracic aortic aneurysms and dissections (TAAD) is an autosomal dominant condition with reduced penetrance and variable expression. Genes predisposing individuals to TAAD have been mapped to 5q13-14 (TAAD1), 11q23 (FAA1) and 3p24-25 (TAAD2). We studied 222 families with predominantly ascending aortic aneurysms leading to type A dissections without prophylactic surgical repair. Four families were identified with a novel clinical presentation involving both ascending (type A dissections) and descending thoracic disease (type B dissections) inherited in an autosomal dominant manner. Of the 28 affected individuals, 15 had type A disease, 4 had type B disease and 6 had both type A and type B disease. In 2 families, 3 persons had cerebral and carotid aneurysms with either ascending or descending disease. Type A dissections were preceded by aortic dilation while type B dissections were documented without aortic enlargement. 5 people had type B dissection and subsequently developed ascending aortic disease. In one family, the age at onset of ascending disease in monozygotic twins was variable, indicating the role of environmental factors in familial TAAD. Clinical history of 2 families suggest a de novo mutation, which has not been conclusively demonstrated for any other families. This study highlights the significance of paying strict attention to family history and clinical details, illuminates the importance of making an accurate diagnosis of familial TAAD in the absence of Marfanoid features, provide risk assessment in genetic counseling and medical management of this subset of families. These observations indicate the need for monitoring of the entire aorta in Type B patients. The presences of both ascending and descending disease, with cerebral and carotid aneurysms, indicate extensive vascular involvement that is a feature of TAAD.

A new observation of acro-cardio-facial syndrome points to wide interindividual clinical variability. B.

Dallapiccola¹, D. Zuccarello^{1, 2}, M.C. Digilio³, R. Mingarelli¹. 1) IRCCS-CSS San Giovanni Rotondo and CSS-Mendel, Rome, Italy; 2) University La Sapienza, Department of Experimental Medicine and Pathology, Rome, Italy; 3) Medical Genetics, Bambino Gesù Hospital, Rome, Italy.

The association of ectrodactyly, cleft lip/palate, congenital heart defect (CHD), genital anomalies and mental retardation was first reported in a Brazilian patient born to consanguineous parents. Two Italian siblings presenting with a constellation of similar defects have corroborated the existence of this syndrome, for which the acronym CCGE (Cleft palate, Cardiac defect, Genital anomalies, Ectrodactyly) was proposed. These first reports suggested an autosomal recessive pattern of inheritance. An additional newborn with ectrodactyly, cleft, ear anomalies, CHD, cortical atrophy of the brain and growth retardation has further improved the definition of this disorder which was redesignated as acro-cardio-facial syndrome (ACFS). We report on a fifth patient with ACFS born to healthy unrelated parents. The patient was hypotonic and showed facial dysmorphisms. Ears were low set, with thin upper helices, prominent and vertical antihelices, large lobes. The scrotum was hypoplastic with cryptorchidism. Right hand was split with agenesis of the third finger. Left hand was grossly normal, with a proximally implanted thumb and a relatively short first metacarpal. Lobster claw right foot was also present, with three rays which included a huge valgus hallux and abnormally modelled and partially fused fourth and fifth toes. On echocardiography a complex CHD was detected, consisting of truncus arteriosus type 1 with dysplastic and stenotic truncal valve. The patient died at one month of age from cardiocirculatory insufficiency. The present patient confirms the severe prognosis of this disorder. ACFS is a clearly recognizable disorder, manifesting with a wide range interindividual and intrafamilial variability, distinct from other known syndromes involving cleft-ectrodactyly. Lobster claw hands, which were associated with split-foot in two cases, was the only constant defect in the five known patients, while four patients showed heart defects and three patients had cleft lip/palate.

An internet-based database on the analysis of autosomal recessive congenital ichthyoses and other inherited disorders of keratinization. *C. Eckl, K.M. Eckl, H.C. Hennies.* Molecular Genetics and Gene Mapping Center, Max Delbrück Center, Berlin, Germany.

Autosomal recessive congenital ichthyosis (ARCI) is a clinically and genetically heterogeneous disorder characterized by generalized scaling of the skin and erythema. Color and shape of the scales and extent of erythema are highly variable, as well as a number of further features. A consistent genotype/phenotype correlation was not identified so far. In order to store and provide data from patients with ARCI and other related skin disorders, we have now developed a concise database service. Different phenotype variables, family history, pedigree, biochemical and histopathological data are stored for each sample. The family history will be automatically transferred to linkage compatible data formats and graphical output of the pedigree, clinical pictures will be included and presented as thumbnails. The service runs on an Apache 2 web server and is powered by a MySQL database management system and accessible through the web using an HTTP interface. For data protection reasons, sample names are stored on a separate server connected with the database by anonymous 32bit sample IDs. Data requests are handled semi-automatically via email using temporary IDs, each valid for immediate access and one dataset. The database stores genotyping data for indirect analysis of all known ARCI loci as well as mutation data obtained by direct sequencing. Further data are being collected within the German Network for Ichthyoses and Related Keratinization Disorders, which aims at comprehensively recording and characterizing such families. The service is open to external users on a collaborative basis and includes different user levels. The main purpose of the database is to assist the work of research groups by providing a common platform for data collection and exchange. Since ARCI and other keratinization disorders are rare, the database not only provides a mutation survey but is valuable for systematically collecting data. Thus, it helps to generate criteria for analyzing a potential genotype/phenotype correlation and further characterization of the phenotypic outcome of specific mutations.

Program Nr: 767 from the 2004 ASHG Annual Meeting

Autism work-up pitfalls; chromosome and genetic testing, metabolic disorders, seizures, immunizations, mercury, EEG, fungus, gluten and casein free diets, and brain MRI. A. Perszyk. Pediatric Multispecialty Ctr, Univ Florida, Jacksonville, FL.

Autism and related disorders are a growing diagnostic category in developmental and genetic clinics. Diagnostic criterion published (DSM IV) for this disorder is the basis for the clinical diagnosis of autism. However, incorrect application sometimes places a label that is neither warranted nor correct. Clinical features of autism are seen in a diverse group of diseases, conditions, disorders, and syndromes that initially present in childhood as the behavioral and social characteristics of infantile autism. A growing number of autism genes (20) have been mapped, both genetic and environmental factors must be considered. Purpose: To define a workable approach to identifying the etiology in children presenting with speech delay and the stereotypical behaviors of autism. Clinical work-up must include a careful search for the cause of autism when it is recognized. Method: Children that meet diagnostic criterion in the Pediatric Developmental Clinic or the Center for Autism and Related Disorders are further evaluated by Medical Genetics. Medical, social, obstetrical, and family history are obtained. Metabolic, genetic testing and imaging studies are then completed. Step-wise and individualized evaluations are completed. Conclusion: Pitfalls in the medical work-up are many and often unique to autism. Commonsense algorithm (suitable for Palm OS device) for autism work-up is presented to minimize failures, lack of follow-through, and avoidance of potholes on this diagnostic road. Obvious consequences are discussed that alter the recurrence risk estimate, dietary treatments, interventions and therapy.

The molecular basis of Ectodermal Dysplasias. *M. Priolo*¹, *M. Seri*², *C. Lagana*¹. 1) Oper. Unit of Med. Genet, Hospital Bianchi-Melacrino-Morelli, Reggio Calabria, Italy; 2) Oper. Unit of Med Genet, Pol. S.Orsola-Malpighi, Bologna, Italy.

The ectodermal dysplasias are a complex group of diseases. They all share anomalies in hair, teeth, nails and sweat gland function sorted in various combinations. The anomalies affecting the epidermal appendages are extremely variable. Few causative genes have been identified, to date. It is possible to approach this group of diseases based on functional and molecular findings and to begin to explain the complex clinical consequences of mutations affecting specific developmental pathways. By studying these pathways, we realised that all the EDs causative genes basically act through two different pathogenetic mechanisms and that clinical findings are highly peculiar for each of the two mechanisms identified, so that proposed a new classification integrating both molecular-genetic data and corresponding clinical findings. Basically, two groups have been identified. The first group includes disorders in which a defect in the epithelial-mesenchymal interaction can be recognised. All these genes regulate expression of proteins devoted to signalling between ectoderm and mesenchyme and, eventually, control differentiation and cell survival. Clinically, two key signs have to be found to fulfil inclusion criteria in this first group. Either a major ectodermal derivatives involvement as in pure EDs or a major skeletal involvement have to be present. The second group includes disorders in which an abnormal function of structural protein has been found. Causative genes present a specific pattern of expression, relative proteins being localised at the adherens junction/gap junction/ apicolateral membrane domains. Clinically, related diseases are all characterised by associated dermatologic features, mainly palmoplantar keratoderma and/or by involvement of highly differentiated epithelia. We review the molecular basis of ectodermal dysplasias in the light of this new clinical-functional classification and most recent findings in research. For each subset of ED, we describe the genes and related proteins involved in terms of: structure of the genes and their role in differentiation of the epidermis and the ectodermal derivative, genotype-phenotype correlation.

The co-occurrence of 22q11 Deletion Syndrome and Parkinson Disease: a new neurological feature? *K. Tam¹, A. Bassett^{1, 2}, E. Chow^{1, 2}*. 1) Clinical Genetics Research Program, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2) Dept of Psychiatry, University of Toronto, Toronto, Ontario, Canada.

We recently assessed a 52-year-old Caucasian male with Parkinson Disease (PD) and 22q11 Deletion Syndrome (22qDS) in our Program. He was diagnosed with PD at 43 years of age based on prominent bilateral hand tremors. His parkinsonian symptoms have since progressed to include dyskinesia, mild dysarthria, impaired dexterity, and postural instability. He requires treatment with levodopa and ropinirole. He had a depressive episode successfully treated with medication soon after his diagnosis. He was employed, as a high school teacher but was unable to continue work approximately 2 years after the diagnosis of PD was made. The patient has not had molecular genetic testing for PD and, there was no family history of PD, movement disorders, psychotic illness, or seizures. At 44 years of age, after his son was diagnosed with 22qDS, the microdeletion was confirmed in him by standard fluorescence in-situ hybridization using the D22S75 probe. On recent physical examination, he was found to have minor scoliosis, a repaired submucous cleft palate, hypernasal speech, and minor facial features. We detected hypocalcaemia on ionized calcium testing and started him on calcium and vitamin D supplementation. It is unclear whether hypocalcaemia was of concern prior to our recent investigations because the patient had inconsistent medical follow-up for 22qDS since his diagnosis. To our knowledge, this co-occurrence of PD and 22qDS in the absence of psychotic illness has not previously been described. One previous report described the presence of parkinsonian symptoms in a patient with 22qDS and childhood-onset schizophrenia (Krahn et al., 1998). Overall, the relationship between parkinsonism in individuals with 22qDS remains unclear and, currently no overlap in the loci of these two disorders has been identified. Determining how and whether hypocalcaemia, which is common in 22qDS, may exacerbate such symptoms warrants further investigation, as does deciphering whether parkinsonian symptoms or PD represent additional characteristics in the 22qDS spectrum.

New Syndrome of Craniofacial Anomalies, Radiohumeral Synostosis, and Rhizomelic Shortness. *Z.N. Al Hassnan, A.S. Teebi.* Dept Med Genetics, King Faisal Specialist Hosp, Riyadh, Saudi Arabia .

Radiohumeral synostosis is a rare skeletal anomaly that might be seen in some craniosynostosis syndromes, notably Antley-Bixler syndrome, and in other disorders in association with skeletal anomalies. Here we report on a patient with syndromic radiohumeral synostosis in a 9 month old Saudi female of first cousin parents with unremarkable family history. Pregnancy ended at term with C-section for breech presentation. Birth weight was 2.4 kg. She was noted a peculiar craniofacial features including very large anterior fontanelle, cranium bifidum occultum, high and broad forehead, high frontal hairline, sparse scalp hair, medial thinning of the eyebrows, hypertelorism, epicanthus inversus, depressed nasal bridge, and exotropia. She has capillary hemangiomas covering the forehead, nose, and the back of the scalp. There was no proptosis and retinal exam was normal. Ears were very low-set, posteriorly angulated and malformed. Philtrum was smooth, and neck was short. Musculoskeletal examination revealed rhizomelic shortness with normal hands and feet. There was fixed flexion deformity of both elbows with no other joints deformities or contracture. There was a sacral dimple. Skeletal survey showed bilateral radiohumeral synostosis. There was no evidence of craniosynostosis on skull X-rays. Ultrasound of the kidneys revealed mild bilateral hydronephrosis. She had frontotemporal atrophy on brain MRI with no CNS malformations noted. Chromosomes were normal in blood and skin fibroblasts. She has had remarkably smooth early infantile course, continued to gain developmental milestones, though mildly delayed, and her weight and head circumference remained within normal.

The craniofacial manifestations in this patient were peculiar and, do not match any of the syndromes known to be associated with radiohumeral synostosis nor those associated with rhizomelic shortness. We think that the association is unique and apparently represents a previously unrecognized syndrome. This disorder might be autosomal recessive, though a sporadic event is a possibility.

Reliability and Validity of the Dysmorphia Checklist. *R. Blackston*^{1,2}, *C. Coles*², *J. Kable*², *R. Seitz*². 1) Div Med Gen, Dept Pediatrics, Emory Univ Sch Medicine, Atlanta, GA; 2) Fetal Alcohol Center, Marcus Institute, Emory University School of Medicine, Atlanta, GA.

We report investigations to determine if severity of dysmorphia in alcohol-exposed children is stable over time and if it is related to cognitive and behavioral outcomes. In a multidisciplinary clinic more than 500 children have been seen since 1997 and evaluated for the effects of prenatal alcohol exposure and environmental factors associated with maternal substance abuse. Characteristic physical features of FAS are measured using a 30-item Dysmorphia Checklist. To examine reliability of this assessment, records of 30 children who were seen on more than one occasion were compiled. The first assessment was done when children were a mean age of 2.9 years (SD=2.47) and the second done blindly when they were mean age 4.5 years (SD=2.52). A strong relationship between outcome of these two assessments ($r=.85$, $p<.000$) was found, indicating a high degree of consistency in the results of this exam. Differences in scores from one assessment to the next were unrelated to the length of time between assessments. The extent to which dysmorphia was related to cognitive and behavioral outcomes was examined in a sample of 275 children. We found that when children are categorized using dysmorphia scores, those with a mean dysmorphia score of 21.3 (SD=7.7) were significantly more likely ($F=4.49$, $p<.004$) to have cognitive scores in the borderline to mild mentally retarded range than were those whose dysmorphia was less severe (e.g., $M=10.4$; $SD=4.8$). Finally, in the same group, we examined behavioral ratings from the Child Behavior Checklist to evaluate whether severity of dysmorphia is related to behavior problems. We found that there were no significant relationships between physical dysmorphia and behavior problems. We conclude that the Dysmorphia Checklist is a stable, reliable tool in the recognition and diagnosis of FAS at any age. Furthermore, the degree of dysmorphia does indicate decreased cognitive levels in children with FAS but was not related to behavior problems suggesting that stable environment, early intervention services and education are important in behavioral outcomes.

A Clinical Epidemiologic Study of Patients with Split Hand Foot Malformation (SHFM) in Manitoba, Canada.

A.M. Elliott¹, M.H. Reed^{1,2,3,4}, A.E. Chudley^{1,3,4}, B.N. Chodirker^{1,3,4}, J.A. Evans^{1,3,4}. 1) Department of Biochemistry & Medical Genetics, University of Manitoba; 2) Department of Radiology; 3) Department of Pediatrics and Child Health; 4) Children's Hospital, Winnipeg, Manitoba, Canada.

We conducted a clinical epidemiologic population study of Manitoba to examine the incidence and epidemiology of SHFM from 1957-2003. The total number of births during this period was 842 124. Forty-five patients with SHFM were identified, resulting in an incidence of 1 in 18 713 births. The majority of patients were ascertained through referrals to the Section of Genetics at the Childrens Hospital, Winnipeg. Overall, 62% of affected individuals were females and 38% were male. The left upper limb (LUL) was the most frequently affected, with 58% of patients having an affected LUL. RUL involvement was seen in 51% of patients. Sixteen percent of patients had all four limbs affected. Split Hand Foot Malformation (SHFM) is classified as a failure of formation of parts according to the International Federation of Surgical Societies of the Hand (IFSSH) Classification and has been categorized as typical or atypical. Affected patients were classified into two main categories: Group I (typical) (31 cases) and Group II (atypical) (4 cases). However, 10 patients were not easily classified into either group and comprised a distinct category (Group III). The three groups were then subdivided into Group A (isolated SHFM) and Group B (SHFM with additional anomalies). Group IB included patients with syndromes in which SHFM has been reported (e.g. EEC, ectrodactyly with tibial agenesis and acrorenal-mandibular syndrome) in addition to patients with associated anomalies that did not constitute a well-described syndrome. Patients with isolated atypical SHFM showed preferential involvement of the upper extremities. The characteristic findings of each subgroup of patients are described and compared. The challenges involving classification, pathogenesis, etiology and implications for genetic counselling are addressed.

Goeminne syndrome-Report of a second family supporting an X-linked inheritance pattern. *B. Fernandez¹, A. MacMillan¹, B. Noble¹, M. Crowley¹, D. Jewer², S.W. Scherer³, M.O. Woods¹.* 1) Discipline of Genetics, Memorial University of Newfoundland, St John's, NL, Canada; 2) Dept of Surgery, Memorial University of Newfoundland, St John's, NL, Canada; 3) Dept of Genetics, University of Toronto, Hospital for Sick Children, Toronto, ON, Canada.

In 1968, Goeminne described a syndrome of congenital progressive torticollis, multiple keloids and cryptorchidism in an Italian family with 6 affected individuals, 4 males and 2 females. Other variable features included facial asymmetry, multiple cutaneous nevi, varicose veins and renal dysplasia. Because the females in this family were less severely affected than the males, McKusick has characterized Goeminne syndrome as X-linked, with incomplete dominance (OMIM #314300). In 1980 and 1982, two unrelated females were reported with apparently balanced X;autosome translocations and partial features of the syndrome. These women were used to map a locus to Xq28, distal to *G6PD*. Finally in 2003, a pair of Belgian authors described a 17-year old affected male, who appeared to be a sporadic case.

We report a second family, originating from Newfoundland, with this rare syndrome. The 46-year old male proband was born with torticollis, scoliosis and bilateral cryptorchidism. He is infertile and of normal intelligence. In mid-childhood, he developed spontaneous keloids and later disfiguring keloids at surgical incision sites. He has several anomalies not described in Goeminne's original pedigree including: macrocephaly, facial dysmorphism and Dupuytren's contractures. DNA on five family members was available for genetic analyses. Microsatellites markers in the region of *G6PD* on Xq28 were analyzed. A 5 Mb haplotype segregates with the Goeminne syndrome phenotype in this family. Specifically, the proband's mother carries a haplotype which was inherited by the proband and his clinically affected sister and niece. However, this haplotype was not inherited by the proband's other sister, who clinically doesn't appear to be a carrier. The haplotype includes *G6PD*, so that the disease locus may be distal to *G6PD* as previously suggested.

Trigonocephaly, short sublingual frenula, atrial septal defect, inguinal hernia, mental retardation with autosomal dominant pattern of inheritance. *M.J. Hajianpour.* Med Dir, Clinical Genetics, GENE TREK, Van Nuys, CA.

The proband is a 10 year old male with trigonocephaly, attached sublingual frenula, atrial septal defect, inguinal hernia, and mild to moderate mental retardation. His father and his half-brother through his father had reportedly inguinal hernia and short sublingual frenula. The chromosome analysis and fluorescence in situ hybridization (FISH) for velo-cardio-facial syndrome / DiGeorge syndrome (VCFS/DGS) were normal. The Opitz trigonocephaly (C syndrome) may present with the above features except for the inguinal hernia, and the inheritance of this condition is autosomal recessive. The VCFS/DGS remains as a differential diagnosis considering about 5% of individuals with clinical manifestations of VCFS/DGS may not show a deletion by FISH. Short sublingual frenula is not a reported feature of VCFS/DGS. This family may present a new autosomal dominant trigonocephaly syndrome with variable expression.

3D dense surface models identify the most discriminating facial features in dysmorphic syndromes. P.

Hammond¹, T. Hutton¹, J. Allanson², B. Buxton¹, L. Campbell³, A. Karmiloff-Smith¹, K. Murphy³, M. Patton⁴, B. Pober⁵, A. Smith⁶, M. Tassabehji⁷. 1) UCL, London, UK; 2) Eastern Ontario Regional Genetics Program, Ottawa, Canada; 3) RCSI, Dublin, Ireland; 4) St Georges Hospital Medical School, London, UK; 5) Children's Hospital, Harvard; 6) NIH, Bethesda; 7) Manchester University, UK.

3D dense surface models (DSMs) can accurately discriminate controls from individuals with a dysmorphic syndrome. Here, we build separate DSMs for the peri-orbital, nasal and peri-oral areas to compare their discrimination rate to that of the full face for Noonan syndrome (NS, n=61), Smith-Magenis syndrome (SMS, n=50), Velocardiofacial syndrome (VCFS, n=95) and Williams syndrome (WS, n=65). Two pattern recognition algorithms were used to calculate classification accuracy for ten DSMs, each computed from a randomly generated 90%-10% split of the dataset into training and unseen test subsets. Below, we quote average true/false positive % rates for the most discriminating algorithm. All subjects, including over 200 controls, are Caucasian and aged less than 20 yrs, except for the SMS-control comparison where age is up to 35. For the NS-Control and WS-Control comparisons, the eyes alone (NS:93/5; WS:98/4) compare very well with the full face (NS: 97/5; WS:95/3) and are much more discriminating than either the nose (NS:73/12; WS:88/9) or mouth (NS:77/8; WS:82/4). For Smith-Magenis syndrome, the tented upper lip (80/2) always features strongly in the full face (78/4) gestalt, so the better discrimination rates of the eyes (90/4) and nose (92/5) are surprising. Given the more subtle VCFS facial phenotype, the better performance of the full face (87/5) over the nose (81/12) and eyes (81/10) was expected. The narrow mouth and shallow groove between lower lip and chin may explain the superior peri-oral performance (86/8), but exaggerated lip tension and expression in VCFS subjects cannot be discounted. Dynamic morphs between average sub-surfaces of the nose, eyes and mouth capture even subtler shape differences between control and syndrome groups than does the full face. The presentation will include comparable results for inter-syndrome comparison.

Cardiovascular malformations and deletion 3p25. A.E. Lin^{1,2}, H. Ardinger³, E. Goldmuntz⁴, T. Hoffman⁵, S. Saitta⁵, N. Spinner⁵, E. Zackai⁵. 1) Genetics & Teratology, MassGeneral Hospital for Children and; 2) Brigham-Women's Hospital (BWH), Boston, MA; 3) Prairie Village, KS; 4) Div. Cardiology, Dept. Pediatrics, and; 5) Div. Genetics, Children's Hospital of Philadelphia (CHOP), PA.

A consistent chromosomal alteration associated with specific types of cardiovascular malformations (CVMs) can lend insight into developmental mechanisms and identify candidate genes. CVMs have been reported with distal 3p del (atrioventricular canal, AVC, said to be more common) warranting a thorough review of the 3p del cardiac phenotype. PATIENTS: Of 36 literature pts with 3p25 del, and 4 new pts (1 from BWH Surveillance Program, 3 from CHOP), 36 had terminal 3p25 del, and 4 had interstitial 3q25-26 del. We excluded 16 pts with 3p25 del plus a dup or inv (9), deletion distal or proximal to 3p25 (6) and mosaic 3p25 del (1). RESULTS: Of 3p25 del pts, CVMs were present in 10/40 (25%) (all pts); and 10/32 who were informative for a CVM (31%). 3/10 (30%) had a complete AVC defect. Single pts had RtAoArch, PA/IVS, MV abn, ASD and ASD/VSD. Unspecified CHD occurred in 2. Compared to the Baltimore-Washington Infant Study [1997], AVC defects were more common (30% vs. 7%). DISCUSSION: 3p25 del is rare, and the number of pts with CVMs is small. Our review of 40 pts confirms that CVMs are common (25-30%) and that AVC defects are overrepresented. However, ascertainment bias of more severe cases is suspected. Our findings are consistent with the study of Robinson et al. [2003] that found 3 nonsyndromic pts with partial AVC had a missense mutation in *CRELD1*, a gene that maps to 3p25.3. Fernandez et al. [2004] reported a pt with 3p del phenotype but no CVM who had a bal trans with breakpoint at 3p26.2-p26.3 giving further evidence that *CRELD1* may play a critical role in the CVMs associated with 3p25 del syndrome. CONCLUSION: Del 3p25 is associated with CVMs in about 25%, 30% of whom may have an AVC defect. Pts with syndromic AVC should be carefully studied to rule out a distal 3p del. *CRELD1* and other genes mapping to 3p25 may play a critical role in causing CVMs in 3p25 del. Complex mosaic trisomy 7 in lymphocytes of a girl with primary microcephaly. *E. McPherson*¹, *J. Mascarello*². 1) Medical Genetics, Marshfield Clinic, Marshfield, WI; 2) Genzyme Genetics, Santa Fe, NM.

A 9-year old girl with severe primary microcephaly (-7SD) and mild developmental delay was found to have a complex mosaic karyotype 48,XXX,+7/47,XX,+mar/46,XX in peripheral lymphocytes. She was the product of an uncomplicated pregnancy to a 22 year old primigravida and her unrelated 28 year old husband. She was born at term with a weight of 3.3 kg, but was immediately noted to be microcephalic. The parents declined any genetic studies at the time. The child walked at 10 months, but her speech was mildly delayed. She spoke in short sentences at age 3. She attends school in regular classes but does require some special help in academic subjects. She has attention deficit disorder. At age 5 she developed granuloma annulare, which persists on her lower limbs. She recently required evaluation for cervical lymphadenopathy. Hematologic evaluation and lymph node biopsy were negative and the lymphadenopathy resolved spontaneously. Two subsequent siblings are clinically normal and the family history is non-contributory. Mosaic trisomy 7 has been reported in fibroblasts of several children with multiple anomalies (usually resembling VACTERL or FAVS) but was not confirmed in lymphocytes. Confined placental mosaicism for chromosome 7 has also been reported, with the fetuses usually having normal postnatal karyotype and being clinically normal or having Russell-Silver syndrome due to maternal UPD7. Clonal, but not constitutional, trisomy 7 occurs in some malignancies. Mosaic trisomy of all chromosomes including 7 has been reported in mosaic variegated aneuploidy, but despite her complex mosaicism, the proband does not meet the criteria for mosaic variegated aneuploidy. This patient is the first to be identified with mosaic trisomy 7 in lymphocytes (with the possible exception of a mother and daughter with mental illness and apparent mosaic trisomy 7 by Q-banding in a 1974 report). The marker is unidentified. The role of the marker and or mosaic triple X in the patient's phenotype (resembling microcephaly vera) and the mechanism leading to her mosaicism remain uncertain. Skin biopsy and uniparental disomy studies are pending.

A Pilot Study on the Inheritance of Pectus Excavatum. *M. Stacey*¹, *H. Harvey*¹, *V. Proud*², *R. Kelly*², *H. Creswick*², *B. Burke*², *T. Gustin*², *K. Mitchell*², *S. Blanton*³. 1) Ctr Pediatric Research, Eastern Virginia Medical Sch, Norfolk, VA; 2) Dept. Pediatrics, CHKD, Norfolk, VA; 3) Dept. Pediatrics, University of Virginia, Charlottesville, VA.

Pectus excavatum (PE) is the most common congenital deformity of the chest wall and occurs when the body of the sternum is displaced posteriorly to produce a funnel-shaped depression. The incidence of PE is approximately 1 in 1000 live births and a reported male to female ratio of 4:1. PE occurs in connective tissue disorders like Marfan syndrome (MS) and Ehlers Danlos syndrome (EDS). The etiology of PE is uncertain although familial tendency has been suggested. Studies on the inheritance of PE are limited. The purpose of this study was to determine if PE is genetic, and if so, whether it is more commonly associated in families with other connective tissue traits like lax joints. Using the EVMS Div. Pediatric Surgery database of over 1200 patients referred for evaluation of PE for possible surgical repair, we searched and identified 21 families with at least 2 affected siblings. Of these, 12 families participated in comprehensive family history interviews and pedigrees were constructed. 568 family members were collected with 281 males, 287 females and 48 individuals reported with PE including 33 males and 15 females. This was a 2.2:1 M to female ratio in this population. Statistical analyses were performed and characterized the inheritance patterns, medical problems, and associated connective tissue traits. While 3 autosomal dominant, 2 autosomal recessive, and 2 X-linked pedigrees were suggested, 5 pedigrees clearly suggested complex, multifactorial inheritance. 16 traits strongly associated with PE included long arms, legs, and fingers, high-arched palate, mitral valve prolapse, heart arrhythmia, scoliosis, lax joints, flexibility, flat feet, childhood myopia, poor healing and easy bruising were found significantly associated with PE ($p < 0.001$) even in families with no clear diagnosis of EDS or MS. Clearly, while there are single gene disorders of connective tissue that cause PE, this study suggests that it is a familial disorder associated with connective tissue and probably polygenic.

Case-control study of the muscular and skeletal geometry in neurofibromatosis type 1 using peripheral quantitative computed tomography. *D.A. Stevenson, L.J. Moyer-Mileur, J.C. Carey, S. Maxwell, J.L. Quick, C.J. Hoff, D.H. Viskochil.* Dept Pediatrics, Univ Utah, Salt Lake City, UT.

The common skeletal dysplasias of neurofibromatosis type 1 (NF1) include long-bone dysplasia, scoliosis, and sphenoid wing dysplasia. The pathogenesis is unknown. Muscle mass is important in the development of the strength of bone as voluntary muscle forces impact skeletal response and help determine the strength of bone. No studies have evaluated the bone strength and architectural structure to muscular compartments of individuals with NF1. Peripheral quantitative computed tomography (pQCT) has emerged as a modality that can address the hypothesis that NF1 individuals have decreased muscle cross-sectional area and a unique bony architecture. We examined 40 individuals with NF1 (age 5-18). Eight had a classic osseous dysplasia [sphenoid wing (1), tibial dysplasia (1), scoliosis (6)]. Cross-sectional measurements (66% tibial site) were obtained using pQCT (XCT-2000, Stratec) and variables were compared to healthy controls without NF1 (N=380) using analysis-of-covariance controlling for age, height, Tanner stage, and gender. Decreases were seen in the total cross-sectional area (NF1=6356 mm²; controls=7313 mm²; p<0.001), muscle and bone cross-sectional area (NF1=4344 mm²; controls=4986 mm²; p<0.001), muscle cross-sectional area (NF1=3886 mm²; controls=4442 mm²; p<0.001), and the Strength Strain Index (NF1=1176 mm³; controls=1314 mm³; p=0.010). When NF1 individuals were separated into 2 groups, with and without osseous dysplasias, there were statistically significant differences compared to controls, but not between NF1 groups. A trend ANOVA showed a downward trend in total [p=0.029], muscle and bone [p=0.004], and muscle cross-sectional areas (mm²) [p=0.006] between all three groups. These data suggest that NF1 individuals have decreased muscle cross-sectional area and bony strength compared to individuals without NF1. Exercise regimens may be of benefit to NF1 individuals to subsequently improve muscle and bone strength. Future studies evaluating activity levels and dietary intake may provide insights into the pathophysiology of the differences observed in this study.

A genetic and anatomic assessment of two cases of sirenomelia. *S.L. Vander Pol¹, J.J. MacKenzie², D. Situ³, G.W. Lyons³, S.C. Pang³, C.W. Reifel³, R.M.L. Smith⁴, S.A.M. Taylor¹*. 1) Pathology and Molecular Medicine; 2) Paediatrics; 3) Anatomy and Cell Biology; 4) Diagnostic Radiology, Queen's University, Kingston, ON, Canada.

Sirenomelia is a rare disorder of blastogenesis with an unknown etiology. It is characterized by partial to complete fusion of the lower limbs. We have had the opportunity to examine two term fetuses with sirenomelia preserved intact for more than 40 years at our centre. Both cases originated in the same rural Canadian community and were born within 8 months of each other. Given the geographical, temporal and superficial similarities in the physical appearances of these two fetuses we speculated that a more detailed assessment would reveal they had a similar spectrum of defects and therefore possibly a similar etiology as well. Both fetuses were subjected to an external genetic assessment, X-ray and MRI studies to identify internal and external abnormalities. FISH and molecular genetic studies were complicated by the lack of information about the original fixative used to preserve these cases. It likely had been ethanol, which leached DNA from external structures. FISH was initially used in an attempt to determine the sex of the fetuses but was unsuccessful. DNA was extracted using a guanidine isothiocyanate method from biopsies of tissue from the thymus and lung. The DNA was extremely damaged with the majority of it being degraded to less than 100 bp. The DNA was repaired by nick translation and ligation before a PCR based assay to determine their sex was performed. Our results revealed that both fetuses were male and that they had an overlapping but different spectrum of abnormalities. Principal differences were noted in ear development, brain structure, the urogenital system, the lower limbs, pelvis and vertebral column. While we hypothesize that defects of the axial mesoderm underlie the abnormalities seen in both fetuses, Fetus 1, which had only caudal defects, was found to have a spectrum of abnormalities most similar to those of the small pelvic outlet syndrome while Fetus 2, which had both caudal and cranial defects, was more similar to cases with axial mesodermal dysplasia.

Causes of death in untreated and treated Prader-Willi syndrome (PWS) individuals with growth hormone (GH).

*M. Angulo*¹, *M. Lamerson*¹, *M. Zak*¹, *J. Heinemann*², *P. Eisen*², *M. Castro-M*¹. 1) Ped Endocrinology & Med Gen, Winthrop-University Hosp, Mineola, NY; 2) PWSA-USA, Sarasota, Florida.

BACKGROUND: Obesity and short stature are among the characteristics PWS. In June 2000, the US-FDA approved GH for the treatment of growth failure in PWS children. GH has shown to have beneficial effects on growth, body composition, and respiratory function. The reports of 12 PWS children (10 M/2 F) fatalities worldwide receiving GH treatment, raised the question as to a causal connection between GH therapy and these fatalities. **OBJECTIVE:** To describe the causes of death and their relationship between weight and death in PWS individuals in comparison to the PWS fatalities receiving GH treatment. **METHOD:** A retrospective review of the circumstances of death, age and weight of 149 PWS individuals (91M/58 F) reported to the PWS Association (USA) up to June 2004. Twenty-seven subjects were under the age of 12 years, 10 between 13 and 19, and 112 between the ages of 20 and 63 years. The 12 worldwide fatalities (age 0.7 to 15.8 years), received GH for a period of 0.2 to 2 years. **RESULTS:** The cause of death was not available in 30 adults and 4 children. From 115 individuals, 42% had respiratory failure, 23% cardiac arrest, 9% sudden death, 7% choked on food, 3.5% thromboembolism, 1.7% DKA, 1.7% renal failure, and 0.9% SIDS, ovarian Ca or lung Ca. Respiratory failure as cause of death was reported in 17 (80%) and 9 (75%) in the non-GH treated and GH treated children respectively. All but two infants and one child of 149 individuals were obese. Weight was available in nine of the 12 GH treated PWS children, and all of them were obese. **CONCLUSIONS:** 1-Mortality risk is most likely increased, given the higher baseline rate of obesity and respiratory compromise in PWS. 2-Obesity and respiratory compromise as cause of death was equivalent in the GH and non-GH treated children which suggest no connection between GH and mortality risk. Larger number of children however will be necessary to compare mortality risk in GH and non-GH treated PWS. 3-Close monitoring of respiratory problems and prevention of obesity in childhood could decrease mortality risk in PWS regardless GH treatment.

Exclusion of the Two Keloid Candidate Loci 2q23 and 7p11 in a Family with Inherited Keloids and Hypertrophic Scars.

*M. Amyere*¹, *L.M. Boon*^{1, 2}, *A.G. Marneros*³, *B.R. Olsen*³, *M. Vikkula*¹. 1) Laboratory of Human Molecular Genetics, Christian de Duve Institute of Cellular Pathology & Université catholique de Louvain, Brussels, Belgium; 2) Centre for Vascular Anomalies, Division of Plastic Surgery, Cliniques Universitaires St-Luc, Université catholique de Louvain, Brussels, Belgium; 3) Department of Cell Biology, Harvard Medical School, Boston, USA.

Keloids consist of pathologic fibrosis which occurs in the skin after trauma and which grow beyond the boundaries of the injury. These cutaneous lesions are formed by excessive deposition of extracellular matrix, mainly collagen. Keloids occur in people of all racial backgrounds; however, individuals of African descent are more susceptible. Linkage of two keloid families has been reported to loci on 2q23 and 7p11 (Marneros *et al.*, 2004). We have performed linkage analysis in a Belgian family to test if it is also linked to one of these loci. The affected individuals of this family showed formation of small keloids and hypertrophic scars. Linkage analysis was performed using dense microsatellite maps inside the linked regions. The LINKAGE and GENEHUNTER packages were used for parametric (LOD) and non-parametric (NPL) analysis. They excluded both the 2q23 and the 7p11 loci. This finding provides further evidence for existence of another locus containing a gene that regulates the formation of keloids and/or hypertrophic scars. (<http://www.icp.ucl.ac.be/vikkula>) (vikkula@bchm.ucl.ac.be).

Autosomal dominant multiple familial trichoepithelioma in a large consanguineous Bedouin family: probable linkage to chromosome 16q12-13. *H. Romi*¹, *A. Zvulunov*², *R. Ofir*¹, *K. Elbedour*², *O.S. Birk*^{1,2}. 1) Laboratory of Human Molecular Genetics, Ben-Gurion University, Beer-Sheva, Israel; 2) Genetics Institute, Soroka University Medical Center, Ben-Gurion University, Beer-Sheva, Israel.

Multiple familial trichoepithelioma (MFT) is an autosomal dominant skin disease characterized by the presence of many small benign epithelial tumors with pilar differentiation predominantly on the face. The appearance of the lesions produces significant cosmetic distortion and causes much discomfort to the patients. A candidate MTF locus has been mapped to chromosome 9p21 in three north American families. Recently, mutations in the disease gene for familial cylindromatosis, the *CYLD* gene located on chromosome 16q12-13, have been shown to underlie MFT in four Chinese families. In order to identify the genetic defect causing autosomal dominant MFT in a large consanguineous Bedouin family in southern Israel, we initially performed linkage analysis with microsatellite markers from 9p21, ruling out linkage to this locus. Using 7 microsatellite markers spanning the *CYLD* gene locus at 16q12-13, we genotyped all available individuals. Our preliminary results strongly suggest linkage association to this region. Sequencing of the *CYLD* gene in the Bedouin patients is underway. These findings imply that *CYLD* defects are the cause of MFT in populations other than the Chinese.

Fetal Diagnosis of Marden-Walker Syndrome. *S.M. Nikkel¹, C. Goldsmith¹, M. Walker²*. 1) Dept Genetics, Children Hosp Eastern Ontario, Ottawa, ON, Canada; 2) Perinatology, Ottawa Hospital - General Campus, Ottawa, ON, Canada.

Marden-Walker syndrome (MWS) is a genetic syndrome characterized by blepharophimosis, joint contractures, immobile facies, decreased muscular bulk, postnatal growth retardation, developmental delay, micrognathia, and cleft palate. The fact that this syndrome has been documented in affected siblings and the children of consanguineous parents makes autosomal recessive inheritance the most likely mode of inheritance. We present a fetus who was found to have paucity of movement, bilateral talipes, and cerebellar anomalies on prenatal ultrasound. The mother was a G₂P₁ woman of Somali origin with a non-consanguineous partner. The early pregnancy was complicated by a maternal portal vein thrombosis that led to bowel necrosis. A partial bowel resection was performed at 8 weeks gestation. A detailed fetal ultrasound at 20 weeks gestation found the above mentioned features. The pregnancy was terminated and consent was given for autopsy. Karyotype was normal 46,XX. A fetal exam showed bilateral flexion deformities at the wrists. There were single palmar creases. There was minimal constriction at the elbows. Talipes was present bilaterally. The sternum was short. The face was markedly dysmorphic. Blepharophimosis and hypertelorism were present. There was a cleft palate. Internal investigations showed renal hypoplasia.

At present the molecular etiology of Marden-Walker syndrome is not known. Diagnosis is based on clinical findings. In a review paper by Williams et al. (1993), clinical criteria were devised. The majority of the mandatory criteria and supporting criteria can not be evaluated on fetal examination (developmental delay, immobile facies, and postnatal growth retardation). However very few syndromes have the constellation of findings seen in this fetus and we believe MWS to be the most likely diagnosis. MWS should be included on the differential on a prenatal ultrasound when decreased mobility, contractures and cerebellar findings are seen. Renal differences and facial changes further support the diagnosis.

Breakthroughs in molecular and cellular mechanisms underlying X-linked mental retardation. *C. Ehlers, R. Fahsold, H. Monir, K. Hager.* Institute Medical Genetics, Dresden, Germany.

Mental retardation (MR) is a frequent cause of serious handicap in children and young adults. It is defined as an overall intelligence quotient (IQ) lower than 70 associated with functional deficits in adaptive behaviour (such as daily-living skills, social skills and communication), with an onset before 18 years. Moderate to severe MR (IQ lower 50) is estimated to affect 0,4-0,8 percent; of the population and the prevalence increases to 2 percent; if mild MR (IQ between 50 and 70) is included, although these estimates vary widely between epidemiological studies. The underlying causes of MR are extremely heterogeneous. They include non-genetic factors that act parentally or during early infancy and cause brain injury, as well as established genetic causes. The Online Mendelian Inheritance in Man (OMIM) database identifies close to 1000 entries, many of which are X-linked conditions (XLMR). The prevalence of XLMR has been estimated as 1.8/1000 males with a carrier frequency of 2.4/1000 females. X-linked mental retardation (XLMR) is a heterogeneous disorder that is defined as either nonsyndromic or syndromic. To date, mutations in the following X-linked genes associated with a nonsyndromic mental retardation phenotype, although some of these genes are also associated with a specific syndromic diagnosis: *FMR2*, *GDI1*, *RSK*, *MECP2*, *SLC6A8*, *ARX*, *AGTR2* and *PQBP1*. All the genes identified to date are rare causes of XLMR-since only a small number of families have been found to carry mutations in the same X-linked gene- and there remains a large number of families with XLMR in which the causative mutation has not been identified yet.

An unusual mutational event in Duchenne muscular dystrophy: A case report. *M. Alcantara¹, M. Cervera², A. Pichardo², L. Orozco¹.* 1) Department of Human Genetics, Instituto Nacional Pediatría, Mexico city, Mexico; 2) Centro de rehabilitación Infantil Tlalnepantla, CRIT, TELETON.

ANTECEDENTS: Duchenne and Becker muscular dystrophies (DMD/BMD) are the most common heritable neuromuscular diseases in human. These diseases are inherited with a X-linked recessive pattern and are due to mutations localized in DMD gene (Xp21.2). The major types of mutations responsible for DMD/BMD are partial intragenic deletions (50-70%), followed in frequency by partial intragenic duplications (6-8%), point mutations (~30%), and other less frequent. **METHODS:** A male patient of 9 years old with diagnosis of DMD and his family, were referred to carry out molecular study and genetic counseling; no familial history of DMD was documented. The index case has a rapid progression of disease, remaining confined in wheelchair at the age of 8 years. In order to characterize the major type of mutations in the DMD gene, we carried out multiplexed polymerase chain reaction (M-PCR) of 21 exons of the DMD gene and a single PCR to analyze the neuronal promotor in the index case. DNA samples from mother and sister were analyzed by a quantitative and multiplexed PCR for evaluation of genetic dosage of deleted exons identified in the index case. As intrasample control we amplified a non-deleted exon (exon 6) and we also analyzed the DNA from healthy male and female individuals. **RESULTS:** Index case shows a double deletion pattern; one of them eliminates the neural and muscular promotors and the other eliminates exon 44, with an integrity of intermediate exons (exons 3 to 43). The evaluation of genetic dosages both in mother and sister were normal. **CONCLUSIONS:** The present case shows an unusual double deletion pattern in the DMD gene still not reported in literature. We propose that the absence of distant exons in the index case, can be explained by double de novo mutation events or by a genic inversion. The normal genetic dosage found in both mother and sister confirm the non-carrier status and support de novo mutational event.

A new microarray-based diagnostic tool for resequencing the whole CFTR gene. *M. Bonin^{1, 2}, C. May^{1, 2}, S. Poths^{1, 2}, U. Mau-Holzmann¹, D. Glaeser³, O. Riess¹.* 1) Medical Genetics Department, Institute for Human Genetics, Tuebingen, BW, Germany; 2) The Microarray Facility, Tuebingen, BW; Germany; 3) Gregor-Mendel-Laboratorium, Neu-Ulm, Germany.

Cystic fibrosis (CF) is the most common genetic disease among Caucasians. The CFTR gene consists of 27 exons and encodes for a protein that acts as an epithelial membrane channel. The recent development of a genotypic CFTR mutation screening has greatly improved diagnostic accuracy but the direct sequencing of the whole CFTR gene is expensive and time-consuming. Here we report the first microarray-based resequencing analysis of the complete CFTR gene. For this purpose, we used the oligonucleotide-microarray technology and designed a CustomSeq-Array for the coding region of the CFTR gene. The sequencing by hybridization (SBH) analysis is a promising new technology which potentially allows rapid and cost-effective screen for all possible mutations and sequence variations in genomic DNA. 35 unrelated CF patients and control persons were analyzed. All exons of each sample were amplified by PCR using specific primers, pooled, labeled, fragmented, and hybridized to the CFTR-CustomSeq array. Our approach unequivocally enables the complete resequencing of the whole CFTR gene with all exons, the exon-intron boundaries, and the corresponding promoter region with a custom-made resequencing array from Affymetrix. All examined mutations could be confirmed by the resequencing process. The tiling strategy provides additionally, in a single experiment, both complete sequencing of each strand and identification of any known or novel SNPs. The CFTR-array provides base calls at more than 99.99% accuracy which is comparable to capillary sequencing. Replicate experiments demonstrated a reproducibility of more than 99.99%. We conclude that array-based sequencing technology has the capability to efficiently and cost-effectively generate large-scale resequencing data of genes. The technology is in particular applicable to large genes with numerous different mutations, like CFTR. Furthermore CustomSeq arrays deliver a complete sequence within 48 hours which opens a revolutionary new era of sequence-based diagnostics.

Distribution of transferrin saturation and serum ferritin among Pacific Islanders living in the U.S.: the Hemochromatosis and Iron Overload Screening (HEIRS) Study. *E.L. Harris¹, B.M. Snively², T.M. Vogt¹, J.L. Holup¹, F.W. Dawkins³, V.R. Gordeuk³, H.D. Le⁴, H.V. Nguyen⁴, L.V. Passmore².* 1) Kaiser Permanente Center for Health Research (KP), Portland, OR, Honolulu, HI; 2) Wake Forest University, Winston-Salem, NC; 3) Howard University (HU), Washington DC; 4) University of California, Irvine (UCI), Irvine, CA.

Little information exists in the literature about hemochromatosis (HH) or iron overload (IO) in Pacific Islanders. The *HFE* C282Y allele is rare. In the HEIRS Study, a multi-site, ethnically diverse, primary-care-based screening study for HH and IO, we enrolled 706 participants of Pacific Island (PI) heritage. Transferrin saturation (TS) and serum ferritin (SF) levels were used to screen for IO (screening cut-offs: TS>50% and SF>300 g/L for men, TS>45% and SF>200 g/L for women). In these analyses, we included participants who did not report being previously diagnosed with HH or IO and did not have an *HFE* C282Y or H63D allele. Three of five Field Centers (KP, UCI, HU) had a sufficient number of PI participants to include in the analysis: 603 PI, 7,773 Asian, and 12,430 Caucasian participants met inclusion criteria. When adjusted for age and Field Center, PI men and women had higher mean SF levels than their Caucasian counterparts (men: 264 g/L vs 153 g/L; women: 96 g/L vs 62 g/L). Their values were similar to those of Asians (men: 265 g/L; women: 104 g/L). In contrast, mean TS levels were similar for PIs and Caucasians (men: 30.1% vs 30.1%; women: 24.2% vs 25.3%). Asians had the highest mean TS levels (men: 35.2%; women: 29.5%). The etiology and clinical significance of these differences is currently unknown. Explanations include differences among ethnic groups in iron metabolism, allele frequencies for other genes affecting iron metabolism, and the prevalence of undiagnosed primary IO, obesity, or other causes of iron elevations. Future HEIRS Study analyses include further evaluation of participants with elevated SF and TS, and gene discovery for non-*HFE* iron overload.

Sotos syndrome as a contiguous gene deletion syndrome that incorporates factor XII deficiency. *J.J. Shen¹, N. Kurotaki¹, C.W. Brown^{1,2}, J.R. Lupski^{1,2}*. 1) Dept Molecular Human Gen, Baylor Col Medicine, Houston, TX; 2) Dept Pediatrics, Texas Childrens Hospital, Houston, TX.

Sotos syndrome is a neurological disorder characterized by overgrowth, advanced bone age, dysmorphic features and mental retardation. Alterations of *NSDI* were recently proven to be a major cause of Sotos syndrome. Of a total of 145 aberrations reported, 87 represented point mutations, and deletions were found in 58 affected individuals. The frequency of microdeletion involving *NSDI* differs between Japanese and other populations; the reason for this observation is unclear. Telomeric to *NSDI* is the gene encoding factor XII (*FXII*), a serine protease in the intrinsic pathway of coagulation. Both increased and decreased levels of FXII reportedly are influenced by polymorphisms within the promoter region. The *FXII* locus lies within the common microdeletion observed in Sotos syndrome.

An individual with Sotos syndrome was determined to have persistently low levels of factor XII activity after minor head trauma resulted in a significant intracranial bleed. This combination of clinical findings was suggestive of a potential contiguous gene deletion syndrome. We conducted a cohort study in order to further test this hypothesis. FXII levels were analyzed in a total of 16 cases of Sotos syndrome with a *NSDI* deletion, and 9 control individuals. The deletion cases were 14 Japanese and two non-Japanese, and included 8 with the common microdeletion. Controls were 4 *NSDI* point mutation cases and 5 unaffected parents of deletion cases. Ten (62.5%) of the deletion patients had FXII deficiency, while in contrast, none of the control individuals exhibited low FXII levels. Based on these results, we hypothesize that the level of FXII in Sotos syndrome patients depends on the type of *NSDI* alteration. If a deletion is the causative mechanism, the remaining hemizygous *FXII* locus contributes to the total assayed level of activity, which may be in the normal range depending on the effect of promoter polymorphisms on gene expression. We propose that reduced plasma FXII levels may provide a useful surrogate marker of Sotos syndrome that arises through deletion of the critical *NSDI* region.

Autosomal recessive oculopharyngeal muscular dystrophy - an underrecognized syndrome? *B.L. Spriggs^{1, 3}, W. Ilse^{2, 4}*. 1) Molecular Diag Lab; 2) Dept of Neurology-Neurosciences, Health Sciences Ctr; 3) Dept of Biochemistry & Medical Genetics; 4) Dept of Internal Medicine, University of Manitoba, Winnipeg, Canada.

Oculopharyngeal muscular dystrophy (OPMD) is typically an autosomal dominant condition involving the trinucleotide expansion of the GCG/GCA repeat in the PABPN1 gene. Individuals with OPMD usually present in the fifth decade with progressive ptosis and dysphagia. The normal allele has 6 GCG repeats and the affected allele has 8 or more GCG/GCA repeats. The presence of two alleles each with 7 GCG repeats results in the autosomal recessive form of OPMD. There has only been one individual reported in the literature with autosomal recessive OPMD due to the presence of two 7 GCG repeats. Based on clinical findings for this one case, it was suggested that symptoms for the recessive form are milder with a later presentation in the sixth decade as compared to the dominant form. We describe a second individual diagnosed clinically with OPMD and confirmed to be homozygous for the 7 GCG repeat allele and hence, to have autosomal recessive OPMD. He presented for neurological assessment at 87 years of age with a history of ptosis, dysphagia and muscular weakness. He had no family history of similar problems and was of Anglo-Saxon descent. The dysphagia, which started 7 years earlier, had been adequately corrected by cricopharyngomyotomy 2 years prior. Examination revealed facial weakness where the patient had significant difficulties in closing his eyes and lips. There was no evidence of myotonia. The clinical findings along with myopathic EMG abnormalities lead to the diagnosis of OPMD, which was confirmed by the sizing of the GCG repeat by PCR. This represents the second known case of autosomal recessive OPMD. For this patient, the symptoms of OPMD were not noted until the eighth or ninth decade, supporting the previous thought that autosomal recessive OPMD is less severe than the dominant form. Given the reported frequency of 2% for the 7 GCG repeat allele, it is surprising that this is only the second reported case since the discovery of *PABPN1* in 1998. However, if the age of onset is frequently not until much later in life, autosomal recessive OPMD may be an underrecognized syndrome.

α^G *Xmn* I polymorphism in α -thalassemia patients in Malaysia. *Y.C. Wong*¹, *E. George*², *K.L. Tan*¹, *S.F. Yap*³, *J.A.M.A. Tan*¹. 1) Department of Molecular Medicine, Faculty of Medicine, University of Malaya, Malaysia; 2) Department of Clinical Laboratory Sciences, Faculty of Medicine and Health Sciences, University Putra Malaysia, Malaysia; 3) Department of Pathology, Faculty of Medicine, University of Malaya, Malaysia.

Beta thalassemia major and intermedia result from homozygous or compound heterozygous states for α -globin gene mutations and the clinical severity is dependent on the types of α -gene mutations involved. However, clinical severity can also be influenced by other genetic factors like increased α -globin gene expression. The *Xmn* I restriction site at -158 position of the α^G -gene has been reported to be associated with increased expression of the α^G -globin gene. The α^G *Xmn* I polymorphism causes a C to T base pair substitution at the -158 position in the promoter region of the α^G -globin gene. Increased expression of the α^G -globin gene and higher production of Hb F is associated with homozygosity for the *Xmn* I cleavage site (+/+) and thus, with less severe anemia and amelioration of the severity of α -thalassemia. Molecular characterization and frequency of the polymorphism in 107 α -thalassemia patients (58 Chinese and 49 Malays) was studied by *Xmn* I digestion after DNA amplification of a 650 bp sequence from the promoter region of the α^G -gene. Genotyping in the Chinese showed that the most frequent genotype observed was homozygosity for the absence of the *Xmn* I site (-/-) (89.7%). The 3 most common mutations in the Chinese - FS 41/42, IVS2-654 and -28 were largely associated with absence (-) of the *Xmn* I site. In the Malays, heterozygosity of the *Xmn* I site (+/-) was most common (63%). Homozygosity for the *Xmn* I site (+/+) was confirmed in 8% of the Malays and absent in the Chinese. The Chinese showed a high frequency of the (-) allele (95%) compared with the (+) allele (5%). The frequency of the (-) allele in the Malays was 60% and 40% for the (+) allele. Thus, the ratio of the (+) allele (presence of the *Xmn* I site) to the (-) allele (absence of the *Xmn* I site) was found to be higher in the Malays (0.66) compared to the Chinese (0.05).

Natural history of autosomal recessive polycystic kidney disease/congenital hepatic fibrosis. *M. Gunay-Aygun*¹, *R. Kleta*¹, *Z. Quezado*², *P. Mohan*³, *T. Heller*⁴, *P. Choyke*⁵, *W.A. Gahl*¹. 1) SHBG, MGB, NHGRI, NIH; Bethesda, MD; 2) CC, NIH; 3) CNMC; Washington DC; 4) NIDDK, NIH; 5) NCI, NIH.

Autosomal recessive polycystic kidney disease/congenital hepatic fibrosis (ARPKD) is a developmental disorder of the kidneys and liver caused by mutations in the PKHD1 gene. Fibrocystin (polyductin), the protein encoded by PKHD1, is expressed on the primary cilia of the renal tubule and bile duct epithelia and functions to maintain the tubular shapes of these structures. Kidney cysts occur as non-obstructive dilations of the collecting ducts; congenital hepatic fibrosis results from ductal plate malformation of the bile ducts. ~50% of ARPKD patients present perinatally; many die in infancy due to pulmonary insufficiency or sepsis. Both kidney and liver disease are progressive with variable rates of deterioration. More than half of the patients require renal transplant before age 20. Portal hypertension results in hypersplenism and esophageal varices. Half of the patients also exhibit cystic dilatation of the intrahepatic bile ducts (Carolis syndrome), with risk of recurrent cholangitis. Hypertension is a major problem affecting more than half of the patients. Only symptomatic therapy is available, and the natural history of ARPKD has not been comprehensively elucidated. We initiated a protocol to collect biochemical and imaging data on the hepatic and renal involvement of ARPKD. To date, 10 individuals 18 mo to 50 y have been evaluated; 4 presented prenatally. 9 had hepatomegaly and increased echogeneity of the liver on ultrasound. Magnetic resonance cholangiography showed cystic dilatation of the intrahepatic bile ducts in 3. Seven had splenomegaly and thrombocytopenia. Among the 4 who had esophagogastroduodenoscopy, 3 (ages 9, 20 and 41 years) had esophageal varices. 4 patients had subnormal renal function; creatinine clearance measurements varied from 45-110 ml/min/1.73m². Hypertension was present in 7 patients. Mutation analysis of the PKHD1 gene will allow for genotype/phenotype correlations. We continue to define the natural history of ARPKD in order to anticipate complications, provide prognoses, and identify outcome parameters for future therapeutic interventions.

Array-based CGH: identification of submicroscopic genomic disorders in clinical genetics. A. Orr-Urtreger^{1,2}, M. Goldstein^{1,2}, G. Rosner¹, A. Bar-Shira¹. 1) Genetics Inst, Tel Aviv Sourasky Medical Ctr; 2) Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel.

Abnormalities in DNA copy number can frequently be found in genetic disorders and tumors. This group of cytogenetic aberrations includes deletions, duplications, amplifications and unbalanced translocations. Array-based comparative genomic hybridization (CGH) allows the examination of DNA samples, derived from patients blood and tumor material, for changes in gene-copy number. By hybridizing differentially labeled test and reference genomes to arrays of hundreds genomic clones, it is possible to analyze many genes that play pivotal roles in clinical syndromes and oncology, and to detect individual and multiple changes simultaneously with high-resolution. Using the Genosensor Array 300 Chip we examined the applicability of this technique in the clinical genetic diagnostic setup. Single-copy-number gains and losses of individual genes and contiguous genes were detected in DNA samples from patients peripheral blood leukocytes. Deletions at 15q11.2-q13 in a newborn with hypotonia, cryptorchidism and hypopigmentation were detected with few discrepancies between the array results and FISH analysis. Contiguous microdeletion of *GSCL*, *HIRA* and *TBX1* genes at 22q11.2 was identified in a previously undiagnosed 12 years old boy with an unusual presentation of the VCF-DiGeorge spectrum. In an infant with multiple congenital anomalies and dysmorphic features, subtelomeric aberrations of 1qtel gain and 11qtel loss were confirmed by this method. In another case with aniridia, a borderline false negative WT1 deletion was observed, most probably because of differences between the size of the genomic deletion and the probe. Overall, good, but not perfect concordance was shown between array-based CGH and FISH diagnoses. This method is therefore becoming a useful adjunct for the rapid and accurate detection of genetic disorders associated with genomic copy number abnormalities and can significantly improve clinical genetic diagnosis and care.

LARALink: A tool for exceptional clinical utility. *J.S. Moldenhauer¹, B. Fayz², D. Wang², A. Platts², D.S. Borgaonkar³, S.A. Krawetz^{1,2,4,5}.* 1) Department of Obstetrics and Gynecology, Wayne State University, Detroit, MI; 2) Bioinformatics Facility, Wayne State University, Detroit, MI; 3) Laboratory of Neurogenetics, National Institute on Aging, National Institutes of Health, Bethesda, MD; 4) Center for Molecular Medicine and Genetics, Wayne State University, Detroit, MI; 5) Institute for Scientific Computing, Wayne State University, Detroit, MI.

Patient care and clinical research are somewhat limited by our ability to rapidly access the expanding pool of knowledge available in the field of genetics. LARALink (Loci Analysis for Rearrangements Link) is a web application that has been designed to allow rapid retrieval of clinically relevant information. The LARALink web application has been used as a tool for the analysis of gene expression by mining publicly available data from UniGene, dbEST, and OMIM. Recently, the site has been expanded to include a direct link to the Chromosomal Variation in Man database and the NCBI GEO database. We recently used this tool for prenatal genetic counseling of a patient with a history of a child with ring chromosome 6. Using cytogenetic parameters we were able to view a comprehensive list of the literature that is available on this condition along with highlights of the clinical features which included microcephaly, prenatal growth restriction, abnormally positioned ears, microphthalmia, hydrocephalus, and hypertelorism. This information was used to guide prenatal ultrasound to help to determine if the current pregnancy might be affected. The LARALink tool can also be applied to cases of cytogenetic aberrations, such as translocations or inversions, in attempts to make genotype/phenotype correlations through the use of cytogenetic breakpoints to identify potential gene candidates. LARALink is a tool that has tremendous potential in its applications to both clinical medicine and research. The data is expressed in a succinct and comprehensive fashion in order to allow rapid access to clinical information that helps to improve patient care and provide direction to future studies. This work was supported in part by grant 442000 to the WSU MCBI node to SAK.

Genotype-Phenotype Correlations for a Unique Disorder: Familial Myopathy, Paget Disease of Bone and Frontotemporal Dementia. *G. Watts¹, S.G. Mehta¹, J. Wymer¹, M. Pasquali², A. Kartashov³, C.D. Smith⁴, K.*

Boycott⁵, S. Markus⁶, S. Ebner⁶, S. Tucker⁷, K. Kimonis¹, A.K. Brownell⁵, V.E. Kimonis¹. 1) Dept. Genetics, Children's Hospital, Boston, MA; 2) Dept. of Pathology, School of Medicine, University of Utah, Salt Lake City, UT; 3) Clinical Research Program, Division of Biostatistics, Children's Hospital, Boston, MA; 4) Dept. of Neurology, University of Kentucky, Lexington, KY; 5) University of Calgary, Alberta Children's Hospital, Calgary, AB, Canada; 6) Praxis für medizinische Genetik, Roritzerstr. 2, 93047 Regensburg, Germany; 7) Eastover Internal Medicine, Carolinas Health Care System, Charlotte, NC.

Inclusion body myopathy (IBM) with Paget disease of the bone (PDB) and frontotemporal dementia (FTD) (IBMPFD, MIM 605382), is a progressive autosomal dominant disorder that was recently identified as being caused by mutations in the VCP (p97 or CDC48) gene. VCP is a member of the AAA protein family and has numerous functions including cell cycle control and targeted protein degradation. Within the fourteen IBMPFD families only four amino acid residues are mutated in VCP, suggesting a mutation hot-spot in the N-domain. To better characterize this disorder, we analyzed clinical, biochemical, and genetic components from 14 IBMPFD families. Haplotype analysis of the IBMPFD families identified two ancestral, disease associated haplotypes; group A: VCP mutation R155H and group B: VCP mutation R155C. The predominant IBMPFD haplotype of group A shares the same VCP mutation as four other families that do not share this haplotype. The R155C families had a significantly earlier age of onset for IBM (p0.05) compared to those with R155H. However, the R155H families had a significantly later age of onset for PDB (p0.05) when compared to R155C and the other VCP mutations. Early onset IBM or PDB did not significantly affect survival compared to the later onset of either phenotype. Interestingly we found that women were twice as likely to have dementia and APOE4 allele was associated with an increased predisposition for dementia. For the first time we demonstrate a phenotypic correlate of a given genetic change in the VCP gene in IBMPFD.

The natural history of severe anemia in cartilage hair hypoplasia. *M.S. Williams¹, R.S. Ettinger¹, P. Hermanns², B. Lee², M. Taskinen³, O. Mäkitie⁴.* 1) Dept Pediatrics, Gundersen Lutheran Medical Ctr, La Crosse, WI; 2) Department of Molecular and Human Genetics & Howard Hughes Medical Institute, Baylor College of Medicine, Houston, Texas USA; 3) Pediatric Hematology, Helsinki University Hospital, Helsinki, Finland; 4) Pediatric Endocrinology, Helsinki University Hospital, Helsinki, Finland.

Case Report: A two-month old Amish infant was referred for evaluation of severe anemia. He was also found to have thrombocytosis. On examination he was noted to be short with rhizomelia and mild distal digital hypoplasia. Skeletal survey showed generalized shortening of the long bones with metaphyseal changes of the proximal femurs and femoral bowing. The diagnosis of Cartilage Hair Hypoplasia (CHH) was confirmed by homozygosity for the 70A>G nucleotide substitution in the RMRP gene. **Methods:** Additional cases of severe anemia (Hgb < 3.0 g/dl or ongoing transfusion requirement) were identified from the Finnish CHH database and from the literature. **Results:** A total of 8 patients were identified. Follow up ranged from 3 months to 40 years. All patients had severe short stature. The clinical course varied from spontaneous recovery, to ongoing transfusions and, in one case, bone marrow transplantation. Other hematologic parameters have been variable. **Discussion:** Roughly 50% of CHH patients have anemia and macrocytosis. The hematologic picture is similar to that seen in Diamond-Blackfan anemia (DBA). While the majority of patients have a mild, self-limited anemia, there exists a severe phenotype. The clinical course of this anemia is variable. The severe anemia is not due to mutational heterogeneity. The possibility of interaction between RMRP and other genes such as IGF-1 has been proposed previously. An alternative hypothesis is that changes within the protein components of the mitochondrial RNA-processing endonuclease (MRP) contribute to the phenotypic heterogeneity. It is of interest to note that 25% of DBA is caused by mutations in ribosomal protein S19 (RPS19). It is not known if RPS19 is part of the MRP complex, or interacts with the complex in some way. Genetic analysis of RPS19 is being undertaken.

Genetic heterogeneity in South African patients with the Huntington disease phenotype. A. Krause¹, C. Hetem¹, S.E. Holmes², R. Margolis². 1) Division of Human Genetics, National Health Laboratory Service and School of Pathology, University of the Witwatersrand, Johannesburg, South Africa; 2) Department of Psychiatry, Johns Hopkins University School of Medicine, Baltimore, USA.

Huntington disease (HD) is an autosomal dominant neurodegenerative disorder, characterized by abnormalities of movement, emotion, and cognition and caused by a CAG repeat expansion in the huntingtin gene on chromosome 4p. A CAG/CTG repeat expansion in junctophilin-3 (JPH3) on chromosome 16q24 has been implicated in a subset of clinically diagnosed HD cases that do not have an expansion in the HD gene. The disorder caused by this mutation has been designated Huntington disease type 2 (HDL2). In a sample of unrelated South African patients tested diagnostically for HD, 84% (78/93) of white patients, but only 36% (18/50) of black patients and 50% (3/6) mixed ancestry patients had the HD mutation. However, 24% (12/50) of black patients and 50% (3/6) of mixed ancestry patients had HDL2 expansions. We have studied 17 HDL2 patients from 15 families, the largest number of families reported from any single center, accounting for 65% of the HDL2 pedigrees identified to date. Expanded repeats ranged in length from 40 triplets (the shortest known HDL2 expansion clearly associated with the disease) to 58 triplets. No juvenile cases have yet been observed, but in some families anticipation appears to be marked. Although clinical and pedigree data are limited at present, 73% (11/15) of families are clearly multiplex, with an autosomal dominant pattern of inheritance. Clinical features appear similar to HD, but remain to be fully documented. The finding that all HDL2 cases reported worldwide, including cases that we have identified in South Africa, have definite or probable African ancestry suggests a common African founder mutation; haplotype analysis is in progress to confirm this hypothesis. We conclude that HDL2 mutations account for a significant portion of the HD phenotype in South Africa, thus warranting HDL2 testing as part of the diagnostic protocol for the HD phenotype. Our findings also suggest that other causes of the HD-phenotype remain to be elucidated.

Microarray-based comparative genomic hybridization of deletion positive Angelman Syndrome subjects: Genotype-Phenotype correlations. *C.A. Bacino¹, S.U. Peters², A.L. Beaudet^{1,2}, T. Sahoo¹.* 1) Mol & Hum Gen, Baylor Col Medicine, Houston, TX; 2) Department of Pediatrics, Baylor College of Medicine, Houston, TX.

Angelman Syndrome (AS) is neurodevelopmental disorder characterized by mental retardation, dysmorphic features, ataxia, seizures and typical behavioral abnormalities including a happy sociable disposition. AS is caused by maternal deficiency of UBE3A, a gene located in an imprinted region within chromosome 15q11-13. Approximately 70 % of the AS patients have maternally derived deletions encompassing the AS/Prader Willi syndrome critical region on chromosome 15. Deletions can be divided into two groups, class I and II with 3 distinct common breakpoints (BP). Class I deletions span from BP1 to the distal most breakpoint BP3. Class II deletions span from BP2 to BP3, and since BP2 is more telomeric to BP1, class II deletions are smaller than class I. We have studied 16 deletion subjects with AS utilizing a chromosome 15 specific genomic microarray-based comparative genomic hybridization and analyzed their phenotypic severity. Array-CGH results are being confirmed by FISH studies. Those with larger deletions appeared to have a more severe phenotype as detailed below. We have also carefully characterized our cohort using standardized testing for cognitive skills, language, and adaptive behavior, and have also administered formal testing for autism: ADOS-G and ADI-R. Previously we have found that a severe phenotype is more commonly associated with a co-morbid autism diagnosis. Preliminary results from 11 of our cohort of 16 patients have been completed. Confirmatory FISH studies are underway. To date, 8/11 are class II and 3/11 class I. For class I deletions, 2 of 3 patients met criteria for autism and had more severe cognitive, language, and adaptive behavior deficits. In contrast, only 2 of 8 patients with class II deletions met criteria for autism and had more significant cognitive, language, and adaptive behavior deficits. Although those diagnosed with class I deletions appeared to be more severely affected, the sample size is being increased to determine if this is significant.

A novel mutation of CDKN1C(p57^{KIP2}) in a familial case with Beckwith-Wiedemann syndrome. *S. Ninomiya, Y. Yokoyama, M. Kawakami, H. Maruyama, T. Morishima.* Dept Pediatrics, Okayama Univ Medical Sch, Okayama, Japan.

Beckwith-Wiedemann syndrome (BWS) is a human imprinting disorder with variable phenotype. Several imprinted genes including the candidate BWS genes are clustered in chromosome 11p15.5. Recently germline mutations in the gene CDKN1C (p57^{KIP2}) have been reported in some BWS patients. We report a novel mutation of p57^{KIP2} in a familial BWS case.

Clinical features: The proband, 7-year-old girl was born at 40 weeks of gestation to nonconsanguineous parents as first-born child. The birth weight was 2,680 g. Physical examination showed macroglossia, exomphalos, ear lobe creases, cleft palate, diaphragmatic hernia, nephromegaly. She had operation for exomphalos and diaphragmatic hernia. She has no embryonal tumor. Second-born child is 2-year-old girl and is healthy. Third-born child was intra uterine fetal death at 12 weeks of gestation. Fourth-born child received the fetal ultra sound echogram examination at 20 weeks of gestation and showed exomphalos and hydronephrosis. The parents selected the induced abortion.

Cytogenetic and molecular genetic studies: The cells were prepared from peripheral blood of the parents and the proband, and from amniotic fluid of the fourth-born child. Chromosome analysis showed normal karyotype without 11p15 duplication or 11p15 translocation/inversion. The sequence of the p57^{KIP2} gene was performed by PCR product direct sequence. The overlapping fragments covered entire coding region and the exon-intron boundaries were used. In the proband the nucleotide change (codon67 CAGTAG) occurred in the exon2 and produced the nonsense mutation. The same change was detected in the mother and the fourth-born child.

Conclusions: p57^{KIP2} is a maternally expressed gene. As in this family the mutation was maternally inherited the expression of p57^{KIP2} is predicted to be inactivation in the two patients. The fact that the proband showed no overgrowth interests us the functional relationship between IGF2 and p57^{KIP2}.

Adulthood Diagnosis of Angelman Syndrome in a patient with Prader-Willi Syndrome Phenotype. *G. Scharer¹, J. Feiger², M. Taylor².* 1) Div. Clinical Genetics/Metabolism, Children's Hospital, Denver, CO; 2) Adult Medical Genetics Clinic, UCHSC, Denver, CO.

Background: Prader-Willi syndrome (PWS) and Angelman syndrome (AS) are considered distinct genetic disorders caused by the loss of function in differentially imprinted genes on chromosome 15q11-q13. Chromosomal deletions, uniparental disomy, imprinting defects and mutations in the UBE3A gene have all been described as etiologic factors in AS, and the clinical phenotypes of both syndromes have been delineated. Recently, several cases of AS have been reported (Gillissen-Kaesbach et al., 1999) of children with a PWS-like phenotype, who were found to have methylation patterns consistent with AS. These children lack most of the typical AS features (i.e. absence of speech, ataxia, seizures, microcephaly, macrostomia or a happy demeanor), but rather present with symptoms more typical of PWS, (i.e. obesity, hypotonia and mild mental disabilities). Case Report: We now report an adult male with a history of marked mental retardation, short stature and strong food-seeking behavior, which had resulted in obesity. Except for expressive language limitations and behavioral anomalies (high level of affection), the 24 year-old patient does not display any of the classical AS symptoms. Head circumference is at the 3rd percentile, the patient has a normal gait and there is no history of seizures or ataxia. Methylation studies were performed to screen for PWS, which we suspected clinically. Southern Blot analysis and methylation sensitive PCR revealed a methylation pattern consistent with AS. High-resolution karyotyping and FISH analysis showed no evidence for structural chromosomal defects, such as deletions or duplications in the PWS-AS critical region. Conclusion: The mechanisms explaining PWS phenotypic features in patients with AS genetic lesions remain unclear. The findings in our patient indicate that AS needs to be considered in the differential diagnosis of adult patients with mental retardation and PWS-like features, in particular when food-seeking behavior and obesity are present. Methylation testing should be performed as deletion testing is likely to be normal in these patients.

Linkage Analysis and Mutation Screening in Families With Triphalangeal Thumb and Associated Hand

Malformations. *M. Sun*^{1,2}, *Q. Liu*¹, *F.X. Wu*¹, *W.H.Y. Luo*¹, *E.W. Jabs*², *X. Zhang*¹. 1) Chinese Academy of Medicine Sciences & Peking Union Medical College, Beijing, China; 2) Johns Hopkins University, Baltimore, MD.

Triphalangeal thumb (TPT) is a congenital limb malformation characterized by a long, finger-like thumb with three phalanges instead of two, and is most often transmitted as an autosomal dominant trait. TPT can occur as an isolated phenotype with variable expression and sometimes is associated with a spectrum of other limb deformities, including polydactyly and syndactyly. Triphalangeal thumb-polysyndactyly syndrome (TPTPS, MIM 190605) is an autosomal dominant genetic disorder which usually shows a duplicated triphalangeal thumb, normal index finger, and cutaneous syndactyly between fingers 3-5. The gene responsible for TPTPS was mapped to the chromosome 7q36 region in 1994 (Heutink et al.). However, the causative disease gene has not yet been identified. We have performed linkage and molecular genetic analyses in two families with TPT, a large Chinese family with typical TPTPS and a Mexican family with TPT associated with preaxial polydactyly. Linkage and haplotype analyses were carried out for 13 genetic markers covering the critical region defined by Heus et al. (1999) for the Chinese family. The data we generated confirmed the linkage of the disease phenotype to chromosome 7q36. Confirmed and predicted genes from the candidate region, *C7ORF2/LMBR1*, *HLXB9*, *RNF32*, *C7ORF13*, *LOC389602*, *LOC393076*, *LOC393889* and *LOC393890*, have been subjected to mutation screening in the Chinese family and no pathogenic mutation was identified. In both of the families, we also performed sequence analyses of the long-range SHH enhancer within intron 5 of the *C7ORF2/LMBR1* gene. A sequence alteration C/T at a conserved base of the ZRS, ZAP Regulatory Sequence domain (position 402) was found in all of the three affected individuals available from the Mexican family. This alteration was not detected in 118 chromosomes from unrelated Mexican controls by restriction enzyme Rsa I, suggesting that the alteration might be a pathogenic point mutation. [Support from the Chinese National 863 Program (2001AA221101) and the International Collaborative Genetics Research Training Program (NIH D43 TW 06176)].

WT1 mutation is a cause of Congenital Diaphragmatic hernia associated with Meacham syndrome. *W. Reardon¹, S. Smith², M. Suri³, J. Grant³, D. O'Neill³, P. Kelehan⁴, D. FitzPatrick², N. Hastie².* 1) Dept Clin Gen, Ctr Medical Gen, Our Lady's Hosp Sick Children, Dublin, Ireland; 2) MRC Human Genetics Unit, Western General Hospital, Crewe Rd, Edinburgh EH4 2XU, UK; 3) Queen's Medical Centre, Nottingham NG7 2UH, UK; 4) National Maternity Hospital, Holles St, Dublin 2, Ireland.

Disruption of the WT1 locus on chromosome 11p is known to cause human disease in Wilms tumour-Aniridia-Genital malformation Mental Retardation syndrome (WAGR), Denys-Drash syndrome and Frasier syndrome. Missense mutations within the WT1 locus have also been reported in diffuse mesangial sclerosis. The major sites of WT1 pathology thus far described in human disease relate to the kidneys and developing gonads. However expression studies during development suggest a wider role for WT1, in particular the high level of expression in the mesothelial lining of the abdominal cavity, which contribute to the developing diaphragm and epicardium. That the WT1 homozygous mouse knock-out, in addition to loss of renal and gonadal development, shows ventricular hypoplasia, pericardial bleeding and diaphragmatic hernia lends further evidence that WT1 is important in heart and diaphragmatic development. We postulate that Meacham syndrome, a rare, sporadically occurring malformation syndrome comprising congenital diaphragmatic hernia, double vagina, sex reversal and cardiac malformations might be caused by mutation of the WT1 locus. We report a missense mutation, Arg366His, in a patient with this malformation syndrome and the de novo nature of that mutation is confirmed. This is the 6th patient described with Meacham syndrome and represents the first evidence that WT1 mutation is associated with this disorder. Moreover, we present data from autopsy record review which suggest that Meacham syndrome is more common than currently recognised and we review an additional 6 cases which we have identified. We consider the implications of our observations in relation to the wider context of congenital diaphragmatic hernia and the wider appreciation of the underdiagnosed condition described by Meacham.

Familial hyper- and hypopigmentation with age-related pattern change. *J.J. Hoo, A.E. Shrimpton.* Departments of Pediatrics and Pathology, S.U.N.Y. Upstate Medical University, Syracuse, NY 13210.

An unusual genetic condition in a three generation family with cafe-au-lait and hypopigmented skin spots is reported. There are several father-to-son transmissions strongly suggesting an autosomal dominant mode of inheritance. The youngest affected family member showed one cafe-au-lait spot and one hypopigmented spot as early as the neonatal period, the oldest affected and living family member is 77 years old. During childhood, the cafe-au-lait or hypopigmented spots were circumscribed, clearly distinguishable from the surrounding normal skin, and did not follow the lines of Blaschko. However, as the affected family members grow older, both kinds of circumscribed lesions fade, and at the same time, more and more hyper- and hypopigmented freckling appears. No other symptoms of type 1 neurofibromatosis [NF1; OMIM#162200] were noted in the family. The involvement of the NF1 gene in this family was ruled out by linkage analysis using polymorphic microsatellite probes flanking the NF1 gene on chromosome 17q11. None of the affected family members showed any other feature of tuberous sclerosis [TS, OMIM #191100] or Noonan syndrome [NFNS, OMIM #601321]. Similarly there was no family history of leukemia, glioma, or hereditary non-polyposis colon cancer, which might indicate a mutation of a mismatch repair gene e.g. MSH2 or MLH1.

Germline mutations in NEP and RASA1 are associated with a subset of patients with Cowden/Bannayan-Riley-Ruvacaba syndrome. X. Zhou, R. Pilarski, K. Waite, C. Eng. Human Cancer Genetics Program, Division of Human Genetics, The Ohio State University, Columbus, OH.

PTEN is a dual specificity phosphatase and is a key regulator of the PI3K/Akt apoptotic pathway. Germline PTEN mutations, including promoter mutations and large deletions, occur in 85% of Cowden syndrome (CS) probands, 65% of those with Bannayan-Riley-Ruvacaba syndrome (BRRS) and 50% of those with Proteus-like syndrome (PSL). Germane to the clinical setting, the genetic etiology remains to be determined in a considerable proportion of CS, BRRS and PSL patients without PTEN mutation. CS is an autosomal dominant multiple hamartoma syndrome with a risk of breast and thyroid cancers, while BRRS is a congenital heritable syndrome with megencephaly, developmental delay, lipomatosis and speckled penis. Because of a variable frequency of arteriovenous malformations (AVM) component to CS, BRRS and PSL, we sought to determine if RASA1, the susceptibility gene for capillary malformation-AVM syndrome encoding RasGAP, could also be a gene for these PTEN mutation negative cases, especially those with AVM. We scanned 16 PTEN mutation negative CS, BRRS and PSL with prominent AVM for RASA1 mutations, and found one (6%) with a germline G12C mutation, not found in 100 normal control chromosomes. This individual has CS features including multiple hemangiomas, lipomas, skin tags and tonsillar and ovarian cysts. We also considered another gene, NEP on 3q25 encoding neutral endopeptidase which has been shown to recruit PTEN to the plasma membrane, enhance its stability and phosphatase activity. We scanned 62 PTEN mutation negative CS or BRRS individuals for mutations in exons 3 and 19 (encoding the steric PTEN interacting and catalytic domains). One of 54 (2%) CS and no BRRS probands had a mutation, Q22R occurring at a highly conserved residue. Further, Q22 is downstream of a series of basic amino acids that directs NEP-PTEN interaction. Thus, Q22R is predicted to disrupt this key interaction. Taken together, our data suggest that genes encoding molecules which interact with PTEN and its downstream pathways may act as susceptibility genes for PTEN mutation negative CS/BRRS.

Molecular characterization of a 230 kb candidate MR region in subtelomeric 9p. *B.L. Griggs^{1,2}, S. Ladd¹, R.A. Saul¹, B.R. DuPont^{1,2}, A.K. Srivastava^{1,2}.* 1) J. C. Self Research Institute of Human Genetics, Greenwood Genetic Center, Greenwood, SC; 2) Department of Genetics, Biochemistry & Life Science Studies, Clemson University, Clemson, SC.

Mental retardation (MR) affects 1-3% of the world wide population. Chromosomal aberrations in the subtelomeric regions have been found in 5-10% of patients with MR and developmental disabilities (MR/DD). The causative genes underlying MR/DD have not been identified in these cases. To facilitate autosomal MR gene identification, we have mapped a critical genomic region associated with MR in two unrelated patients with MR/DD and chromosomal rearrangements involving 9p24. In one patient, a male with MR, no speech, seizures, and some dysmorphic facial features (significant balding, square chin, prominent supraorbital ridges, recessed eyes, and midface hypoplasia), we identified a genomic deletion of approximately 230 kb in subtelomeric 9p. In the second patient, a female with MR and ectodermal dysplasia and a balanced translocation $t(X;9)(q13.1;p24)$, we mapped the 9p24 breakpoint to a region overlapping with the centromeric end of the 230 kb subtelomeric deletion. The ectodermal defects in the female patient are due to the disruption of the EDA gene at Xq13.1. Thus, the MR in the patient with the translocation is presumably associated with the 9p24 breakpoint. Genes located within the critical region are being analyzed to determine if haploinsufficiency or gain of function of a gene deleted or present at or near the deletion/translocation breakpoints contributes to the MR in the patient with the $t(X;9)$ translocation. The finding of a genomic interval common to two patients with MR/DD supports the notion that at least one central nervous system specific gene affecting neurological development is located within the 9p24 critical region.

Intellectual Indicators in Adults with 22qDS. *M.S. Watson¹, D.A. Young¹, A.S. Bassett^{1, 2}, E.W.C. Chow^{1, 2}.* 1) Department of Psychiatry, University of Toronto, Toronto, Canada; 2) Centre for Addiction and Mental Health, Toronto, Canada.

Background: Past research has revealed a consistent finding of higher Verbal IQ (VIQ) than Performance or non-Verbal IQ (PIQ) scores in children and adolescents with 22q11 Deletion Syndrome (22qDS). This has suggested that a non-verbal learning disability may be a common feature of 22qDS (Swillen 1999 et al., Woodin et al., 2001). However, little is known about IQ test performances in adults with 22qDS, and if this Verbal and Performance IQ split is maintained into adulthood. **Objective:** To compare verbal and performance IQ scores in adults with 22qDS. **Methods:** Full WAIS-R intelligence protocols were used to determine full-scale VIQ and PIQ scores in 47 adults with 22qDS (26 M, 21 F; mean age = 28.34 years). 25 subjects had a DSM-IV diagnosis of schizophrenia (SZ) and 22 participants had no history of psychosis (NP). **Results:** There was no significant within-subject difference between VIQ and PIQ for the whole sample (mean VIQ = 71.94, SD = 7.4, mean PIQ = 71.53, SD = 8.3, paired $t = 0.5$, $p = 0.62$). Results were similar when the subgroup of subjects with schizophrenia was analyzed separately (mean VIQ = 70.32, SD = 6.7; mean PIQ = 69.8, SD = 6.0, paired $t = 0.63$, $p = 0.54$) from the non-psychotic subgroup (mean VIQ = 73.77, SD = 7.8; mean PIQ = 73.5, SD = 10.0, paired $t = 0.18$, $p = 0.86$). There were also no significant differences between the SZ and NP groups on VIQ scores (mean difference = -3.45, SD = 7.3, $t = -1.63$, $p = 0.11$) or PIQ scores (mean difference = -3.7, SD = 8.1, $t = -1.51$, $p = 0.14$). **Conclusions:** These results indicate that adults with 22qDS do not show the reported difference between VIQ and PIQ that has been found in children. Notably, results were not affected by the presence of a psychotic illness. These results suggest that the observed VIQ - PIQ difference observed in children may be related to an uneven neuro-developmental process in 22qDS.

Gonosomal mosaicism in a family with segmental neurofibromatosis type 1 (SNF1). *C. Consoli*¹, *S. Green*², *D. Balderson*³, *D. Cooper*¹, *C. Moss*², *M. Upadhyaya*¹. 1) Institute of Medical Genetics, Cardiff University, Cardiff, Wales, UK; 2) Departments of Dermatology and Neurology, Birmingham Children's Hospital, Birmingham B4 6NH, UK; 3) Selly Oak Laboratory, Birmingham B29 6JD, UK.

Segmental neurofibromatosis type 1 (SNF1) is characterised by the regionally limited distribution of the cutaneous features of NF1. SNF1 is not infrequent (1 in 50,000) but the majority of reported cases are sporadic. The identification of NF1 gene mutations in children with classical NF1, one of whose parents has segmental NF1, should provide the means to study the development of affected and unaffected tissues in the parents. We have studied a family in which the daughter has generalised NF1, whilst her mother exhibits symptoms of segmental NF1. A nonsense mutation in exon 31 (R1947X) of the NF1 gene was identified in the lymphocyte DNA of the affected child by denaturing high performance liquid chromatography (dHPLC). Skin biopsies were taken from both affected and unaffected regions of the mother's body; fibroblasts and keratinocytes were then cultured. Direct mutation analysis of NF1 exon 31 failed to identify the R1947X mutation in DNA samples derived from these cell lines. DNA fragments containing exon 31 were then cloned from each cell line and clones were screened using allele-specific PCR. The R1947X mutation was identified in 19% (29/146) of keratinocyte clones derived from the mother's affected tissues and in 11% (12/136) of clones derived from affected fibroblasts. The nonsense mutation was however undetectable in clones derived from clinically unaffected tissues. This finding provides support for the postulate that some patients with segmental neurofibromatosis are gonosomal mosaics. Thus, the mother with segmental NF1 is presumed to be a gonosomal mosaic who expresses the mutant NF1 allele both in her germline cells and in a variable proportion of her somatic cells. These data should potentiate both molecular diagnostic testing and the provision of genetic counselling in family numbers, but could also lead to a better understanding of the molecular mechanisms underlying SNF1, by helping to identify the cellular lineages manifesting the mutation.

Hutterite brothers both affected with 2 forms of limb girdle muscular dystrophy (LGMD2H and LGMD2I). P. Frosk, K. Wrogemann, C.R. Greenberg. University of Manitoba, Winnipeg, MB, Canada.

Limb girdle muscular dystrophy is very common in the Hutterite population of North America. We have recently reported the homozygous D487N mutation in *TRIM32* associated with the mild form of Limb Girdle Muscular Dystrophy type 2H (LGMD2H). We have also identified Hutterite patients with LGMD2I, homozygous for the common L276I mutation in *FKRP*. To date all Hutterites with LGMD have been shown to have one of these two mutations. A comparison of the 2 phenotypes in the Hutterites is in press (Human Mutation). We now report a Hutterite family ascertained by a father known to have LGMD2H. Two of five sons (7 and 10 years old), studied due to parental concern of decreased stamina, were found to be homozygous for **both** the *TRIM32* D487N and *FKRP* L276I mutations. Both had slender builds with no muscle hypertrophy or atrophy, no objective signs of muscle weakness, normal cardiac and respiratory exams, and elevated CK values of 1555 and 1055 U/L respectively (normal <165 U/L). The older boy had a muscle biopsy showing an active dystrophic process. Echocardiograms are pending. The other 3 sons (4, 6 and 11 years old), currently asymptomatic, had normal physical examinations and CK levels of 160, 151 and 213 U/L respectively (normal <165 U/L). They were found to be homozygous and heterozygous for the *TRIM32* and *FKRP* mutations respectively, identical to their asymptomatic 33 year old mother (CK level 117 U/L; normal 28-110 U/L) and their 40 year old affected father who had moderate slowly progressive proximal muscle weakness and a CK level of 2030 U/L (normal 52-175 U/L). Our experience with 45 Hutterites affected with LGMD2H alone and 21 Hutterites with only LGMD2I suggests that LGMD2I is more severe with an earlier age at onset and higher CK levels. Preliminary analysis of these 2 boys with both forms of LGMD does not reveal differences in age at or mode of presentation, physical findings, or CK levels compared to individuals affected with LGMD2I alone. This suggests that the effects of these two mutations are not acting synergistically at a young age. It remains to be seen whether there will be signs of interaction between these two LGMDs as the patients get older.

Description of a New French-Canadian Recessive Form of Limb-Girdle Muscular Dystrophy with Prominent Quadriceps Atrophy. *J. Jarry¹, M.F. Rioux¹, M. Vanasse², Y. Robitaille², G. Karpati³, B. Brais¹.* 1) Laboratoire de Neurogenetique, Centre de Recherche du Centre Hospitalier de l'Universite de Montreal, Quebec, Canada; 2) Hopital Ste-Justine, Montreal, Quebec, Canada; 3) Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada.

Limb-girdle muscular dystrophies (LGMDs) are a heterogeneous group of disorders characterized by progressive weaknesses of the limb girdle muscles. Advances in genetics have allowed the characterization of ten recessive forms. We have identified a cohort of sixteen individuals from twelve different French-Canadian families displaying a phenotypically distinct recessive form of LGMD associated with quadriceps atrophy and myalgia. All patients were examined, genealogical data was collected, serum creatine kinase (CK) levels were measured in blood samples from affected and non-affected individuals alike, and EMG results and muscle biopsies were reviewed. Males and females are equally affected, while the number of affected cases is consistent with a recessive mode of inheritance. CK levels are always elevated but demonstrate important variability even in the same family. (from 1.5 to 30 times normal) EMG results show mostly myopathic changes. Immunohistochemistry studies of muscle biopsies demonstrated normal staining for dystrophin and sarcoglycans. Using an affected-only homozygosity mapping strategy on two of the largest families we performed a 10-cM genome-wide scan using the Weber 8 panels. Analysis of the different candidate regions is on-going. This study is the first description of a large French-Canadian cluster of cases of a new recessive LGMD with quadriceps atrophy.

An alternative for FISH: MLPA-based detection of genetic imbalances (aneuploidies), from sample to result within 6 hours. *M.E. Kalf^{1,2}, S.J. White¹, M. Kriek¹, L. Vahlkamp², R. van Beuningen², J.T. den Dunnen¹, G.J. van Ommen¹, M.H. Breuning¹.* 1) Leiden University Medical Center, Leiden, Netherlands; 2) PamGene International B.V., 's-Hertogenbosch, Netherlands.

Diagnosis of syndromes caused by chromosomal abnormalities is performed using cytogenetic analysis. Since cells need to be cultured, a diagnosis takes at least 3 days. In some cases, for example trisomy 18 and trisomy 13 the prognosis is such that treatment is usually withheld. The time required to determine whether these chromosomal aberrations might be involved or not is an important issue. If not, the appropriate treatment can be arranged in a timely manner.

We have tested Multiplex Ligation-dependent Probe Amplification (MLPA) in combination with a porous micro array substrate (PamChipTM array) as a tool for detection of such aneuploidies. Compared with planar arrays, the PamChip array has several advantages, including the larger surface area, the possibility to vary hybridization stringency during analysis and most interestingly a decreased hybridization time of about 10 minutes.

For each of the chromosomes to be tested (13, 18, 21, X) six probes were designed, as well as some control probes. To facilitate array-based analysis, each MLPA probe contains a non-hybridizing tag sequence. For analysis, oligonucleotides complementary to the tag sequences were spotted on the PamChip.

By comparing spot intensities between controls and patients it was possible to detect different aneuploidies within 6 hours from blood sample until result. Using the methodology developed, we performed a blind study on 25 patients and typed all correctly. Preliminary results showed that even mosaic cases (50%) could be detected. To facilitate wide-spread application several protocols were tested successfully, including MLPA performed on buccal swabs, amniotic fluid samples and amplified genomic DNA. The limit of the method was tested using 200 probes in one assay; excellent results were obtained. Our results thus indicate that it should be feasible to design powerful assay to screen for genetic imbalances with a resolution at the gene level.

Cutis laxa arising from an autosomal dominant splice mutation in exon 24 of the elastin gene (ELN) in a three months old boy and his father with highly variable phenotype. *C. Kraus¹, I. Hausser², M. Essayi³, J. Kunze⁴, A. Reis¹, L. Neumann⁴.* 1) Inst Human Genetics, Univ Erlangen, Erlangen, Germany; 2) Electron Microscopic Laboratory, Dermatology, University Clinic, Heidelberg, Germany; 3) Department of Neonatology Charit Campus Mitte, Berlin, Germany; 4) Institute of Human Genetics, Charit Campus Virchow-Klinikum, Berlin, Germany.

Congenital cutis laxa is a rare, genetically heterogeneous connective tissue disorder. The systemic involvement of elastic tissue is characterized by high clinical variability. The typical aspect is marked skin laxity lacking elastic recoil which is accompanied nearly always by rarefaction, loss, fragmentation or severe disorganisation of dermal elastic fibres. In three cases of autosomal dominant cutis laxa, causal frameshift mutations within the gene coding the structural protein Elastin, a main component of elastic fibres, could be identified. Here we report a three month old boy with cutis laxa and his clinically unaffected father. Mutation analysis in the Elastin gene was carried out by sequencing all coding exons in genomic DNA. A cytosine to thymine substitution was identified at the last position of exon 24. To further characterize the implication of the mutation, total RNA was extracted from cultured fibroblasts. RT-PCR and subsequent sequencing of a fragment encompassing the critical region revealed an in frame deletion of exon 24, probably, resulting in a stable protein lacking amino acids 526-540. This is consistent with former observations that suggest that the phenotype of cutis laxa is the result of a dominant negative effect compared to SVAS caused by loss of function mutations in the ELN gene. Interestingly, the mutation was also present in the father who had no signs of cutis laxa, suggesting that the mutation is associated with a high phenotypic variability. Nevertheless, herewith we report the fourth family with autosomal dominant cutis laxa, caused by a mutation in the Elastin gene.

Construction of high throughput gene analysis system using DNA microarrays. *Y. Takahashi, J. Goto, S. Tsuji.*
Neurology, The University of Tokyo, Bunkyo-ku, Tokyo, Japan.

[Introduction] With recent progresses in molecular genetics, a number of causative genes for hereditary diseases have been identified, and it is imperative to identify individual mutations of the corresponding genes in clinical practice. Given this background, we are confronted with strong demand for a high throughput system capable of analyzing individual genes from a large number of patients. To accomplish this aim, we have designed new microarrays using GeneChip™ CustomSeq resequencing system (Affymetrix). We designed three microarrays: TKYPD01 for Parkinson disease and related disorders, TKYALS01 for amyotrophic lateral sclerosis (ALS), and TKYAD01 for Alzheimer disease and other dementias. These microarrays contained the exon and their flanking intron sequences of the causative genes, disease susceptibility genes, modifier genes, and related genes which presumably play a key role in these diseases. Promoter sequences of several genes were also included. The purpose of this study is to validate the accuracy of these microarrays to identify individual mutations. [Materials and Methods] Genomic DNA samples were obtained from patients with familial ALS as well as from normal controls with informed consent. Twelve DNA samples with seven SOD1 mutations (L129*del(TT), G93S, I149T, V118L, H46R, L84V, and S134A) and a polymorphism, all of which had been previously identified using direct nucleotide sequencing, were used. The genomic DNA was amplified using specific primers for each exon, and the PCR products were pooled, fragmented, labeled, and hybridized on TKYALS01 microarrays. [Results and discussions] All the point mutations and the polymorphism were unambiguously detected. For the deletion mutation, the signals of probes at the deletion site, as well as those of ten adjacent probes, were apparently weak compared with those derived from normal controls. In addition, we found previously unidentified single nucleotide polymorphism at 5-UTR in two patients. These results indicated that this microarray system was a robust tool for identifying point mutations, and potentially useful for deletion mutations as a high throughput analysis system.

Pseudoxanthoma Elasticum: mutation analysis and phenotypical characterization in Belgian patients and heterozygous carriers. *O. Vanakker^{1,3}, P. Coucke¹, B.P. Leroy¹, D. Voet², E. De Baere¹, P. Van Acker¹, A. De Paepe¹.*
1) Center for Medical Genetics, Ghent University Hospital, Belgium; 2) Department of Internal Medicine, Ghent University Hospital, Belgium; 3) Research Assistant of the Fund for Scientific Research Flanders (Belgium).

Pseudoxanthoma Elasticum (PXE) is a heritable connective tissue disease comprising cutaneous, ocular and cardiovascular manifestations. It is caused by mutations in the ABCC6 gene on chromosome 16p13.1. It is generally believed that the inheritance of PXE happens in a recessive manner. Systematic clinical and molecular screening of carriers has, to our knowledge, not yet been reported.

We present 38 Belgian families of PXE-patients. The diagnosis was established on clinical and histological grounds. Molecular analysis revealed 63 mutations, 15 of which are novel. Different types of mutations were found in homozygous (22%), heterozygous (25%) or compound heterozygous (53%) form, although the R1141X mutation is most frequent.

In a subgroup we analysed the phenotype of patients and carriers through history-taking, clinical, ophthalmological and ultrasonographical examinations. We found the typical skin and retinal lesions in all patients but in none of the carriers. In 45% of PXE patients we detected calcifications in the liver, kidneys and spleen. Remarkably, some of the carriers showed similar lesions. In addition we found bilateral microlithiasis in all male patients so far but also bilateral calcification of the rete testis in carriers. These findings suggest that in both patients and heterozygous carriers, calcifications of the abdominal organs and testicles may be part of the PXE phenotype. Since the latter are considered a risk factor for malignancy, follow-up is warranted.

In patients homozygous for the R1141X mutation, we looked for genotype-phenotype correlations. Although this needs further confirmation, this subgroup seems not only to have a more severely affected cardiovascular system, but also severe retinal problems. Further correlations are still under investigation.

Body Temperature and Sleep Disturbance in Smith-Magenis Syndrome (SMS). *W.C. Duncan¹, R.S. Morse², D. Krasnewich¹, A.C.M. Smith¹.* 1) MAP/NIMH; 2) MGB/NHGRI, NIH/HHS, Bethesda, MD.

The sleep disturbance in Smith-Magenis syndrome (SMS) extends from early childhood through adulthood and is the major correlate of negative behavior during childhood. The disturbance is characterized by increased daytime sleepiness and reduced nighttime sleep that is strongly linked to early morning awakening. The disturbance may be partly attributed to an inverted 24-hour pattern of melatonin (low nighttime levels and elevated daytime levels). In all other organisms, melatonin is elevated at night. In addition, the sleep disturbance could be related to an altered timing of the circadian rhythm in body temperature. In humans, the 24-hour rhythms of melatonin and body temperature are often used as biological markers of the central circadian clock. Therefore, the unique phenotypic inverted melatonin pattern observed in SMS suggests that circadian clock phase is inverted in SMS. Preliminary evidence argues against this, since the timing of the circadian rhythms of cortisol and growth hormone are relatively normal in SMS. To more definitively estimate circadian clock phase and its possible relationship to disturbed sleep in SMS, the circadian rhythm of body temperature was measured in 6 subjects with FISH confirmed SMS (age 4-13 y). Temperature was measured at home from the ear or forehead once every 3 hours for 48-72 hours by parents who were trained in the procedure. Care was taken to measure temperature only during quiet behavior and rest. For each subject the circadian rhythm was formally characterized by a least-squares sine wave fit to the data. In each case a clear non-inverted circadian rhythm of body temperature was identified with circadian peaks present during the daytime and troughs at night. The data suggest that the circadian clock is not inverted in SMS. Further, the fact that the average temperature peak tended to occur early in SMS (12:45PM 2:20h:m) suggests that early timing may be related to the early morning awakening commonly seen in SMS sleep patterns. If so, such information would be beneficial for understanding the specific biological basis of the sleep disturbance, and for developing possible treatment strategies.

The repetitive behavior subphenotype in autism. *M.L. Cuccaro¹, S.L. Donnelly¹, C.M. Wolpert¹, R.K. Abramson², H.H. Wright², G.R. DeLong¹, A. Ashley-Koch¹, M.A. Pericak-Vance¹.* 1) Center for Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) WS Hall Psychiat Instit, Univ of South Carolina, Columbia, SC.

Restricted and repetitive behaviors and interests are a defining feature of autism. A repetitive behavior subphenotype has been developed to create subgroups for genetic analyses of autism. The current study examined developmental influences (chronological age and developmental level) on the repetitive behavior subphenotype. 162 participants with autism (age range 3 to 21 years) were drawn from an ongoing autism genetics study. Participants consisted of 130 males (M age = 94 months, SD = 45) and 32 females (M age = 105 months, SD = 44) from both family history positive and negative families. Clinical diagnostic and behavioral assessments included the Autism Diagnostic Interview-Revised (ADI-R), Aberrant Behavior Checklist (ABC), and Vineland Adaptive Behavior Scales (VABS). The repetitive behavior subphenotype was measured using the ADI-R and The ABC. Using the ADI-R, two repetitive behavior factors were constructed: Repetitive Sensory Motor Behavior (RSMB) and Insistence on Sameness (IS). The ABC Stereotypy Factor was also examined. Analyses indicated that the RSMB factor was significantly negatively correlated with both age ($r = -.16$, $p = 0.04$) and developmental level ($r = -.20$, $p = 0.01$). The IS factor was significantly positively correlated with age ($r = .16$, $p = 0.05$). While significant, these correlations suggest weak relationships. The ABC Stereotypy factor score failed to attain significant correlations with either age or developmental level. Multiple regression analyses were conducted using age, developmental level, and RB measures as predictors. For the RSMB and IS factors, predictor variables account for a limited amount of the variance (RSMB $R^2 = 14\%$; IS $R^2 = 11\%$). Both age at exam and the VABS Adaptive Behavior Composite score contributed significantly to the dependent variables. The results suggest that the repetitive behavior subphenotype is not uni-dimensional. Given the increasing use of this subphenotype in genetic analyses of autism, it is critical that subsequent investigations explore the full range of this potential subphenotype.

Unusal phenotype for cystic fibrosis. *W. Eyaid*¹, *M. AlBalwi*², *M. Al-Ghahab*³. 1) W.Eyaid, Dept Pediatrics, MBC 1510, King Abdulaziz Medical City, Saudi Arabia; 2) M. A. AlBalwi, Departemnt of Molecular Pathology and Genetics King Abdulaziz Medical City, Riyadh, Saudi Arabia; 3) M. Al-Ghahab, Dept of Pediatrics, MBC 1510, King Abdulaziz Medical City, Saudi Arabia.

A 14 months old boy was born for a first cousin parents as a product of 40 wk gestation with appropriate birth growth parameters. The parents lost a daughter at 7/12 of age with a history of failure to thrive (FTT). She had normocytic normchromic anemia, hepatosplenomegaly, hypoalbuminemia and congenital amputation of right hand. Our patient was admitted at 2 months of age to investigate his anemia, thrombocytopenia and FTT. On examination he had postnatal growth retardation, fair skin, blond spare scalp hair, hepatosplenomegaly and petechial rash. His Hemoglobin electrophoresis was normal and ranging between 6.5-7.2. Serum ferritin was 1151 and normal serum copper and ceruloplasmin were seen. Normal Bone marrow aspiration and liver biopsy showed iron deposit. Work up for storage disease like Nieman-pick and Gaucher was unremarkable. He developed chronic cough and readmitted for bronchiolitis and diarrhea. Elevated sweat chloride test was seen three times at age of 7/12 and result showed 111 mmol/L, 95 mmol/L and 107 mmol/L (NL < 60 mmol/L) respectively. He was started on medication for chest and diarrhea. On follow up, his anemia resolved and his liver was just palpable. His height and weight were 50% for 7 months at 14 months of age. DNA mutation analysis for cystic fibrosis showed presence of 1548delG mutation in exon 10 in both alleles of the CFTR gene. This is a common pathogenic mutation reported among Saudi population. Our cases showed a significant difference in the CF clinical presentation that have not been reported before, however, they had the common mutation that may have some influence on clinical presentation due to CFTR gene modification product.

Phenotypic Heterogeneity in Congenital Cataract Cases from India. *V. Kumar¹, D. Singh², K. Guleria¹, K. Sperling³, J.R. Singh¹.* 1) Centre for Genetic Disorders, Guru Nanak Dev University, Amritsar, Punjab, India; 2) Dr. Daljit Singh Eye Hospital, Sheranwala Gate, Punjab, India; 3) Institute of Human Genetics, Augustenburger Platz 1, 13353, Berlin, Germany.

Methods: More than 710 cases affected with bilateral congenital cataract were investigated at Dr. Daljit Singh Eye Hospital, Amritsar. Detailed ophthalmic examination, that included slit-lamp examination and 3-D photography of the lens to record the cataract type, was undertaken in all the cases. **Results:** Apart from the few known cataract types like; polar, nuclear, total, zonular, sutural, cerulean, coralliform etc. we have reported more than 100 distinct phenotypes in these cases, over 20 being novel phenotypes, not documented in literature so far. **Conclusions:** We have observed a wide phenotypic heterogeneity in our cases of congenital cataract, indicating its inherent genetic heterogeneity. The identification of responsible genes, causative mutations and modifiers will be of great help to draw a precise correlation between genotypes and different phenotypes observed so as to understand the exact mechanism of cataractogenesis, but the utmost need is of a uniform classification for congenital cataract.

Hair whorls and Handedness: Informative phenotypic markers in non syndromic cleft lip with or without cleft palate (NS CL/P) cases and their unaffected relatives. *N.M. Scott, S.M. Weinberg, K. Neiswanger, M.L. Marazita.*
Center for Craniofacial and Dental Genetics, University of Pittsburgh, Pittsburgh, PA.

CL/P is a common birth defect with a wide range of birth prevalences (1/500-1/2000) and a complex etiology. Studies have demonstrated differences in brain structure and cognitive traits between individuals with CL/P and controls. Accordingly, in the current study, we hypothesized that altered brain development is part of the phenotypic spectrum of NS CL/P by assessing non-right handedness (NRH) and atypical hair whorls (HW) in CL/P families. Though previous investigators have shown increased levels of NRH in CL/P, atypical hair whorls (counter-clockwise and double) are more direct markers of altered brain development, and have yet to be studied in CL/P. The study population consisted of 41 NS CL/P cases and 124 of their unaffected relatives. The Edinburgh handedness inventory was used to determine handedness; scores of 50 or less were considered NRH.

Trait	CL/P	Unaff. Relatives	All Subjects	General Pop.
NRH	31.7%	18.5%	21.7%	10.0%
Atypical HW	4.9%	21.8%	17.6%	9.9%

The proportion of NRH was increased in both the CL/P ($p < 0.0001$) and unaffected relatives ($p < 0.001$) versus the population rate, and in CL/P cases versus the relatives (though not significant). All subjects had increased rates of atypical hair whorls versus the population rate ($p < 0.001$). These results imply that aspects of brain development comprise part of the extended phenotype of orofacial clefting, both in affected individuals and their non-cleft relatives. Funded by NIH grants DE-13076, DE-016148.

Autosomal recessive distal spinal muscular atrophy (Chronic DSMA) with congenital onset : clinical picture and genetic study of 4 cases. *L. Viollet^{1,2}, I. Maystadt³, M. Zarhrate¹, A. Munnich¹.* 1) INSERM U393, Hopital Necker Enfants Malades, 149 rue de Sevres, 75743 PARIS, Cedex 15, France; 2) Service de Pediatrie et Reeducation Neuro-respiratoire, Hopital Raymond Poincare, 92380 Garches, France; 3) Department of Human Genetics, Catholic University of Louvain, Brussel, Belgium. FNRS, Brussel, Belgium.

Autosomal recessive Chronic Distal Spinal Muscular Atrophy (Chronic DSMA or Distal Hereditary Motor Neuronopathy type III) is a rare neuromuscular disorder characterized by progressive anterior horn cell degeneration, leading to motor weakness and muscular atrophy predominating in the distal part of the limbs and accounts for less than 10% of all spinal muscular atrophy cases. We collected a series of 12 European unrelated Chronic DSMA patients, with a broad range of age at onset, extending from 0 to 12 years. We mapped Chronic DSMA gene in a short genetic interval on chromosome 11q13.3. We showed evidence of a common haplotype at this locus in 8/12 patients, suggesting a partial linkage disequilibrium in the European population. Four patients presenting a Congenital Onset Chronic DSMA had a generalized hypotonia at birth with bilateral equinus varus feet and flexed fingers attitude. No neonatal respiratory distress was present. Outcome was marked by delayed motor milestones and a low progression of paralyzes during childhood. Progressive restrictive respiratory insufficiency was observed, due to diaphragmatic paralysis. Neurophysiological assays showed a severe muscle denervation with normal nerve conduction velocities and distal sensory potentials were detected. No SMN gene deletion was found in these patients. Haplotype analysis at the 11q13.3 locus revealed that all of the four patients harbored the common "European" haplotype. These data strongly supported the view that this congenital phenotype was linked to the Chronic DSMA locus on chromosome 11q13.3. Identification of the mutation responsible for Chronic DSMA will hopefully allow the molecular diagnosis of this congenital onset condition and will probably help understanding the mechanisms of anterior horn cell degeneration in childhood onset spinal muscular atrophies.

The polymorphism A1298C in the MTHFR gene is distributed according to gender, and it is associated maternally to neural tube defects in the State of Yucatan, Mexico. *L. Gonzalez-Herrera¹, I. Castillo-Zapata¹, G. Garcia-Escalante¹, D. Pinto-Escalante¹, A. Gonzalez-Del Angel².* 1) Genetics Lab, CIR, Univ Autonoma de Yucatan, Merida, Yucatan, Mexico; 2) Department of Research in Human Genetics. Pediatrics National institute.

Neural tube defects (NTD) are highly prevalent in the State of Yucatan, Mexico. NTD include congenital malformations such as anencephaly, spina bifida and encephalocele. MTHFR is a candidate gene for NTD in the folate metabolism pathway. The polymorphism A1298C in the MTHFR gene has been associated with NTD. Research has spurred interest in maternal genetic effects, because folate variants could influence the risk of NTD through the maternal, the embryonic, or both genotypes. In this study, we evaluated the frequency of the allele A1298C-MTHFR according to gender, and its association with NTD in the State of Yucatan, Mexico. We genotyped by PCR-RFLPs, 99 subjects with NTD, 82 of their respective mothers and 44 of their fathers to compare with 110 control subjects: 63 women and 47 men with healthy offspring. Genotypic frequencies in control group were in agreement with Hardy-Weinberg expectations ($p > 0.33$). The frequencies of the allele C and heterozygous AC genotype were significantly higher in males than in females ($p = 0.017$ and $p = 0.032$, respectively), suggesting an heterozygous advantage. Interestingly, we found significant association for allele 1298C ($p = 0.025$) and for the heterozygous AC genotype ($p = 0.034$) only in mothers of NTD. Comparison on the basis of the type of NTD, showed that the polymorphism A1298C was significantly associated with mothers of anencephaly cases only ($p = 0.029$). We found no evidence of a contribution for NTD through the interaction of both maternal and embryonic genotypes ($p > 0.05$). Our results suggested that the polymorphism A1298C-MTHFR is associated with the risk for NTD mainly through the maternal genotype rather than through the embryonic genotype. So, the allele C and the heterozygous AC genotypes are maternal risk factors for having offspring with anencephaly in the population of Yucatan (OR= 2.23 IC:1.12-4.46 and OR= 2.57 IC:1.14-5.78, respectively).

A genetic study on dominantly inherited spontaneous pneumothorax caused by bullous lung lesions. K.

*Aittomaki*¹, *H. Tapanainen*², *P. Tukiainen*², *M. Somer*³. 1) Dept Clinical Genetics, Helsinki Univ Central Hosp, Helsinki, Finland; 2) Dept of Pulmonary Medicine, Helsinki Univ Central Hosp, Helsinki Finland; 3) Dept of Clin. Genetics, Family Federation of Finland, Finland.

Primary spontaneous pneumothorax (PSP) is a fairly common condition occurring with the minimum frequency of 7,4:100 000 in males and 1,2:100 000 in females. PSP is mostly sporadic but also known to occur in families. The purpose of this study was to recognize possible lung lesions underlying inherited susceptibility to pneumothorax and to study the genetics of the condition. A large Finnish family with inherited spontaneous pneumothorax occurring in three consecutive generations was identified. Altogether 29 family members (7 with pneumothorax, 22 without) were studied with high-resolution computed tomography (HRCT) of lungs. When the result was abnormal lung function testing was also performed. Bullous lung lesions were identified by CT in 13 individuals, 7 affected and 6 unaffected. One individual had bullae detected during lung operation. All those who had had one or more episodes of pneumothorax had these changes. The number of bullae varied from 1 to 30 and the diameter from 1 to 6 cm. While 93% (14/15) of known gene carriers had the lung lesions, lung function testing was normal in all but three. Including the data on occurrence of spontaneous pneumothorax and HRCT findings, autosomal dominant inheritance was seen in the pedigree. The clinical findings and the recognition of autosomal dominant inheritance enabled the performance of genome-wide linkage analyses in this family to identify a susceptibility locus for PSP. While the results are presently being analyzed we already can conclude that we have identified an inherited form of spontaneous pneumothorax caused by highly penetrant bullous lung lesions in a family of Finnish origin. The pedigree clearly shows autosomal dominant inheritance with high penetrance in gene carriers. Thus, individuals at risk of familial spontaneous pneumothorax can be identified with HRCT. This is of importance for making the correct diagnosis in case of unexpected chest pain.

Nutritional profile and folate plasma level in women in Argentina, Guatemala, and Venezuela, and prevalence of neural tube defects. *T. Mosby*¹, *L.H. Clemens*³, *D. Slawson*³, *M. Tolarova*². 1) Pediatric St. Jude Children's Research Hospital 332 N. Lauderdale, Memphis, TN; 2) Craniofacial Genetics, Department of Orthodontics, University of the Pacific School of Dentistry, San Francisco, CA; 3) University of Memphis, Memphis, TN.

It is well understood nowadays, that a vast majority of neural tube defects (NTD) are caused by a combination of genetic factors creating a susceptibility that is triggered by an environmental factors. Among environmental factors, deficiency in mothers nutrition, and specifically low daily intake of folate seems to be a major player. It has been clearly demonstrated that birth prevalence of NTD has significantly decreased in the USA and Canada after introduction of the mandatory fortification of grains with Folic Acid (FA). In March 1996, the FDA authorized addition of synthetic folic acid (FA) to enriched grain products at the level of 140 g per 100 grams of grain, with a mandatory compliance to be achieved by January 1998. The increase in average daily intake of FA in the US population was estimated to be 100-200 g of FA daily in the pre-mandatory period. However, the actual measured intake of FA from fortified foods ranged from 215 to 240 g/day. In the present study, a prediction formula by Wald et al. (2002) was used to calculate how different levels of FA fortification might decrease the birth prevalence of NTD in Argentina, Venezuela, and Guatemala. Detailed nutritional information and blood specimens were collected from subpopulations of 342 women of childbearing age in Argentina (n=110), Venezuela (n=85), and Guatemala (n=147), and daily folate intake and plasma folate levels were analyzed. Based on the results a decrease of birth prevalence of NTD in dependence on increase of FA intake was calculated. This study demonstrates that decrease of birth prevalence of NTD by approximately 50% could be achieved by increasing the daily FA intake by 0.4 mg/day in Argentina, by 0.8 mg/day in Venezuela, and by 1.0 mg/day in Guatemala. These results can be used for future recommendation of sufficient fortification levels in those countries. The fieldwork for this study was supported by Rotaplast International Inc.

Evolution of a complex phenotype in a unique patient with a paternal uniparental disomy for every chromosome cell line and a normal biparental inheritance cell line. *C. Bryke, A. Garber, J. Israel.* Comprehensive Genetic Services, Milwaukee, WI.

We previously described an infant with mosaic paternal isodisomy (UPID) for every chromosome and normal biparental inheritance (BPI) (ASHG 67(4):366 #2051 (2000)). She was a growth retarded baby with an ASD, hepatomegaly, macrodactyly, hypotonia and developmental delay. UPID for every chromosome, proven by STR analysis, was found in peripheral blood, adrenal, liver and uroepithelial cells. Buccal cells had normal BPI. The UPID and BPI lines had the same paternal haplotype. The phenotype of known patUPD syndromes has evolved in this child who is now 5. At birth she had transient neonatal diabetes (patUPD6). At 8 months she had features of McCune-Albright syndrome and underwent adrenalectomy for corticosteroid excess due to nodular adrenal hyperplasia (patUPD20). At 18 months a liver mass and elevated AFP level led to hepatic lobectomy for focal nodular hyperplasia. This finding and limb asymmetry suggested the diagnosis of Beckwith-Wiedemann syndrome (patUPD11). Her unsteady gait, lack of speech, blue eyes, blond hair, significant developmental delay, and staring spells are consistent with Angelman syndrome (patUPD15). Her prominent philtrum and the unusual radiographic appearance of her chest with caudal bowing of the anterior ribs and cranial bowing of the posterior ribs are likely the result of patUPD14. She also has developed features that do not fit well with the UPD syndromes described to date. Her large capillary hemangioma, striking labial enlargement, and hypertrophic lower extremity, ear, and toe could be due to Klippel-Trenaunay-Weber (KTW) syndrome. The extensive hyper- and hypopigmentation on her chest is compatible with Hypomelanosis of Ito (HI). These findings suggest that KTW and HI may be due to patUPD. Several co-existent UPDs, mosaicism, and possible paternal homozygous mutant recessive genes all contribute to this patient's complex phenotype. The lymphoblastoid UPID and BPI cell lines which have been isolated from this patient will be an invaluable resource for identifying maternally imprinted genes and differentially expressed genes.

Radiological and Clinical Comparisons in Fragile X-Associated Tremor Ataxia Syndrome. *S. Cohen*^{1, 2}, *J. Adams*², *D. Hess*², *S. Rivera*², *L. Gane*², *S. Jacquemont*², *F. Tassone*³, *P. Hagerman*³, *R. Hagerman*². 1) Human Development, UC Davis, Davis, CA; 2) M.I.N.D. Institute, UC Davis Medical Center, Sacramento, CA; 3) Biological Chemistry, UC Davis Medical Center, Davis, CA.

Introduction: Older adult males (>50 years) with the FMR1 premutation (55-200 CGG repeats) have been identified as being at high risk for developing a neurological disorder called fragile X-associated tremor/ataxia syndrome (FXTAS). Features of FXTAS include cerebellar ataxia, intention tremor, cognitive decline, and brain atrophy with associated white-matter disease (wmh). This study compares radiological changes as seen in structural MRI images, as well as clinical measures of performance and verbal ability, across 3 groups of older males premutation carriers with and without FXTAS, as well as with age-matched controls who do not carry the FMR1 mutation. **Subjects:** 31 symptomatic (FXTAS) and 8 asymptomatic male premutation carriers (ages, 51-91; M=68.82), and 19 male controls without the premutation allele (ages, 51-79; M=64.11). Subjects participated in a battery of neurological and neuropsychological tests, structural MRI, and provided blood for molecular analyses. **Results:** Compared with the asymptomatic (carrier) and control groups, the FXTAS group had significantly increased whole brain wmh [Kruskal-Wallis (KW)=8.317, p<0.01] and cerebellar wmh (KW=11.039, p<0.01), and decreased whole brain volume (KW = 18.598, p<0.001). FSIQ (F=4.383, p< 0.05), and PIQ (F=5.869, p<0.01) were significantly lower for those with FXTAS compared with typical controls, but not with unaffected premutation carriers. With controlling for age, VIQ was not significantly different across groups. Compared with typical controls, but not with unaffected carriers, those with FXTAS also had significantly worse motor planning and control as measured via the motor portion of the UPDRS (F=3.975, p<0.05), and the ICARS (F=3.877, p<0.05). **Discussion:** FXTAS males have significant volume loss and white matter hyperintensity in the brain. They also have significant cognitive and motor deficits compared to controls. Verbal language fluency and comprehension seem to be less compromised in FXTAS males than performance ability.

A combined approach to factor VIII genetic analysis in haemophilia A patients. *A.D. Laurie¹, J.R. Harraway¹, C.R. Sheen¹, M.P. Smith², P.M. George¹.* 1) Molecular Pathology, Canterbury Health, Christchurch, New Zealand; 2) Department of Haematology, Christchurch Hospital, New Zealand.

Haemophilia A is an inherited bleeding disorder caused by mutations in the factor VIII gene, located on the long arm of the X-chromosome. In our laboratory we are tackling the research and diagnostic testing for factor VIII gene mutations from several different angles. To improve the reliability of screening for the common intron 22 inversion, which accounts for ca. 20% of all cases of haemophilia A, we are developing a FISH-based approach which we hope will replace the current long-range PCR technique. We have also developed a microsatellite linkage method using five markers on the X-chromosome which can be used to track affected alleles when the factor VIII gene mutation is not known. Both of these techniques are suitable for single cell analysis and may be used in pre-implantation genetic diagnosis (PGD), a service which we hope to offer in the near future. In addition, we routinely screen haemophilia A patients for an inversion in intron 1, and perform a complete screen of all 26 exons using denaturing high performance liquid chromatography (DHPLC) which detects missense mutations and small insertions/deletions. Exons with suspicious DHPLC profiles are further analysed by nucleotide sequencing to identify the mutation. In a cohort of 21 local haemophilia A patients who were negative for the intron 22 inversion, we detected the intron 1 inversion in three patients and missense mutations in 12 patients. A female patient who has severe haemophilia A was heterozygous for a single adenine insertion in exon 14. Our work utilises a diverse range of molecular techniques to identify and track factor VIII gene mutations in our local patients, providing valuable support to clinicians and building a useful resource for research on haemophilia A.

COMPLETE ANDROGEN INSENSITIVITY SYNDROME DUE TO AR GENE DIFFERENT MUTATIONS IN AUNT AND NIECES: CASE REPORT. *E.Silveira. Ramos, P.L. Takeuchi, F.C. Dolabella, F.M. Araujo, L. Martelli, S.A. Santos, M.A.V. Calerani, C. Vretos.* Department of Genetics, School of Medicine of University of São Paulo, Ribeirão Preto, São Paulo, Brazil.

The androgen insensitivity syndrome (AIS) causes deficiency or absence of virilization in 46,XY individuals with normal androgen production and metabolism. AIS is a X-linked disorder, mapped at Xq11-12, estimated to be present in 1:20,000-64,000 male births. Variable phenotypic expression has allowed the classification into complete forms (CAIS) and partial forms (PAIS). A variety of different strategies for mutational screening of the androgen receptor gene (AR) have revealed over 300 mutations in AIS. The heterogeneity in the phenotypic expression of AIS is due to a variety of mutations in all eight exons in the AR gene. The authors reported one family (an aunt, three nieces, and the child of a niece who is a normal carrier) referred to the Multidisciplinary Staff of Studies of Sexual Determination and Differentiation at the University Hospital - School of Medicine of Ribeirão Preto at University of São Paulo, in which there were five cases of the CAIS. The clinical exam showed female external genitalia in all cases and after gonadectomy in four of them the histological studies showed the presence of bilateral testis. One patient, the youngest one, presented inguinal hernia at birth and underwent surgical procedure in another service. Cytogenetic analysis showed 46,XY karyotypes. Molecular studies by PCR-SSCP of AR gene (exons 2, 3, 4, 5, and 6) were made and alteration in exon 3 only for one patient (the aunt) was found. Molecular biology tests for exons 1, 7, and 8 for AR gene are in process. To verify the discordant mutation in the patient, the pedigree was verified and we noted that the original family was, in fact, composed by a marriage between two distinct families that have discordant mutations in AR gene. The world incidence of CAIS is estimated in 1:64,000; therefore the frequency expected to occur a marriage between two affected distinct families is almost statistically insignificant.

Allele distribution of FMR1 gene in Korean women. *H. Ryu*¹, *D.J. Kim*², *S.Y. Park*², *S.M. Kim*², *J.M. Kim*², *J.W. Kim*², *M.H. Lee*², *J.H. Kim*¹, *M.Y. Kim*¹. 1) Dept OB/GYN, Samsung Cheil Hos, Sungkyunkwan Univ, Seoul, Korea; 2) Department of Obstetrics and Gynecology, Sungkyunkwan University School of Medicine, Seoul, Korea.

Fragile X syndrome is one of the most common forms of inherited mental retardation and is caused by the expansion of CGG trinucleotide repeats in the FMR1 gene. Diagnostic test for Fragile X syndrome should ideally combine both PCR and Southern blot analysis. The objective of this study is to ascertain the distribution of FMR1 CGG repeat in general Korean women. We evaluated 700 unrelated Korean women who visited for antenatal care or preconceptional counseling. PCR analysis allowed an accurate determination of the repeat length in the normal and premutation range using fluorescence. When single PCR band was detected, we performed southern blot analysis for determination of homozygote and heterozygote with full mutation. In this study, twenty-five percent of tested women were homozygote. 95.3% of alleles had repeats ranging from 22 to 37 repeats. The most frequent allele (34.4 %) was the repeat of 29, followed by the 30 (24.8 %) and the 28 (6.8 %) repeat alleles. Eight cases were found to have repeat numbers in high borderline range (45~54 repeats). Our results provide a basic information for fragile X carrier screening in Korean population.

INSENSITIVITY ANDROGEN SYNDROME ASSOCIATED WITH MICROCEPHALY, MENTAL DEFICIENCY AND HYPOPLASY OF FOURTH METATARSI: CASE REPORT. *C. Vretos, P.L. Takeuchi, F.C. Dolabella, L.C. Caetano, S. Tucci Jr., E.S. Ramos.* Department of Genetics, University of Ribeirão Preto, São Paulo, Brazil.

Among all intersexuality pathologies, the androgen insensitivity syndrome (AIS) is an entity that causes deficiency or absence of virilization in 46,XY individuals with normal androgen production and metabolism. AIS is an X-linked disorder and estimated to be present in 1:20,000-64,000 male births. Variable phenotypic expression has allowed the classification into complete (CAIS) and partial forms (PAIS). While individuals with CAIS have female external genitalia, affected cases of PAIS have variable ambiguity. If reread as girls, both groups also undergo gonadectomy to eliminate the risk of gonadal malignance. The heterogeneity in the phenotypic expression of AIS is due to a variety of androgen gene mutations in all eight exons of the AR gene. The authors reported two sisters who parents were cousins with the partial form attempted at the Multidisciplinary Staff of Studies of the Sexual Determination and Differentiation of the University Hospital School of Medicine of Ribeirão Preto-University São Paulo. The clinical exam showed ambiguous external genitalia and after gonadectomy the histological studies presented bilateral testis in both cases. However, the youngest sister had another anomalies associated, as mental deficiency, microcephaly, dental abnormalities, cubitus valgus, fourth metatarsal hypoplasia, spina bifida in L5 and cervical scoliosis. Cytogenetic analysis showed 46,XY karyotypes. Molecular biology studies for AR gene (exons 2, 3, 4, 5 e 6) were made and no abnormal PCR-SSCP runner was found. Molecular biology tests of exons 1, 7, and 8 for AR gene are in process. The authors discuss that the alterations found in the youngest patient may have distinct etiology of androgen insensitivity syndrome.

Manitoba Oculotricooanal syndrome (MOTA) is not allelic to FRAS1 gene causing Fraser syndrome. E.

Babaoglu¹, F.A. Kocaoglu², F. Ornek², I. Vargel³, B. Akin⁴, C. Li⁵, A.E. Chudley⁵, A.N. Akarsu⁴, A. Tukun¹. 1) Medical Genetics, Ankara University, Ankara, Turkey; 2) Ankara Hospital, Ophthalmology Service, Ankara, Turkey; 3) Kirikkale University Medical Faculty, Dept. of Plastic and Reconstructive Surgery, Kirikkale, Ankara, Turkey; 4) Gene Mapping Laboratory, Pediatric Hematology Unit, Department of Pediatrics, Hacettepe University Medical Faculty Ankara, Turkey; 5) Section of Genetics and Metabolism, Childrens Hospital and the University of Manitoba, Winnipeg, Manitoba, Canada.

Manitobaoculotricooanal syndrome (MOTA; OMIM 248450) is a rare autosomal recessive craniofacial malformation with hypertelorism and a variable combination of unilateral eye malformations, such as anophthalmia, obstruction of the nasolacrimal duct and upper eyelid coloboma, anterolateral hair and anal abnormalities (*Am. J. Med. Genet.* 1992;42(6).793-799). It was first reported in an inbred large Manitoba Indian family in central Canada and a recent follow-up of the family has revealed 6 further cases with a suspected seventh case from the Netherland. Here we present an autosomal recessive Turkish kindred with upper eyelid coloboma, agenesis/dysgenesis of eyebrows, wedge of scalp hair in fronto-temporal region extending to eyebrows, hypertelorism, depressed nose, ankyloblepharon filiforme totalis and anophthalmia. This family shows striking similarity to MOTA with overlapping features to autosomal recessive frontofacionasal dysostosis (FFND; OMIM 229400) and Fraser syndrome (OMIM 219000). Recently, mutations in FRAS1 gene which encodes a putative extracellular matrix protein has been reported as a cause of Fraser syndrome. Linkage analysis between the DNA markers, D4S2363, D4S2630, D4S2947, D4S3003 and the disease phenotype clearly excluded 4q21 region containing FRAS1 gene. Recent molecular studies in one Manitoba family with MOTA excluded mutations in the FRAS1 gene (personal communication, Anne Slavotinek, UCSF). Homozygosity mapping also excluded the following loci: FGFR1-3 on chromosomes 8p12, 10q26 and 4ptel, TWIST and IRF6 on chromosomes 7p21 and 1q32-q41 respectively.

Structural central nervous system (CNS) anomalies in Kabuki make-up syndrome. *T. Ben-Omran, A. Teebi.*
Division of Clinical & Metabolic Genetic, Hosp Sick Children, Toronto, ON, Canada.

Kabuki make-up syndrome (KMS) [OMIM# 147920] is a rare multiple congenital anomaly retardation (MCA/MR) syndrome commonly diagnosed at a genetic clinic. Duplication of chromosome 8p22-8p23.1 was recently demonstrated in multiple cases of KMS from different races, suggesting a possible common etiologic basis. KMS is characterized by a peculiar facial appearance with long palpebral fissures and long eyelashes, eversion of the lower lateral eyelid, arched and notched eyebrows. Other features include prominent and anteverted ears, as well as a characteristic dermatoglyphic patterns with prominent fingertip pads. Mental retardation has been found in over 90% of patients. Since the facial appearance often reflects the developing brain, it is not unexpected to observe a relatively higher frequency of CNS anomalies compared with disorders with minimal facial dysmorphism. CNS anomalies have been noted in approximately 30% of patients with KMS, the majority of which have microcephaly. Seizures have been seen in 50% of all patients. A spectrum of structural CNS anomalies has been reported including microcephaly with no apparent structural defects, enlarged ventricles, cysts, hydrocephalus, periventricular changes, polymicrogyria, heterotopia, calcification, and chiari I malformation. Here we report on two unrelated patients with typical Kabuki make-up syndrome and structural CNS anomalies. Case 1: 11-year-old girl with the typical clinical findings of KMS and Chiari I malformation. Case 2: 3 year-old boy with typical clinical features of KMS and Dandy Walker variant. Literature pertaining to the association of Kabuki make-up syndrome with structural CNS anomalies is reviewed, and the importance of brain imaging studies in the management of patients with KMS is emphasized.

De novo deletion 6q25.1q25.3 in a girl with normal development. *M.T. Carter¹, M.J. Huggins², J. Xu³, M.J.M. Nowaczyk^{3,4}.* 1) MD Program, McMaster University, Hamilton, Ontario, Canada; 2) Department of Pathology and Molecular Medicine, and Hamilton Regional Laboratory Medicine Program, Hamilton, Canada; 3) Department of Obstetrics and Gynecology, McMaster University, Hamilton, Canada; 4) Department of Pediatrics, McMaster University, Hamilton, Canada.

We report a girl with a de novo interstitial deletion of 6q25.1q25.3 and with minimal developmental delays at age 32 months. Her mother was referred to prenatal genetics service at 32 weeks gestation when a sonographic evaluation showed intrauterine growth retardation, small chest circumference and shortened long bones, a left axial displacement of the heart chambers, and a large patent foramen ovale/secundum atrial septal defect. A genetic amniocentesis was performed and showed an abnormality of 6q. Minor anomalies observed after delivery observed in this girl include triangular face, frontal bossing with metopic prominence, short and upward-slanting palpebral fissures, asymmetry of upper eyelids, shallow orbits, prominent inferior orbital crease, wide mouth, long and flat philtrum, redundant skin and wrinkled skin, joint laxity, small thorax, proximal limb shortening and a deep and wide sacral dimple. She has pigmentary anomalies of retinas and hypoplasia of external genitalia. To rule out possibility of this abnormal chromosome 6 resulted from a translocation, FISH of metaphase chromosomes using whole chromosome paint (wcp) 6 was conducted. The wcp 6 painted uniformly along the entire length of chromosome 6 including the distal 6q and did not hybridize to any other chromosomes, indicative of no translocation involved. The parents have a normal karyotype and thus the proposita has a de novo abnormal karyotype 46,XX, del(6)(q25.1q25.3). In patients with 6q deletion reported to date mental retardation has been a consistent finding; cardiac defects, eye abnormalities and cleft palate are found commonly. To our knowledge this is the first patient with interstitial deletion of 6q25 who presents minimal delays in psychomotor development. Disruption of an estrogen receptor gene *ESR1*, which maps to 6q25.1, may be responsible for the genital and retinal anomalies observed in patients with the 6q deletions.

New syndrome with features of cleidocranial dysplasia with de novo three-way chromosome translocation, 46,XY,t(4;6;21)(p16;p21.1;q21). *K. Casas, P.L. Wilson, J.L. Lee, R. Muneer, S. Li, J.J. Mulvihill.* Department of Pediatrics, Section of Genetics, University of Oklahoma Health Sciences Center, Oklahoma City, OK 73104.

In the past, chromosome translocations in persons with a mendelian trait have been clues to gene mapping. In 1992, our predecessors discovered a 3-way translocation in a 3-year old boy with an uncharacterized syndrome with multiple dysmorphism. The family sought re-evaluation as he was turning 11 years old and had bone pain. Repeat cytogenetic analysis with FISH identified apparently balanced translocations: chromosome 4 (4p16->4pter) translocated onto chromosome 6 at sub-band 6p21.1; chromosome 6 (6p21.1->6pter) translocated onto chromosome 21 at the middle of band 21q21; and chromosome 21 (21q21->21qter) onto chromosome 4 at band 4p16. Both parents had normal karyotypes. Family history was negative for fetal wastage, consanguinity, and similarly affected individuals. Physical examination revealed a male with hypermobile joints, kyphoscoliosis, pes planus, hyperplastic 4th and 5th toes, soft skin, two cafe-au-lait macules, umbilical hernia, and easy bruisability. Skeletal radiographs showed delayed fontanel closure, hypoplastic clavicles, 11 ribs, hypoplastic pubic rami, and widened symphysis pubis. The gene maps adjacent to all breakpoints were screened for genes implicated in skeletal dysplasia, connective tissue disorders, and syndromes. In comparing the patient's features to traits of the above conditions, the best association was with cleidocranial dysplasia. Involvement of RUNX2 in the breakpoint at 6p21.1 is likely. Connective tissue features in the patient that are not typical of cleidocranial dysplasia suggest involvement of a second gene in his unique syndrome. The patient and family were counseled regarding reproductive risks and the possible adverse clinical effects of his chromosomal translocations.

Diagnosis of microdeletion syndromes by Real-Time PCR based on the measurement of gene copy number. *Y.H. Cho, E.S. Shin, J.H. Kyhm, C.H. Lee.* Dept Medical Genetics, College of Medicine, Hanyang University, Seoul 133-791, Korea.

Deletion or duplication of genes or genomic regions have been identified as a genetic cause of various disorders, including mental retardation. To facilitate the detection of such cases, different techniques such as FISH, polymorphic marker, CGH and real-time PCR have been developed. Gene copy number analysis by real-time PCR can be targeted directly to a selected subregion of the gene of interest, and does not depend on the availability of informative flanking markers or parental DNA. There are some recurring chromosomal microdeletion syndromes causing MR such as Prader-Willi, Angelman, DiGeorge and Williams which were 5~10% of chromosomal microdeletion syndromes and idiopathic MR and would not have been detected by conventional cytogenetic analysis in addition. In order to determine the gene copy number of the 4 target genes in MR group by real-time quantitative PCR, conventional cytogenetic analysis and fragile X detection were performed previously in 102 MR group and 47 normal control group (GTG-banding(-) and Fragile X(-)). Real-time quantitative PCR using SYBR Green I has been used in this study. The relative gene copy number was quantified by the comparative Ct method. Five cases of DiGeorge syndrome patients were confirmed by FISH method and its range of target gene ratio was 0.36-0.60. The target gene ratio in normal controls ranged from 0.74-1.37, 0.74-1.39, 0.73-1.35 and 0.73-1.32 in DiGeorge, Williams, Prader-Willi and Angelman syndrome in order. The target gene ratio in MR group ranged from 0.73-1.35, 0.73-1.37, 0.73-1.27 and 0.73-1.35 in DiGeorge, Williams, Prader-Willi and Angelman syndrome in order. Eventhough, we could not detect any rearrangement of target regions in this MR group, this method is simple and reliable DNA diagnostic tool for the some recurring chromosomal microdeletion syndrome and permits of high sample throughput and can therefore be used in large-scale screening projects.

Evaluation of genotoxic effects of Tetradifon (an organochlorine pesticide: CAS N 116-29-0) in female wistar rats. *R. Badraoui, N.B. Abdelmoula, T. Rebai.* Laboratoire d'Histologie, faculte de medecine de sfax, Tunisia.

Tetradifon is a potent organochlorine acaricide with an estrogen like structure. It is used as an herbicide against a wide variety of vegetables. The wide spread use of this chemical is likely to pollute the environment. Only few studies have been reported for the evaluation of its short and long-term toxic effects including genotoxicity and carcinogenicity and there have been conflicting results in in vitro and in vivo test systems. In this work, we have evaluated tetradifon for its ability to induce genotoxic damages in female wistar rats. A single dose of 2430 mg/kg BW was administrated orally for 12 female rats. Twelve others rats, non traeted, served as a control. Animals were sacrificed at 6 and 12 weeks. Genetic toxicity studies were conduced in rats bone morrows, by chromosomal tests (sister-chromatid exchange (SCEs) and cytogenetics assays). The treated animals cells show a non statistical significant increase in either the frequency of SCEs and chromosomal aberrations (CAs) in comparison to the control rats. The oxidative stress status of treated and no treated animals have been also evaluated by assessment of lipid peroxidation (measurement of the thiobarbituric acid reacted substances (TBARS) as malondialdehyde (MDA)). There were a statistically significant difference between the 2 groups of animals suggesting that Tetradifon induce an oxidative stress. These results indicate that tetradifon is likely not directly genotoxic in female wistar rats. But we suggest that its inducting of an oxidative stress via oxydants defences may leads to indirect mutagenecity that should be evaluated by a series of in vivo genotoxicity assays (cytogenetics, micronucleus, comet assay).

Gene Expression Profiling at the Subnuclear Level in the Rat Hypothalamus and Hippocampus with High-throughput Multiplex RT-PCR. *G. Yue¹, M. Azaro¹, Q. Yang¹, G. Hu¹, M. Luo¹, R. Gao¹, R. Nagele³, J. Neubauer², J.Y. Li¹, K. Yin⁴, H. Li¹.* 1) Department of Molecular Genetics & Microbiology, CINJ/UMDNJ-RWJMS, New Brunswick, NJ 08903; 2) Department of Medicine, UMDNJ-RWJMS, New Brunswick, NJ 08903; 3) Department of Molecular Biology, UMDNJ-SOM, Stratford, NJ 08084; 4) Department of Cell Biology, UMDNJ-SOM, Stratford, NJ 08084.

Gene expression profiling at the subnuclear level of the hypothalamus is essential for understanding its subnuclear molecular interactions and functions. Laser capture microdissection was used to dissect rat brain cryosections. Sections between Bregma Scale -3.3 mm to -3.54 mm were used. Neurons from the hypothalamic arcuate nuclei, periventricular nuclei and dorsomedial nuclei were selected for the analysis. One hundred to 200 neurons were used from a nuclear region in a section for each RT-PCR. Neurons of the dentate gyrus of the hippocampus were also collected for comparison. More than 150 neural transmitters and function-related factors such as enzymes, receptors, and pathway-linking factors were selected for analysis. All amplicons are unique and surrounding at least one intron. Primers were designed with computer programs. One-step RT-PCR method was used to simultaneously amplify 164 distinct mRNA species (including controls) by multiplex RT-PCR. RT-PCR products were used as template to generate single-stranded DNA (ssDNA) with specific nested primers. The ssDNA was analyzed with the microarray and single-base extension methods. Out of the 164 mRNA species, 70 (42%) were detected from arcuate nuclei, 65 (40%) from periventricular nuclei, 73 (44.5%) from dorsomedial nuclei, and 71 (43%) from dentate gyrus. The signature gene expression in the dentate gyrus of the hippocampus was consistent with previous studies.

Program Nr: 836 from the 2004 ASHG Annual Meeting

CyDAS: a Cytogenetic Data Analysis System. *B. Hiller, J. Bradtke, H. Balz, H. Rieder.* Institut fuer Klinische Genetik, Philipps-Universitaet Marburg, Marburg, Germany.

Cytogenetic analysis is a valuable tool in genetic tumor diagnosis and research. Its results are communicated using ISCN formulae. But evaluation of large data sets is hampered by a lack of computer programs which can deal with ISCN data. CyDAS - which is available both online (www.cydias.org) and as a desk top version - can analyse ISCN data and extracts virtually all information contained in an ISCN formula. Furthermore, it calculates meta-information like break points, structural aberrations, gains and losses, dependencies between aberrations and karyotype evolution pathways. ISCN formulae are checked for syntax and content. This is a very important feature, since in data from the Mitelman database, some 10% of entries from 1995 or later were found to contain errors. Typical errors are: non-existing break points, wrong description of derivative chromosomes, insufficient information like missing break points or missing aberrations in derivative chromosomes, or unacceptable break points for translocations or dicentric chromosomes. CyDAS was used to analyse all 883 entries of patients with adenoma of the kidney from the Mitelman database for recurring chromosome changes. In 827 entries without karyotype errors breaks were most frequent at 3p11~21, 5q22, 1q21, Xp11 and 3q21. Gains were most frequently recorded at chromosomes 7 and 5q, and losses were most frequent at chromosomes 3p and Y. Dependency analysis of aberrations at the ISCN level showed that karyotypes containing at least one of +12,+16,+17, or +20 were most likely to contain also +7 (probability >0.7), followed by -Y (probability >0.45). Karyotype evolution analysis revealed +7 as the major start point, followed quite randomly by +17, +16, +12, +20 and -Y; other important pathways start with -Y followed by either +7 or -14, and with -14 followed by either -9, +7, or -3. All data were visualized by graphics. Overall, CyDAS proved to be a very useful tool to check karyotypes for errors and to ensure high quality of cytogenetic data for further analyses. Hot spots of genomic rearrangements and pathways of karyotype evolution may easily be identified. Supported by the DFG (Ri1123/2-1).

Identification of discrete chromosomal deletion by binary recursive partitioning of microarray differential expression data. *X. Zhou*¹, *S.W. Cole*², *N.P. Rao*³, *Z. Chen*⁴, *D.T. Wong*^{1,5,6}. 1) Dental Research Inst, School of Dentistry; 2) Division of Hematology-Oncology, Department of Medicine; 3) Department of Pathology & Laboratory Medicine; 4) Department of Human Genetics, David Geffen School of Medicine; 5) Jonsson Comprehensive Cancer Center; 6) Molecular Biology Institute, University of California at Los Angeles, Los Angeles, CA.

Gene copy-number abnormalities (CNA) are characteristic of solid tumors, and also found in association with congenital multiple anomalies and mental retardation. The ultimate impact of copy number abnormalities is manifested by the altered expression of the encoded genes. We have previously developed statistical methods for the detection of chromosomal aberrations using microarray expression data (Zhou et al., *Hum. Genet.*, 2004 114(5):464-467). In this study, we adapted these analytic techniques to detect small chromosomal deletions based on differential gene expression data. Using three cell lines with known chromosomal deletions as model system, we compared mRNA expression in these cells with that observed in diploid cell lines of matched tissue origin. The results showed that genes from deleted chromosomal regions are substantially over-represented ($p < .000001$ by chi-square) by genes identified as under-expressed in deletion cell lines, relative to normal matching cells. Using a likelihood-based statistical model, we localized the breakpoints of the chromosomal deletion in each cell line. In one of such cell lines, our analyses refined the previously identified chromosomal deletion region. We identified a 10p14-10p12 deletion instead of the previously identified 10pter-10p12 deletion, which was further confirmed by fluorescence in situ hybridization (FISH). These data show that microarray differential expression data can be used to detect and map the boundaries of discrete and cryptic chromosomal loss and gains.

Mohr-Majewski syndrome :a new argument for a continuous spectrum between oro-facio-digital syndrome and short-rib syndrome. *F. Mochel¹, V. Mucignat², H. Ducou-Le Pointe³, F. Gold², M. Le Merrer¹.* 1) Genetic Department, Hopital Necker-Enfants Malades, Paris, France; 2) Neonatal Department, Hopital Armand Trousseau, Paris, France; 3) Radiology Department, Hopital Armand Trousseau, Paris, France.

We report on a male newborn that presents the complete spectrum of the clinical manifestations observed in both Mohr syndrome (hypertelorism, micrognathia, cleft lip and palate, lobulated tongue and hallucal polysyndactyly) and Majewski syndrome (short ribs, short mesomelic limbs, laryngeal stenosis and polysyndactyly). This new case supports the well-known hypothesis elaborated in 1978 by McKusick about a continuous spectrum between oro-facio-digital syndromes (OFDS) and short-rib (-polydactyly) syndromes (SRPS). However, the premature death of the patient at 9 months of age emphasizes the severity of the prognosis related to respiratory insufficiency, contrasting with normal psychomotor evolution in this case. Despite its highly suspected autosomal recessive inheritance, the basic molecular defect of OFDS type IV remains unknown.

Characterization of a new gene disrupted by a balanced translocation t(2;7)(q35;p22) in a fetus with polymicrogyria and nodular heterotopia. *V. Cantagrel¹, C. Missirian², C. Cardoso¹, N. Philip², D. Figarella-Branger³, A. Moncla², L. Villard¹.* 1) Inserm U491, Faculté de Médecine La Timone, Marseille, France; 2) Département de Génétique Médicale, Hôpital d'Enfants de La Timone, Marseille, France; 3) Biopathologie Nerveuse et Musculaire, Faculté de Médecine La Timone, Marseille, France.

Polymicrogyria (PMG) is a development defect of the human cerebral cortex which results in an excessive number of small gyri and an abnormal organisation of cortical cell layers. PMG often is accompanied by mental retardation and epilepsy. The etiology of this cortical dysplasia is heterogenous but it was recently shown that a genetic origin is definitely present in several cases. We present clinical, cytogenetic and molecular data for a 33 week-old female fetus who was terminated based on the presence of hydrocephaly in combination with a de novo balanced translocation. Detailed examination of the fetus did not reveal signs of infection or inflammation but shows partial syndactyly of digits and toes. Neuropathology showed periventricular astrocytic gliosis and hypervascularisation in addition to nodular heterotopia throughout the white matter. Examination of the cerebral cortex revealed polymicrogyria with a predominance in the posterior areas. The presence of PMG and nodular heterotopia suggests a neuronal migration or neuronal organisation defect. The simultaneous occurrence of a balanced rearrangement provides a unique opportunity to identify a potential gene defect responsible for this phenotype. In order to precisely characterize the translocation, we have cloned and sequenced the two breakpoints. It is molecularly balanced with no loss or gain of genetic material. The 7p22 breakpoint region does not contain any gene. On the contrary, the 2q35 breakpoint disrupts the coding region of a novel gene. Its product has no significant homology to any other known protein. Our results make this new gene a good candidate to be responsible for the neuronal migration defect observed in the studied patient and the detailed analysis of its expression during development is currently underway.

Disruption of a new X-linked gene highly expressed in brain in a family with two mentally retarded males. *A.M. Lossi¹, V. Cantagrel¹, S. Boulanger², D. Depetris¹, M.G. Matti¹, J. Gecz³, C.E. Schwartz⁴, L. Van Maldergem², L. Villard¹.* 1) Inserm U491, Facult de Mdecine La Timone, Marseille, France; 2) Institut de Pathologie et de Gntique, Loverval, Belgium; 3) Department of Genetic Medicine, Women and Childrens Hospital, Adelaide, Australia; 4) Greenwood Genetic Center, One Gregor Mendel Circle, Greenwood, SC, USA.

Mental retardation (MR) affects 2 to 3% of the human population and up to 50% of these cases is genetically determined. Although several genes responsible for MR have been identified, a large number of cases is still not explained. We have identified a pericentric inversion of the X chromosome $inv(X)(p22.3;q13.2)$ segregating in a family where two male carriers have severe MR whereas female carriers are not affected. The molecular characterization of this inversion led us to identify two new genes which are disrupted by the breakpoints : KIAA2022 in Xq13.2 and P2RY8 in Xp22.3. KIAA2022 encodes a protein which lacks significant homology to any other known protein. It is highly expressed in the brain. P2RY8 is a member of the purine nucleotide G-protein coupled receptor gene family. It is located in the pseudo-autosomal region of the X chromosome. It is not expressed in brain. Because the haplo-insufficiency of P2RY8 in carrier mothers does not have a phenotypic effect, we propose that the severe MR of the affected males in this family is due to the absence of the KIAA2022 gene product. However, screening 20 probands from X-linked MR families did not reveal any mutations in KIAA2022. Given the large genetic heterogeneity of XLMR this result may not be unexpected. Nonetheless, the high expression of this gene in foetal brain and in the adult cerebral cortex is consistent with its speculated a role in brain development and/or cognitive function.

Deletion of 5q14-q21 associated with temporal periventricular heterotopia. *E. Pallesi¹, C. Missirian², A. Ramazzotti³, C. Raybaud⁴, B. Chabrol⁴, R. Guerrini³, A. Moncla², L. Villard¹, C. Cardoso¹.* 1) INSERM U491, Faculte de Medecine la Timone, Marseille, France; 2) Departement de Genetique Medicale, Hopital des enfants de la Timone, Marseille, France; 3) Institute of Child Neurology and Psychiatry, IRCCS Fondazione Stella Maris, Calambrone, Italy; 4) Departement de Neurologie, Hopital des enfants de la Timone, Marseille, France.

Periventricular Heterotopia (PH) is a heterogeneous disorder which is characterized by collection of neurons in the subependymal white matter. These neurons have failed to migrate in the developing cortex which would therefore be expected to have a defective organization. Two genes have been identified to cause PH. The FLNA gene, in Xq28, causes X-linked dominant classical bilateral periventricular nodular heterotopia (BPNH) and ARFGEF2, in 20q13, causes autosomal recessive BPNH associated with microcephaly. In our current project to identify new candidate genes involved in PH, we have studied a male patient with a de novo interstitial deletion 5q14-q21 resulting from an unbalanced translocation between chromosomes 1 and 5. His brain MRI shows heterotopic nodules within the temporal lobes which define a subtype of PH previously described by Li et al. 1997. In addition, our patient presents severe mental retardation, hypotonia, iris coloboma, facial dysmorphism and symptomatic epilepsy. CGH array and FISH analysis were used to precisely define and delineate the rearrangement. We have excluded the presence of a causative gene within the 1q31 breakpoint and we found 18 well characterized genes in the 15 Mb deleted region. RT-PCR expression analysis in human tissues and brain regions identified two candidate genes expressed either in the temporal lobes or throughout the brain. Sequencing analysis of these genes in sporadic PH patients with no mutations within FLNA and ARFGEF2 genes should allow the identification of the temporal PH causative gene, and provide new insights into the genetic and developmental basis of this cortical malformation.

Breakpoint mapping in a patient with an X;9 translocation, mental retardation and overgrowth. S.J.T.

Vermeulen¹, B. Menten¹, J. Depuydt¹, G. Mortier¹, A. De Paepe¹, J. Vandesomepele¹, N. Carter², F. Speleman¹. 1) Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium; 2) The Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus Hinxton, Cambridge, United Kingdom.

Constitutional de novo chromosomal rearrangements in patients with mild to severe mental retardation and congenital abnormalities have been instrumental in the identification of disease genes. We present a patient with mental retardation, overgrowth and a de novo apparently balanced chromosomal rearrangement 46,XX,t(X;9)(q12;p13.3). Using FISH we were able to locate the Xq12 breakpoint within a BAC-clone within the gene encoding oligophrenin (OPHN1). This observation is reminiscent to the t(X;12) case reported by Bienvenu et al. (1997) which also involves loss of function of the OPHN1 gene. Moreover, mutations in the OPHN1 gene have subsequently been reported in patients with mental retardation, (Billuart et al., 1998). These observations strongly suggest that the Xq12 breakpoint is responsible for the mental retardation in our patient. Overgrowth has not been reported in patients with a mutation in or structural rearrangement of the OPHN1 gene. The 9p13.3 breakpoint was shown to be located within a gene dense region. The derivative chromosomes were flowsorted and the breakpoints cloned and sequenced. No evidence was observed for disruption of a coding sequence. Several genes including the carbonic anhydrase IX gene (CA9) are located within the immediate vicinity of the 9p13.3 breakpoint. Only the latter gene showed a significant overexpression in our patient. As CA9 overexpression is implicated in cell proliferation (Saarnio et al., 1998) we consider this gene as a candidate for the observed overgrowth in this patient. References: Bienvenu, T. et al. *Eur J Hum Genet* 5, 105-9 (1997), Billuart, P. et al. *Nature* 392, 923-6 (1998), Saarnio, J. et al. *J Histochem Cytochem* 46, 497-504 (1998).

Chromosomal mosaicism in the developing human brain: high aneuploidy incidence could explain neuronal loss during ontogenesis. *Y.B. Yurov¹, V.M. Vostrikov¹, V.V. Monakchov¹, I.Y. Iourov¹, S.G. Vorsanova².* 1) Dept Cytogenetics, NCMH, RAMS, Moscow, Russian Federation; 2) Institute of Pediatrics and Children Surgery Russian Ministry of Health, Moscow, Russia.

There are a limited number of molecular cytogenetic studies of the chromosome complement in the human brain. In the present study fluorescence in situ hybridization (FISH) was used for analysis of interphase chromosomes in human embryonic central nervous system (CNS) cells cultured in vitro. Ten organotypic cultures of embryonic human brain cells were analyzed. Ten post-mortem adult brain samples were used as control for aneuploidy scoring. From 1000 to 3000 hybridized cells were analyzed for each sample using three-color FISH. The level of aneuploidy (per individual chromosome) was in the range of 0.2-13%; in embryonic CNS cells (mean values for chromosome 1 - 5.0%; chromosome 9 - 6.2%; chromosomes 13 and 21 - 3.7%; chromosomes 14 and 22 - 2.8%; chromosome 15 - 3.0%; chromosome 16 - 4.9%; chromosomes 18 - 1.8%; chromosome X - 5.8%; chromosome Y - 5.7%). The level of aneuploidy in post-mortem brain cells was in the range of 0.1 - 1.2%. Our results indicate that embryonic CNS cells and adult brain cells are significantly different in the mosaic aneuploidy incidence. Therefore, we could propose that selective loss of neuronal cells with abnormal chromosome complement is taking place during early ontogenesis. However, relatively small, but significant, amount of aneuploid neurons could survive and exist in the adult brain. High level of chromosomal aneuploidy in embryonic human neuronal cells could, therefore, leads to genetic mosaicism in fetal and, probably, adult CNS. Cryptic chromosomal mosaicism of the brain have no a distinctive phenotypic appearance; however it could affect the development as well as functions of the brain. We are also suggesting that the abnormal chromosome complement in neurons of human brain may have a relevance to many neuropsychiatric diseases. Supported in parts by grant Copernicus 2 and INTAS-03-4060.

Correlation between immunohistochemistry (Hercep Test) and FISH for HER-2 in breast cancer patients In Taiwan. *C. Liu*¹, *B. Wang*², *W. Tsai*², *K. Yeh*³, *H. Chang*³, *C. Yeh*³, *S. Chang*². 1) Vascular and Genomic Research Center, Changhua Christian Hospital, Changhua, Taiwan; 2) Ctr Medical Genetics, Changhua Christian Hospital, Taiwan; 3) Dept Pathology, Changhua Christian Hospital, Taiwan, Taiwan.

Accurate diagnostic assessment of HER-2 is essential for the appropriate application of the humanized anti-HER-2 monoclonal antibody trastuzumab (Herceptin) to the treatment of patients with metastatic breast cancer. The diagnostic test needs to be applicable to archival, fixed tissue removed at excision. We compared the assessment of HER-2 by immunohistochemistry (IHC; Hercep Test) and FISH (fluorescence in situ hybridization) in 60 breast carcinomas from patients being considered for trastuzumab therapy. 0/20 IHC 0/1+ were FISH positive, 1 of 20 (5%) IHC 3+ tumors were FISH negative. Overall, 48% of these IHC /2+ were FISH positive. These data support an algorithm in which FISH testing is restricted to IHC 2+ tumors in reference centers. We conclude that this FISH approach is practical in screening patients for Herceptin treatment, but the results may not extrapolate to laboratories with less experience or using different methodologies.

Subtelomeric deletions of chromosome 6p; molecular and cytogenetic characterization of 6 new cases in 3 families with phenotypic overlap with Ritscher-Schinzel (3C) Syndrome. C. DeScipio¹, L. Schneider¹, T.L. Young², N. Wasserman¹, D. Yaeger¹, P.G. Wheeler⁴, M.S. Williams⁵, R. Geschwind¹, A.E. Chudley⁶, J. Saraiva⁷, A.A.G.L. Schinzel⁸, A. Toutain⁹, N.B. Spinner^{1,3}, I.D. Krantz¹. 1) Division of Human Genetics; 2) Division of Ophthalmology; 3) Clinical Labs, The Children's Hospital of Philadelphia, Philadelphia, PA; 4) New England Medical Center, Tufts University School of Medicine, Boston, MA; 5) Gundersen Lutheran Medical Center, La Crosse, WI; 6) Section of Genetics and Metabolism, Children's Hospital and University of Manitoba, Winnipeg, Manitoba; 7) Servio de Génética, Hospital Pediàtrico de Coimbra, Portugal; 8) Institute of Medical Genetics, University of Zürich, Zürich, Switzerland; 9) Centre Hospitalier Universitaire de Tours, France.

We describe 6 cases of subtelomeric chromosome 6p microdeletions from 3 unrelated families; each has clinical findings consistent with the cranio-cerebello-cardiac (3C or Ritscher-Schinzel) syndrome consisting of facial dysmorphism, congenital heart defects (primarily septal defects), Dandy-Walker malformations, and hearing loss. Due to the phenotypic overlap of 3C syndrome with these 6 cases and other 6p25 deletions reported in the literature, we propose that microdeletions of 6p25 or mutations of a gene within this region may be responsible for 3C syndrome. We have molecularly and cytogenetically defined a critical region containing 7 genes spanning 1.3 Mb, delineating the smallest deletion of this region reported to date. In order to determine whether 6p is commonly deleted in 3C syndrome, we screened seven unrelated 3C individuals for deletions in this interval and none were detected. Direct sequencing of two forkhead genes (*FOXC1* and *FOXF2*), from within this critical region was carried out in the seven 3C probands. No disease-causing mutations were identified. Mutational analysis of the remaining 5 genes in the critical region is underway. While the phenotypic overlap between the 6p subtelomeric deletion syndrome and 3C syndrome is fairly striking it is possible that they may be phenocopies of each other.

Molecular characterisation of a translocation associated with hypoplastic left heart. *H. Gill¹, A. Davies¹, G. Sharland¹, B. Ng², N. Carter², M. Splitt¹, J. Simpson¹, C. Mackie Ogilvie¹, R. Roberts¹.* 1) Division of Medical and Molecular Genetics, Guy's Hospital, London United Kingdom; 2) The Wellcome Trust Sanger Institute, Cambridge.

AIMS We identified a proband with HLH and *de novo*, apparently balanced, reciprocal translocation. We aimed to fine map the translocation breakpoints, characterise them at the molecular level, and investigate any possible candidate genes in these intervals.

METHODS Fluorescent in situ hybridization was undertaken to narrow the breakpoints, utilising first bacterial artificial chromosomes and then fosmids as probes. Further narrowing of the region involved polymerase chain reaction (PCR) analysis of derivative chromosomes purified using a fluorescence-activated cell sorter. Finally, direct sequencing was used to confirm the exact breakpoint.

RESULTS Our work has revealed a complex chromosomal rearrangement with four distinct breakpoints on two chromosomes. Three of these breaks occurred within a 4-Mb region of chromosome 1; the fourth is on chromosome 3. We have characterised all four breakpoints at the molecular level.

DISCUSSION The rearrangement is likely to have arisen by a combined inversion of material on chromosome 1 and translocation between 1 and 3, either as a concerted event or as two sequential ones. Neither rearrangement was observed in the proband's parents. Although none of the breakpoints disrupt a known gene, two of them lie within a few kilobases of three candidate disease genes. One is known to be disrupted in an autosomal recessive encephalopathy. The others encode a serotonin receptor and an orphan steroid hormone receptor, both expressed in fetal heart. As the effects of dominant mutations in the encephalopathy gene are unknown, we consider all three genes as potential players in the aetiology of HLH in this individual.

Ongoing work: We are currently undertaking studies to investigate any alteration in function and/or expression levels in the proband in order to explain the disease mechanism.

Program Nr: 847 from the 2004 ASHG Annual Meeting

Molecular analysis in Williams syndrome in a sample of Mexican patients. *S. Cuevas, C. Venegas, S. Kofman.*
Genetica, Hospital General de Mexico, Mexico D.F., Mexico.

Williams syndrome (WS) is a contiguous gene deletion disorder due to deletion of 7q11.23 region. It occurs in 1 of 20,000-50,000 new born. Clinically, the classical WS phenotype is characterized by elastin arteriopathy, supraaortic stenosis, connective tissue anomalies, particular facial appearance, growth and psychomotor retardation with impaired visuo spatial cognition and specific language as well as behavior anomalies. Around of 95% patients with WS present deletion of the 7q11.23 region. The aim of the present study was to identify through FISH analysis the critical region of WS (WSCR) in a sample of Mexican patients. Most patients with classical phenotype harbored the WSCR deletion while patients with atypical phenotype had no deletion. Only one case with apparently classical phenotype showed no deletion of the WSCR. The occurrence of WSCR deletion was similar to that reported in the literature. We state the importance of performance molecular studies in the patients with probable WS to offer and correct genetic counseling.

Towards a first genotype-phenotype correlation of small supernumerary marker chromosomes (sSMC). *T. Liehr, K. Mrasek, U. Claussen, H. Starke.* Institute of Human Genetics and Anthropology, Jena, Germany.

Small supernumerary marker chromosomes (sSMC) are present in 0.043% of newborn. In about 30% of sSMC carriers an abnormal phenotype is observed. Clinical outcome of sSMC presence is difficult to predict as different phenotypic consequences can appear due to (i) differences in euchromatic DNA-content, (ii) uniparental disomy (UPD) of the sSMCs homologous chromosomes, and/or (iii) different degrees of mosaicism. We did own studies on >150 cases with sSMC and performed a review of the literature (i.e. presently 1505 cases with sSMC) available at http://mti-n.mti.uni-jena.de/~huwww/MOL_ZYTO/sSMC.htm. A first genotype/phenotype correlation for sSMC was deduced from that. Thus, small proximal trisomies of Xp, Xq, 1p, 1q, 2p, 4q, 5p, 6q, 7q, 8p, 8q, 12p, 12q, 14q, 17q, 18q, 19q, 20p, 20q, lead to clinical manifestations, while small partial proximal trisomies of 2q, 5q, 7p, 15q, 17p, 18p, 21q, 22q may not be associated with significant clinical symptoms. No general correlation could be found in connection with mosaicism of sSMC (47,+mar/46) and clinical symptoms. Recent own studies using new centromere and subcentromer-specific probe-sets ([sub]cenM-FISH; Starke et al., 2003, Hum Genet 114:51-67) gave evidence that this may be at least in parts due to the fact, that many patients do have different derivative-types of a sSMC however, these could not be detected and characterized before the development of subcenM-FISH. In summary, almost 50 year after description of the first sSMC, molecular cytogenetics provides finally approaches for their comprehensive characterization. The new knowledge coming from that will lead to an improved genetic counseling of cases with de novo sSMC. Supported by the Dr. Robert Pflieger-Stiftung.

Sex-preferential hotspots for non-allelic homologous recombination within segmental duplications in Williams-Beuren syndrome deletions. *N. Rivera, J. Lucena, M. Bayes, L.A. Perez Jurado.* Genetics Unit, Dept. of Experimental Sciences Universitat Pompeu Fabra, Barcelona, Spain.

The sporadic occurrence of Williams-Beuren syndrome (WBS) in most cases indicates a high rate of de novo deletion formation at 7q11.23. Most WBS deletions arise from non-allelic homologous recombination (NAHR) between two specific blocks (B) of region-specific segmental duplications (SDs) that show 99.5% sequence identity over 105 kb. Both, intrachromosomal (1/3) as well as interchromosomal (2/3) recombination events have been reported. Heterozygosity for large chromosomal polymorphisms such as paracentric inversions between SDs, appears to further predispose to chromosome misalignment in some progenitors of WBS patients. To define the region of exchange in WBS deletions, we have analyzed by dosage multiple paralogous sequence variants, until being able to amplify by PCR and sequence the novel junction fragments from the recombinant WBS-BlockB. The previously defined NAHR hotspot (positional preference for strand exchange) within block B, has been narrowed-down to a 1,4 kb region of complete sequence identity. Deletions with breakpoints at this site occur in 1/3 of cases with no parental predisposing allele and show clear biases in favor of paternal and intrachromosomal origin. Two additional NAHR hotspots located within the final 38 kb region of block B, account for all WBS deletions (n=18) in which the transmitting progenitor is an inversion-carrier. Seventy-five percent (6/8) of breakpoints of paternal origin mapped in a 950 bp hotspot, while 90% (9/10) of maternal crossovers were located in a different 1,4 kb hotspot, thus supporting the hypothesis that two distinct sex-dependent mechanisms are involved (P=0.02). Alu repeats and other putative recombination stimulating sequence are located inside and around the hotspots. Therefore, as shown for other genomic disorders, NAHR between SDs does not occur randomly; instead, several parent-of-origin-preferential recombination hotspots can be identified within the SDs.

FISH-mapping of telomeric 14q32 deletions: is there a seizure gene? *K. Schlade-Bartusiak¹, T. Costa², A.M. Summers³, D.W. Cox¹*. 1) Medical Genetics, University of Alberta, Edmonton, Alberta, Canada; 2) IWK Health Centre, Halifax, Nova Scotia, Canada; 3) North York General Hospital, Toronto, Ontario, Canada.

Ring chromosome 14 is associated with typical clinical features including prenatal and postnatal growth retardation, mental retardation, characteristic facies and retinitis pigmentosa. Seizures are present in all cases. Seizures could be due to deletion of a locus in the preterminal region of 14q on one homologue. The presence of such a locus on 14p seems unlikely, as in patients with Robertsonian translocations of chromosome 14 seizures are not frequently found. Seizures seen in r(14) patients may be also due to the mitotic instability of the ring chromosome leading to mosaicism. However, seizures are not universally present with all ring chromosomes. In the present study we have used BAC probes in the distal region of chromosome 14q to characterize deletions in six patients determined cytogenetically to have a ring or terminal deletion on chromosome 14, with breakpoints at 14q32.32-32.33. We observed marked differences in the size of deletions in the patients studied. The deletions ranged from 0.6 Mb to 5 Mb. In one patient, the apparent terminal deletion was actually due to a 7.5 Mb interstitial deletion: del(14)(q32.12q32.31). There was no common region of deletion in r(14) as opposed to terminal deletions. We found exactly the same localization of breakpoints in one r(14) patient and one terminal 14q deletion patient. The phenotypes of these patients shared common features, such as microcephaly, hypotonia and global developmental delay, but the r(14) patient phenotype was more severe and included seizures and retinitis pigmentosa. Thus, it seems unlikely that there was a specific locus in 14q32.3 that predisposed to seizures or retinitis pigmentosa. The cause of these features in r(14) patients was probably the formation of the ring itself. The ring formation changes the chromatin architecture of the chromosome. Despite the size of the deletion on 14q, the juxtaposition of the DNA from q-arm near the inactive heterochromatin of the centromere and p-arm could cause silencing of adjacent genes.

Program Nr: 851 from the 2004 ASHG Annual Meeting

Delineation of 1p36 deletion sizes using a panel of FISH prob. *A. Adeyinka, T. Brimmer, E.C. Thorland, S.A. Adams, S.M. Jalal.* Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN.

Deletion of 1p36 is a recently delineated syndrome characterized by dysmorphic features, developmental delay and psychomotor retardation. This terminal deletion is often difficult to detect cytogenetically. Among 2257 consecutive patients with idiopathic mental retardation, developmental delay and/or mild to moderate dysmorphism that were studied from 2001 to 2003 using subtelomeric FISH probes, eight patients with anomalies of 1p36 were identified. Six had terminal deletions of 1pter and two had unbalanced translocations resulting in a derivative chromosome 1 with del(1)(pter). Three of the six patients with del1pter and one of the two with unbalanced translocations had loss of the p73 probe signal, whereas the others retained the P73 locus, implying a breakpoint range of 1p36.3-1p36.1. To better delineate the deletion sizes in these patients we have applied a panel of FISH probes developed from PACS and BACs about 0.5Mb to 1Mb apart on 1p36. Preliminary findings from three patients with loss of the p73 probe and a fourth patient with a der(1)t(1;13) ascertained by G-banding revealed breakpoints ranging in size from ~ 4Mb to more than 7.5 Mb from the telomere. The difference in deletion sizes, may in part account for some of the phenotypic differences observed among patients with del(1)(p36).

Microduplication 22q11.2 syndrome: clinical and molecular cytogenetic analysis of a new case. A. Ardalan¹, F. Lebas², L. Finkel¹, V. Mucignat², S. Ducrocq², S. Marlin³, V. Malan¹, F. Gold², JL. Taillemite¹, MF. Portnoi¹. 1) Laboratoire de Cytogenetique, Hopital Saint-Antoine, 75012, Paris, France; 2) Service de Neonatologie, Hopital Armand-Trousseau, 75012, Paris, France; 3) Service de Genetique, Hopital Armand-Trousseau, 75012, Paris, France.

Recently, some patients with variable clinical phenotype, ranging from mild learning disability to the presence of severe congenital malformations or some overlapping features with DG/VCF syndromes, have been shown to harbor a chromosome duplication 22q11.2 of the genomic region that is deleted in patients with DGS/VCFS. The microduplication of 22q11.2, establishing the complementary genome disorder of the 22q11.2 deletion syndrome, appears to be a new chromosomal microduplication syndrome. The reported cases have been identified primarily by interphase FISH and could escape identification and be missed by routine cytogenetic analysis. Hence, this new syndrome might be underdiagnosed. We report on a 2-month-old girl, who presented with cleft palate, minor dysmorphic features including short palpebral fissures, widely spaced eyes, long fingers, and hearing loss. She was referred to rule out 22q11.2 microdeletion diagnosis of VCFS. Her mother had mild mental retardation, learning disabilities and similar facial features. FISH analysis of interphase cells showed three DG/VCFS critical region (N25)-probe signals with two chromosome specific identification probes in each cell. FISH analysis did not reveal the duplication on the initial testing of metaphase chromosomes, on review, the area was brighter on one chromosome 22 in each metaphase spread. Her parents were tested. The mother had the same interstitial duplication of 22q11.2. To define precisely the size and the proximal and distal breakpoints of the duplication, FISH with a panel of chromosome 22q11.2 specific BAC clones have been performed. This case illustrates the importance of scanning interphase nuclei when performing FISH analysis for any of the genomic disorders. The paucity of reported cases of 22q11.2 microduplication likely reflects a limitation in the techniques used and/or a significantly milder phenotype than do patients with deletion.

Familial complex 3q;10q rearrangement unravelled by subtelomeric FISH analysis. A. Battaglia^{1,3}, A. Novelli², C. Ceccarini², J.C. Carey³. 1) Stella Maris Clinical Research Inst for Child & Adol Neuropsychiatry, Pisa, Italy; 2) CSS Mendel Inst., Rome, Italy; 3) Division of Medical Genetics, Dept. Pediatrics, Univ. of Utah, SLC, USA.

In recent years, subtelomeric rearrangements have been identified as a major cause of MCA/MR syndromes. As of now, more than 2,500 individuals with mental retardation have been tested and subtelomeric rearrangements were detected in about 5%. Therefore, subtelomeric FISH analysis is indicated as a second tier test after high-resolution-G-banding analysis in subjects with otherwise unexplained developmental delay/mental retardation and/or MCA. We describe a female patient and her 3 maternal female cousins, all showing an undiagnosed MCA/MR syndrome, associated with the same complex subtelomeric rearrangement. Subtelomeric FISH testing performed between 3 and 18 years after the initial karyotype showed, in all 4 subjects, distal trisomy 3q and distal monosomy 10q as follows: 46,XX,ishder(10)t(3;10)(q29;q26.3)mat(D10S2488+,D10S2490-,D3S1272+,D10Z1+). BACs demonstrated that the 3q dup was 5 Mb while the 10q del was about 3.2 Mb. Parental subtelomeric FISH analysis revealed the proband's mother and her 3 of 4 brothers and 1 of 2 sisters to have a cryptic balanced 3:10 telomere translocation. The brothers with the balanced translocation were the father to the proband's cousins. All 4 affected girls showed a similar phenotype with pre/postnatal growth retardation, microcephaly, severe DD/MR, very poor/absent speech, and a distinct pattern of malformation. There were coarse face with low frontotemporal hairline, thick eyebrows, epicanthal folds, prominent/squared nose, large ears, prominent chin; brachydactyly; hypotonia. Communication was gesture mediated; graphic abilities were limited to scribbling. To our knowledge, a complex subtelomeric rearrangement as the one seen in our patients has not been reported. Monosomy 10q has been described either isolated or as part of a complex rearrangement involving telomeres other than the 3q. Trisomy 3q29 has not yet been reported, but our patients resembled cases with 3q25 trisomy suggesting that the critical region of duplication for this phenotype is in 3q29.

A Complex Chromosomal Rearrangement associated with Mowat-Wilson Syndrome. *E.L. Engenheiro^{1,3}, M. Pinto², G. Soares², I. Marques³, V. Kalscheuer⁴, N. Tommerup¹*. 1) Wilhelm Johannsen Centre for Functional Genome Research, Institute of Medical Biochemistry and Genetics, University of Copenhagen, Blegdamsvej 3, 2200 Copenhagen N; 2) Instituto de Genética Médica Jacinto Magalhães, Porto, Portugal; 3) Unidade de Citogenética, Faculdade de Medicina da Universidade de Coimbra, Portugal; 4) Max Planck Institute for Molecular Genetics, Berlin, Germany.

We report the first case of a complex chromosomal rearrangement (CCR) associated with Mowat-Wilson Syndrome (MWS). The CCR is a de novo $t(2;12;18)(q22.3; 12q22; q21.33)$ in a 19 year old female whose phenotype includes severe mental retardation, agenesis of corpus callosum, myopia, microcephaly, epilepsy and cerebral atrophy. Part of this phenotype, except for myopia, is equal to Mowat-Wilson Syndrome (MWS) (OMIM #235730), an autosomal dominant complex developmental disorder, which is known to be caused by heterozygous deletions or truncating mutations of the *ZFX1B* homeobox zinc finger gene. The breakpoint on chromosome 2 has been mapped by Fluorescence In Situ Hybridisation (FISH) using bacterial artificial chromosomes (BACs) to a ~200 kb region between RP11-95o9 and RP11-294g19 which includes the 5-end of *ZFX1B* and a cluster of recently discovered ultraconserved elements (UCs). These UCs which are 100% conserved in human, rat and mouse genomes, are located in the vicinity or overlapping with genes that are thought to be essential for the ontogeny of mammals and other vertebrates (Bejerano et al. 2004). The 12q22 breakpoint is within a ~600 kb region flanked by BACs RP11-3k15 and RP11-490g8 that contains 5 annotated genes, and the 18q21 breakpoint is within a cluster of Serpin B genes. Except for myopia, the phenotype is entirely compatible with MWS caused by truncation or disturbance of *ZFX1B*. This first CCR associated with MWS illustrate that CCRs may be associated with monogenic disorders. Furthermore, the CCR includes a breakpoint on chromosome 18q21, which has been referred to as a possible hotspot for CCR occurrence (Batanian and Eswara 1998).

Pericentric inversion, inv(14)(p11.2q22.3), associated with Goldenhar syndrome. *J.C. Hawkins, J.K. Northup, D. Matalon, R. Matalon, L.H. Lockhart, G.V.N. Velagaleti.* Dept. Pediatrics, University of Texas Medical Branch, Galveston, TX.

Goldenhar syndrome, also called hemifacial microsomia (HFM)(MIM 164210) is a birth defect involving 1st and 2nd branchial arch derivatives with an incidence of 1/5000. The variable phenotype includes mostly unilateral deformity of the external ear and small ipsilateral half of the face with epibulbar dermoid and vertebral anomalies, prompting the designation oculoauriculovertebral dysplasia (Gorlin et al., 1963). Most cases are sporadic, though autosomal recessive and autosomal dominant inheritance have been proposed. A Genome wide search for linkage in 1 family suggested linkage to a region of 10.7 cM on chromosome 14q32, between the microsatellite markers D14S987 and D14S65. Analysis of the candidate gooseoid gene within this region showed no mutations in several sporadic cases (Kelberman et al., 2001). We report an 8 month-old, Hispanic male referred for genetic evaluation. He is the 2nd child of a 33 year-old, G7P2A5 diabetic mother. On physical examination, his height (66 cm), weight (6.7 kg) and OFC (42.5 cm) were all below the 5th percentile. He has an asymmetric face, micrognathia and a crumpled ear. He has a complex cardiac anomaly including ASD, VSD and PDA. A Skeletal survey showed butterfly vertebra in T7 and hemivertebra in T9. There was also absence of epiphyseal ossification in the proximal humeri, distal femur and proximal tibia. Based on the phenotypic features, HFM was diagnosed. Chromosome analysis from cultured peripheral blood lymphocytes showed a pericentric inversion of chromosome 14, with the karyotype 46,XY,inv(14)(p11.2q22.3). FISH analysis with BAC probes from 14q confirmed the inversion and also assigned the distal breakpoint to q22.3. Preliminary analysis of MIM databases showed that the bone morphogenetic protein BMP4 is localized to 14q22-q23 region. BMP4 is a vital regulatory molecule that functions through out the development. In mouse Bmp4 is found to be essential for proper atrioventricular septation. Further FISH analysis with BAC probes localized to the 14q22.3 region is in progress to map the breakpoint and to see what role BMP4 has in HFM.

Variable presentations of 11q- deletion disorder (Jacobsen Syndrome). *M. Hummel¹, F. Keller¹, P. Grossfeld², JE. Coad¹, SL. Wenger¹.* 1) West Virginia Univ, Morgantown, WV; 2) University of California, San Diego, CA.

11q- deletion disorder (previously called Jacobsen syndrome) is a chromosome deletion disorder involving the long arm of chromosome 11, and is characterized by psychomotor retardation, cardiac defects, blood dyscrasias and craniofacial anomalies. The incidence is estimated to be 1 in 50,000. Most cases arise from either a de novo deletion or an unbalanced segregation from a balanced carrier. We describe 3 new cases of 11q- each with different presentations. Case 1: 18 mo female who presented with developmental delays, facial dysmorphism and low platelets. Thrombocytopenia initially was attributed to alloimmune based on the presence of maternal antiplatelet antibodies. Platelet counts improved but have never normalized. Facial dysmorphism included downslanted palpebral fissures, ptosis and broad high forehead. Chromosome analysis was 46,XX,del(11)(q23.3). Parental studies were normal. Molecular studies revealed the retention of probes L7-17 and D11S1299 characterizing this as a small to moderate deletion. Case 2: 26 yo woman seen for abnormal fetal karyotype. Ultrasound showed IUGR, unilateral hydronephrosis, and clinodactyly. Amnio found a fetal karyotype of 46,XX,del(11)(q23.3). Parental studies were normal. No abnormalities were found on fetal echocardiography. Case 3: A newborn female presented with CHD, dysmorphic features and low platelets. Cardiac defect was a DORV. Clinically the patient had ptosis and hypertelorism with broad nasal bridge. Bone marrow biopsy to evaluate persistent thrombocytopenia (30k-60k) showed atypical megakaryocytes, suggestive of Paris-Trousseau syndrome. Chromosome analysis 46,XX,del(11q)(q23.3q24.4) (11q telomere FISH probe present.) Parental studies were normal. FISH mapping demonstrated retention of subtelomeric probes as well as of probes located centromerically at ~8 megabase intervals, consistent with a small interstitial deletion. Each case was ascertained through a different presentation. Platelet defects in combination with delays prompted consideration of 11q- deletion disorder in the pediatric cases. The prenatal case shows deletions of 11q should be included in the evaluation of the fetus with anomalies.

Shorter Telomeres in Older Individuals with Down Syndrome and Dementia. *E.C. Jenkins¹, M.T. Velinov¹, L. Ye¹, S. Li¹, E.C. Jenkins Jr.¹, H. Gu¹, W.B. Zigman¹, N. Schupf^{2, 1}, S. Sklower Brooks¹, D. Pang¹, W.P. Silverman¹.* 1) New York State Institute for Basic Research in Developmental Disabilities, Staten Island; 2) Gertrude H. Sergievsky Center, Columbia University, New York, New York.

Chromosome ends or telomeres are specialized structures consisting of highly conserved TTAGGG repeats that become shorter with every cell division while protecting the important coding sequences from damage during cell proliferation. A gradual loss of telomeric DNA in dividing somatic cells can contribute to replicative senescence, apoptosis, or neoplastic transformation with age. The association between telomere shortening and in vitro cellular senescence has been well established (Proc Natl Acad Sci USA 1992;89:10114-8). Information is also accumulating relative to in vivo cellular aging and telomere shortening (J Am Geriatr Soc 2001;49(8):1105-9). Since telomere shortening has been recently associated with Alzheimer's disease (AD) status in the general population (Neurobiol Aging 2003;24:77-84), we hypothesized that a similar association might exist for adults with Down syndrome (DS), a population at increased risk for accelerated aging and AD. Individuals with DS also have decreased life expectancy and have been shown to have shorter telomeres than controls. We used quantitative telomere protein nucleic acid FISH analysis of metaphase and interphase preparations to compare telomere length from six trisomy 21 individuals with dementia and their age- and sex-matched peers without dementia (all 12 individuals had Down syndrome). All analyses were conducted blind to dementia status. We observed shorter telomeres in the demented individual in all of the six pairs studied ($p=0.028$). From this preliminary study, we conclude that telomere shortening is associated with dementia in trisomy 21 and suggest that additional research may show that telomere shortening could be an indicator of dementia status. This work was supported in part by the New York State Office of Mental Retardation and Developmental Disabilities, Alzheimer's Association grant IIRG-99-1598, and by NIH grants PO1 HD35897, RO1 HD37425, and RO1 AG014673.

Large Deletion in Rett Syndrome Detected by MPLA/ CGH Analysis. *T.A. Maher¹, X.L. Huang¹, J.M. Milunsky^{1,2,3}.* 1) Center for Human Genetics; 2) Department of Pediatrics; 3) Department of Genetics and Genomics; Boston University School of Medicine, Boston, MA.

Rett Syndrome, primarily affecting females, is an X-linked disorder with a frequency of ~1 in 12,000. Typically the syndrome is a neurologic developmental disorder and one of the most common causes of female mental retardation. Molecular testing consists of sequencing the four exons of the methyl-CpG-binding protein-2 (MECP2) gene. This has been shown to detect approximately 80% of mutations in patients. The mutational spectrum consists of missense, nonsense, small deletions and complex rearrangements. Recently, a relatively new method, Multiplex Ligation-Dependent Probe Amplification (MPLA), has been applied to Rett analysis. MPLA is multiplex, quantitative PCR method to determine copy number. Probes are specific to each of the four exons and control regions outside the gene. This technique has detected whole exon deletions that were missed by sequencing.

An 18 year old female's sample was submitted for sequencing of the MECP2 gene. She has typical Rett syndrome features including autism and no speech. She remains ambulatory. After sequencing analysis of the four coding regions, no nucleotide changes were detected. Here we report a large deletion detected using the MPLA method. MPLA analysis was completed and a deletion of exon 4 was detected along with a deletion of one of the control probes some ~7Mb away. This result was confirmed using high resolution comparative genome hybridization (CGH) with the deletion estimated to be ~9Mb. Further studies continue to refine the deletion and determine if other genes may be involved. MPLA analysis is relatively straight forward to implement and will increase the mutational spectrum of Rett. We have instituted this method as part of our clinical testing protocol.

Phenotype-Genotype correlations of dicentric Y chromosomes: the third review of literature. *N. Abdelmoula¹, A. Amouri², MF. Portnoi³, A. Bahloul⁴, A. Saad⁵, T. Rebai¹.* 1) Lab d'Histologie, Fac de Medicine de Sfax, Tunisia; 2) Lab de cytogenetique, Inst Pasteur de Tunis, Tunisia; 3) Lab de cytogenetique, Hopital Saint-Antoine, Paris, France; 4) Service d'Urologie, Hopital Habib Bourguiba, Sfax, Tunisia; 5) Lab de cytogenetique, Hopital Farhat Hached, Sousse, Tunisia.

Dicentric Y chromosomes have been reviewed twice in 1995 by Hsu LYF. and Tuck-Muller C. who showed that dic(Y) are the most common Y structural abnormalities and that their influence on gonadal and somatic development is extremely variable. Here, we report a third comprehensive review of the literature concerning dicentric Y chromosomes reported since 1994. We find 78 new cases for which molecular studies (PCR or FISH) have been widely applied to investigate SRY (68% of cases), GBY, ZFY, RFS4Y, GCY and different genes at AZF region. For dic(Yq), all cases (20) were mosaic for 45,X and 4 of them were also mosaic for a 46,XY cell line. When breakpoints were available (15/20 cases), they were in Yp11. 50% of cases were phenotypic female and 20% phenotypic male while 20% of cases were reported with gonadal dysgenesis. Gonadal histology was defined in 8 cases but only in one case, gonadal tissue was genetically investigated because of gonadoblastoma. For dic(Yp), mosaicism concerned only 45,X cell line and was found in 50 cases while the remainder five cases were homogeneous. When breakpoints were available, it was at Yq11 in 50 cases and at Yq12 in two cases. 54% of cases were phenotypic female, 26% were phenotypic male and 18% were associated with genitalia ambiguous. SRY was analyzed in 33 cases, sequenced in 9 cases and was muted in only one case. Gonads were histologically explored in 34 cases and genetically investigated in 8 cases. Gonadoblastoma was found in only two cases. Through this review, it seems that phenotype-genotype correlations are still not possible and that homogeneous studies of dic(Y) in more patients using molecular tools for structural characterization of the rearranged Y chromosome and assessment of mosaicism in many organs are necessary to clarify the basis of the phenotypic heterogeneity of dicentric Y chromosomes and then to help phenotypic prediction of such chromosome rearrangement.

FISH evaluation of 15q11-13 microdeletions in sperm nuclei. *E. Anton, J. Blanco, J. Egozcue, F. Vidal.* Unitat de Biologia Cel.lular (Facultat de Ciències), Universitat Autònoma de Barcelona. 08193-Bellaterra. Spain.

Most of the cases of Prader-Willi Syndrome (PWS) (70 %) are due to a paternal 15q11-13 microdeletion. The majority are considered to be originated *de novo*, as the consequence of functional meiotic errors occurring during the process of gametogenesis. With the aim of investigating if fathers of PWS children have an increased tendency to form sperm cells with *de novo* microdeletions or whether this is a random phenomenon, we have performed a fluorescence in situ hybridization (FISH) study in semen samples from 5 control men and 5 fathers of children affected by PWS. A triple-color FISH approach using probes for the centromeric region of chromosome 6 labeled in Aqua (used as a ploidy control), centromeric probe for chromosome 15 labeled in Green and a locus-specific probe for the 15q11-13 region labeled in Orange (Vysis Inc.) were used. Basal hybridization failure for the 15q11-13 probe was evaluated in lymphocytes, resulting in a 2.06%. All analyses were blindly conducted with respect to the genetic origin of the syndrome. In control donors, percentages of spermatozoa lacking an orange signal fell within the values expected from hybridization failures. Similar results were observed in the semen sample of the only father having a PWS child originated by uniparental disomy. Results in fathers of children affected by microdeletions showed a divergent pattern with an increased frequency of spermatozoa with the 15q11-13 microdeletion in one of the four cases analyzed. Although more patients should be analyzed to gather more significant data, these preliminary findings do not suggest a predetermined differential meiotic behavior in these men though some individuals might have a predisposition to produce microdeleted gametes. In this sense, FISH in sperm nuclei could be a useful tool to help in the evaluation of recurrence risks.

Acknowledgements: Special thanks to the PWS fathers for their collaboration and to Dr. M. Guitar and Dr. E. Gabau for their help in the recruitment of the donors. Research support: grant 2001FI/00457 (DGR) and project SAF2003-04312 (DGI) (Spain).

Program Nr: 861 from the 2004 ASHG Annual Meeting

Micronuclei in human lymphocytes treated with chloroquine *in vitro*. *I.P. Aranha, C.L.R. Chagas.* Inst Biol, PHLC S-525-6, Univ Estado Rio de Janeiro, Rio de Janeiro, Brazil.

Chloroquine is a drug that was initially used for the treatment of malaria but has also been successfully used for the treatment of arthritis and lupus eritematosus. In the present study, the micronucleus assay in human lymphocytes was used to assess the effects of chloroquine *in vitro*. Micronuclei appear during cell division as a result of acentric chromosome fragments or whole chromosomes, outside the nucleus. Blood was collected from healthy donors 18 to 30 years old. Peripheral whole blood cells were incubated at 37°C and 5% CO₂ for 72h, in enriched RPMI 1640 medium in the presence of chloroquine (15ng/ml). Cells not exposed to the drug served as control for the experiment. Cytochalasin B (4g/ml) was added to the cultures 44h postinitiation. After fixation, cells were stained with Giemsa Gurr (2%) and analysed under optical microscope. In the test group, from 3382 binucleated cells analysed 17 micronuclei were observed, while in the control group, from 2899 binucleated cells analysed 1 micronucleus was found. Using the chi-square test with Yates correction, the results were very significant ($p=0.0013$) showing an association of chloroquine and the occurrence of micronuclei.

Molecular and cytogenetic characterization of an idic(Y)(p11.23) chromosome in a boy with right testicular dysgenesis, left gonadism and growth retardation. A. Bahloul¹, N. B. Abdelmoula², A. Amouri³, MF. Portnoi⁴, M. Hachicha⁵, A. Saad⁶, T. Rebai¹. 1) Service d'Urologie, CHU H Bourguiba, Sfax, Tunisia; 2) Lab d'Histologie, Faculte de Medecine de Sfax, Tunisia; 3) Lab de Cytogenetique, Inst Pasteur de Tunis, Tunisia; 4) Lab de Cytogenetique, Hopital Saint-Antoine de Paris, France; 5) Service de Pediatrie, CHU H Chaker, Sfax, Tunisia; 6) Lab de Cytogenetique, CHU F Hached, Sousse, Tunisia.

We report a 15 years old boy who was referred for ambiguous genitalia and growth retardation with short stature (below the 4th percentile). His external genitalia were represented by a small phallus with urethral opening at its perineal insertion and a labioscrotal folds fused with minimal rugation. At surgery, ambiguous genitalia was corrected in male senses. No right gonad was founded and a left rudimentary gonad, appearing as a testis with epididymus and vas deferens, was removed during the operation. Histological assessment of this gonad demonstrated it to be an immature testis which contain immature seminiferous tubules with Sertoli cells but without spermatogonies. Chromosome analysis carried out from peripheral blood using RHG, GTG and CBG banding showed a 45,X cell line and an other in which the Y chromosome was replaced by an abnormal apparently metacentric chromosome. The abnormal chromosome was interpreted to be a dicentric isochromosome composed of two copies of the long arm, centromere, and proximal portion of the short arm of the Y chromosome. The cytogenetic interpretation was supported by FISH analysis using the Y heterochromatin specific probe (DYZ1), the Y alphaloid centromere specific probe (DYZ3), the X chromosome specific DNA probe (STS Xp22.3 Region probe with DXZ1 chromosome) and the LSI SRY (Yp11.3)/CEP X(DXZ1) dual color DNA probe. FISH exhibited two copies of SRY making evidence for duplication of pericentromeric sequences of Yp and corroborated a dicentric chromosome. The ratio of mosaicism was estimated by FISH analysis of 250 cells. PCR analysis using both SRY and ZFY primers were positive. The abnormal chromosome constitution in our patient was then written: 45,X[35]/46,X,dic(Y)(qter-p11.32::p11.32-qter)[65].

Multicolour banding and PCR analysis of two small derivative Y chromosomes. *S. Bal¹, M. Tomiuk¹, T. Anderson¹, D. Tucker¹, D. Riordan¹, A. Mhanni^{2,3}, A.E. Chudley^{2,3}, I. Chudoba⁴, B. Morash^{1,2,3}, A.J. Dawson^{1,2,3}.* 1) Cytogenetics Laboratory, Division of Laboratory Medicine and Pathology, Health Sciences Centre, Winnipeg, Manitoba, Canada; 2) Section of Genetics, Department of Pediatrics and Child Health, Health Sciences Centre, University of Manitoba, Winnipeg, Manitoba, Canada; 3) Department of Biochemistry and Medical Genetics, University of Manitoba, Winnipeg, Manitoba, Canada; 4) Metasystems, Altlussheim, Germany.

A 31/2 year old male was referred to the Genetics Clinic because of speech and language delay, short stature, mild dysmorphisms and Duane anomaly of the eye. Chromosome analysis showed an unbalanced male karyotype with a modal chromosome number of 47. There was a missing Y chromosome and two different sized markers whose origin could not be determined by conventional cytogenetics. Both markers occurred de novo as both parents have normal karyotypes. FISH analysis showed a Y centromere on both markers with a larger signal present on the smaller marker, der(Y2), than on the larger marker, der(Y1). FISH analysis also showed that SRY was present on der(Y1), consistent with the proband's male phenotype, but not on der(Y2). FISH analyses with PAR1/PAR2 subtelomere probes were negative on both der(Y)s. Subtelomere FISH analysis was otherwise normal. Q-banding did not show Yqh fluorescence on either derivative. Multicolour Y chromosome banding showed that der(Y1) is derived from the Y centromere and short arm whereas der(Y2) is derived from the Y centromere and pericentromeric short and long arms. Der(Y2) had a larger centromere than der(Y1), in agreement with our previous results. PCR analysis of the spermatogenesis region of Yq11 showed that the proximal AZFa was present whereas the more distal AZFb and AZFc were deleted, likely resulting in short stature and infertility. The proband has two older brothers who also have speech and language delay but who have normal Y chromosomes. This suggests that the speech and language delay in our proband is likely coincidental to the der(Y)s, which likely accounts for the short stature and variable dysmorphisms previously reported in association with Yq deletions.

Phenotypic implications of infrastructural rearrangements of the Y chromosome: investigation by FISH using

BACs. *M. Beaulieu Bergeron*^{1,4}, *M. DesGroseillier*^{1,4}, *R. Fetni*⁵, *P. Brochu*³, *E. Lemyre*^{2,4}, *N. Lemieux*^{1,3,5}. 1) Département de Pathologie et biologie cellulaire, Université de Montréal, Montréal, Québec, Canada; 2) Département de Pédiatrie; 3) Département de Pathologie and; 4) Centre de recherche de l'Hôpital Sainte-Justine, Montréal, Québec, Canada; 5) Department of Pathology, McGill University Health Center, Montreal, Quebec, Canada.

Both males and females can carry infrastructural rearrangements of the Y, which are often unstable and complex. Despite the fact that the Y chromosome contains very few known genes, abnormalities of this chromosome can cause various phenotypes, especially in females, such as Turner syndrome, sex reversal or sexual ambiguity, and gonadoblastoma. In males, less severe clinical implications include infertility and azoospermia. We characterized 15 patients with isodicentric Y chromosomes and 7 patients with sex reversal. FISH was performed using probes SRY (Yp11.3), 91H4.5 (Yp11.2), DYZ1 (Yq12), DYZ3 (Y centromere) and WCPY (whole chromosome painting of the Y). BACs (Bacterial Artificial Chromosomes) were also used in some cases in order to refine the molecular breakpoints. SRY was found to be present in 14 cases of idic(Y). The different phenotypes seen in those 14 cases might be explained by the variable proportion of the 45,X cell line. As for the 4 cases of sex reversal with a der(X), the presence of SRY was confirmed in all, generating the male phenotype of those patients. One other case of sex reversal is explained by the duplication of DAX, resulting in a female development despite the presence of SRY. Finally, we are currently unable to explain the female phenotype seen in two patients with a predominant 46,XY cell line. In conclusion, this study highlights the necessity of using BACs to refine the molecular breakpoints of infrastructural rearrangements of the Y. Indeed, these BACs will allow us to determine if a common molecular region is implicated in specific rearrangements of this chromosome. As a result, this will not only help increase the correlation between the genotype and its clinical implications, it will also improve both genetic counselling and cares offered to patients carrying such anomalies. *Supported by RMGA-FRSQ.*

Recurrent breakpoints in balanced autosomal translocations in man. *P.A. Benn¹, M.J. Benn²*. 1) Gen/Dev Biol/Human Genetics, Univ Connecticut Health Ctr, Farmington, CT; 2) Farmington High Schl, Farmington, CT.

Objective: To evaluate the distribution of chromosome breakpoints in balanced reciprocal translocations in man.

Methods: Data were extracted from North American and European collaborative studies on couples receiving prenatal diagnosis (Daniel et al AJMG 33, 14-53, 1989). Robertsonian translocations, inversions, t(11;22)(q23-q25;q11-13), and complex rearrangements were excluded. When multiple cases with identical re-arrangements were identified through a single laboratory, the carriers were assumed to be related and the translocation was counted only once. When identical re-arrangements were identified through different laboratories, the rearrangement was counted more than once. The distribution of breakpoints was compared with that expected if breakage occurred randomly. $P < 0.01$ was considered statistically significant.

Results: After exclusions, 905 translocations with 1810 breakpoints were analyzed. There were 34 instances where identical translocations were reported by two or three laboratories and 19 (56%) of these involved reports by laboratories based in different countries. Breakpoints were non-randomly distributed. 476 (26%) of the breakpoints were assigned to the 44 terminal bands with 21q22 most commonly involved (27 cases). After excluding the terminal band breakpoints, there remained significant departures from random with an excess of breakpoints assigned to chromosome 15 and a deficit for chromosomes 12 and 19. Interstitial bands 1q32 (24 cases), 4q31 (20 cases) and 13q14 (22 cases) were each involved in over 1% of all breakpoints.

Conclusion: Balanced translocation breakpoints presumably reflect regions susceptible to rearrangement, differences in the selection against rearrangements, the chromosomal locations of essential genes, and possible ascertainment bias. These factors result in a non-random distribution in the observed breakpoints in human translocations.

Possible association of chromosome instability to recurrent abortions. *L. Bobadilla-Morales¹, M. Cervantes-Luna¹, T. García-Cobian¹, G. Zúñiga-González², J. Corona-Rivera¹, A. Corona-Rivera¹.* 1) Lab de Genetica Humana, Univ Guadalajara, CUCS, Guadalajara, Mexico; 2) CIBO-IMSS, Guadalajara, Jal., Mexico.

Recurrent pregnancy loss, is observed in 1 to 2 % of fertile women. The pathophysiological mechanism has not been well established. On the other hand, chromosome instability consists of structural spontaneous or induced aberrations. In this work we show a non consanguineous healthy couple with recurrent abortions and no constitutive chromosome aberrations, but with two tetradial chromosomes in routine female study. The couple was of 30 and 29 ys old, male and female respectively. They showed three recurrent abortions of around 13 weeks of gestation, the first of them was diagnosed as anembrionic and the third one as molar. We performed a second evaluation to the search of chromosome instability in the couple and controls by testing three different culture conditions: gamma radiation (GR), Uv light (UvL) and mitomicyn-C (MC) in 72 hs blood cultures alternatively exposed to 1 Gy of GR 3 hs prior harvesting, UvL for 30 minutes 3 hs prior harvesting and MC (20 ng/ml) after 24 hs of set up. Chromosome analysis was done in 60 mitosis in the couple and controls. UvL and MC condition scores were not different to controls. GR chromosome damage was of 22% versus 2% in controls and statistically significant only in the female who exhibited 23% of chromatid breakages, 14% of chromatid gaps, 31% of chromosome gaps, 9 % of fragments as well as 3 tetradials and one triradial. Additionally, exfoliated buccal cell micronuclei resulted moderately increased in the female. Then, chromosome instability evidences were observed in the female. Two previous reports found increased micronuclei and spontaneous breakage or aphidicolin induced fragile sites in couples with more than two spontaneous abortions, proposing an etiologic relation. In this case, the presence of spontaneous tri and tetradials and increased GR induced damage resembles instability behavior of Ataxia-Telangectasia and supports chromosome instability in the female. We propose that chromosome instability can be involved in some, otherwise cryptic, repetitive abortion cases.

Karyotypic discrepancy between the amniocytes and CVS in prenatal diagnosis and the skin tissue of the abortues. *J. Bourgeois, J. Xu.* Pathology and Molecular Medicine and Lab Medicine, Hamilton Health Sciences and McMaster University, Hamilton, ON, Canada.

A 41 year old G2P1 woman was seen in the prenatal diagnosis clinic for advanced maternal age at 14.5 weeks gestation. The routine dating ultrasound performed during her assessment was abnormal with a cystic hygroma and hydrops being noted. Counseling and chorionic villous sampling (CVS) were performed on that same day. Only 4 metaphase cells were obtained from this small (5mg) CVS sample and all had 47,XY,+13. A follow-up anatomic 18.0 week ultrasound was performed which showed resolution of the hydrops but with some persistence of the cystic hygroma. Confirmatory amniocentesis was done that same day. Prenatal interphase FISH of uncultured amniocytes using a set of the probes for chromosomes X, Y, 13, 18 and 21 resulted in 96% (48/50) of the nuclei having additional signal indicative of trisomy 13. Routine G-banding analysis of 12 in situ colonies from 4 coverslips all had 47,XY,+13. Following additional counseling regarding these results, the patient was admitted for pregnancy discontinuation with induction of labor at 19+ weeks gestational age. A single male fetus with phenotypic features consistent with a chromosomal anomaly such as trisomy 13 was delivered. Fetal skin was obtained for karyotyping and of the 10 cells, all showed trisomy 13 as well as a pericentric inversion of chromosome 5; 47,XY,inv(5)(p13q35),+13. There was no evidence of laboratory errors that might cause this discrepancy. Although parental karyotyping is being perused, this type of pre and postnatal karyotype result discrepancy is extremely rare and the exact reason for this remains unknown. A possible explanation would be the presence of isolated fetal mosaicism involving at least the fetal skin tissue that was not present in the chorionic villi or amniocytes.

Molecular mapping and phenotype of three unrelated subjects with a novel deletion 5q14.3q15. A. Boys¹, J. Ryan¹, I.E. Scheffer², W. Francis¹, D. Francis¹, I. Hayes¹, P. La¹, E. Northrop¹, H.R. Slater¹. 1) Victorian Clinical Genetics Services, Melbourne, VIC, Australia; 2) Epilepsy Research Institute and Department of Medicine, University of Melbourne, and Austin & Repatriation Medical Centre, Melbourne, VIC, Australia.

Cytogenetic deletion of the region 5q14.3 to q15 and its clinical significance has not been described. We report a subtle interstitial deletion of this region in three unrelated boys referred over a period of 10 years. The three patients have a variety of clinical abnormalities, which include severe global developmental delay, severe intellectual disability, cranial and facial dysmorphism, and visual impairment. All three boys had febrile seizures, and myoclonic seizures from birth were prominent in two. The locations and sizes of the deletions have been determined using BAC clones and FISH. Subjects 1, 2, and 3 have deletions of 7Mb, 10Mb, and 6Mb respectively. The deleted region of Subject 2 encompasses the deletion of Subject 1. There is a 1Mb overlap region common to all subjects with three known genes in this common overlap, ie. CETN3, RPC32, and MASS1. Of particular interest is the partial deletion of MASS1 in Subject 1. This gene shares part of its exonic structure with another gene called VLGR1, which itself has known isoforms. Mutations within MASS1 have been described with audiogenic seizures in the mouse and in a family with febrile and afebrile seizures. MASS1 is therefore an attractive candidate gene for the epilepsy phenotype in these del (5q) patients.

***De novo* monosomy 9p24.3-pter and trisomy 17q24.3-qter characterized by microarray CGH in a fetus with an increased nuchal translucency.** S. Brisset¹, M. Benkhalifa², A. Coulomb L'Hermine³, V. Mairovitz⁴, E. Gautier⁵, G. Tachdjian¹. 1) Dept Genetics, Hosp Antoine Beclere, Clamart, France; 2) ATL R&D, Voisins le Bretonneux, France; 3) Anatomie Pathologique, Hosp Antoine Beclere, Clamart, France; 4) Gynecologie-Obstetrique, Hosp Antoine Beclere, Clamart, France; 5) Centre de Diagnostic Prenatal, American Hospital of Paris, Neuilly, France.

Increased nuchal translucency (NT) during the first trimester of pregnancy is a useful marker to detect chromosomal abnormalities. We report a prenatal case of molecular cytogenetic characterization of an abnormal derivative chromosome 9 identified through NT. Amniocentesis was performed on a 29-year-old female because of an increased NT (4.4 mm). Chromosomal analysis revealed an abnormal 46,XX,add(9)(p24.3) karyotype. FISH (fluorescence *in situ* hybridization) with a chromosome 9 painting probe confirmed the presence of an additional euchromatic material on the short arm of one chromosome 9. A subtelomeric 9p specific probe showed a terminal deletion of one 9p. However, it was not possible to resolve the origin of this additional material on 9p. Parental chromosomes were normal. The parents were informed of the poor prognosis and a termination of pregnancy was performed at 22 weeks of gestation. In order to characterize the origin of the additional material, we performed a microarray comparative genomic hybridization (microarray CGH) using a human genomic array containing 2500 clones spanning the genome at approximately 1 Mb intervals (Spectral Genomics, Houston, TX, USA). Microarray CGH confirmed the deletion of distal 9p and showed a terminal trisomy 17q. These results were confirmed by FISH analyses using the BACs clones spotted on the array. Array CGH provided accurate information as to the breakpoint regions and the size of both distal 9p deletion and terminal 17q trisomy. The fetus was therefore a carrier of a *de novo* derivative chromosome 9 arising from a t(9;17)(p24.3;q24.3) translocation and generating a monosomy 9p24.3-pter and a trisomy 17q24.3-qter. This case illustrates that microarray CGH is a powerful and sensitive technology to identify *de novo* unbalanced chromosomal abnormalities and can be applied in prenatal diagnosis.

Trisomy 13 due to $rea(13q;13q)$ is caused by $i(13q;13q)$ and not $t(13q;13q)$ in the majority of cases. *M. Bugge*^{1,2}, *C. deLozier-Blanchet*³, *M. Bak*¹, *C.A. Brandt*^{4,5}, *J.M. Hertz*⁴, *J.B. Nielsen*^{2,6}, *L. Duprez*⁷, *M.B. Petersen*^{2,8}. 1) Wilhelm Johannsen Centre for Functional Genome Research, IMBG, Panum Institute, Copenhagen, Denmark; 2) Department of Medical Genetics, John F.Kennedy Institute, Glostrup, Denmark; 3) Division of Clinical Genetics, University of Geneva, Switzerland; 4) Department of Clinical Genetics, Aarhus University Hospital, Denmark; 5) Department of Clinical Genetics, Vejle County Hospital, Denmark; 6) Department of Clinical Genetics, Rigshospitalet, Copenhagen, Denmark; 7) Department of Genetics, Erasme Hospital, Brussels, Belgium; 8) Department of Genetics, Institute of Child Health, Athens, Greece.

It has been demonstrated, that trisomy 21 caused by $rea(21q;21q)$ de novo is due to $i(21q;21q)$ and not $t(21q;21q)$ in the majority of cases. We have used 20 PCR-based DNA polymorphisms to determine, whether trisomy 13 due to $rea(13q;13q)$ de novo in six cases is caused by $t(13q;13q)$ or $i(13q;13q)$, to determine the parental origin of the rearrangements and the mechanisms of formation. The six probands were three liveborn children with clinical features characteristic of Patau syndrome and three fetuses diagnosed prenatally by amniocentesis or CVS. Five cases were isochromosomes with two identical q arms, one of maternal and four of paternal origin. One case was a Robertsonian translocation of maternal origin.

Duplication of chromosome 3p25.3-p26.2 produces features similar to Prader-Willi syndrome. *M.G. Butler, N. Kibiryeve, M. Dasouki, J.H.M. Knoll, D.C. Bittel.* Children's Mercy Hospitals and Clinics and University of Missouri-Kansas City School of Medicine, Kansas City, MO.

Prader-Willi syndrome (PWS) is the most common genetic cause of morbid obesity and results from a functional loss of paternally expressed genes from the chromosome 15q11-q13 region. PWS is associated with neonatal hypotonia, failure to thrive, developmental delay, hypogonadism and the onset of hyperphagia between the ages of 2 to 4 years. Herein, we describe an eight year old male referred for PWS. He had pervasive developmental disorder (PDD) with marked obesity and delayed speech. Chromosome 15q11q12 methylation testing and fragile X studies were normal. Chromosome analysis by GTG-banding and fluorescence *in situ* hybridization with a whole chromosome 3 paint probe suggested a duplication of 3p25.3p26.2, a finding supported by comparative genomic hybridization. At the time of examination he was 131 cm tall (50th centile), weight was 52.7 kg (> 97th centile) and head circumference was 53 cm (25th centile). The subject had rapid weight gain at 4 years of age which has continued. The duplicated region of chromosome 3p includes several genes which may contribute to obesity and PDD, most notably, ghrelin (*GHRL*) and oxytocin receptor (*OXTR*). Ghrelin is an important appetite-stimulating hormone produced by the stomach which induces adiposity. Plasma ghrelin levels are reported to be significantly higher in individuals with PWS, while oxytocin is undetectable in the hypothalamus of PWS subjects. Plasma ghrelin was 250 pg/ml in our subject. Similarly, a transporter of GABA identified in the 3p25-p26 region, *SLC6A11*, is of interest because GABA, an inhibitory neurotransmitter, is increased in individuals with PWS and may be involved with multiple neurodevelopmental aspects of PWS. Interestingly, the *PPARG* gene is adjacent to the duplicated region of our subject. Defects in *PPARG* can lead to type 2 diabetes and predisposition to obesity. The expression levels of these genes and others located in 3p25-p26 are under investigation to determine if overexpression as a consequence of the duplication contributes to the physical and behavioral problems seen in our subject.

Determination of the origin and mechanisms of formation of three constitutive structural aberrations of chromosome 5. *A. Cervantes, N. Monroy, E. Galvez, M.C. Chima, R. Alvarez, L. Camberos, S. Kofman.* Genetica, Hospital General Mexico, F. Medicina. UNAM, Mexico DF, Mexico.

We investigate the parental origin and delimited the breakpoints in three different deletions of chromosome 5 using microsatellite analysis. The karyotypes with GTG bands of the patients were: 46,XY,del(5)(p13.3); 46,XY,del(5)(p15.3?) and 45,XX,del(5)(q22q31),der(13;14)(q10;q10). The karyotypes of mother of case 1, both parents of case 2, and the father of the last one were normal, while her mother was carrier of the robertsonian translocation. The father of case 1 was not studied. PCR amplification of genomic DNA of all of them was done using CA/GT microsatellites for chromosome 5 from the ABI-PRISM Linkage Mapping Set ver 2.0-PE and the products analyzed on an ABI310 automated sequencer. The results showed the lost of paternal alleles in the three cases. The breakpoints were assigned between D5S418 and D5S426 in case 1, confirming the terminal deletion from 5p13.1. The paternal alleles of D5S418(5p13.1) and D5S407(5q11.2) were absent in case 2 showing two interstitial deletions and the presence of 5 pairs of alleles on 5p15.3. In the girl, the deleted segment was between D5S2027 and D5S436. It has been proposed that structural aberrations occur by non-allelic homologous recombination on specific susceptible sites, originated by the genome architecture due to the presence of segmental duplications or low copy repeats, LCRs. The investigation for reported LCRs, as odorant receptors, was negative in the cytogenetic breakpoints; but some duplicons are located in 5p13, 5p14 and 5q21, additionally these regions have been implicated in other constitutive or acquired abnormalities and are rich in coding genes, LINE and SINE elements that could be involved in the rearrangements.

A translocation t(6;7)(p21;q22) associated with autism and mental retardation: localization, and identification of candidate genes at the breakpoints. *S. Choufani¹, J. Vincent^{1,3}, J. Skaug¹, W. Roberts², P. Szatmari⁴, J.M. Friedman⁵, S.W. Scherer¹.*

1) Genetics & Genomic Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) The Child Development Center, The Hospital for Sick Children, Toronto; 3) Neurogenetics Section, Centre for Addiction and Mental Health, Toronto; 4) McMaster University, Hamilton; 5) Dept. of Medical Genetics, University of British Columbia, Vancouver.

Autism is a severe neurodevelopmental disorder characterized by impairments in social interaction and communication skills, coupled with unusual interest patterns and stereotyped behaviors. Genetic linkage evidence for an autism susceptibility locus (or loci) points to several regions of the genome, most notably a 50 Mb interval at 7q21 to 7q35. Supporting evidence for an autism susceptibility locus on 7q has come from cytogenetic studies of autism patients with chromosomal abnormalities. We describe here a male proband with mental retardation and autism who has a balanced translocation - t(6;7)(p21;q22). This translocation was inherited from an apparently normal father. Using fluorescence in situ hybridization, we have localized the breakpoints on both chromosomes and have identified - nearby candidate genes. These include the neural pentraxin 2 gene (NPTX2) on 7q22 and human homologue of the mouse dystonin gene (BPAG1) on 6p22. It is conceivable that either of the two breakpoints could define a new locus for autism and/or a form of mental retardation. NPTX2 is thought to be involved in excitatory synaptogenesis and could, therefore, be considered as a functional candidate for autism. In order to examine whether a genetic variation of this gene is involved in autism, we screened the 5 exons and flanking intronic sequence of the human NPTX2 gene, using direct sequencing, in 69 unrelated individuals with autism from multiplex families. We identified a total of 6 new variants, 3 coding and 3 intronic variants. We are currently testing the presence of each variant in control samples.

Genomic microarray facilitated identification of a der(4)t(4;11)(p16.3;p15.5) in a patient with a modified Wolf-Hirschhorn syndrome phenotype. *B.C. Cowley, D.A. Stevenson, J.C. Carey, P. Bayrak-Toydemir, R. Mao, A.R. Brothman.* Pediatrics, University of Utah, Salt Lake City, UT.

Wolf-Hirschhorn syndrome (WHS) is a 4p microdeletion syndrome sometimes not detectable by high resolution cytogenetics. We report a *de novo* cryptic 11p duplication found by genomic microarray with a cytogenetically detected 4p deletion. This patient, daughter of phenotypically normal parents, presented with physical features including hypertelorism, hypotonia, and multiple minor anomalies. Initial cytogenetic analysis revealed a 46,XX,del(4)(p16.3) karyotype at the 550-band level and the WHS region was confirmed to be deleted by FISH. Additional genetic abnormalities were suspected based on unusual features, including a large facial hemangioma and a full-cheeked robust appearance to her face. Her growth was atypical with normal prenatal and postnatal growth parameters; she had persistent hypoglycemia in the neonatal period, and she lacked the typical severe feeding difficulties seen in WHS. High-resolution dye-reversal genomic microarray analysis using a 2-4 Mb Human BAC chip (Spectral Genomics, Houston, TX) was performed. The 4p deletion was confirmed and its breakpoints further defined (the most proximal clone showing deletion was RP11-91B20), and an 11p duplication was also observed (the most proximal clone showing duplication was RP11-371C18). FISH using subtelomeric probes (Vysis, Downers Grove, IL) confirmed these abnormalities. The revised karyotype is thus 46,XX,der(4)t(4;11)(p16.3;p15.5). Parental chromosome analysis and FISH showed no abnormalities. Molecular short tandem repeat markers (D11S2071 and D11S4177) narrowed the breakpoint for the 11p duplication between 1.3 to 1.4 Mb from the telomere. In addition, marker D11S2071 demonstrated the duplication is of paternal origin. The 11p gain is thus hypothesized to be the cause of the modified WHS phenotype. The resolution of genomic microarray facilitated detection of an otherwise cryptic abnormality. This case is evidence for the value of genomic microarrays in clinical settings and their utility in precisely defining the genetic component behind unusual or ill-defined abnormalities.

DELINEATION OF THE CRITICAL REGION FOR GENITOURINARY ABNORMALITIES WITHIN DELETION 10q26.3. *C.A. Curtis, A.B. Zinn, S. Schwartz.* Center for Human Genetics, University Hospitals of Cleveland and Department of Genetics, Case Western Reserve University, Cleveland, OH.

A 5-day-old newborn male was referred for chromosomal analysis when he was found to have bilateral single palmar creases, widely-spaced nipples and choking spells. Cytogenetic studies revealed an unbalanced male karyotype with 45 chromosomes, including a derivative chromosome 10 that resulted from a translocation between the distal long arm of chromosome 10 (breakpoint in 10q26.3) and the proximal long arm of chromosome 22 (breakpoint in 22q11.21). Parental karyotypes were normal. Preliminary FISH studies confirmed that the derivative was deleted for the 10q subtelomere and the chromosome 22 centromere but retained the TUPLE1 locus of 22q11.21. The patient's physical examination was normal, including his genitalia, except for several minor craniofacial dysmorphic features. ECHO revealed a bicuspid aortic valve. A renal ultrasound and a voiding cystourethrogram were normal. Based on data from the Human Genome Browser (July 2003 freeze), the deleted region of 22q comprises a maximum of 1.3Mb. Additional BAC FISH studies revealed that the 10q deletion breakpoint was between RP11-941B15(+) and RP11-1141L20(-), indicating that the chromosome 10 deletion involved the terminal 3Mb of 10q. Ogata et al (2000) suggested that gene(s) involved in renal tract development and male sex differentiation are located within the 10q26 region. They estimated that the gene(s) responsible for the genital anomalies lies within the terminal 4.5Mb of 10q, distal to D10S1248, whereas the gene(s) responsible for the renal anomalies lies within the terminal 6.8Mb segment, distal to D10S186. The absence of both genital and renal malformations in our patient narrows the region associated with genital defects to ~1.65Mb, between D10S1248 and RP11-1141L28, and narrows the region associated with renal anomalies to ~4Mb, between D10S186 and RP11-1141L28. This case suggests that the most telomeric 3Mb region of 10q does not include the critical regions for either the urinary or genital abnormalities observed in patients with terminal deletions of 10q.

Real-time quantitative PCR (Q-PCR), Fluorescence In Situ Hybridization (FISH) and microarray based Comparative Genomic Hybridization (array-CGH) for the detection of submicroscopic chromosomal deletions in patients with features of holoprosencephaly spectrum. V. David¹, C. Bendavid¹, I. Gicquel¹, C. Henry², MR. Durou³, S. Odent⁴, C. Dubourg¹. 1) Fac de Medicine, UMR 6061 CNRS, Rennes, Cedex, France; 2) CHU Pontchaillou, Laboratoire de Cytogenetique, Rennes, France; 3) CHU Pontchaillou, Laboratoire de Genetique Moleculaire, Rennes, France; 4) CHU Hopital Sud, Unite de Genetique Medicale, Rennes, France.

Holoprosencephaly (HPE; 1/16000 live births; 1/250 conceptuses) is the most frequent congenital malformation of the brain. The clinical spectrum ranges from alobar HPE to semilobar and lobar HPE with accompanying facial anomalies. HPE can be due to environmental factors, major chromosomal abnormalities, polymalformative syndromes or be isolated. Ten genes (SHH, ZIC2, SIX3, TGIF, PATCHED, TDGF1/CRIPTO, GLI2, FAST1, DISPATCHED, HNF3) have been implicated in HPE but point mutations in these genes are responsible for less than 20 per cent of HPE cases. In the 80 per cent remaining, we suspect either other genetic alterations and particularly large deletions in the known HPE genes, or the implication of other genes not yet identified. This led us to use three different approaches to detect microdeletions. First we are investigating specific genes involved in HPE. We are developing real-time quantitative PCR (Q-PCR) applied to TGIF, SHH, ZIC2, SIX3 and GLI2, using SYBRGreen and TaqMan technologies for 200 newborns and 70 fetuses with HPE. We are also testing 40 lymphoblastoid cell lines using multicolour FISH targeting six genes (TGIF, SHH, ZIC2, SIX3, DISPATCHED and HNF3). Concurrently we initiated a comparative genomic hybridization (CGH) array approach to identify microdeleted regions all over the genome, using 2500 BAC arrays (Spectral Genomics). We already found a microdeletion in TGIF by Q-PCR on a fetus DNA sample, and we refined the size of this deletion to 10 Mb on chromosome 18p by the CGH array. We will present our results of Q-PCR and FISH applied to SHH, ZIC2, SIX3, TGIF, GLI2, DISPATCHED and HNF3, and our preliminary results of CGH array.

Stable ring chromosome 6 due to a centromeric fission. *M. de Blois¹, D. Sanlaville¹, A. Bachelot², C. Ozilou¹, S. Chevallier¹, M.C. Waill-Perrier¹, S. Romana¹, M. Vekemans¹, C. Turleau¹.* 1) Cytogenetics laboratory, Hopital Necker Enfants Malades, Paris, France; 2) Service of endocrinology, Hopital Necker Enfants Malades, Paris,.

A 43 year-old man was referred to us because of azoospermia. Peripheral blood lymphocytes chromosome analysis using GTG and RHG banding techniques, revealed a structurally abnormal chromosome 6p and an extra ring chromosome. FISH studies using chromosome 6 specific painting and subtelomeric probes showed respectively that the ring chromosome originated from chromosome 6 and that the 6p subtelomeric sequences were present on both the normal and the abnormally short chromosome 6. The absence of MCA/RM suggested that both structurally abnormal chromosomes 6 were totally stable. Using CBG banding technique, a signal was observed on the ring chromosome 6 but no signal was observed on the structurally abnormal chromosome 6. However further FISH studies using a chromosome 6 specific satellite probe showed a signal on both abnormal chromosomes 6. Presumably both structurally abnormal chromosomes resulted from an interstitial deletion of the short arm of chromosome 6 and a centromeric fission. Therefore we interpreted the karyotype as 47,XY,del(6)(qterp10::p22.3pter),+r(6)(p10p22.3) and the azoospermia as resulting from meiotic disturbance due to an abnormal synapsis of chromosome 6 homologues. Several observations of interstitial deletions associated with a ring chromosome have been reported in the literature. A neocentromere is observed either on the ring chromosome or on the deleted chromosome. As in the present observation satellite sequences were present on both the deleted chromosome and the ring chromosome, we concluded that its mitotic stability did not result from the presence of a neocentromere. It is well known that centromere fission played an important role during evolution but so far only a small number of cases have been reported in humans.

Array-CGH (aCGH) characterization of a distal 12q duplication in a child with mild language delay and partial epilepsy. *M. Demos*¹, *B.P. Coe*², *J.C. Wang*³, *B. Lomax*³, *M. Connolly*⁴, *W.L. Lam*², *P. Eydoux*³. 1) Medical Genetics, Children's and Women's Hosp; 2) B.C. Cancer Agency; 3) Cytogenetics Laboratory, Children's and Women's Hosp; 4) Pediatric Neurology, Children's and Women's Hosp; Vancouver, B.C., Canada.

Chromosomal abnormalities associated with epilepsy include terminal deletion of chromosome 1q and the inverted duplication chromosome 15 syndrome. To our knowledge, distal rearrangements of chromosome 12q have not been considered to have a high association with epilepsy. We describe a 3 year old girl with epilepsy and mild language delay due to a chromosome rearrangement at 12q24. Seizures began at 2 years of age with fever then re-occurred with or without fever. They were complex partial or secondarily generalized. Examination revealed head circumference above the 98th percentile and mild generalized hypotonia. Head CT scan was normal and EEG showed bifrontal dysrhythmia. Her karyotype revealed additional material on the terminal region of chromosome 12q, interpreted as a duplication of 12q24. A similar rearrangement was present as a mosaic in the mother. Duplication of chromosome 12q24 was confirmed using a subtelomeric 12q probe. Using a Sub-Megabase Resolution Tiling-set (SMRT) array-CGH (aCGH), we were able to confirm the duplication of chromosome 12q24, and narrow down the duplicated region to 12q24.32-q24.33. Further, we identified a potentially deleted region in the proximal end of band 12q24.32. Our aCGH data will be confirmed by FISH using BAC probes. To our knowledge, only 4 cases of pure duplication 12q24-qter have been reported. In our patient, epilepsy may have resulted from duplication of region 12q24.32-qter, or from the potentially deleted region 12q24.32. Further characterization of our patients imbalance may allow the identification of new gene(s) associated with epilepsy. Our results illustrate the power of aCGH for the characterization of chromosomal rearrangements, allowing the detection of imbalances overlooked by conventional cytogenetics. We believe that aCGH data may be necessary for the interpretation of clinical data associated with chromosomal anomalies.

Distal 2q deletion and 10p duplication detected by genomic microarray in a dysmorphic globally delayed child.

K.M. Dent, J.C. Palumbos, B.C. Cowley, E. Aston, A. Rope, A.R. Brothman. University of Utah, Dept. of Pediatrics, Salt Lake City, UT.

We report a 21-month-old Caucasian female with dysmorphic features, abnormal brain MRI, and global developmental delay. Patient ES was the 8 lb 1 oz, 21.5 inch product of a 39-week pregnancy delivered via caesarean section to a G5 P2 SA 3 28 year old female. The pregnancy was uncomplicated and there was no report of in utero exposures. On physical exam, height was at the 75-90th centile, weight at the 25-50th centile, and OFC at the 25-50th centile. Notable facial features include short, upward slanting palpebral fissures with Brushfield spots, prominent forehead, sparse hair, midface hypoplasia, beaked nose with a short columella, long philtrum, and a small mouth with down-turned corners. She has wide-spaced nipples, normal genitalia, and generalized hypotonia. She was not sitting or walking and had less than 10 single words at 16 months of age. Brain MRI demonstrated decreased bone mass and enlarged ventricles. Family history is significant for 2 spontaneous abortions in the mother, two paternal uncles with severe mental retardation and no reported birth defects, four additional paternal aunts and uncles who are alive and well with normal intelligence, and a single spontaneous abortion in the paternal grandmother. Parents are non-consanguineous. High resolution chromosome studies demonstrated a 46, XX, del(2)(q37.3) karyotype. The deletion was further characterized by genomic microarray analysis using the Spectral Genomics (Houston, TX) 1 Mb platform. Genomic microarray indicated a deletion from 2q37.1 to the telomere and duplication of 10p15.1 to the telomere. The corrected karyotype was thus 46, XX, der(2)t(2:10)(q37;p15) indicating monosomy of distal 2q and partial trisomy of distal 10p in this patient. FISH analysis with 2q and 10p subtelomere probes confirmed this finding. Parental studies are pending. This case indicates the power of genomic microarray analysis for rapid and thorough characterization of subtle chromosomal abnormalities. Its clinical use will better characterize chromosome disorders resulting in an immediate impact on genetic counseling for families.

Molecular characterization of breakpoints of an X-Y translocation in a girl with sex reversal. M.

DesGroseilliers^{1,2}, C. Hamelin^{2,3}, C. Deal^{2,3}, E. Lemyre^{2,4}, N. Lemieux^{1,2}. 1) Département de pathologie et biologie cellulaire, Université de Montréal; 2) Centre de recherche, Hôpital Sainte Justine; 3) Département d'endocrinologie, Hôpital Sainte Justine; 4) Division de génétique médicale, Hôpital Sainte Justine, Montréal, Québec, Canada.

We report the case of a female infant born after a normal pregnancy and delivery whose high resolution karyotype was 46,X,der(Y)t(X;Y)(p21.1;q11.23). She presented at 9 d with weight loss and respiratory distress, and physical exam showed facial dysmorphism, female external genitalia and marked hypotonia; an ASD (type II) and gastro-oesophageal reflux were subsequently documented. The presence of Mullerian structures (uterus and Fallopian tubes) was described at the time of gonadectomy (age 1.5 y). Dysgenetic gonads containing no germinal cells were noted on histological examination, as was the presence of bilateral vas deferens and rete testis in addition to normally-developed Fallopian tubes. Her infancy was characterized by intermittent failure to thrive due to multiple hospitalizations for respiratory infections and a chronic pneumopathy, but height and weight have been maintained at the 25th-50th centile with gavage feeding. Neurological evaluation at age 4 revealed global developmental delay, persistent central hypotonia, multifocal myoclonia and MRI findings including gyral simplification, a hypoplastic corpus callosum and periventricular loss of white matter suggestive of abnormal cellular migration. The GTG-banded karyotype showed an SRY+ Y chromosome, with additional X chromosomal material in terminal Y revealed by FISH probes WCPY and WCPX. The breakpoint in Yq occurred between BAC clones RP11-1077O23 and RP11-933N2, both located in Yq11.23, whereas the breakpoint in Xp occurred between markers DXS1068, located in Xp11.4, and DXS538, located in Xp21.1. Partial disomy of Xp genes including DAX1, explains the gonadal phenotype of the patient, as has been reported previously. Her neurological prognosis remains reserved, as has also been reported in other XY females with extensive disomy for X chromosome genes (This research was supported by grant from Réseau de Médecine Génétique Appliquée-FRSQ).

Array-CGH: a new tool for the characterization of constitutional structural cytogenetic abnormalities. *P.*

*Eydoux*¹, *S.K. Watson*², *J.C. Wang*¹, *W.L. Lam*². 1) Cytogenetics Laboratory, Children's & Women's Hosp; 2) B.C. Cancer Agency; Vancouver, BC, Canada.

Genome imbalances are a major cause of cancer, developmental delay and congenital anomalies. Techniques for the study of genomic diseases include karyotyping and Comparative Genomic Hybridization (CGH), a DNA-based technique first developed using differentially labeled test and control DNA hybridized on target metaphase chromosomes. Array-CGH (aCGH) has been recently developed, where the target is no longer metaphase chromosomes but DNA spotted on slides. aCGH was very successful in identifying new regions of imbalances (deletions and amplifications) and new genes involved in cancer genesis or progression. aCGH has also been used for the detection of common microdeletions. A few studies of patients with mental retardation yielded promising results using 1-3Mb resolution arrays, identifying genome imbalances potentially responsible for the phenotype. Using a tiling resolution array consisting of 32433 overlapping BAC clones covering the entire human genome (SubMegabase Resolution Tiling set: SMRT array), we studied patients with chromosomal abnormalities including apparently balanced translocations, unbalanced translocations, deletions and duplications. This technique can be implemented in a clinical setting. In a one-step experiment, SMRT-aCGH precisely identified the regions of imbalance. Some of these regions were overlooked by conventional cytogenetics. These results were confirmed by FISH using BACs chosen according to the aCGH data. Therefore, identification of the breakpoint regions was greatly facilitated by our aCGH results and gave new insight on the type of chromosomal rearrangements. Using the Human Genome data, this powerful approach allows identifying genes which may have a role in the phenotype of structural chromosomal anomalies and also facilitates the study of the genomic structure at the breakpoints and its role in the occurrence of chromosomal rearrangements. We believe that aCGH is a useful adjunct to cytogenetic studies and must be performed prior to attempting phenotype-genotype correlations.

Disruption of Friend of Gata 2 gene (FOG-2) by balanced chromosomal translocation t (8;10) is associated with endocrinological and heart defects. *P. Finelli^{1,2}, M.T. Bonati¹, D. Giardino¹, S. Russo¹, M.P. Recalcati¹, E. Valtorta¹, D. Colombo¹, A.I. Pincelli³, F. Cavagnini³, L. Larizza^{1,2}.* 1) Laboratory of Medical Genetics Istituto Auxologico Italiano, Milan; 2) Department of Biology and Genetics, University of Milan; 3) Ospedale San Luca, Istituto Auxologico Italiano, Milan.

We report on a 11 years old male with early puberty, high levels of blood FSH and LH, bilateral gynecomastia and advanced bone age. An interatrial septum heart defect was identified at birth. Laboratory investigation started with karyotypic analysis revealing the presence of a de novo balanced translocation 46,XX,t(8;10)(q24.1;q22.1). In order to precisely define the location of translocation breakpoints we performed FISH analyses with BAC clones mapping to the chromosomal bands 8q22-q24 and 10q21-q22. We mapped the translocation bkps to 8q23.1 and 10q21.1 by FISH results given by the encompassing BACs 161E14 and 269I2, respectively. Fine mapping of the rearrangement demonstrated that the 8q bkp falls within the Friend of GATA protein 2 gene (FOG-2) located in 8q23.1 and disrupts it, whether the 10q bkp does not fall within a coding sequence. The zinc finger protein encoded by FOG-2 is a widely expressed member of the FOG family of transcription factors. The FOG proteins modulate the activity of proteins belonging to the GATA family, which are key regulators of hematopoiesis and cardiogenesis and play also a role in early gonadal development and sexual differentiation in mammals. It has been demonstrated that the FOG-2 protein can both activate and down-regulate expression of GATA-target genes, suggesting different regulation of gene expression in different promoter contexts. FISH experiments also mapped the FOG-2 bkp within IVS3, a finding which predicts a truncated protein where only the first of the eight zinc finger motifs of the wild type the protein is maintained. It is presently unknown whether haploinsufficiency or the altered function of a truncated protein are responsible for the observed clinical phenotype.

Supernumerary 15q inverted duplication associated with interstitial chromosome 15q duplication. *P. Flodman, C. Modahl, L. Mays, P.A. Filipek, M.E. Bocian, M. Hanouni, M.A. Spence, M. Smith.* Dept. of Pediatrics, Univ California, Irvine, CA.

Duplications of 15q11-q13 may arise as interstitial duplications or the duplication process may lead to generation of an extra bisatellited chromosome, a 15q inverted duplication (inv.dup.(15)). Huang et al., Cook et al. (1997) determined that these duplications are only of significance if they contain the Prader Willi Angelman syndrome (PWAS) critical region and if they arise from a maternally derived chromosome.

Structural changes within chromosome 15 may predispose to development of an 15q inverted duplication chromosome during meiosis. Long et al. (1998) reported that patient with a PWAS region negative inv.dup.(15) had an interstitial triplication of proximal 15q11-q13, including the PWAS region, on one member of the chromosome 15 pair. We report results of molecular cytogenetic studies in a patient who was first noted to have behavioral problems at age 29 months. On developmental evaluation at 36 months, he exhibited stereotypical play and used fewer than 6 words. At 48 months he met ADI/ADOS criteria for autistic disorder. Overall IQ (Stanford Binet) was 92, with relative strength in abstract/visual and quantitative reasoning, and weakness in verbal reasoning. The child is somewhat obese and has cupped pinna but is not otherwise noted to be dysmorphic. The marker chromosome hybridizes only to probes located between 15 centromere and BP1. It does not hybridize to BACs from the BP1-BP2 region or to BACs from the PWAS region (BP2-BP3 region). Molecular cytogenetic analysis revealed that, in addition to the inv.dup.(15), an interstitial duplication is present on one member of the "normal" chromosome 15 pair. This interstitial duplication was detected using BACs that encompass the Necdin, Makorin, MAGEL2 and NECDIN encoding region and BACs for the SNURF SNRPN-UBE3A region. Results of our studies indicate that detailed FISH studies not only of the inverted duplication but also of the "normal" members of the chromosome 15 pair are required to determine the clinical significance of small 15q inverted duplications.

CRYPTIC SRY MOSAICISM IN A 45,X MALE. *I.K. Gadi¹, J.R. Tepperberg¹, L. Wisniewski¹, PalD. Singh-Kahlon¹, E.S. Cantu¹, C. Bullen¹, F. Nieves¹, D. Spitz².* 1) Dept Cytogenetics, Laboratory Corp of America, Res Triangle Pk, NC.27709; 2) The Cancer Institute, 1395 State Rd #7, Wellington,FL33414.

A 22 year old man with anemia and mastocytosis was referred to cytogenetics to rule out leukemia. Analysis of bone marrow unstimulated cultures showed a 45,X chromosome complement with an apparently normal G-banding pattern in all cells. No leukemic clonal chromosome anomalies were observed. Loss of the Y chromosome is generally considered a normal male aging phenomenon, although a 45,X leukemic clone was plausible with a submicroscopic alteration. It was equally plausible that the absence of the Y chromosome in a young male would reveal cryptic localization of the testis determining gene, SRY. Interphase FISH studies of the marrow showed 11% of the cells positive for a SRY hybridization signal. A few metaphases were found showing localization of SRY at the distal short arm of a G-group chromosome. Our hypothesis is that there was a rare Y-autosomal translocation during meiosis with subsequent constitutional mitotic loss of SRY from the G-group chromosome. The gonadal tissue is very likely to have a higher ratio of SRY bearing cells than the blood in order to support apparently normal male differentiation. Clinical and molecular Y chromosome DNA follow-up to confirm infertility is pending.

Low-copy repeats and monosomy 1p36. *M. Gajecka*¹, *B.C. Ballif*¹, *C.D. Glotzbach*^{1,2}, *K.A. Bailey*^{1,2}, *L.G. Shaffer*^{1,2}.
1) Health Research and Education Center, Washington State University, Spokane, WA; 2) Sacred Heart Medical Center, Spokane, WA.

Some chromosomal rearrangements have been shown to arise through nonallelic homologous recombination between low-copy repeats (LCRs). In investigating the molecular basis of monosomy 1p36 we observed two putative LCRs within the terminal 3.5 Mb of 1p36. Because regions of the genome that contain LCRs and segmental duplications are difficult to map and sequence, it was necessary to closely examine this region to verify its precise structure and sequence. We identified the LCRs by systematically performing BLAT searches with 10 kb segments of genomic sequence from BACs mapping to distal 1p36 against actual draft sequence of the human genome. Using monochromosomal hybrids of chromosome 1, several BAC clones from the analyzed region and fosmids spanning these BAC clones, we performed multicolor fiber FISH and PCR walking to verify the current 1p36 genomic assembly (July 2003). We identified a 66 kb paralogous sequence (LCR 1p36A) that is present in two non-overlapping BACs. Additionally, LCR 1p36A shows homology to a number of chromosome ends, demonstrating segmental duplication of the 1p telomere-associated repeats. In a similar manner, a second LCR (LCR 1p36C) was identified ~2.2 Mb from the 1p telomere. This LCR is 10.8 kb in size and is found in two copies in an inverted orientation. We also examined the evolutionary conservation of 1p36 LCRs in primate cell lines and reference DNA from human, hamster and mouse. Our results reveal a complex evolution of LCR 1p36A during primate speciation. We propose a model for the evolution of LCRs in 1p36. Of the 95 monosomy 1p36 cases ascertained to date, eight (8.4%) were classified as interstitial deletions. Seven of the interstitial deletion breakpoints and three terminal deletion breakpoints are located within this distal LCR region. Our results suggest a role for genomic architectural features in the generation of terminal deletions of 1p36.

Chromosomal, molecular and morphological analysis of a human embryo with homogeneous trisomy of chromosome 8. *G. Goudefroye^{1,2}, J. Guirchon², C. Ozilou², N. Morichon-Delvallez², A. Munnich¹, M. Vekemans^{1,2}, T. Attié-Bitach^{1,2}, H. Etchevers¹.* 1) INSERM U393, Hôpital Necker Enfants Malades, 149 rue de Sèvres, 75743 Paris Cedex 15, France; 2) Service de Cytogénétique, Hôpital Necker Enfants Malades, 149 rue de Sèvres, 75743 Paris Cedex 15, France.

Our group studies developmental gene expression in normal human embryos obtained from voluntary interruptions of pregnancy, in accordance with ethical guidelines established by French law. A chromosomal anomaly was suspected in one human embryo at Carnegie stage 11 (third week of development) on the basis of abnormal morphology. The embryo had severe malformations of the cardiovascular and central nervous systems. The karyotype of its chorionic villus sample showed a homogeneous trisomy of chromosome 8, whereas FQ-PCR analysis confirmed the meiotic origin of the non-disjunction.

Only a few cases of human trisomy 8 have been reported to date in children or adults. With one recent neonatal exception, the other previous cases reported all showed mosaicism due to mitotic non-disjunction early during zygotic development. Our case demonstrates that homogeneous trisomy 8 is compatible with implantation and early embryogenesis. Nonetheless, by Carnegie stage 11, the heart was bifid, yolk sac vessels were abnormally dilated, the prosencephalon and branchial arches were absent and the somites were small and irregularly shaped. These severe systemic malformations are not compatible with further development, confirming the lethality of trisomy 8 of meiotic origin. In addition, this case justifies the systematic karyotyping of human embryos used for research purposes, as we have observed other trisomies in apparently normal cases; likewise, chromosomal abnormalities may be responsible for other occasional malformations in the embryos we study.

Detection of Turner syndrome with high-throughput quantitative DNA analysis. *J.R. Gruen¹, H. Meng¹, K. Hager², S. Rivkees¹.* 1) Department of Pediatrics, Yale Child Health Research Center, Yale Univ School of Medicine, New Haven, CT; 2) WM Keck Foundation Biotechnology Resource Laboratory, Yale Univ School of Medicine, New Haven, CT.

Turner syndrome (TS) occurs in 1 in 2,000 to 5,000 live female births each year making it one of the most common chromosomal syndromes. Features include short stature, gonadal dysgenesis, and cardiovascular and renal malformations. TS occurs when an X chromosome is completely deleted (45X; 50% of girls with TS), portions of an X chromosome are deleted, or with sex chromosome mosaicism (46XX:45X). Girls with TS may also have occult Y chromosome sequences that are associated with an increased risk for germ cell tumors. Yet despite an estimated 800 new TS cases diagnosed each year, the majority of girls are not detected until after 10 years of age, resulting in delayed treatment and evaluation. Our goal is to develop a high-throughput, sensitive, and economical approach for the early detection of TS during infancy that can be performed as part of routine newborn screening. We assembled a panel of 20 informative single nucleotide polymorphism (SNP) markers distributed through the X chromosome and 10 on the Y chromosome. We then assessed heterozygosity and quantitative DNA pyrosequencing signal in 17 46XX normal females, compared to 6 45X TS subjects, 11 TS mosaics, and 13 other subjects with various sex chromosome aneuploidies. We also tested markers for the detection of Y chromosome material. With just 10 informative SNP markers from the X chromosome we could identify all 45X TS subjects by detecting loss-of-heterozygosity. We also distinguished all the TS mosaics from normal heterozygous samples by comparing the quantitative pyrosequencing signal strengths of paired alleles in the same subject. We also identified Y chromosome material in subjects where Y fragments were previously identified by karyotype and in one subject where karyotype analysis lacked sensitivity. There were no false positive or false negative outcomes in this small trial. These results suggest that inexpensive high-throughput screening, including detection of mosaicism, is possible for TS using quantitative genotyping approaches.

Interphase FISH mapping of chromosomal rearrangements on paraffin-embedded archival patient material. *L. Harewood, J.A. Fantes, D.R. FitzPatrick.* MRC Human Genetics Unit, Edinburgh, United Kingdom.

Disease-associated balanced chromosomal rearrangements (DBCRs) have proved to be extremely important in the mapping of disease loci and positional cloning of disease-causing genes. There is no apparent loss of genetic material in these cases, although small deletions around the breakpoints cannot be excluded. This suggests that the phenotype arises from direct interruption of one or more genes or regulatory elements. The identification and molecular characterisation of breakpoints in individuals with de novo DBCRs can help identify new disease genes or loci. Generally, this type of mapping is done using fluorescent in-situ hybridisation (FISH) on metaphase preparations. However, these are not always available. In this study, we have performed FISH on nuclei dissociated from archive paraffin embedded tissue sections from two cases with distinct phenotypes and de novo, apparently balanced translocations: namely, a t(1;2)(q41;p25.3) with bilateral renal dysplasia and a t(2;12)(p25.1;q23.3) with upper limb peromelia and lower limb phocomelia. By isolating nuclei and performing FISH using BAC probes combined with chromosome specific paints, the breakpoints were mapped to within a few hundred Kb. The genes in the breakpoint regions could then be examined and those that were considered good candidates studied further. This method excludes the need for viable patient material, allowing the study of more cases and hence the identification of further disease genes or loci.

Molecular cytogenetic identification of a cryptic terminal deletion of 15q. *K. Harrison¹, I. Sumargo¹, C. Forster-Gibson^{1,2}*. 1) Dept Pathology & Molecular Medicine, Queen's University, Kingston, ON, Canada; 2) Dept Family Medicine, Queen's University, Kingston, ON, Canada.

We report a 27 year-old male with a cryptic terminal deletion of 15q26.3-qter. He was born at 36 weeks gestation weighing 4 pounds 5 ounces. Miscarriage was threatened at 5 months. As a neonate he had a poor suck. Developmental milestones were globally delayed. As an adult he had short stature; relative macrocephaly; triangular facies; a prominent forehead; a short, narrow nose with a pinched appearance; high arched palate; a central dimple in his chin; brachydactyly; broad hands and feet; hyperextensible fingers and prominent distal interphalangeal joints. As a teen, he had elective mutism and continues to have episodic aggression, destructive behaviour and self-abuse. He has been treated for depression. He had hyperlipidemia but not diabetes mellitus. A skeletal survey and CT scan of the head were normal. There were no identified congenital malformations. Cytogenetic evaluation of lymphocytes identified a 46,XY karyotype (550 bands). Fluorescence in situ hybridization (FISH) screening for a subtelomere rearrangement was requested. Hybridization with subtelomeric probes (ToTelVysion, Vysis) identified a deletion of 15q26.3. A subsequent review of the G-banded metaphases confirmed the deletion to be truly cryptic, not identifiable by retrospective analysis. The karyotype was revised to 46,XY.ish del(15)(q26.3-qter)(D15S936-). Parental chromosome studies have been requested. Cases of distal 15q deletions have been reported to have craniofacial abnormalities, IUGR, developmental delay, and failure to thrive. Ring 15 syndrome involving distal 15q deletions, presents with growth retardation, variable mental retardation, microcephaly, hypertelorism, and triangular facies resembling Russell-Silver syndrome. Our patients clinical features, such as short stature, developmental delay, and triangular facies reminiscent of Russell Silver syndrome, overlapped with the phenotypes described for ring 15 syndrome and cytogenetically visible distal 15q deletions. We believe this is the first description of a submicroscopic deletion of 15q26.3-qter identified by FISH analysis.

Confined placental mosaicism in cases with intrauterine growth retardation of unknown causes. *K. Hiraki, H. Masuzaki, K. Miura, S. Shoko, Y. Fujimoto, T. Ishimaru.* Dept OB/GYN, Nagasaki school of Med, Nagasaki, Nagasaki, Japan.

Objective: Confined placental mosaicism (CPM), which is defined by the presence of abnormal karyotypes only in the placenta while the fetus itself is usually diploid, has been reported to be detected in 1-2% of chorionic villus sampling (CVS) at 10-12 weeks of gestation, and in over 20% of pregnancies with intrauterine growth retardation (IUGR). In this study, the frequency of CPM in cases with IUGR of unknown causes was investigated, and the relation between CPM and IUGR was discussed. **Material and Methods:** To identify CPM, we first screened 50 patients whose infants had IUGR ($-1.5SD$) of unknown causes. Routine screening of other risk factor for IUGR (for example, fetal infections, TORCH syndrome, pre-eclampsia or cord factor) was negative in all cases. Neonatal and placental blood was collected and tissue samples were obtained from at least two sites of placentas at delivery. Standard karyotyping was then carried out. Cellular DNA was extracted from leucocyte of the neonate and their parents, and was genotyped at various dinucleotide repeat polymorphic loci (ABI linkage mapping set MD10). To identify uniparental disomy (UPD), parent-child transmission pattern of polymorphic markers was analyzed. ABI377 autosequencer was used for above genotyping study. **Results:** Nine of 50 cases (18%) examined were diagnosed to have CPM, while UPD was excluded in all cases with CPM. **Conclusion:** CPM was detected in 18% cases with IUGR of unknown causes, suggesting that CPM could be contribute to cause of IUGR though how CPM causes IUGR remains unknown. As UPD was excluded in all cases with CPM, infants IUGR analyzed here may be contributed to other factors, probably to placental dysfunction.

Heterozygotes for the microinversion of the Williams-Beuren syndrome region have an increased risk for affected offspring. *H.H. Hobart¹, R.G. Gregg², C.B. Mervis³, B.F. Robinson⁴, K.W. Kimberley¹, C.M. Rios¹, C.A. Morris⁵.* 1) Molecular Cytogenetics Laboratory, Dept. Pediatrics/Genetics, University of Nevada School of Medicine, Las Vegas, NV; 2) Dept. Biochemistry and Molecular Biology and Center for Genetics and Molecular Medicine, University of Louisville, Louisville, KY; 3) Dept. Psychological and Brain Sciences, University of Louisville, Louisville, KY; 4) Dept. of Psychology, Georgia State University, Atlanta, GA; 5) Dept. Pediatrics/Genetics, University of Nevada School of Medicine, Las Vegas, NV.

Williams-Beuren syndrome (WBS) is a genomic disorder, a contiguous gene microdeletion syndrome, with a prevalence of 1/7500. The typical microdeletion of the WBS chromosome region (WBSCR), the "classic" deletion, includes about 1.6Mb of sequence and 21 genes. The WBSCR is bounded by blocks of similar repeats that likely predispose to deletion due to mismatch pairing. Microinversions of the WBSCR also have been observed. While the parental inverted chromosome has been shown sometimes to be subsequently deleted in WBS individuals, previous sample sizes were not sufficient to determine if parental inversion increased the risk for occurrence of a deletion. The purpose of the present study was to address this question. Samples from 171 2-parent families and 23 1-parent families and their child with classic WBS were studied to determine parental inversion status and parent of origin of the deleted chromosome. Results indicated that: 1) the estimate of population frequency of the WBSCR inversion, based on inversion status in the non-transmitting parent, is 5.06% (95% CI: 1.8%-8.3%). 2) There is no sex difference in inversion frequency. 3) The transmitting parent is equally likely to be male or female. 4) The frequency of the inversion in transmitting parents is 22.5% (95% CI: 16.5%-28.4%). 5) A person heterozygous for the WBSCR inversion has a significantly increased risk for offspring with WBS (odds ratio: 4.45, 95% CI: 2.21-8.96), though few cases of recurrence of WBS have been reported.

Prenatal diagnosis of supernumerary marker chromosomes derived from chromosome 6. *B. Huang^{1,2}, P. Pearle³, J. Philipson³, P. Cotter⁴.* 1) Genzyme Genetics, Orange, CA; 2) Division of Human Genetics, University of California Irvine, Irvine, CA; 3) California Pacific Medical Center, San Francisco, CA; 4) Children's Hospital Oakland, Oakland, CA.

Supernumerary marker chromosomes (SMC) are relatively common in prenatal diagnosis. As the clinical outcomes vary greatly, a better understanding of the karyotype-phenotype correlation for different marker chromosomes will be helpful for predicting the phenotype. We present two cases of prenatally detected small marker chromosomes derived from chromosome 6. In the first case, amniocentesis was performed due to abnormal maternal serum screening indicating an increased risk for neural tube defect. Chromosome analysis showed a 47,XY,+mar[12]/46,XY[10] karyotype. In the second case, the patient was referred for amniocentesis due to advanced maternal age. Chromosome analysis revealed a 47,XX,+mar[6]/46,XX[10] karyotype. The sizes of the marker chromosomes in these two cases appear to be similar. The pregnancies were continued and the babies were born. The presence of the marker chromosomes were confirmed in peripheral blood chromosome analyses. Fluorescence in situ hybridization studies with a chromosome 6 painting probe and a chromosome 6 alpha satellite probe identified the marker to be chromosome 6 in origin in both cases. The clinical manifestations seen in the first baby include small for gestational age, feeding difficulties at birth, hydronephrosis, deviated septum and dysmorphic features, while minimum phenotype was observed in the second baby. The difference in the clinical presentation in these two patients may have resulted from the difference in the actual gene contents of the marker chromosomes and the differential distribution of the mosaicism.

Analysis of a cryptic unbalanced translocation t(17;18)(p13.3;q23) identified by subtelomeric FISH and defined by array-based comparative genomic hybridization [CGH] in a patient with mental retardation. *K.S. Hwang^{1, 2}, P. Pearson³, P.A. Lennon¹, M.L. Cooper¹, J. Wu¹, Z. Ou¹, P. Stankiewicz¹, W.W. Cai¹, S.W. Cheung¹.* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Obstetrics and Gynecology, Tri-Service General Hospital, Taipei, Taiwan; 3) St. Josephs Hospital Laboratory, Phoenix, AZ.

The development of molecular cytogenetics techniques has made it possible to identify microdeletions and cryptic chromosome rearrangements in mentally retarded and dysmorphic individuals who could not be diagnosed by conventional cytogenetics analysis. We report on a 3-year-old girl who presented with mental retardation, growth deficiency, speech delay, and dysmorphic features including hypertelorism, up-slanting palpebral fissures, midfacial hypoplasia, and superiorly pointed ears. The initial G-banding analysis performed by another laboratory revealed a 46,XX,t(3;8)(q26.2;p21.1)mat chromosome pattern. However, the clinical features were suggestive of the 18q-syndrome. Subtelomeric FISH analysis revealed an additional submicroscopic chromosome aberration. A derivative chromosome 18 was identified that resulted from a deletion within chromosome 18 at band q23 and replacement by a third copy of a chromosome 17p region at band p13.3. Subsequent array-based CGH with an extended set of subtelomeric BAC and PAC clones confirmed the identified abnormality and defined more precisely the size of the terminal 18q23 deletion and the 17p13.3 duplication. Molecular cytogenetics characterization of the cryptic rearrangement with these methodologies and follow up studies will be presented. This case further demonstrates the diagnostic usefulness of combining conventional cytogenetics with new molecular chromosome analysis methods for clinical interpretation of subtle chromosome abnormalities.

Molecular analysis of an inv dup(15) demonstrating localization and sequence of the precise breakpoint region and suggestion of the underlying mechanism. *L. Jeng¹, M. Eichenmiller¹, A. Wandstrat², S. Schwartz¹.* 1) Case Western Reserve Univ and Univ Hosp of Cleveland, Cleveland, OH; 2) Univ Texas Southwestern, Dallas, TX.

Inv dup(15) is the most common supernumerary marker chromosome (SMC) and is seen in 50-60% of SMC cases. Molecular analysis has shown maternal origin in all large de novo cases and breakpoints localized most commonly to 15q11-q14, with at least four different breakpoints suggested. Available data suggests involvement of low copy repeats (LCRs) in the PWS/AS region in formation of smaller inv dup(15), but little is known about formation of the largest class of this marker.

In order to further characterize a larger inv dup(15) breakpoint and elucidate the underlying mechanism, we analyzed one inv dup(15) isolated within a somatic cell hybrid using PCR amplification of microsatellites, sequence analysis of single nucleotide polymorphisms, and long-range PCR (LR-PCR) in conjunction with data available on the UCSC Genome Browser on Human. We successfully isolated junction fragments spanning the breakpoint using three PCR primer sets and sequenced over the breakpoint in one of these. Initial studies on a second inv dup(15), with a similar breakpoint cytogenetically, isolated within a somatic cell hybrid did not show the same junction fragments by LR-PCR. This suggests that while the breakpoint may be in the same LCRs, it may not occur at the exact same site.

These studies are of importance as [1] analysis of an inv dup(15) reveals that its breakpoints occur within LCRs localized to 15q13.2 and 15q13.3; [2] the abnormality is not a precise mirror image since the breakpoints are in two different repeats; [3] the two repeats are within 2 Mb of each other and are 99.7% identical, but are oriented in opposite directions; [4] using LR-PCR it is possible to sequence through the breakpoint demonstrating breaks in a Line element and a Sine element within the two LCRs; and [5] this study conclusively demonstrates that LCRs are important in the mechanism of production of the larger inv dup(15), similar to what is seen for the more proximal LCRs important in Prader-Willi and Angelman syndromes.

Chromosome X instability associated with developmental delay? *S. Josefsberg Ben Yehoshua¹, A. Chun-Hui Tsai¹, J.B. LeRoux³, L. McGavran^{2,3}*. 1) Division of Clinical Genetics and Metabolism, The Childrens Hospital/ University of Colorado Health Sciences Center (UCHSC), Denver, CO; 2) Department of Pathology, UCHSC, Denver, CO; 3) Colorado Genetics Laboratory, Denver, CO.

We report a family with abnormalities of the X chromosome. The proposita, a 31 year old G7 P4 SAB2, developmentally appropriate, pregnant woman, had two second trimester miscarriages. Chorionic villus sampling (CVS) of the fetus showed a 46,X,der(X)t(X;Y)(p22.33;q11.22) karyotype. Fluorescence in situ hybridization (FISH) revealed that SRY is absent, as is Y centromere. Both the subtelomeric Xp/Yp sequences and the STS (Steroid Sulfatase) sequences are lost on the derivative X, and the Kallmann gene locus is present. The breakpoint on the X chromosome is therefore between STS and Kallmann gene loci. The same rearrangement was found in the proposita herself and her youngest daughter; who is 5 years old developmentally appropriate short, microcephalic girl. The third child is a developmentally delayed 11 year old boy, with behavioral problems, tall for the family, small penis and limited supination and incomplete pronation of both fore arms. He was found to have Klinefelter syndrome, karyotype 47,XXY. His degree of developmental delay is worse than expected for Klinefelter syndrome children. Her oldest daughter and second son (different fathers) are developmentally delayed and both have a normal karyotype. A 46,X,der(X)t(X;Y) karyotype was also documented in the abortus material from the miscarriage that was submitted for cytogenetic study. We hypothesize that the developmental delay in the family could be due to an abnormality of the maternal of the non-der(X) chromosome. We hypothesize that the proposita and her youngest daughter are developmentally appropriate due to skewed X-inactivation; and her developmentally delayed children are delayed partially due to the inheritance of mutations on the second, non-rearranged maternal X chromosome. X inactivation studies and FISH studies for the SHOX gene are pending and will be presented at the meeting.

Detection of a deletion of the *FMR1* gene during routine screening for Fragile X. *N.B. Kardon*^{1,2}, *B. Levy*^{1,2}, *R. Kornreich*¹, *L. Edelmann*¹. 1) Department of Human Genetics, Mount Sinai School of Medicine, New York, NY; 2) Department of Pediatrics, Mount Sinai School of Medicine, New York, NY.

In our laboratory, Fragile X testing is performed using a combination of PCR to determine CGG repeat size and Southern blot analysis to distinguish wild-type, pre-mutation and full-mutation status. During routine screening for Fragile X, we identified a 39 year old female with complete lack of methylation at the *FMR1* locus, essentially a male Southern blot pattern, and a single allele size of 19 CGG repeats by PCR analysis. After ruling out the possibility of a laboratory error, cytogenetic analysis was requested and a GTG banded karyotype was obtained. The karyotype was determined to be 46,XX,del(X)(q27q28). Therefore, the Fragile X results are explained by deletion of the *FMR1* locus with skewed inactivation of the deleted X chromosome in peripheral blood. Fluorescence in situ hybridization (FISH) using an Xq/Yq TelVysion probe (Vysis) indicated that the deleted X chromosome did not contain the X telomere sequences. Comparative genomic hybridization (CGH) confirmed the deletion of the Xq27 and Xq28 bands, but did not reveal any additional gain of material. The patient has a normal medical history and has given birth to a normal male child and has had at least two first trimester spontaneous abortions. Her family history revealed that she has a normal brother and her mother had two or three miscarriages. Her mother was 42 at menopause. Cytogenetic analysis of GTG banded chromosomes indicated that her mother was carrying the same deleted X chromosome without an apparent additional abnormality, such as a balanced translocation with the X chromosome. We are currently trying to determine whether the deleted X arose through a translocation in a grandparent or whether it represents a true terminal deletion. To our knowledge this is the first report of an X deletion being identified through routine carrier screening for Fragile X, and also represents a new case of stable transmission of a deleted X chromosome from mother to daughter. Presumably, the lack of phenotypic expression from this deletion in both generations is due to skewed X inactivation of the deleted X chromosome.

Maternal paracentric inversion of chromosome 9 and recurrent pregnancy loss. *W.G. Kearns¹, R. Pen¹, D.E. Tourgerman², S.F. Hoegerman³.* 1) Ctr for Preimplant Genet, Rockville, MD; 2) USC Reprod Endo & Infer, Los Angeles, CA; 3) Dept of Biol, College of William & Mary, Williamsburg, VA.

Paracentric inversion carriers are at risk of producing genetically unbalanced gametes. These include a dicentric, an acentric fragment, the normal chromosome or the inverted chromosome. Cells with the dicentric or acentric fragment will eventually become monosomic due to chromosome breakage or loss. Embryos containing cells with a dicentric or acentric fragment of chromosome 9 may not implant or result in fetal loss due to eventual monosomy of chromosome 9. We performed IVF and PGD on a couple due to multiple losses. She is a carrier of a paracentric inversion [46, XX, inv(9)(q21.2q22.3)]. PGD-aneuploidy was performed for chromosomes 9,14,15,22,X & Y. We next performed PGD for telomeric sequences of chromosome 9. Experimental conditions and fluorescence microscopy was performed according to routine protocols. 11 of 13 embryos were aneuploid. 7 of 11 had three chromosome 9 centromeres. Expected paracentric segregation does not predict trisomic cells, therefore 9p and 9q telomere sequences were analyzed to determine the presence of a dicentric chromosome 9. 5 of 7 trisomy 9 blastomeres showed three 9p and one 9q sequence. The other two showed two 9p and two 9q sequences. Each of the remaining (n = 6) diploid chromosome 9 embryos tested showed the correct number of 9 telomeric sequences. Dicentrics whose centromeres are joined by their q arms will have two p-arm and no q-arm telomeric sequences. Cells with a dicentric and a normal chromosome will therefore have a total of 3 p-arm and one q-arm telomeres. This was found in 5 of 7 embryos with three chromosome 9 centromeres. The apparent presence of a dicentric chromosome in a high percentage of embryos suggests the possibility that the recombinational event took place during a mitotic division in the maternal germ line. To our knowledge, this is the first report of a dicentric chromosome in embryos from couples undergoing IVF-PGD and the first suggesting mitotic recombination as a mechanism for the generation of a dicentric chromosome. This dicentric chromosome may play a role in the couples recurrent pregnancy loss.

Maternal cell contamination in cord blood in a newborn baby with ambiguous genitalia: a warning. *A. Khan¹, D. Whelan^{1,2}, J. Xu²*. 1) Pediatrics; 2) Pathology and Molecular Medicine, Hamilton Health Sciences and McMaster University, Canada.

A newborn baby was referred to clinical genetics because of ambiguous genitalia, imperforate anus, bilateral hydronephrosis, club feet, leg contractures and dysmorphic facial features. Analysis of 50 cells from the cultured cord blood showed a mosaicism of 46,XY in 45 cells and 46,XX in 5 cells. While this mosaic karyotype was considered to be consistent with the clinical finding of the ambiguous genitalia, a follow-up confirmation using skin biopsy and peripheral blood was recommended. Of 100 cells from cultured skin tissue, 98 had a 46,XY and 2 had a 45,X. These two 45,X cells were interpreted to be a result of random loss of the Y chromosome from the original normal male cell line. Examination of 100 cells from cultured peripheral blood all had 46,XY. FISH using an SRY probe at Y11.3 showed no evidence of anomalies of this locus in all 10 cells examined. While a cause for the presence of multiple congenital anomalies is yet to be established, we conclude that the female cell line in the cord blood originated from maternal cell contamination (MCC). MCC can go undetected in cases with a female karyotype when cord blood is used for analysis. Our case illustrates that caution should be exercised in interpretation of a finding of mosaicism for male/female cell lines from use of cord blood, especially in cases of ambiguous genitalia. Confirmation using other tissues and supplemental tests such as FISH for SRY locus should be considered for accurate diagnosis and clinical management.

Applications of personalized molecular cytogenetic diagnostics. *J.H.M. Knoll¹, P.K. Rogan^{1,2}*. 1) Children's Mercy Hospital, Schools of Medicine and; 2) Computer Science and Engineering, University of Missouri-Kansas City.

Subtle variations in chromosomal abnormalities are increasingly recognized as having profound impacts on the diagnosis and prognosis of congenital and acquired cytogenetic disorders. Routine distinction of such differences among individuals with the same diagnoses is now feasible with molecular cytogenetic methods as a result of the completion of the euchromatic human genome DNA sequence. We have introduced a new type of reagent for definition of chromosome abnormalities at extremely high resolution for virtually any euchromatic sequence. Single copy (sc) DNA probes, designed by computational analysis of the genome reference sequence, have been developed and validated for >40 inherited and acquired diseases and >80 distinct chromosomal regions, including subtelomeric domains. Probe synthesis involves determining the boundaries of single copy intervals within a specified disease locus, amplifying one or more of these intervals, then purifying and labeling of the amplicon. Sc probes of >2 kb occur on average every 22-31 kb, which is similar to the best resolution obtained by genomic Southern analysis and other methods. scFISH probes can be custom designed and produced rapidly and at a modest cost. In this study, molecular cytogenetic heterogeneity is demonstrated with scFISH in patients having the same clinical diagnosis, although heterogeneity is not evident in these patients using commodity cytogenetic reagents. Furthermore, the repertoire of available commercial reagents is often not optimized for diagnosis of private or infrequent chromosomal rearrangements. This study demonstrates variations in microdeletion size in the Smith-Magenis and Angelman/Prader-Willi syndromes, and precisely delineates chromosome breakpoint intervals in Chronic Myelogenous Leukemia. We have also developed a set of subtelomeric scFISH probes in close proximity to chromosome termini to improve detection of translocation carriers and unbalanced rearrangements. Information obtained with these probes can, in some instances, predict clinical outcomes within subgroups of patients defined by these cytogenomic abnormalities.

Syndromic hearing loss associated with a familial inversion of 7q. *K. Kocher*¹, *C.C. Morton*^{1,2}. 1) Harvard Medical School, Boston, MA; 2) Brigham and Women's Hospital, Boston, MA.

Hearing loss is a common disorder affecting about one per thousand newborns with half of all cases attributed to genetic causes. Hundreds of syndromic forms of hearing loss have been described; however, in many cases the underlying genetic mutations have not yet been identified. Here we report a family with five members spanning three generations who have partial hearing loss and craniofacial defects, including micrognathia and abnormal pinnae. GTG-banding showed that all affected family members carry a balanced paracentric inversion of 7q inv(7)(q21.3q35). FISH experiments were performed to further define the breakpoints on the derivative chromosome 7. Successive FISH experiments, using BACs as probes, were used to identify split BACs that hybridized to both 7q21.3 and 7q35 on the derivative chromosome 7. The FISH analysis mapped the 7q21.3 breakpoint within the BAC RP11-879e11 and the 7q35 breakpoint within the BAC RP11-643a21. Southern blot analysis using PCR products as probes is currently being performed to further refine these breakpoints. The 7q35 breakpoint disrupts the contactin-associated protein-like 2 (*CNTNAP2*) gene between exons 8 and 9, while the 7q21.3 breakpoint lies approximately 70 kb and 85 kb upstream of the *DLX6* and *DLX5* genes, respectively. *DLX5/6* are interesting candidate genes as *DLX5* knock-out mice have inner ear defects along with craniofacial abnormalities (Acampora et al. 1999, Depew et al 1999). Further analysis of *DLX5/6* and *CNTNAP2* is planned in order to identify the gene causing hearing loss in this family.

Clinical phenotype of microdeletions at 3p24 and 5p12 detected by whole genome microarray. *M. Koochek¹, C. Harvard², P. Malenfant³, S. Creighton¹, JJA. Holden^{3,4}, E. Rajcan-Separovic², MES. Lewis¹, and the ASD-CARC; www.autismresearch.ca.* 1) Depts of Medical Genetics; 2) & Pathology, University of British Columbia, Vancouver, Canada; 3) Depts of Physiology; 4) & Psychiatry, Queen's University, Kingston, Canada.

Cri du chat syndrome (CDCs) is a well defined clinical entity with an incidence of 1/15,000-1/50,000. The critical region (CR) for CDCs has been mapped to 5p15, with the hallmark cat-like cry sublocalized to 5p15.3 and the remaining clinical features to 5p15.2. We report findings in a patient with a complex chromosomal rearrangement and a cryptic microdeletion of the CDC-CR detected using a 1Mb genomic array. In addition to 5p-, derived from a de novo paternal translocation between 5p15.2 and 7p13, the proband has a single clone loss at the 3p breakpoint of a de novo paternal inv(3)(p24q24). Deletions were confirmed using microsatellite analysis and FISH. The 5p deletion encompasses ~2.2 Mb mapping to the border between bands 5p15.2 and 5p15.3. The single clone deletion maps to 3p24.3-3p25, for which there is no known phenotype. The clinical features of our proband differ from the characteristic CDC phenotype, which may reflect the effect of both microdeletions and/or further refine the CDC-CR. Typical features of CDC that are present in the proband include moderate intellectual disability, speech delay and dysmorphic features (e.g., broad and high nasal root, hypertelorism and coarse facies). Expected CDC features that are not present are: growth delay, microcephaly, round facies, micrognathia, epicanthal folds, motor delay and the signature high pitched cry. Behavioural traits include ADHD and unmanageable behaviour including, aggression, tantrums, irritability and self destructive behaviour. Several of these behaviours have been previously reported in patients with 5p-. Although most agree on the cat cry critical region there is discrepancy in the location of the region associated with the more severe manifestations of CDCs. The clinical description of this proband and the characterization of his 5p deletion further refine phenotype-genotype correlations in CDCs. Supported by research grants from CIHR and OMHF.

Two unrelated patients with rare interstitial deletion of 9q with mild dysmorphic features. A. Kulharya, S.M. DeLany, D.B. Flannery. Dept Pediatrics, Medical Col Georgia, Augusta, GA.

Interstitial deletions in the long arm of chromosome 9 are rare. The few cases reported in literature do not delineate a characteristic phenotype among patients with overlapping deletions of 9q. We report two unrelated female patients with a *de novo* deletion in 9q. Previous chromosome analysis in both patients was reported as normal elsewhere. In one of these two patients, the deletion was initially identified by whole genome microarray comparative genomic hybridization (array CGH). The first patient was seen in the genetics clinic at 4 months of age because of developmental delay and dysmorphic features. Height and weight were below the 2nd percentile; head circumference was at 15th percentile. No organomegaly was observed; cardiac exam was normal. Chromosome analysis at our lab demonstrated a karyotype of 46,XX,del(9)(q32q34.1). The second patient had been followed for three years by various specialties before being seen in our genetics clinic at three years of age. The pregnancy had been complicated by oligohydramnios and IUGR. MRI showed a slight decrease of white matter in the parietal region. She had been initially diagnosed with abnormal fat distribution and hypothyroidism. She has mild dysmorphic features, developmental delay, seizures and speech delay. A whole genome array CGH using Spectral Chip 2600 (Spectral Genomics) with BAC clones distributed over the entire genome was performed in the second patient. The array-CGH demonstrated the deletion of clones distributed over a distance of 3 Mb (RP11-45A16 and RP11-57K19 to 9q32-q33.3 and q34.11-q34.2 respectively). Retrospective chromosome analysis showed a visible deletion with breakpoints at q32 and q34.1 in chromosome 9. Parental karyotypes in both patients were normal. Of the approximately 20 cases of interstitial 9q deletion reported in literature, only 2 patients have deletions similar to our patient. Based on G-banding pattern, alternative breakpoints for these deletions in 9q are possible. For accurate assessment of a chromosome abnormality, high resolution chromosome analysis and array CGH are sensitive techniques and allow better genotype phenotype correlation. *de novo*.

Characterization of the Region of 4q Associated with Hereditary Benign Intraepithelial Dyskeratosis. *W.S. Lambert¹, J. Clapp², J.E. Hewitt², M. Bembe¹, K. Bastress¹, R. Lemmers³, S.M. van der Maarel³, R. Allingham⁴, J. Vance¹, M.A. Hauser⁵.* 1) Center for Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Institute of Genetics, Queens Medical Center, University of Nottingham, United Kingdom; 3) Center for Human and Clinical Genetics, Leiden University Medical Center, Leiden, The Netherlands; 4) Department of Ophthalmology, Duke University Medical Center, Durham, NC; 5) Center for Human Genetics, Department of Ophthalmology, Duke University Medical Center, Durham, NC.

Hereditary benign intraepithelial dyskeratosis (HBID) is an autosomal dominant cell proliferation disorder characterized by opaque epithelial plaques of the conjunctiva and oral mucosa. Redness, irritation, and obstruction of vision secondary to corneal involvement can occur. This disorder has been linked to chromosome 4q and a near-telomeric DNA duplication in this region (Allingham RR, et al. *Am J Hum Genet* 2001). We have evidence that the HBID duplication includes a partial duplication of the D4Z4 repeat located in the sub-telomeric region of 4q. The D4Z4 region has been suggested to play a role in the transcriptional control of 4q genes. We have used RT-PCR and TaqMan gene expression analysis to determine if the partial D4Z4 duplication in HBID results in abnormal expression of 4q genes. Total RNA from a normal conjunctival (CCj) cell line, a HBID ocular lesion (HCj) cell line, normal conjunctival tissue, and HBID ocular lesion tissue, as well as from human-mouse hybrid cell lines containing either the normal chromosome 4 or the chromosome containing the HBID duplication was used in synthesis of first strand cDNA. Polymerase chain reaction (PCR) and real time PCR using TaqMan assays were performed. In addition, genomic real-time PCR was used to determine the HBID duplication boundaries. In general, control cell lines and tissue demonstrated higher expression levels of 4q35 genes than did cell lines and tissue from HBID lesions. Using genomic real-time PCR and other methodologies, we have determined the boundaries of the HBID duplication to within 39 kb. This information will aid us in determining the role of D4Z4 in controlling gene expression in HBID.

Diverse cytogenetic findings in Korean patients with DiGeorge/velocardiofacial syndrome (DG/VCFS)

phenotypes. *J.-Y. Lee¹, S.-J. Yoo^{1, 2}, J.-S. Kim¹, S.-E. Im¹, E.-Y. Choi¹, E.-M. Kwon¹, E.-J. Seo^{1, 2}, H.-W. Yoo^{1, 3}.* 1) Medical Genetics Clinic & Lab, Asan Medical Center, Seoul, Korea; 2) Department of Laboratory Medicine, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea; 3) Genome Research Center for Birth Defects & Genetic Disorders, Department of Pediatrics, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea.

DiGeorge/Velocardiofacial syndrome (DG/VCFS) caused by chromosome 22q11.2 microdeletion shows various clinical features such as conotruncal heart defect (CTHD), abnormal facies, thymic hypoplasia, cleft palate, hypocalcemia due to hypoparathyroidism, developmental delay and mental retardation. However, phenocopies of DG/VCFS are reported in patients with other chromosomal aberrations, dysmorphic syndromes, and malformation syndromes caused by teratogens. From Sep., 1999 to May, 2004, 311 patients with phenotypic or prenatal sonographic features consistent with 22q11.23 microdeletion have been tested by standard cytogenetic and FISH method using TUPLE1 probe from peripheral lymphocytes and prenatal specimen (AF, CB, CVS). Ninety two patients (29.6%) had 22q11.2 deletion. Twenty patients (6.4%) showed no TUPLE1 deletion, but other chromosomal abnormalities. We reviewed the cytogenetic and phenotypic findings of those 20 patients. They revealed diverse karyotypic features including abnormal chromosome 22 (4 patients), partial trisomy 18q (2 patients), del(2q) (2 patients), del(3p), del(4p), dup(4p), del(4q), del(6q), and del(11q). These 20 patients presented with various phenotypic features mimicking DG/VCFS; CT HD (in 13 patients), facial dysmorphism (6), cleft palate (4), developmental delay (5), hypocalcemia (3), renal anomaly (3), hypothyroidism (1), and others. In conclusion, diverse karyotypes were identified in the patients with DG/VCFS phenotypes. These subsets of patients deserve further molecular genetic investigations, which may lead to the discovery of new genetic loci for phenotypic features of DG/VCFS.

Cytogenetic characterisation and phenotype of an unusual supernumerary chromosome(1) marker. *G. Lefort¹, P. Blancher², A.M. Chaze¹, P. Vago³, A. Pinton⁴, F. Pellestor⁵, J. Puechberty², P. Sarda².* 1) Cytogenetics Laboratory, Hopital Arnaud de Villeneuve, Montpellier, France; 2) Department of Medical Genetics, CHU Arnaud de Villeneuve, Montpellier, France; 3) Department of Medical Cytogenetics, CHU Clermont-Ferrand, France; 4) UMR 898, INRA-EMVT, Toulouse, France; 5) CNRS UPR 1142, Montpellier, France.

A 40-year-old gravida 2, para 1 woman was referred for amniocentesis at 16 WG for advanced maternal age. Amniotic fluid chromosome studies diagnosed mosaicism for a " de novo " small supernumerary marker chromosome (SMC) in a male fetus : 47,XY,+mar[13] / 46,XY[8]. M-FISH studies indicated that the SMC contained euchromatic chromosome 1 material, and this was confirmed by positive whole chromosome 1 painting. FISH with probes for centromeric chromosome 1 and subtelomeric chromosome 1p and 1q regions was negative. Microdissection followed by reverse chromosome painting suggested that the marker contained pericentromeric 1p and 1q material. In the light of these results fetal prognosis was discussed with the parents who elected to terminate pregnancy despite normal 20 and 24 WG ultrasound scans. Autopsy of the 25 WG fetus showed slight craniofacial dysmorphism, bilateral camptodactylia and rocker bottom feet, but no organ malformation. Cytogenetic studies on amniotic fluid at termination and on tissues at autopsy (skin, lung, heart, kidney,) confirmed variable mosaicism in all samples. The cytogenetic characteristics and partial trisomy 1 phenotype are discussed .

Detection of subtelomeric rearrangements by FISH. *C. Lozzio, T. Ryan, E. Bamberger, E. Ralston, C. Worthington, W. Carter, M. Huckaba, P. Leopper.* Dept Medical Genetics, Univ Tennessee, Knoxville, TN.

Subtelomeric chromosome rearrangements are one of the causes of mental retardation with or without dysmorphic features and/or congenital anomalies. We studied 673 cases with developmental delay or mental retardation, dysmorphic features and/or congenital anomalies with or without family history of mental retardation and/or miscarriages. We used the Vysis ToTelVysion probe panel. The following cryptic deletions were detected: del 4ptel and 4p16.3 (Wolf-Hirshhorn critical region) in a 2 yrs old female with developmental delay, failure to thrive, dysmorphic features and microcephaly; del 4ptel only in the mother with bipolar disorder and her two children with developmental delay and hyperactivity; del 4qtel in a 4 yrs old female with speech delay and dysmorphic features; del 9qtel in a 9 yrs old female with mental retardation, autistic behavior and dysmorphic features; del 12qtel in a newborn with cleft lip/cleft palate and congenital heart defect; del 13qtel in a 7 yrs old with speech defect, poor motor coordination and dysmorphic features. Two cryptic familial rearrangements were observed: one was a balanced translocation 1ptel;8qtel in a normal 4 yrs old twin of a child with the der(1)t(1ptel;8qtel) unbalanced translocation who had developmental delay, ataxic gait, dysmorphic features and microcephaly; the other familial aberration was a der(4) t(10qtel;4qtel) plus two normal chromosomes 10 causing trisomy 10qtel in a 2 months old with dysmorphic features and in his father with history of learning problems. In this case the 10qtel was translocated to the 4qtel without loss of either telomere. A "de novo" der(13)t(5p;13q) was found in a 4 yrs old with developmental delay, microcephaly and Factor VIII deficiency. Two cases had rearrangements of the sex chromosomes: one was a del Yqtel and dup Yptel in a 4 yrs old with speech delay, dysmorphic features and bilateral radioulnar synostosis; the other case was a del Xqtel replaced by the XpYptel and no signals for STS or KAL at Xp22.3 in a newborn female with polydactyly. Phenotype karyotype correlations and hypothesis on the mechanisms of telomere breakage and rejoining are important aspects of this study.

Disruption of *ROBO2* in a patient with Vesicoureteral Reflux (VUR). W. Lu^{1,8}, R.E. Peters¹, H.L. Ferguson¹, F. Quintero-Rivera^{2,8}, R. Eisenman³, D. Sanlaville⁴, S.A. Feather⁵, A.S. Woolf⁶, M.R. Eccles⁷, D.J. Harris^{3,8}, A.H. Ligon^{1,8}, B.J. Quade^{1,8}, G.A.P. Bruns^{3,8}, J.F. Gusella^{2,8}, C.C. Morton^{1,8}, R.L. Maas^{1,8}. 1) Brigham & Women's Hospital, Boston, MA; 2) Massachusetts General Hospital, Boston, MA; 3) Children's Hospital, Boston, MA; 4) Hôpital Necker-Enfants Malades, Paris, France; 5) St James's University Hospital, Leeds, UK; 6) University College London, UK; 7) University of Otago, Dunedin, New Zealand; 8) Harvard Medical School, Boston, MA.

Vesicoureteral Reflux (VUR) is a common genetic disorder in children with an incidence of ~ 1 in 100. It is characterized by reflux of urine from the bladder into the ureters and kidneys. VUR is found in 30% of young children with a urinary tract infection. These patients may present later in life with proteinuria, hypertension and reflux nephropathy, which collectively account for 15% of cases of end-stage renal disease. VUR results from an anatomic deformity of the ureterovesical junction and has in some cases been suggested to represent an autosomal dominant trait. Despite the high incidence of VUR in the pediatric population, the genetic basis of VUR remains unknown. To identify genes that cause VUR, as part of the Developmental Genome Anatomy Project (DGAP), we studied a patient (DGAP107) with bilateral grade IV VUR and ureterovesical junction defects requiring surgical correction, and a balanced chromosomal translocation 46,X,t(Y;3)(p11;p12). Using fluorescence *in situ* hybridization, we identified a split BAC clone at the 3p12 breakpoint in DGAP107. The breakpoint disrupts intron 2 of the *ROBO2* gene, a human homolog of the *Drosophila roundabout* gene that is involved in axonal pathfinding. By RT-PCR and Northern analysis, *ROBO2* is highly expressed in human embryonic kidney and brain. *Robo2* knockout mice show multiple ureters with supernumerary ureteric buds. Murine *Robo2* has been implicated in the developmental events that restrict ureteric bud outgrowth, and hence kidney induction, to a single site in embryo. DNA sequence analysis of *ROBO2* in familial VUR is underway to test the hypothesis that loss of function variants in human *ROBO2* are causally linked to some cases of VUR.

Program Nr: 908 from the 2004 ASHG Annual Meeting

Tetrasomy Y syndrome in a child with two idic(Y)(q11.2). *J.T. Mascarello¹, V. Kimonis²*. 1) Genzyme Genetics, Santa Fe, NM; 2) Dept of Genetics, Children's Hospital, Boston, MA.

We present the eighth case of a patient with clinical features of tetrasomy Y syndrome. This patient is the third case attributable to isodicentric chromosomes derived from the Y chromosome and is the first to involve breakpoints in the proximal long arm such that the isochromosome is of a size that could be confused with a structurally normal Y. Like most other patients with tetrasomy Y syndrome, this patient was mosaic, with 25% of cultured lymphocytes containing one isodicentric Y and 75% containing two. At nine years of age, clinical features exhibited by our patient that have also been noted in multiple other patients with tetrasomy Y included: developmental delay, impulsive behavior, prominent alveolar ridges, long philtrum and skeletal abnormalities comprised of radio-ulnar synostosis, asymmetric limb length and fifth finger clinodactyly.

No implication of 8p22-p23.1 duplication in 28 Japanese patients with Kabuki make-up syndrome. *N. Miyake*^{1,2,3}, *N. Harada*⁴, *O. Shimokawa*^{1,4}, *N. Sasonkina*¹, *A. Ookubo*¹, *N. Matsumoto*⁵, *N. Niikawa*^{1,3}. 1) Department of Human Genetics, Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan; 2) Department of Pediatrics, Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan; 3) CREST, Japan Science and Technology Agency, Kawaguchi, Japan; 4) Kyushu Medical Science Nagasaki Laboratory, Nagasaki, Japan; 5) Department of Human Genetics, Yokohama City University Graduate School of Medicine, Yokohama, Japan.

Kabuki make-up syndrome (KMS) was characterized by peculiar facial appearance resembling the Kabuki actors make-up, mild to moderate mental retardation, skeletal abnormality, postnatal growth retardation, and dermatoglyphic abnormality. Many affected organs may imply that KMS is a contiguous syndrome, but its cause remains unknown. In 2003, Milunsky and Huang reported that all of 6 KMS patients they examined had an approximate 3.5-Mb duplication at 8p22-p23.1 revealed by comparative genomic hybridization (CGH) and fluorescence in situ hybridization (FISH) using 4 BAC clones (RP11-112G9, RP11-252K12, RP11-31B7, and RP11-92C1) as probes. They also suggested that a paracentric inversion, detected by RP11-122N11, separated from the duplicated region may contribute to the occurrence of the disease. We analyzed 28 Japanese cases of typical KMS using 15 BAC clones covering the 8p22-8p23.1 region by FISH. However, none of BACs, except for one, showed duplicated signals in any of our cases. Exceptional RP11-122N11 displayed a duplicated pattern of signals in all KMS patients as well as in normal controls, i.e., 15 of 22 KMS cases showed a homozygous duplication and 7 heterozygous, and thus the allele frequency for the duplication is 0.84 in KMS. Similarly, 40 and 12 out of 52 normal controls had a homozygous and a heterozygous duplication, respectively (allele frequency = 0.885). Thus, FISH findings using RP11-122N11 supported that it could detect a duplication polymorphism. In conclusion, our data suggest that the cause of most KMS patients is still unknown, and further studies will absolutely be necessary.

45,X/46,X,psu idic(X)(pter->q26::q26->pter) mosaicism in a patient with premature ovarian failure. *S.K. Murthy, S. Naveed, M.T. Al Ali.* Department of Medical Genetics, Al Wasl Hospital, Dubai, United Arab Emirates.

A 30 years old female with premature ovarian failure (POF) was referred to the cytogenetic lab for chromosome analysis. She appeared to be normal with no stigmata of Turner syndrome. There was no family history of any reproductive abnormalities. Routine G-band chromosome analysis showed an abnormal female karyotype with mosaicism for X-chromosome. Twenty-two of the 45 metaphases analysed had 45,X chromosome complement while the remaining 23 metaphases had 46 chromosomes with one normal X chromosome and one pseudo isodicentric X chromosome involving breakpoint at Xq26. The pseudo isodicentric X was confirmed by C-Banding. X-chromosome mosaicism and/or deletions involving Xq is usually associated with abnormal sexual development and reproductive performance, often associated with POF. Two specific regions on Xq have been defined as POF loci, POF1 at Xq26-q28 and POF2 at Xq13.3-q21. It has been reported that distal deletions involving POF1 results in POF at ages 24-39 years, whereas translocations involving the POF2 locus causes POF at an earlier age of 16-21 years. Detail clinical assessment revealed the presence of possible functional oocytes. The patient opted for IVF and is being followed up. Variant Turner with mosaicism involving pseudo isodicentric (X)(q26) is very rare. Possible mechanism of the origin of the two cell lines and their correlation with POF in our patient will be discussed.

Genetic analysis of male patients referred with infertility. *M.V. Narayana¹, B. Sudheerbabu¹, J.V. Solanki², U. Ratnamala¹, U. Radhakrishna¹.* 1) Molecular Genetics Laboratory, Green Cross Blood Bank & Genetic Research Centre, Ahmedabad; 2) Department of Animal Genetics and Breeding, Veterinary College, Gujarat Agriculture University, Anand-388001, India.

Infertility is a well-known clinical manifestation of various ethical factors and is defined as an inability to conceive after 12 months of unprotected intercourse. The prevalence of infertility couples ranges between 2 and 16%, with 50% of cases due to male infertility. Many cases of male infertility are due to identifiable severe defects in sperm production, which are classified as Azoospermia, Oligospermia, Abnormal motility or morphology and some are idiopathic. Several factors are associated with infertility few of them included infection, immunological factors, anatomic abnormalities, environmental etiologies, endocrinologic dysfunctions and some are influenced by genetic factors. We have analyzed 80 male infertility patients for possible chromosomal anomalies. After the detailed family history and pedigree analysis, routine PHA stimulated peripheral blood cultures were set up and karyotyping was done after GTG banding and other banding techniques were performed as required. A high incidence of 20% (n=16) of chromosomal abnormalities was observed among 80 infertility patients referred (i.e. both structural and numerical). Those included 5% with balanced reciprocal translocations (N=4), 3.75% with sex reversals (n=3) and 12.5% with gonosomal aneuploidies/mosaicisms (n=9). These data suggests that patients with history of infertility should be investigated cytogenetically. DNA microsatellite and FISH analysis are in progress in few patients found with rare chromosomal translocations and also Y chromosome microdeletions analysis. u_c_rao@hotmail.com.

Program Nr: 912 from the 2004 ASHG Annual Meeting

Molecular cytogenetic characterization of a familial der(1)del(1)(p36.33)dup(1)(p36.22p36.33) associated with a variable phenotype. *J.K. Northup^{1,2}, V.S. Tonk^{3,4}, G.N. Wilson⁵, S. Yatsenko⁶, P. Stankiewicz⁶, J.R. Lupski^{6,7,8}, G.V.N. Velagaleti^{1,2}.* 1) Depts. Pathology and; 2) Pediatrics, University of Texas Medical Branch, Galveston, TX; 3) Depts. of Pediatrics and; 4) Pathology, Texas Tech University, Lubbock, TX; 5) Cook Children's Hospital, Fort Worth, TX; 6) Depts. of Molecular & Human Genetics and; 7) Pediatrics, Baylor College of Medicine, Houston, TX; 8) Texas Children's Hospital, Houston, TX.

Rearrangements involving chromosome 1p36 are very frequent, with deletions occurring at a frequency of ~1 in 5000 live births. Recently, using G-banding and whole chromosome painting, we identified a familial duplication dup(1)(p36.3) in a family associated with variable mental disability, attention deficit-hyperactivity disorder, and a distinctive facial appearance (Tonk et al., 2003). Subsequent subtelomere FISH analysis showed a concomitant terminal deletion in three affected family members. Several BAC and PAC probes mapping to 1p36.22-p36.33 revealed duplication of this region both on metaphase chromosomes and in interphase nuclei. Probes from 1p36.13-p36.21 region showed a normal hybridization pattern. We estimated the size of the deletion to ~550 Kb, and the duplication to ~10 Mb. Interestingly, chromosome 1p36.22 is known to harbor an intriguing gene cluster of locally repeated sequences. Unequal crossing over within these repeats was suggested to be the mechanism for deletions and duplications involving this region. However, recent studies of the del (1)(p36) cases have shown that the breakpoints vary widely and do not cluster. It has been suggested that breakage-fusion-bridge cycles might explain the origin of constitutional terminal deletions associated with interrupted inverted duplications (Ballif et al., 2004). Electronic analysis of DNA sequence in 1p36.33 revealed that this region contains low copy repeats. Further studies are in progress to define the breakpoint junctions and to elucidate the mechanism of this chromosome rearrangement.

A newborn with severe intrauterine growth retardation and dysmorphic features and multiple numerical and structural chromosomal anomalies: a chromosome instability syndrome? *M.J.M. Nowaczyk^{1,2}, J. Xu¹*. 1) Department of Pathology & Pediatrics, McMaster University, Hamilton, Ont., Canada; 2) Department of Pediatrics, McMaster University, Hamilton, Ont. Canada.

A newborn baby boy had multiple dysmorphic features, severe IUGR (weight at 50 centile for 26 weeks gestation 40 weeks), hepatomegaly and thrombocytopenia and anemia requiring transfusions. The parents were 1st cousins once removed and both had a normal karyotype. Routine cytogenetics of the child's blood taken at age of 2 days showed multiple numerical and structural anomalies in all 20 cells examined. At least 9 cells had X and Y chromosomes and 1 cell had 45,X. Chromosome number varied from 43[1], 44[1], 45[5], 46[4], 47[2], 48[2], 69[1] to tetraploidy 92[4]. Structural anomalies included markers in 10 cells, dicentrics in 5 cells, and rings in 2 cells. Of 21 cells examined in a repeat blood taken at age of 13 days, 2 had 46,XY and 19 had similar multiple numerical and structural aberrations. Chromosome number varied: 44[2], 45[5], 46[3], 47[3], 48[6]. Five cells had 1 marker, 6 had 2 markers, and 2 had 3 markers. The markers looked different from cell to cell. Six cells had distal deletions and/or additions, each with del(1)(q11) and del(6)(q11); add(4)(q35) and del(7)(q11.1); del(2)(q22); del(10q); del(12)(q21); del(18)(p11.2). Of 20 cells examined from skin tissue, 15 had 46,XY. The remaining 5 cells each had a different aberration: 45,XY,-20; 45,XY,-17; 43,Y,-X,-8,-11; 45,XY,t(14;15)(q10;q10); 89,XYY,-14,-15,-18. While mosaicism cannot be ruled out, these 5 abnormal cells are likely a result of technical artefact. Our routine analyses so far showed no cytogenetic hallmarks of Roberts syndrome (e.g. puffing at centromere or premature centromere separation (PCS)), ataxia-telangiectasia (increased aberrations involving chromosomes 7, 14 and X), Fanconi anemia (increased chromatid breakages and quadri- or tri-radial figures) or mosaic variegated aneuploidy syndrome (+8, +18, +/-PCS). While this case awaits further cytogenetics and DNA investigations, we welcome any comments and suggestions.

Low-copy repeats and acrocentric heterochromatin mediate a familial chromosome translocation t(14;17)(p13;p12). Z. Ou¹, S.P. Sparagana², M. Jarmuz³, B. Nowakowska^{1,4}, P. Furman¹, L.G. Shaffer^{3,5}, P. Stankiewicz¹, J.R. Lupski^{1,6}, S.W. Cheung¹. 1) Dept. of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Texas Scottish Rite Hospital for Children, Dallas, TX; 3) Health Research and Education Center, Washington State University, Spokane, WA; 4) Dept. of Medical Genetics, Institute of Mother and Child, Warsaw, Poland; 5) Sacred Heart Medical Center, Spokane, WA; 6) Dept. of Pediatrics, Baylor College of Medicine, Houston, TX.

Recently, several molecular studies of chromosome translocation breakpoints revealed nonhomologous recombination as a prevailing mechanism for the formation of nonrecurrent constitutional translocations. However, more cases have to be studied to elucidate the role of the genome architecture in the origin of nonrecurrent chromosome rearrangements. We report the clinical and molecular cytogenetic data of a familial translocation t(14;17)(p13;p12). A 6-year-old girl and her 5-year-old brother were diagnosed with mental retardation, speech delay, short stature, Charcot-Marie-Tooth disease type 1 (CMT1A), large eyes with splotchy melanization of the sclera, long straight eyelashes, down-slanting palpebral fissures, protruding ears, micrognathia, and short neck. G-banding chromosome analysis showed a der(14)t(14;17)(p13;p12) in both siblings, inherited from their father, a carrier of the balanced translocation. Chromosome microarray analysis revealed that the *PMP22* gene was duplicated and mapped the chromosome 17 breakpoint between the Smith-Magenis syndrome and CMT1A chromosome regions, within a breakage prone, ~383 kb low-copy repeat (LCR17pA). Subsequent FISH studies narrowed the 17p breakpoint to BAC clone CTD-3157E16. Interestingly, this clone was previously identified at the breakpoint of the evolutionary chromosome translocation t(4;19) in gorilla. The chromosome 14p breakpoint was mapped distal to the ribosomal DNA, outside the region commonly rearranged in Robertsonian translocations. Our data support previous observations that higher-order genomic architectural features such as LCRs and repetitive DNA sequences, play a role in the origin of nonrecurrent chromosome translocations.

Unexpected Fertility In Men with Robertsonian Translocation (22q;22q) and a New Paternal Uniparental Disomy 22. *K. Ouldim, A. Sbiti, H. Natiq, A. Arazam, A. Laamari, F. El-Kerch, A. Sefiani.* Department of medical genetics, INH, Rabat, Rabat, Morocco.

Uniparental disomy (UPD) describes the inheritance of a pair of chromosomes from only one parent and may comprise the whole chromosome or confined to only a small segment. Several conditions have been resulted from UPD. We report in this study an unexpected fertility in a couple with the repeated abortions. They had a boy with a normal phenotype. The cytogenetic analysis of the father and his son revealed the presence of a robertsonian translocation (22q;22q). The mothers karyotype was normal. A molecular study with chromosome 22 microsatellite markers and the paternity test confirmed the inheritance of this paternal translocation with the lack of the maternal 22 chromosome. A few cases of UPD22 are reported : one case of the paternal UPD 22 and three cases of the maternal UPD 22. All have been associated with infertility. Our finding showed that the inherited paternal UPD 22 has no effect on his son phenotype and represented the second case reported in the literature of the total paternal UPD 22 with the normal phenotype. The mechanisms which probably leading to UPD 22 in our case was discussed.

Validation of the Chromosome Microarray analysis (CMA) for detection of the 1.5Mb, 3Mb and 6Mb microdeletions in DiGeorge/Velocardiofacial syndrome. A. Patel¹, M.L. Cooper¹, J. Li¹, Z. Ou¹, W. Yu¹, X. Lu², J. Kim², C. Shaw¹, C. Chinault¹, S.W. Cheung¹. 1) Dept Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Spectral Genomics, Houston, TX.

The 22q11.2 deletion syndrome which includes DiGeorge and velocardiofacial syndromes(DGS/VCFS) is one of the most common microdeletion syndrome with an estimate incidence of 1:4000. There are several sets of low copy repeat (LCRs) genomic elements within the 22q11.2 region which undergo non-allelic homologous recombination during meiosis leading to this frequent microdeletion syndrome. Approximately 87% of the DG/VCFS patients have an identical deletion of 3Mb involving the most proximal and distal LCR. A smaller subset of patients (10%) has a smaller 1.5Mb deletion and even rarer are the atypical deletions or translocations. We have designed a chromosomal microarray analysis (CMA) chip to detect majority of the microdeletion syndromes including the DG/VCFS syndrome. Eight non-overlapping clones spanning the DG/VCFS region were included in the CMA CHIP to detect deletions spanning from 1.5Mb to 6Mb. In a preliminary validation study, five DG/VCFS patients that were known have a deletion of 22q11.2 by FISH analyses using the TUPLE1 probe were studied by our chromosome microarray. The Chromosomal Microarray analysis was 100% concordance with the FISH data and furthermore it allowed the exact delineation of the deletion sizes in these patients. Three patients had the common 3Mb deletion, 1 patient had the smaller 1.5Mb deletion and one patient had a 6Mb deletion. The sizes of the deletions were confirmed by FISH analysis. Thus, the CMA offers a rapid and a high throughput method for accurately detecting the various sized 22q11.2 deletions. DG/VCFS has a wide phenotypic spectrum however, it is thought there is much less heterogeneity at the genetic level. Routine CMA analysis for all DG/VCFS patients will not only allow for an accurate identification of the size of the deletion but will also quickly identify patients with smaller and atypical deletions for a more exact genotype/phenotype correlation and determination of risks associated with the 22q11.2 deletion syndrome.

Molecular cytogenetic and CGH-array studies in patients with autistic disorder. *S. Patil¹, E. Westin¹, R. Frantz², E. Ashley³, J. Piven³, V. Sheffield¹, T. Wassink².* 1) Department of Pediatrics, Div Medical Genetics, University of Iowa, Iowa City, IA; 2) Department of Psychiatry, University of Iowa, Iowa City, IA; 3) Department of Psychiatry, University of North Carolina, Chapel Hill, NC.

Autism is a neurodevelopmental disorder characterized by severe ritualistic-repetitive behaviors, impaired social interaction and impaired communication/language. Based on published cytogenetic studies, it is known that about 5-8% of cases of autism are associated with chromosome abnormalities. As part of an ongoing project on the molecular genetics of autism, we have recruited 76 patients with autistic disorder at the Autism Research Center in North Carolina. So far in these patients, we have performed routine chromosome analysis, as well as FISH analysis, using specific probes for chromosome 15q11.2q13 probes (DS15S11, SNRPN, D15S10, GABRB3), chromosome 22q11.2 probes (N-25 and TUPLE1 in 20 cases), and the subtelomere FISH panel (VYSIS). In addition, CGH-array studies (GenoSensor) have been carried out on 18 of these individuals. Five patients (6.6%) had chromosomal abnormalities [XXY, XY, inv dup (15q) supernumerary chromosome, del(2)(q37.1q37.3) and Y chromosome with chromosome 15 satellites on Yq]. None of the cases showed N-25 or TUPLE1 deletion. The subtelomere FISH panel confirmed 4 of these abnormalities. However, no new rearrangements were detected. The CGH array confirmed all five abnormalities described above, plus four (22%) additional deletions or duplication of certain markers. These include: two patients with deletion of marker D2S447 on 2qtel, deletion of PRKCZ at 1p36.33 in one patient, and duplication of D14S308 at 14qtel in one patient. Details of our experience with the CGH-array will be presented. Other molecular studies are being carried out to confirm these findings. Because of the limitations of detecting subtle abnormalities with routine cytogenetics, application of CGH-array methodology would yield a higher rate of detection of deletions/duplications, and importantly aid in the identification of novel genomic regions and genes involved in autism.

Multiple anomalies among siblings due to unbalanced chromosome 2;17 translocations. *J. Pfothenhauer¹, A. Yenamandra², J.A. Phillips, III¹, M.P. Cohen¹, M.L. Summar¹, V.L. Hannig¹, G.E. Tiller¹.* 1) Div Med Genetics, Vanderbilt Univ Sch Med, Nashville, TN; 2) Genetics Associates, Nashville, TN.

We present 3 sibs with multiple congenital anomalies secondary to a maternal (2;17)(q37;q25) balanced translocation. The couple's first pregnancy resulted in a healthy daughter. The second pregnancy produced a female with VSD, ASD, hypoplastic left heart and aortic arch with coarctation. Karyotype revealed 46,XX, der(2)t(2;17)(q37;q25), with partial monosomy 2q and partial trisomy 17q. Dysmorphic features included brachycephaly, prominent brow, flat facies, upslanting short palpebral fissures, mild synophrys, depressed nasal bridge, long philtrum, thin downturned lips, prominent frenulum, short neck, redundant nuchal skin, and mild 2-3 toe syndactyly. The baby underwent NG tube placement, 2-stage Norwood repair, angioplasty, and a bilateral Glenn shunt. At 5 months of age she contracted RSV bronchiolitis and died of respiratory failure. The father's blood karyotype was normal 46,XY. The mother's blood karyotype revealed the balanced translocation (cited above) in all cells studied. A third pregnancy was miscarried in the first trimester, but no products of conception were retrieved. The fourth pregnancy was found by amniocentesis to have 46,XX,der(2) t(2;17)(q37;q25)mat, the same unbalanced translocation previously found. At delivery, physical exam revealed acrocyanosis, low forehead and low hairline, extremely small fontanelles, hypertelorism, epicanthal folds, upturned nose with depressed nasal bridge, lowset posteriorly rotated ears, micrognathia, and multiple VSDs. By 2 years of age the child exhibited hypotonia, developmental delay, feeding problems, an umbilical hernia, and planovalgus deformities of her feet. The fifth pregnancy culminated in a healthy appearing female infant. Echocardiogram was normal. Physical exam was unremarkable except for small fontanelles and upturned nares. A karyotype revealed an unbalanced translocation 46,XX, der(17) t(2;17)(q37;q25)mat, with partial trisomy 2q and partial monosomy 17q. This family presents the interesting phenomena of 2 reciprocal products of adjacent segregation among 3 independent meiotic events.

Mosaicism involving two structural abnormalities of chromosome 18 in a patient with a mild phenotype. *M. Poscente, D. Turchetti, S. Cugusi, C. Graziano, G. Romeo, M. Seri.* Lab. Medical Genetics, University of Bologna Medical School, Italy.

A pregnant woman was referred for genetic counselling because of an abnormal fetal karyotype at amniocentesis performed for advanced maternal age. The fetal karyotype was 46,XX,del(18)(p11.22pter) and the deletion was detected to be maternal in origin. The pregnancy was terminated at 23 weeks. The clinical evaluation of consultant revealed some typical findings of 18p- syndrome (palpebral ptosis, midface hypoplasia, ophthalmological and dental abnormalities). Moreover, she presented scoliosis and asymptomatic mitral valve prolapse but no evidence of growth and/or mental retardation. Because of milder phenotype compared to described 18p- syndrome, an in-depth karyotype analysis was performed: a 100 peripheral blood metaphases analysis revealed a mosaic karyotype with three cell lines, all with a chromosome 18 structural rearrangement. The final karyotype was defined as: 46,XX,del(18)(p11.22pter)[79]/46,XX,idic(18q)(qterp11.22::p11.22qter)[20]/47,XX,idic(18q)(qterp11.22::p11.22qter)x2[1]. FISH analysis with specific BAC probes localized the breakpoint region in 18p11.22 and confirmed the deletion comprising the 18p subtelomeric region. The patient, therefore, has a homogeneous del(18)(p11.22pter) and a mosaic dup(18)(qterp11.2) because of the isodicentric structure in 20% of cells. Structural chromosome rearrangements are rarely seen in mosaic form with the exception of mitotically unstable chromosomes such as dicentric. The formation of the fused chromosome can be explained by postzygotic exchange of sister chromatids on the short arm of chromosome 18, followed by breakage and U-shape reunion of sister chromatids; the deletion of the short arm is a possible initiating mechanism with dicentric 18 chromosome, as described in studies on i(X). The few abnormal features seen in our patient may represent a mild expression of the 18p- phenotype inhibiting the effects of the mosaic partial trisomy 18.

Genetic analysis of infertile males from Bangalore, India. *M.G. Prabhakara¹, M. Babu¹, M. Ali¹, V. Bajaj¹, G.B. Manjunath¹, S. Khare¹, K.M. Prasannakumar², A. Kumar¹.* 1) MRDG, Indian Institute of Science, Bangalore, Karnataka, India; 2) Department of Endocrinology and Metabolism, MS Ramaiah Medical College, Bangalore, India.

Approximately 13-18% couples of child bearing age are infertile. Male infertility accounts for approximately half of it. Male infertility is known to have a genetic basis in many cases. Several studies have been performed on the cytogenetic and molecular basis of male infertility in patients from the western populations. Recently, four groups from India have independently reported molecular basis of male infertility in cases from Kolkata, Delhi, Hyderabad and Varanasi. However, there is no report on the genetic basis of male infertility in patients from Bangalore. To this end, we have begun to ascertain cases with male infertility from Bangalore. We have ascertained so far a total of 53 cases with male infertility from Bangalore. These cases were either azoospermic or oligospermic. The G-banding chromosome analysis showed a normal male karyotype in all except one case. The karyotype of one infertile patient was 47,XYY. PCR-based microdeletion analysis of the Y-chromosome using a battery of 29 primer sets from AZF regions (viz. sY746, sY740, sY86, sY2320, sY741, sY84, DFFRY, sY742, sY615 and sY743 from AZFa region; sY98, sY100, sY110, sY80, sY113, sY118, sY124, sY127, sY1211, sY134 and sY143 from AZFb region; sY153, sY148, sY156, sY255, sY254 and sY158 from AZFc region; and, SRY from the p-arm and sY160 from the heterochromatic region) showed deletions in four patients (4/53; 7.5%) in the AZFc region only. Interestingly, patients from other regions of India have shown deletions in all three AZF regions. This suggests a regional variation in the deletions of AZF regions in Indian male infertile patients. The sizes of the deletions were variable in these patients. Deleted segment in only one patient extended to the heterochromatic region of the Y-chromosome. (The financial assistance from the ICMR, New Delhi is gratefully acknowledged).

FISH analysis of meiotic segregation in the sperm of a complex chromosome rearrangement carrier. J.

*Puechberty*¹, *G. Lefort*², *A. Weise*⁴, *T. Liehr*⁴, *P. Sarda*¹, *F. Pellestor*³. 1) Department of Medical Genetics, CHU Arnaud de Villeneuve, Montpellier, France; 2) Department of Cytogenetics, CHU Arnaud de Villeneuve, Montpellier, France; 3) CNRS UPR 1142, Montpellier, France; 4) Institut of Human Genetics, Jena, Germany.

Complex chromosome rearrangements (CCRs) are rare events involving at least three breakpoints located on at least two chromosomes. They are usually diagnosed during the investigation of infertility or sometimes at prenatal diagnosis. The advent of molecular cytogenetic techniques has led to a better characterization of RCCs and genetic counseling has benefitted by this advance. We report a CCR initially detected by classical cytogenetic techniques and subsequently analyzed by FISH techniques. **CASE REPORT** : Chromosome studies were done following recurrent spontaneous abortions. Blood lymphocyte karyotype in the 49-year-old man showed an apparently balanced translocation with three breakpoints on chromosomes 5, 13 and 14 : t(5;13;14)(q23;q21;q31). In order to evaluate the reproductive possibility of this patient we performed FISH analysis of the meiotic segregation in sperm using region-specific probes overlapping the translocation breakpoints. A preliminary study analysed 218 spermatazoa. The frequency of alternate and unbalanced forms (adjacent 1, 4 : 2 and 5 : 1) were respectively 28% and 72%. Because of the high percentage of unbalanced forms, IVF with PGD were not undertaken. The information obtained from meiotic sperm studies is useful for genetic counseling and is an aid to sterile male translocation carriers when deciding which couples should benefit from assisted reproductive technologies.

Program Nr: 922 from the 2004 ASHG Annual Meeting

Ring chromosome 9 [r(9)(p24q34)]: a report of two cases. *S.M. Purandare, J. Lee, S. Hased, M.I. Steele, P.R. Blackett, J.J. Mulvihill, S. Li.* Department of Pediatrics, University of Oklahoma Health Sciences Center, Oklahoma City, OK.

We report clinical and molecular cytogenetic studies in two patients with ring chromosome 9. Cytogenetics and fluorescent in situ hybridization (FISH) analyses using the p16 gene probe on 9p21, the ABL gene on 9q34, chromosome 9 alpha satellite-centromeric probes, and TelVision 9p and 9q probes that detect subtelomere-specific sequences on chromosome 9p and 9q revealed 46,XX,r(9)(p24q34).ish r(9)(305J7-T7-,p16+,ABL+, D9S325-) and 46XY,r(9)(p24q34).ish r(9)(305J7-T7-,p16+,ABL+, D9S325-). Based on FISH analysis at least 115 kb was deleted on terminal 9p, and at least 95 kb from terminal 9q. In comparison with other reports of r(9), deletion 9p, and deletion 9q, both patients had clinical characteristics of ring 9 and additional features of deletion 9q or deletion 9p syndrome. The variability between the two cases with r(9) despite similar breakpoints identified by GTG-banding and FISH may be explained by submicroscopic differences between deletion breakpoints, ring instability, interaction of other genes on the phenotype, and variation in fetal environmental conditions.

Clinical and molecular cytogenetic findings resulting from an unusual recombinant chromosome 16 derived from a paternal ins(16). *R. Ray¹, K. Brierley¹, C. Asquith-Smith¹, P. Chakraborty^{1,2}, J. McGowan-Jordan^{1,2}.* 1) Genetics, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada; 2) University of Ottawa, Ottawa, Ontario, Canada.

We report the clinical and molecular cytogenetic findings in a 6-year-old girl referred for a genetic evaluation. Clinically, she has a history of congenital hydrocephalus, moderate developmental delay, hypotonia and autistic features.. Chromosomal analysis on peripheral lymphocytes revealed an unbalanced female karyotype which was initially assigned as: 46,XX,?rec(16)dup(16q). To characterize the rearranged chromosome 16, fluorescence in situ hybridization (FISH) analysis with a series of probes was performed. Using whole chromosome 16 paint showed that the entire abnormal chromosome was comprised of chromosome 16 material. Analysis of additional probes demonstrated that: (1) the CFBF locus (16q22) localized to the long arm (2) the MYH11 (16p13.1) was found to hybridize distal to the CFBF locus in the long arm and (3) the long arm subtelomeric probe, Z96319 was present terminally on both the long arm and short arm of the abnormal chromosome 16. The results indicate that a portion of the short arm from band 16p11.2 to band 16p13.1 was inserted into the long arm of the same chromosome at band q22 resulting in trisomy for the terminal region of the long arm of chromosome 16 (16q22 to 16qter) and monosomy for the terminal region of the shot arm (16p13.1 to 16pter). Analysis of parental peripheral lymphocytes identified the father to carry an ins(16)(q22p11.2p13.1). By FISH, the abnormal 16 chromosome painted completely with the whole chromosome 16 painting probe. Analysis of additional probes, CFBF, MYH11 and Z96319 confirmed this interpretation. Taken together, there appears to be no discernable loss of chromosomal material on the paternal ins(16). Carriers of such chromosomal rearrangements are at increased risk of transmitting an unbalanced chromosome to their offspring. Therefore, his daughter is likely the result of a meiotic event involving the abnormal paternal chromosome 16. Her final karyotype was: 46,XX,rec(16)dup(16q)ins(16)(q22p11.2p13.1).

Prenatally Detected Extra Structurally Abnormal Chromosome: The Dilemma of Genetic Counseling. O.

Reish^{1,2}, R. Gobazov¹, M. Roseblat¹, V. Libman¹, M. Mashevich¹. 1) Genetic Inst, Assaf Harofeh Medical Ctr, Zerifin, Israel; 2) Sackler School of Medicine, Tel Aviv University, Tel Aviv Israel.

We describe a series of 3 cases with prenatally detected Extra Structurally Abnormal Chromosome (ESAC). Cases 1 and 2 were unrelated singletons, case 3 was one of monozygotic twins and all were spontaneously conceived. In all cases amniocentesis was performed due to advanced maternal age and the ESAC was a co-incidental finding. Fluorescent In Situ Hybridization (FISH) analyses demonstrated that all ESACs were bisatellited. Cases 1 and 2 were inv dup (15), and in case 3 the ESAC was derived from either chromosome 14 or 22. Cases 1 and 3 were de novo while case 2 was maternally transmitted. Mosaicism was detected in case 3 only in the range of 80%. FISH studies to the Prader Willi and Cat Eye regions in the inv dup (15) and the 14/22 ESACs respectively, did not show any hybridization signal. In all cases uniparental disomy was excluded. Following an extensive genetic counseling the pregnancy of case 1 was terminated while the other 2 were carried to term. The decision making process particularly of monozygotic twins with hetero karyotypes is presented.

Mental retardation, hyperphagia and obesity due to inherited 22q13.33 deletion. *J. Roberson¹, D. Van Dyke², A. Wiktor².* 1) Dept Medical Genetics, Henry Ford Hosp, Detroit, MI; 2) Mayo Clinic, Rochester, MN.

CJ is a 22 year old female who had been followed since infancy for moderate to severe mental retardation, excessive food-seeking behavior, obesity, aggressive behavior and drooling. She was born after a full-term uncomplicated pregnancy to parents who were moderately mentally impaired. She was adopted by a maternal relative. Birth weight was 7 lb. 12 oz. At age 2 her overall functioning on the Bayley Scales of Infant Development was 10 1/2-11 1/2 months. At age 22 years she is non-verbal, she indicates her wants by pointing or getting the object she wants. Growth was at the 50th percentile for height and weight through age 5 years. Stature remains at the 50th percentile but her weight was 95th percentile by age 8 years. She weighs 231 lb. at age 22 years (markedly above the 98th percentile). Head circumference was above the 98th percentile by age 10 years. She does not have dysmorphic features. She displays aggressive behavior, touch-avoidance, sleep difficulties, excessive food-seeking activity such as stealing food, eating from the garbage and tantrums if she is not given the food she wants. Chromosome analysis, Smith-Magenis FISH testing, Fragile X and Prader-Willi/Angelman syndrome DNA testing and thyroid function studies were normal.

CJ's mother also had negative chromosome analysis and Fragile X testing. She is a 43 year old who also has moderate learning delays, very limited language skills, obesity, and insulin dependent diabetes. No other maternal relatives have mental retardation.

Subtelomeric FISH probes identified a 22q13.33 deletion in mother and daughter. The ARSA probe was not deleted. The previously described phenotype in distal 22q deletion includes generalized hypotonia, severe delay of expressive language, dolicocephaly, abnormal ears, ptosis, dysplastic toenails, and relatively large hands. This patient and her mother demonstrate the previously reported severe language delays; however, their obesity, excessive food-seeking behavior and lack of dysmorphic features differ from the previously documented cases.

Monosomy 1p36/trisomy 5q35.1 in a baby girl with seizures, hypotonia and developmental delay. *G.M. Ronen¹, J. Xu²*. 1) Pediatrics; 2) Pathology and Molecular Medicine and Lab Medicine, Hamilton Health Sciences and McMaster University, Canada.

We describe the first report of monosomy 1p36/trisomy 5q35.1 in a girl who presented initially at 3 months with complex partial and secondary generalized seizures, progressive microcephaly (-4SD), hypotonia, failure to thrive and global developmental delay (DD). Dysmorphic features included low forehead, large cheeks, closely spaced eyes, mildly slanted palpebral fissures, small ears, slight saddle nose, thin upper lip, smooth philtrum, high arched palate, retrognathia and short neck. EEG and cranial ultrasound were normal. Cytogenetics of the blood sample showed that the patient had a de novo unbalanced female karyotype of 46,XX, der(1)t(1;5)(p36;q35.1) with monosomy for 1p36 and trisomy for 5q35.1. This interpretation is based on analysis of G-banding, spectral karyotyping using all 24 whole chromosome paints (wcp) and FISH using wcp5, 1p telomere probe (TelVysion 1p, Vysis) at 1p36, 5p probe D5S23/D5S721 (control probe of LSI probe EGR1) at 5p15, and 5q telomere probe (TelVysion 5q, Vysis) at 5q35. FISH using SNRPN found no evidence of anomalies of Prader-Willi syndrome critical region at 15q11-q13. Monosomy 1p36 is a new syndrome with well recognized features including growth and mental retardation; seizures; visual problems; large anterior fontanelle; asymmetric, low-set, dysplastic ears; deep-set eyes; depressed nasal bridge; pointed chin and fifth finger clinodactyly (Slavotinek et al., *J Med Genet* 1999, 36:657-663). Trisomy 5q35.1 is relatively rare but has been reported often in combination with other chromosome aberrations. While the clinical picture of the trisomy 5q is still emerging, it seems to share many findings with the monosomy 1p, such as DD, seizures, some dysmorphic features (Groen et al., *Am J Med Genet* 1998, 80:448-453). Future case reports would further help establish the karyotype/phenotype correlation and the clinical outcome of such patients.

The contribution of human chromosome 14p sequences to the breakpoint region of 14q21q Robertsonian translocations determined by single nucleotide polymorphism (SNP) analysis. A.L. Rosa^{1,2}, M. Jarmuz¹, K.A. Bailey^{1,2}, C.D. Glotzbach^{1,2}, L.G. Shaffer^{1,2}. 1) Health Research and Education Center, Washington State University, Spokane, WA; 2) Sacred Heart Medical Center, Spokane, WA.

Robertsonian translocations (ROB) are the most common chromosomal rearrangement in humans with 1:1000 carriers in the general population. The contribution of chromosome 14 sequences to ROB breakpoints is of particular interest because rob(13q14q) and rob(14q21q) constitute about 86% of the total ROB. We have performed high-density PCR-based marker walking over a ~330 kb DNA sequence containing extensive segments of homology between the p-arms of the various acrocentric chromosomes. The region is suspected to contain the physical site for the occurrence of most of the ROB breakpoints. The analyzed sequences are rich in highly repetitive DNA elements. A surprisingly dense concentration of single nucleotide polymorphisms (SNPs) in paralogous copies of STSs was recognized in a subregion of ~12 kb. Using fully sequenced BACs, multiple linked SNPs were defined in short DNA fragments (100-300 bp) distributed over a large interval of ~300 kb. Patches of this region are contained at the p-arm of the various acrocentric chromosomes. The precise chromosomal origin of the analysed BACs (13p, 14p, 15p, 21p or 22p) was unknown. Extensive analyses of the defined SNPs were used to define arbitrary haplotype phases for the various BACs. The chromosomal origin of each BAC was assigned by determining equivalent individual SNP haplotypes on human acrocentric chromosomes carried by monochromosomal hybrid cells. Results of BAC chromosome assignments were confirmed by FISH analyses. The availability of SNP haplotypes allowed us to study partial 14p and 21p chromosome contributions to the breakpoint region in 14q21q ROB. SNP analyses of hybrid cells carrying single *de novo* ROB chromosomes indicate that a large part of the breakpoint region in 14q21q ROB is contributed by 14p sequences.

Development and validation of a chromosome 15 DNA microarray for comparative genomic hybridization and application to autism. *T. Sahoo, C.A. Shaw, W. Yu, A.L. Beaudet.* Dept Human & Molec Gen, Baylor Col Medicine, Houston, TX.

Array based comparative genomic hybridization (CGH) provides a high resolution genome-wide scan for identifying DNA copy number variations. We are developing a high density large-clone based DNA microarray for detection of abnormalities involving chromosome 15. Additionally, we are implementing a robust CGH analytical tool for accurate and reproducible interpretation of genomic copy-number gains and losses. Prader-Willi syndrome (PWS) and Angelman syndrome (AS) are known to map to 15q11-q13, a region which includes a 3-4 Mb domain subject to genomic imprinting. Paternal and maternal deletions of 15q11-q13 cause PWS and AS respectively. Cytogenetic abnormalities of chromosome 15q11-q13 also cause autism. Interstitial duplications and isodicentric 15q found in association with autism are usually of maternal origin suggesting both a gene-dosage effect and involvement of genomic imprinting. An initial version of our chromosome 15 microarray consisting of ~100 BAC-PAC clones provides a genome scanning resolution of better than one clone per Mb across chromosome 15 with the highest density across the PWS/AS interval and previously identified regions of instability on chromosome 15. Inclusion of subtelomeric clones for all other autosomes and a set of clones specific for chromosomes X and Y permits detection of cryptic unbalanced rearrangements. Initial validation of this technology involves specificity and sensitivity of detection using cytogenetically identified 15q rearrangements in autistic disorder. Chromosome 15-specific microarray CGH is enabling accurate identification of the whole spectrum of abnormalities (segmental gains and losses) seen in autism spectrum disorders and Prader-Willi/Angelman syndrome. Accurate prediction of the extent and boundaries of recurrent rearrangements in these disorders is providing clues towards an understanding of the mechanism leading to these rearrangements. Continuing development of array CGH will help identify deletions, duplications, and unbalanced structural rearrangements contributing to autism and provides a more cost-effective and sensitive approach to a molecular karyotype.

An unusual familial centromeric rearrangement involving chromosomes ?14/22 and 15 - A rare variant or translocation? *M. Sathanoori*^{1, 2}, *C. Minyon*¹, *M. Zimmer*³, *U. Surti*^{1, 2}. 1) Magee-Womens Hospital, Pittsburgh, PA; 2) University of Pittsburgh, Pittsburgh, PA; 3) Children's Hospital of Pittsburgh, Pittsburgh, PA.

A 2 y.o female child with hypotonia and developmental delay was referred for cytogenetic workup to R/O Prader-Willi Syndrome. Conventional cytogenetic analysis revealed a normal karyotype at 625 G-band level. FISH using the SNRPN probe (which includes D15Z1 and PML probe) revealed two normal signals for SNRPN and only one signal for D15Z1. Subsequent FISH analysis was performed with -satellite probes of acrocentric chromosomes (DZ13/21; DZ14/22; D15Z and D15Z4) and D15S11. The results are indicated in the table below. The finding of extra signal with DZ14/22 in both the mother and the proband indicates that this is a rare familial rearrangement. D15Z1 cross-hybridizes with #14 in 10-15% of individuals in the general population. A literature search failed to detect any variant #15 with absence of D15Z and presence of DZ14/22. Since our case has a 14/22 centromere on #15, it is a matter of debate as to whether it should be considered a variant #15 or a cryptic t(?14/22;15). A recent paper by Cockwell et al (2003) discusses the clinical significance of cryptic pericentromeric rearrangement and pregnancy outcome in couples with recurrent pregnancy loss. In addition to cryptic telomeric rearrangements, attention should be given to possible cryptic centromeric rearrangements.

Probe	D15Z1	D15Z	D15Z4	D15S11	SNRPN	PML	14/22	13/21
Locus	p11.2	p11-q11	p11-q11	q11-q13	q11-q13	q22	p11-q11	p11-q11
Case	+	+	+	++	++	++	+++++	++++
Control	++	++	++	++	++	++	++++	++++

Male infertility associated with a familial translocation : t(1;13)(q24;q10). A. Sazci¹, N. Ercelen², E. Ergul¹, G. Akpinar¹. 1) Dept Medical Biol & Genetics, Kocaeli Univ, Kocaeli, Turkey; 2) V.K.V American Hospital, Department of Genetics, Guzelbahce sk. No:20, 34365, Nisantasi, Istanbul, Turkey.

Chromosomal rearrangements are a well-recognised cause of reproductive failure in males, with a significantly high rate of cytogenetic anomalies observed in azoospermia (13.7%). We report the case of a family with one sister and one brother in which the brother inherited a t(1;13)(q24;q10) translocation from his mother. The case with a clear translocation between the long arm of the chromosome 1 and the long arm of chromosome 13 t(1;13) (q24;q10) is described. The karyotype of the case was 46,XY,t(1;13)(q24;q10). Father and sister had normal karyotypes. We performed cytogenetic analysis and fluorescence in situ hybridization (FISH) for definition of chromosomal breakpoints. The translocation was found in a phenotypically normal male at the age of 38 who was born in Bulgaria from Turkish parents, and married for 9 years. Histological examination of testicular biopsies revealed spermatogenic failure. Although he had undergone bilateral varicocelectomy, his spermatogenic failure was not improved. Microdeletion analysis at the azoospermia locus (AZFa,b,c and d) of the Y chromosome revealed no deletions, thus suggesting another mechanism causing infertility in this translocated carrier. Molecular analysis of the family for atherothrombotic genes indicated that the proband and sister had a MTHFR T677T/A1298A compound genotype, while mother had a APOE4/4 genotype. In conclusion, this is the first case showing the t(1;13) (q24;q10) translocation involved in infertility in a male carrier but not in a female carrier.

Xp22.3 DELETION IN A GIRL ASSOCIATED WITH AUTISM, MENTAL RETARDATION AND MILD DYSMORPHIC FEATURES. *F. Scaglia, A. Patel, S. Peters, P. Panichkul, M. Shinawi.* Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX.

Males who are nullisomic for the Xp22.3 chromosomal region exhibit a phenotype consistent with the loss of one or more of the genes located in this region. Females with similar Xp deletions seldom manifest the same phenotype. It has been reported previously that *de novo* chromosomal deletions of Xp22.3 were found in three unrelated autistic females. Mutations in *Neurologin-4(NLGN4)*, located at Xp22.3, were found in two autistic brothers and in a large family with members affected by X-linked mental retardation, with or without autism, suggesting that this gene could be involved in autistic disorders. Here we describe a 10-year-old girl with an interstitial deletion of Xp22.3 who presented with mild dysmorphic features, autistic behavior and mild mental retardation. Her physical examination revealed a bulbous nose, hypertelorism, small ears, and a short, webbed neck. A brain MRI showed a mildly hypoplastic cerebellar vermis. Results of the Autism Diagnostic Observation Schedule and the Autism Diagnostic Interview Revised revealed that she exceeded the cutoffs for autism on both instruments. A chromosome analysis was subsequently carried out on peripheral blood lymphocytes from the proband and a *de novo*, cytogenetically visible deletion was detected at Xp22.31-p22.13. Results of detailed FISH analysis revealed that the telomeric breakpoint was localized between markers DXS8090 (4Mb) and DXS1056 (5.8Mb) and the centromeric breakpoint is between markers DXS1067 (8.9Mb) and DXS1043 (10.5Mb), so that the maximum size of the deletion is 6.5Mb. Of particular interest is the inclusion in this critical region of the *NLGN4* and the variably charged, X chromosome mRNA on CRI-S232A (*VCX-A*) genes that were recently implicated in autism and X-linked mental retardation, respectively. Other molecular studies are underway to analyze the parental origin of the abnormality, the X-inactivation pattern, and the epigenetic control of these genes. We propose that functional nullisomy, with or without skewed X-inactivation, in certain brain structures, or X-inactivation-independent haploinsufficiency for these genes can contribute to autism and mental retardation.

Detection of submicroscopic chromosome aberrations in children with idiopathic mental retardation by array-

CGH. *J. Schoumans¹, C. Ruivenkamp², A. Nordgren¹, AC. Thuresson³, E. Holmberg⁴, M. Nordenskjold¹, BM.*

Anderlid¹. 1) Dept of Molecular Medicine, Karolinska Institute, Stockholm, Sweden; 2) Dept of Human and Clinical Genetics, LUMC, Leiden, The Netherlands; 3) Dept of Clinical Genetics, Uppsala University Childrens Hospital, Uppsala, Sweden; 4) Department of Clinical Genetics, Sahlgrenska University Hospital/East Gothenburg, Sweden.

Novel high-resolution, whole-genome technologies, such as array based comparative genomic hybridization (array-CGH), improves the detection rate of submicroscopic chromosomal abnormalities. This opens new opportunities to re-investigate cases where conventional cytogenetic techniques, such as G-banding, FISH and metaphase CGH failed to detect any underlying genetic cause. We performed a high resolution genome-wide screening using array CGH on 40 patients with idiopathic mental retardation and dysmorphic features, in order to detect submicroscopic chromosomal rearrangements. We used a commercially available microarray from Spectral Genomics, containing 2600 BAC clones spaced at approximately 1 Mb intervals across the genome. Standard chromosomes analysis (450 bands) and multi-subtelomeric FISH screening was normal in all cases. We detected two interstitial deletions on 2q23-24 and 2q24-31 (size estimated 10 and 14 Mb respectively), one interstitial deletion on 4p16 (size estimated 7 Mb) and one terminal duplication on 9pter (size estimated < 1Mb). The deletions on 2q were confirmed by FISH, the duplication on 9p was confirmed by MLPA and confirmation of the 4p deletion is ongoing. Further investigation of parental samples revealed that both 2q deletions and the 9p duplication occurred de novo. The deletions on 2q were both visible by high resolution G-band analysis (>550 bands) but not by standard chromosome analysis (450 bands). The 9p duplication was not detectable by G-banding nor by subtelomeric FISH. In summary, we detected chromosome imbalances in 10% (4 out of 40) of the investigated cases. We therefore conclude that array CGH is an important tool for detection of submicroscopic rearrangements and is a promising technique for the future diagnostic setting.

Refinements in multiplex ligation-dependent probe amplification (MLPA) yield a robust, cost-efficient, high-throughput technology to assess genomic imbalance in pediatric populations. *R. Schultz^{1,4}, C. Duncan¹, F. Elder^{1,4}, K. Wilson^{1,4}, C. Read^{2,4}, N. Garcia^{3,5}, L. McDaniel¹.* 1) Dept Pathology, Univ Texas SW Medical Ctr, Dallas, TX; 2) Dept Ob/Gyn, Univ Texas SW Medical Ctr, Dallas, TX; 3) Dept Pediatrics, Univ Texas SW Medical Ctr, Dallas, TX; 4) McDermott Center, Univ Texas SW Medical Ctr, Dallas, TX; 5) Childrens Hospital of Dallas, Dallas, TX.

Conventional cytogenetics and fluorescence in situ hybridization (FISH) offer valuable tools to evaluate selected newborn populations; although some tests (e.g., the subtelomeric FISH panel) are fairly labor-intensive and expensive. MLPA offers another approach to detect unbalanced chromosomal alterations. This previously described assay employs hybridization of oligonucleotide (oligo) pairs to immediately adjacent genomic DNA sequences, with subsequent ligation and PCR amplification. The use of common flanking sequences, common primers and uniquely sized spacers for all oligo pairs facilitates multiplexing >40 targeted pairs in a single reaction. We have refined MLPA to establish a single, cost effective, and high throughput assay that can be readily applied to pediatric specimens using oligos targeted to all chromosomal ends and specific internal loci. Reactions are run on an ABI3100 and fragments analyzed with GeneMapper software. Analysis has been revised to evaluate peak area relative to an internal control with results expressed as a percent of total fluorescence for a specimen. The data are reproducible with small deviation permitting automated identification of abnormal results. Reconstruction experiments demonstrate reliable detection of mosaicism down to 25%. Screening specimens submitted for multiple congenital anomalies or developmental delay has identified various genomic abnormalities including deletions of 1p36, 18q21-qter, 13pter, and 5pter, as well as trisomies. The technology has high-throughput capabilities and is being developed as a general screen for appropriate populations. As a research tool, a revised oligo set has been devised to screen infants with diaphragmatic hernia for microdeletions in previously implicated chromosomal intervals.

Non-recurrent 17p11.2 deletions are generated by homologous and non-homologous mechanisms. *C.J. Shaw¹, J.R. Lupski^{1,2,3}*. 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Dept Pediatrics, Baylor Col Medicine, Houston, TX; 3) Texas Children's Hospital, Houston, TX.

Several recurrent, common chromosomal deletion and duplication breakpoints have been localized to large, highly homologous low copy repeats (LCRs). A well characterized example of this is the genomic interval 17p11.2-p12, wherein recurrent deletions and their reciprocal duplications result in hereditary neuropathy with liability to pressure palsies (HNPP), Charcot-Marie-Tooth disease type 1A (CMT1A), Smith-Magenis syndrome (SMS), or dup(17) (p11.2p11.2) syndrome. The mechanism responsible for these rearrangements, non-allelic homologous recombination (NAHR) between LCR copies, has been well established. However, fewer studies have examined the mechanisms responsible for non-recurrent rearrangements with non-homologous breakpoint regions. Here we analyze four uncommon deletions of 17p11.2, involving the SMS region. Using somatic cell hybrid lines created from patient lymphoblasts, we utilize a PCR-based strategy to refine the deletion breakpoints and to obtain sequence data at the deletion junction. Our analyses revealed that two of the four deletions are a product of Alu/Alu recombination, while the remaining two deletions result from a non-homologous end joining (NHEJ) mechanism. Of the breakpoints studied, 3/8 are located in LCRs, and 5/8 are within repetitive elements, including Alu and MER5B sequences. These findings suggest that higher-order genomic architecture, such as LCRs, and smaller repetitive sequences, such as Alu elements, can mediate chromosomal deletions via homologous and non-homologous mechanisms. These data further implicate homologous recombination as the predominant mechanism of deletion formation in this genomic interval.

BAC probes with FISH delineates a 6q interstitial deletion in an individual with a Prader-Willi like phenotype. *S. Shetty, J. Lauzon, M. Innes, J. Chernos.* Department of Medical Genetics, University of Calgary, Alberta Children's Hospital, Calgary, Alberta, Canada.

Prader-Willi syndrome (PWS) is associated with obesity, hyperphagia, hypotonia and developmental delay. Many individuals present with a similar constellation of findings and are found not to have the typical molecular and cytogenetic findings of PWS. Different conditions including other chromosomal abnormalities have been associated with a PWS-like phenotype such as interstitial deletions of 6q. The SIM1 gene is mapped to 6q16.3-q21 region. It has been proposed as a candidate gene for obesity and may play a role in the phenotype of these individuals.

We report a case of an individual with a PWS-like phenotype with small interstitial deletion of the long arm of chromosome 6. This 23 year-old man was seen for evaluation of his learning disabilities and compulsive eating habits. He had hyperphagia and history of food-seeking behaviours. He had neonatal hypotonia and feeding problems. His weight increased significantly at the age of 8. Physical features included short palpebral fissures, full lips and brachydactyly with tapered fingers. Previous investigations included a normal muscle biopsy, Fragile X and PWS methylation testing.

Cytogenetic analysis at 500-525 band resolution revealed a karyotype of 46,XY, del(6)(q14q16). In order to delineate the breakpoints precisely, molecular cytogenetic studies were performed using directly labelled BAC probes with FISH, which showed an interstitial deletion of 6q16 region.

To our knowledge this is the first case of an individual with a 6q interstitial deletion and a PWS-like phenotype to be diagnosed by a molecular cytogenetic approach. BAC probes for the 6q16 region were useful in identifying the apparent deletion of the SIM1 gene region in this patient. Using directly labelled BAC probes with FISH is a reliable and inexpensive approach for delineating interstitial deletions. This technology may provide an economical and efficient adjunct to the cytogenetic studies of patients with PWS like phenotype and normal PWS methylation or 15q11.2 FISH studies.

Mosaic whole-arm duplication of the long arm of chromosome 1 identified in an amniocentesis and confirmed in different tissue samples at birth. *P.L. Sinanaj¹, A.E. Deupree¹, E. Williamson¹, E. Varga², S.A. Berend¹.* 1) Genzyme Genetics, Santa Fe, NM; 2) University of Kansas Medical Center, Kansas City, KS.

Chromosome 1 is the largest human chromosome and contains approximately 10% of the genome. Full trisomy of the long arm of chromosome 1 results in multiple, major anomalies and is not compatible with survival to term. Mosaic trisomy 1q is also rare; previous reports have described multiple anomalies in affected fetuses including diaphragmatic hernia, hypoplastic lungs, and cleft palate. We report a case involving a patient referred for amniocentesis due to hydrocephalus, ureteropelvic junction (UPJ) obstruction, and an atrial-septal defect identified on ultrasound. Cytogenetic analysis using standard GTG banding techniques revealed a mosaic chromosome pattern with fifteen colonies (15/18, 83%) showing a direct duplication of the long arm of chromosome 1 (q21.1q43). The remaining three colonies showed a normal female chromosome constitution. It was unclear if the three colonies containing normal female cells represented maternal cell contamination indicating a fetus with full trisomy for 1q or if this represented true fetal mosaicism. Parental chromosome analyses indicated that this was a de novo rearrangement. The baby was delivered at 30 weeks gestation and died approximately one hour after birth. Cord blood and tissue samples were obtained and sent for confirmation of the prenatal analysis. Chromosome analysis was performed on each of the tissue samples and the abnormal cell population was confirmed in all tissue types and found in different proportions: cord blood (6/104, 6%), skin (1/30, 3%), muscle (1/30, 3%), and tendon (17/30, 57%). Interestingly, the proportion of abnormal cells varied greatly in the different tissue types.

Program Nr: 937 from the 2004 ASHG Annual Meeting

An Automated Platform for Quantitative FISH Analysis. *F. Tafas, M.W. Kilpatrick, I. Ichetovkin, A. Seppo, Y. Kim, Y. Agarwall, P. Tsipouras.* Ikonisys Inc, New Haven, CT.

In the course of the last decade, FISH analysis has emerged as a standard of care in clinical testing. However, FISH is expensive, labor intensive, requires a high skill level and can be difficult to interpret. A fully automated system for FISH analysis would, therefore, be of great value for the clinical testing laboratory. The Ikoniscope™ is a customized system developed specifically for cell identification and analysis. Epi-fluorescence optics and a slide management system provide high speed and accuracy of slide movement. Fast focusing is achieved with the assistance of an infrared-laser device. Slides are fed to the stage by an automated slide/cassette feeder allowing unattended processing of 175 slides. The system is specifically designed for automated microscopy and is capable of operating in a networked fashion in large clinical laboratory settings on a 24/7 basis. Image capture is performed through a monochrome CCD camera offering high sensitivity and resolution as well as high-speed image acquisition. Prior to slide processing an exposure setting procedure ascertains proper signal intensity for acquisition and processing. Highly optimized image analysis algorithms provide automated counting of the number of FISH signals for each chromosome. The viewer software component of the system displays 10x images of all fields scanned, and 100x images of nuclei and the FISH signals within them for all nuclei automatically chosen for high magnification analysis. These results are displayed, along with the automatically determined FISH signal quantitation, and an interactive set of tools to assist the cytogeneticist in confirming the number of FISH signals present. In a preliminary study of 30 slides prepared for conventional interphase FISH analysis of amniocentesis samples, the system demonstrated its potential for providing FISH counting results highly correlated with fully manual assessment. In addition to improving the ease of undertaking FISH based assays and the quality of data generated, this platform has the potential to improve both the sensitivity of FISH analysis and the accuracy of the result produced.

9p subtelomere deletion: pathogenic mutation or normal variant? *C. Techakittiroj¹, K. Kim¹, H. Andersson^{1,2}, J. Thoene^{1,2}, M. Li^{1,2}.* 1) Hayward Genetics Ctr, Tulane Univ Medical Sch, New Orleans, LA; 2) Departments of Pediatrics, Tulane University Health Science Center, New Orleans.

FISH using chromosome-arm-specific subtelomere probes has proven to be a powerful tool in identifying cryptic chromosome rearrangements among patients with multiple congenital anomalies (MCA) and/or mental retardation of unknown causes. We report a patient with MCA and an inherited deletion of 9p subtelomeric region. The patient was a newborn boy with prenatal history of polyhydramios, cystic hygroma, and IUGR. At birth, he was noted to have a flat face, bilateral anotia, skin pits and tags along the mandible, webbed neck, undescended left testis, arachnodactyly, bilateral arthrogryposis, meconium ileus and peritonitis. Echocardiogram revealed multiple cardiac anomalies including type two truncus arteriosus and total anomalous pulmonary venous return. MRI showed abnormal brain development and fluid accumulation in the posterior fossa. High resolution chromosome studies displayed a normal male karyotype: 46, XY; however, subtelomere FISH studies revealed deletion of 9p subtelomeric region. Parental chromosome studies appeared normal; though, the mother, who is phenotypically normal, was found by subtelomere FISH to carry the same deletion as the baby. The 9p subtelomere deletion thus may not be responsible for the phenotype of the baby. Alternatively, the 9p subtelomere deletion could be responsible for the babys phenotype if further deletion and/or duplication had occurred during the transmission of the 9p subtelomere deletion from the mother to the child. Another possible cause of the childs MCA might be loss of heterozygosity due to an autosomal recessive gene mutation at the paternal 9p subtelomeric region. Molecular studies comparing the 9p subtelomere deletion in the mother and in the child are needed to further illustrate the etiology of the MCA in this patient.

Isolated ambiguous genitalia with 46,XY,del(11)p13 karyotype. *L. Telvi*¹, *C. Bouvattier*², *C. Nezelof*¹, *J.P. Barbet*¹, *P. Bougneres*². 1) Cytogenetics Laboratory, Hopital St Vincent de Paul, Paris, France; 2) Pediatrics Department, Hopital St Vincent de Paul, Paris, France.

We report a child with 46,XY,del(11)(p13)(RHG)(RTBG) karyotype. He showed ambiguous genitalia and no ocular, no renal abnormalities. The patient was born on 7.22.1987, to non consanguineous parents after 40.5 weeks of gestation. The birth length and weight were 46.5 cm and 2600 g respectively. At birth, the patient presented with a 18x10 mm genital bud, fused and striated labioscrotal folds, bilateral cryptorchidism and no palpable gonads, no uterus, no vagina. The SRY gene was found present after FISH technique. At five months, the patient was operated for feminizing genitoplasty. Two small (10x8x4 mm) testis was taken and found histologically normal. The patient presented retarded psychomotor development with an IQ = 73. No mutation was found for androgen receptor (exons 1&8). The parents and the older sister and brother were clinically normal. The WT1 gene located at chromosome 11p13 is required for normal genitourinary system. Mutations of the WT1 gene usually leads to WAGR syndrome, Denys-Drash syndrome or Frasier syndrome. Mental retardation, genitourinary, ocular and renal abnormalities or gonadoblastoma are frequently associated with these syndromes. This patient presented with a deletion at 11p13 site showed isolated genitourinary anomalies. We compare this patient to all reported cases.

Dual Structural Alterations in a Case with Angelman Syndrome. *J.H. Tepperberg, H. Waters, I. Gadi, S. Griffin, L. Wisniewski, P.R. Papenhausen.* Dept Cytogenetics, Laboratory Corp of America, Res Triangle Pk, NC.

We report a cryptic complex karyotype in a 1.2 year old female referred with non-specific developmental delay. Chromosome analysis showed a supernumerary ring-like marker chromosome in 16 of 21 metaphases examined. The remaining cells appeared to be normal. Parental studies are pending. Ring chromosomes are generally mitotically unstable, as is in this case, and the amount of euchromatin can vary considerably. Although euchromatin origin can usually be ascertained, prognosis is often difficult. A Multiprobe alpha satellite pericentromeric FISH device (CytoCell, Inc.) was used to identify the marker chromosome and showed that the marker chromosome was derived from chromosome 15. Additional FISH to rule out a trisomy or tetrasomy dosage effect using a SNRPN DNA probe (15q11.2), showed that the supernumerary chromosome 15 was SNRPN negative. Surprisingly, one of the chromosome 15 homologues showed a chromosome 15q11.2 SNRPN deletion in all cells examined. Reverse transcription PCR showed that the SNRPN transcript was present, and is thus consistent with a diagnosis of Angelman syndrome. The ring chromosome, to our knowledge appears to be benign. A plausible theory is that a meiotic I unequal exchange between the homologues of the maternal chromosome 15 resulted in the formation of a duplication 15q on one homologue and a deletion on the second. Subsequently, ring formation occurred from the duplicated chromosome, with breakage proximal to SNRPN, and concomitant non-disjunction. This would ultimately result in the observed chromosome complement.

An XX male carrier of the SRY gene with skewed inactivation of the normal X chromosome. *M.A. Thomas^{1,2}, A.M.V. Duncan^{2,3,4}, R. Fetni^{3,4}.* 1) F. Clarke Fraser Clinical Genetics Unit, Division of Medical Genetics, Department of Pediatrics, Montreal Children's Hospital, Montreal, Quebec, Canada; 2) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 3) Department of Pathology, Montreal Children's Hospital, Montreal, Quebec, Canada; 4) Department of Pathology, McGill University, Montreal, Quebec, Canada.

Introduction: One cause of XX maleness is the presence of the testis determining SRY gene on one of the X chromosomes, due to a recombination between the X and Y chromosomes during paternal meiosis. Ninety percent of these individuals have normal male external genitalia, however, some have ambiguous genitalia or are true hermaphrodites. Differential inactivation of the X chromosome carrying SRY and the size of the translocated SRY region have been suggested as the major mechanisms for this phenotypic variability. **Case:** We present a 36-year-old male who was found to have azoospermia during an evaluation for infertility. Hormonal testing demonstrated hypergonadotropic hypogonadism. Chromosomal analysis showed a 46, XX karyotype. FISH studies confirmed the presence of SRY in the terminal part of Xp. The X-inactivation pattern was analyzed in 50 lymphocytes by replication studies, combined with FISH, and showed more than 90% of the normal X was late replicating, and therefore, inactivated. **Discussion:** Although the SRY gene plays a critical role in male differentiation, there are XX male carriers of SRY who have ambiguous genitalia or are true hermaphrodites. This has raised the question of whether there is another factor that contributes to male differentiation in XX males. Skewed inactivation of the X chromosome carrying the translocated SRY gene has been found in true hermaphrodites and individuals with ambiguous genitalia. Our case demonstrates a male with normal external genitalia who has skewed inactivation of the normal X, thus allowing sufficient SRY expression for male differentiation. This assumes that the gonadal cells demonstrate the same distribution of X-inactivation as lymphocytes.

Phenotype and origin of two subtelomeric deletion/duplication of 1q/1p and 16p/16q. *F. Tihy, J. Michaud, E. Lemyre.* Dept Genetics, Hosp Ste-Justine, Montreal, PQ, Canada.

Duplication/deletion chromosomal rearrangements are often described as the result of meiotic recombination in the gametes of pericentric inversion carriers. With the use of sub-telomeric probes in fluorescent in situ hybridization, cryptic dup/del rearrangements can now be detected.

We diagnosed two such cryptic dup/del rearrangements: one involving the subtelomeric regions of chromosome 1 and the other of chromosome 16. Those particular rearrangements and their phenotypes have not yet been described to our knowledge. In the first case, a subtelomeric dup 1p/del 1q was diagnosed in a boy with moderate developmental delay, microcephaly, corpus callosum hypoplasia, hypopituitarism, pre-auricular pit, bifid uvula, aplasia cutis, an ASD, and a VSD. The mother carried a semi-cryptic inversion involving both subtelomeric regions. She previously had a phenotypically normal son. With the length of chromosome 1, there is probably as much chance to have an even number of crossing over resulting in a balanced gamete or an odd number of crossing over leading to an unbalanced gamete. The second patient was diagnosed with a del 16p/dup 16q. His phenotype involved moderate mental retardation, hypertelorism, Pierre Robin sequence, laryngomalacia, ASD, primary arterial pulmonary hypertension and C2-C3 subluxation. This rearrangement occurred de novo and was not the recombinant of an inversion.

In both cases the findings of the cryptic del/dup allowed proper genetic counselling for the families.

De novo isodicentric X chromosome: 46,X,idic(X)(q24). A. Tsai¹, C. Rawlinson¹, C. Walton¹, L. McGavran², J.P. Johnson³. 1) Div Clinical Gen & Metabolism, Childrens Hosp, Denver, CO; 2) Colorado Genetics Laboratory, Denver, CO.; 3) Shodair Childrens Hospital Genetics Laboratory, Helena, MT.

We present a 9-year-old patient with a de novo isodicentric X chromosome, karyotype of 46,X,idic(X)(q24), noted to have normal growth and development, and no dysmorphic features. Comparison of the proband with previously reported patients with an isodicentric X chromosome, of various breakpoints in Xq, showed that many patients have characteristic features as a result of the isodicentric X chromosome. These include a range from normal phenotype, the lack of secondary sexual characteristics development, secondary amenorrhea, and primary amenorrhea with unpredictable ages of onset. The X-inactivation study on peripheral blood revealed 99% inactivation of the isodicentric X chromosome. This patient demonstrates the absence of unusual physical characteristics associated with an isodicentric X chromosome in late childhood which has not been reported before, as well as the importance and need for further characterization by molecular and cytogenetic studies in patients with an isodicentric X chromosome.

Unbalanced 16;22 translocation leading to multiple anomalies and the -thalassemia trait in an Acadian patient. F.

*Tsien*¹, *A. Talariski*^{1, 2}, *M. Marble*^{1, 2}. 1) Genetics, LSU Health Sciences Center, New Orleans, LA; 2) Children's Hospital of New Orleans, New Orleans, LA.

Alpha-thalassemia occurs predominantly in populations of Mediterranean, African, or Southeast Asian descent. There are two duplicate copies of the α -globin gene located on the short arm of each chromosome 16, for a total of four α -globin loci. Patients with α -thalassemia trait are typically asymptomatic and have deletion of two α -globin genes. In the Mediterranean and Southeast Asian populations the deletions are usually in *cis* while in the African American population, the deletions are typically in *trans*. We present a 3-year old Southwestern Louisiana Acadian patient with a history of transient anemia, mild synophrous, prominent forehead, downslanting palpebral fissures, bowed upper lip, ectrodactyly and syndactyly of the toes, atrial septal defect, seizures, and developmental delay. Chromosomes appeared normal. Southern blot revealed a deletion of two α -thalassemia genes in *cis*. Fluorescent *in situ* hybridization (FISH) with subtelomere probes showed the presence of a derivative 16 chromosome. The der(16) resulted from a translocation between 16p and 22q, causing monosomy for the 16p13.3 and trisomy for 22q13.3. Previous reports of 16p subtelomere deletions have shown minimal phenotypic effects. Since our patient's translocation involves the 16p subtelomere, it is likely that his multiple anomalies are due to trisomy in the 22q subtelomere region. Phenotype/cytogenetic correlations in previous reports of 22q trisomy have usually involved a larger portion of the 22q, and the overlapping effects from the other involved chromosome, making it difficult to delineate a specific phenotype associated with trisomy for this region. Further reports of trisomy for the 22q subtelomere region should help determine if there is a consistent phenotype. Patients who are found to have α -thalassemia trait due to deletion of two α -globin genes in *cis*, but are not a member of an ethnic group in which this typically occurs, should have molecular and cytogenetic evaluations including subtelomeric FISH, especially if multiple anomalies and developmental delay are also present.

Partial trisomy of 16q and partial trisomy of Xq in a girl with 47,XX,+der(X)t(X;16)(q10;q10?). *C. Uria Gomez*^{1,2}, *G. Arteaga Ontiveros*², *E. Blanco Aguirre*³, *M.J. Gonzalez Gutierrez*². 1) Dept Genetics, Inst Natl de Perinatologia, Mexico, Mexico; 2) Genecon Diagnostico Laboratorio, Toluca Mexico; 3) Hospital General Adolfo Lopez Mateos, Toluca Mexico.

Partial trisomy of chromosome 16q is an uncommon chromosome disorder, and association with partial trisomy Xq is a rare event. Patients with only partial trisomy 16q show dysmorphic features and multiple congenital anomalies such as distinctive facies, mental retardation, vertebral, genital and anal abnormalities, cleft palate, renal anomalies and camptodactyly. X inactivation is random but in cases of carriers of unbalanced X;autosome translocation the abnormal chromosome is almost always inactivated. We present a two months-old girl who was referred to us for cytogenetic analysis because she presented dysmorphic features. Chromosomal analysis in peripheral blood lymphocytes with GTG bands showed 47,XX,+der(X)t(X;16)(q10;q10?) in all the metaphases. Parental chromosomes appeared normal. Derivative chromosome was further confirmed with C-bands and FISH using whole chromosome paints for 16 and X. Additionally we use centromeric probe for the X, and a signal in the derivative chromosome and in both X chromosomes was observed. This is an unusual chromosome abnormality. To our knowledge there are no reports about an association between partial trisomy 16q and Xq. We discuss the cytogenetic findings and the abnormal phenotype, but further studies to determine the role of X inactivation on the resulting phenotype as well as association of 16q trisomy in this patient will be necessary to characterize phenotype-karyotype correlation.

Position effects due to chromosome breakpoint mapping ~1 Mb upstream and ~1.3 Mb downstream of *SOX9* in two cases with Campomelic dysplasia. *G.V.N. Velagaleti*^{1,2}, *G. Bien-Willner*³, *J.K. Northup*², *L.H. Lockhart*¹, *S.M. Jalal*⁶, *J.R. Lupski*^{3,4,5}, *P. Stankiewicz*³. 1) Depts. Pediatrics, and; 2) Pathology, Univ Texas of Medical Branch, Galveston, TX; 3) Depts. Molecular & Human Genetics, and; 4) Pediatrics, Baylor College of Medicine, Houston, TX; 5) Texas Children's Hospital, Houston, TX; 6) Dept. Pathology, Mayo Clinic, Rochester, MN.

Campomelic dysplasia (CD) is a semilethal skeletal malformation syndrome with or without XY sex reversal. In addition to multiple mutations within the *SOX9* gene on 17q24.3, several chromosome translocations and inversions with breakpoints scattered over 1 Mb upstream to *SOX9* leading to haploinsufficiency have been described (Pfeifer et al. 1999). Here, we present an apparently balanced translocation t(4;17)(q28.3;q24.3), segregating in a family with a mild acampomelic CD and Robin sequence. Both breakpoints have been identified by FISH within single BAC clones. The 17q breakpoint maps ~ 0.9 Mb upstream of *SOX9*, which is within the same BAC clone as in the previously reported case. A somatic cell hybrid has been generated in our case and the breakpoint is being currently sequenced. DNA sequence analysis of the 17q breakpoint revealed a region conserved in human, chimpanzee, and mouse and candidate transcripts have been identified. Interestingly, Jamshidi et al. (2004) reported an isolated Robin sequence in a family segregating with a balanced translocation t(2;17)(q24.1;q24.3). The 17q breakpoint in this family maps very close to our breakpoint. We also report a prenatal identification of acampomelic CD with a male to female sex reversal in a fetus with a de novo apparently balanced complex karyotype 46,XY,t(4;7;8;17)(4qter->4p15.2::17q25->17qter;7qter->7p15::4p15.2->4pter;8pter->8q12.2::7p21.2->7pter;17pter->17q25::8q12.2->8qter). All breakpoints have been mapped within single BAC clones. Surprisingly, the 17q breakpoint maps ~1.3 Mb downstream of *SOX9*. This is the first report of CD with the chromosome breakpoint mapping distal to *SOX9*. We discuss the possible molecular mechanisms responsible for the position effect.

Sequencing of the breakpoint junction fragments of an X;autosome translocation in a female with Duchenne muscular dystrophy. *A.M. Vianna-Morgante, I.E. Kerkis, A.C.V. Krepischi-Santos.* Departamento de Biologia, Instituto de Biociências, Universidade de São Paulo, São Paulo, Brazil.

We sequenced the breakpoints of a de novo balanced translocation $t(X;22)(p21.1;q13.1)$, ascertained through a female with Duchenne muscular dystrophy (DMD), aiming at disclosing the mechanism originating the rearrangement. The derivative X chromosome was of paternal origin and was shown to be always active. Breakpoint mapping was performed by FISH and DNA analyses in the patients cells and in somatic cell hybrids. The X chromosome breakpoint was mapped to intron 47 in the *DMD* gene (Xp21.1), contained in BAC RP11-607K23. The *DMD* gene disruption in association with the inactivation of the normal X led to the dystrophy phenotype. Chromosome 22 breakpoint was mapped to a sequence cloned in BAC RP11-60G6, and then located between genes *GRAP2* and *BC031099*. The junction fragments of both derivative chromosomes were cloned by PCR using primers constructed with reference to chromosome X and 22 sequences flanking each mapped breakpoint. The exchange sites on chromosomes X and 22 have in common two adjacent base pairs (GC). Comparison of the junction sites with the sequences on the normal chromosomes revealed the loss of six base pairs, four from chromosome 22 as well as two of the shared GC pairs. The two remaining GC pairs are on the der(22). Nonhomologous end-joining then appears as the mechanism originating this translocation. (This study was supported by FAPESP and CNPq).

Analysis of an add(21)(q22.2) characterized as der(21)t(1;21)(q42.1;q22.2) by fluorescence *in situ* hybridization in a patient with mental retardation and primary amenorrhea. D.T. Walsh¹, K.H. Ramesh¹, V.R. Pulijaal¹, M. Zohouri¹, R.A. Conte¹, D. Wei¹, T. Zhou¹, A.R. Deshikar¹, R. Freeman², L.A. Cannizzaro¹. 1) Department of Pathology, Montefiore Medical Center, Bronx, NY; 2) Department of Ob/Gyn, Montefiore Medical Center/Albert Einstein College of Medicine, Bronx, NY.

Chromosomal studies were conducted on a 30 year old patient presenting with primary amenorrhea. Other clinical features include mental retardation; IQ of 38, the patient is nonverbal but responsive to verbal commands. Additionally, a systolic heart murmur was detected and endocrinological testing revealed elevated gonadotropin levels, consistent with ovarian failure. A pelvic ultrasound indicated a very small uterus and underdeveloped ovaries. High-resolution peripheral blood chromosomal analysis revealed an abnormal female karyotype, with an abnormal chromosome 21 having additional chromosomal material of unknown origin at band q22.2. This additional material was further characterized by fluorescence *in situ* hybridization (FISH) as being derived from the terminal end of the long arm of chromosome 1 (1q42.1-1qter). FISH and GTG results indicate the karyotype of this patient to be: 46,XX,add(21)(q22.2).ish der(21)t(1;21)(q42.1;q22.2)(wcp1+,D1S378+,wcp21+,VIJyRM2029-). The patient is trisomic for 1q42.1-1qter and monosomic for 21q22.2-21qter regions. Confirmation of the der(21), whether it was de novo or due to malsegregation of a parental t(1;21)(q42.1;q22.2) could not be established, as her parents were not available for cytogenetic evaluation. Primary amenorrhea has often been linked with X chromosome anomalies, especially X-autosome translocations, indicating a role played by genes present in the X chromosome in the development of ovaries. This study and other reported autosomal translocations support the idea that the genes present in autosomes may also play a role in gonadal development.

Array-CGH characterization of an inversion duplication of chromosome 5p in a patient with congenital defects.

J.C. Wang¹, B.P. Coe², B. Lomax¹, P. MacLeod³, M. Parslow³, W.L. Lam², P. Eydoux¹. 1) Cytogenetics, Children's and Women's Hosp, Vancouver, B.C; 2) B.C. Cancer Agency, Vancouver, B.C; 3) Pathology and Medical Genetics, Victoria General Hospital, Victoria, B.C., Canada.

Inverted intrachromosomal duplications of chromosome 8p and 2q have been well characterized. In contrast, inverted duplication of chromosome 5p has rarely been reported and the causing mechanism is unknown. A 4-year-old boy with language and motor skill delay was studied. He initially presented as a premature newborn at 32.5 weeks with congenital anomalies including hypotonia, failure to thrive, seizures, and pre-auricular skin tags. The parents were non-consanguineous and there was no contributing family history. Karyotyping revealed a de novo rearranged short arm of chromosome 5. FISH analysis using subtelomeric and cri-du-chat critical region probes demonstrated a deletion in the subtelomeric region, while the cri-du-chat region (5p15.2) was duplicated. Comparative Genomic Hybridization (CGH) showed a gain in the 5p14-5p15.2 region and a probable loss within 5p15.3. Sub-Megabase Resolution Tiling-set (SMRT) array-CGH (aCGH) was used to further characterize this rearrangement. The deleted region spanned from the telomeric region to the distal part of 5p15.31, while the duplication concerned the proximal region of band 5p15.31 to the distal end of 5p14.3. This result was further proven using FISH with BAC probes mapping to the breakpoint regions. This study illustrates the power of aCGH for the characterization of chromosomal rearrangements. In a one-step experiment, we were able to narrow down the deleted and duplicated regions of chromosome 5p, and to locate the breakpoints within a region covered by a small number of BACs, thus allowing further FISH experiments for precise location. These results were consistent with inversion-duplication occurring in this chromosomal region. Using the human genome data, this approach will allow rapid identification of genes potentially responsible for the phenotype. Further characterization of the breakpoints may also uncover underlying genomic features, such as duplicons, explaining the occurrence of this rearrangement.

Prenatal diagnosis of a fetus affected with Down syndrome and deletion 1p36 syndrome by fluorescence in situ hybridization and spectral karyotyping. *B. Wang¹, L-J. Hsieh¹, T-C. Hsieh², G-P. Yeh², M-I. Lin¹, M. Chen^{1,2,3}.* 1) Ctr Medical Genetics, Changhua Christian Hosp, Changhua, Taiwan; 2) Dept. Obstetrics and Gynecology, Changhua Christian Hosp, Changhua, Taiwan; 3) Dept. Obstetrics and Gynecology, National Taiwan University Hospital, Taiwan.

A fetus having partial trisomy of the distal part of chromosome 21q due to a de novo translocation is reported here. A 29-year-old woman received amniocentesis at 18 weeks of gestation because of abnormal ultrasound findings including bilateral choroid plexus cysts, atrioventricular septal defects, rocker-bottom feet, and possible hydrocephalus. Cytogenetic analysis revealed 46,XY, add (1)(p36.3), in which an additional material of unknown origin was attached to one of the terminal short arm of chromosome 1. Parental blood studies showed normal karyotypes in both parents. Spectral karyotyping (SKY) was then performed and the origin of the additional material locating at chromosome 1p was found to be from chromosome 21. Conventional FISH analysis was also used and confirmed the SKY findings by use of a chromosome 21 specific painting probe, a locus specific probe localized within bands 21q22.13-q22.2 and a 21q subtelomeric probe. A hidden Down syndrome caused by a de novo translocation in this fetus was therefore diagnosed and the karyotype was designated as 46,XY, der(1)t(1;21)(p36.3;q22.1) .ish der(1)(WCP21+, LSI 21+, 1pTEL-, 21q TEL+) de novo. Clinical features of the 1p36 deletion syndrome are also reviewed and may contribute to some features of this fetus. Termination of pregnancy was performed at 20 weeks of gestation. To our knowledge, our case appears to be the first case having partial monosomy 1p and partial trisomy 21q caused by de novo translocation being diagnosed prenatally.

Molecular delineation of two chromosomal abnormalities in autism. *T.H. Wassink¹, V.C. Sheffield^{2,3}, J. Piven⁴, S.R. Patil².* 1) Dept Psychiatry, Carver Coll Med, Univ Iowa, Iowa City, IA; 2) Dept Pediatrics, Carver Coll Med, Univ Iowa, Iowa City, IA; 3) Howard Hughes Medical Institute; 4) Dept Psychiatry, Univ North Carolina, Chapel Hill, NC.

Autism is attributable to chromosomal abnormalities in at least 5% of cases; we describe here two such cases. Case 1 is a male, the older of two affected siblings. He has mild mental retardation, impaired fine motor skills, and slightly dysmorphic facial features (wide-set eyes and depressed nasal bridge). His language development was delayed, his social activity is limited, he has circumscribed interests, and he engages in verbal rituals and compulsions. His younger sibling has more severe language impairment and social dysfunction, and his mother experienced language delay and problems with articulation. The patient was found through participation in a linkage study to have maternally derived disomy of chromosome 1. Follow-up genotyping of densely spaced polymorphic markers showed that the chromosome was primarily heterodisomic except for two regions of isodisomy attributable to recombination. Case 2 is a singleton male with autism found to have an interstitial 13q deletion [46,XY,del(13)(q33.2q34)]. This patient experienced significant delays in the development of language and social behavior. His articulation is poor, his vocabulary limited, and his expressive language has not yet progressed beyond single words. The extent of the deletion was narrowed using polymorphic markers to a 7 MB interval near the end of 13q. The relationships of these abnormalities to other findings in autism, and additional candidate genes that they suggest, are discussed.

Trisomy 8 mosaicism, a new case of the old syndrome. *J. Watts¹, M. Janes¹, J. Xu².* 1) Pediatrics; 2) Pathology and Molecular Medicine and Lab Medicine, Hamilton Health Sciences and McMaster University, Canada.

A male infant was born at 26 weeks gestation, weight 810 gm. Fetal ascites and abdominal calcification were present on antenatal ultrasound. Cytogenetics analysis of cultured blood taken at age of 6 days showed a trisomy 8 mosaicism; 47,XY,+8[7]/46,XY[23]. The cultured cells of the skin tissue from abdomen at 3 months and 17 days revealed trisomy 8 in all 30 cells examined. The cultured blood cells taken at age of 5 months and 24 days showed a normal male karyotype in all 30 cultured cells. He developed intestinal obstruction due to malrotation requiring a Ladd procedure, complicated by necrotising enterocolitis, and prolonged feeding problems necessitating gastro-jejunal feeds. Gastric emptying was virtually absent. He was dysmorphic with long ears, dysplastic pinnae with bilateral superior points and small external auditory meatus, a small pointed nose, clinodactyly of both 5th fingers and hypoplastic toenails. Partial agenesis of the corpus callosum, left-ventricular non-compaction, an atonic bladder and cataracts were present. As a consequence of prematurity, he had broncho-pulmonary dysplasia, intraventricular hemorrhage leading to a porencephalic cystic, and detached retinae from retinopathy of prematurity. Hypothyroidism was present, possibly due to prematurity. Multiple episodes of sepsis occurred. While clinical findings of trisomy 8 syndrome have been documented in more than 100 cases, dysmotility as found in the present case is not commonly described. Although surgical events may have played a role, its severity in this case together with the bladder atonia, suggests an underlying neuromuscular functional abnormality as a consequence of the chromosomal anomaly. In addition, ventricular non-compaction is a new finding, and may account for cardiac failure in previous cases where major anatomic defects were absent.

An unbalanced translocation involving 15q11.2 in a phenotypically normal individual. *L. Wisniewski, P. Papenhausen, J. Tepperberg, I. Gadi, P. Singh-Kahlon, E. Cantu.* LabCorp, Research Triangle Park, NC.

A 34 year old phenotypically normal male was referred for chromosome analysis due to a history of recurrent miscarriage. GTW banding revealed an unbalanced translocation between the long arm of chromosome 15 and the short arm of chromosome 20, 45,XY,-15,der(20)t(15;20)(q11.2;p13). There was no evidence of mosaicism for the balanced form. C banding confirmed that the derivative was monocentric. The G banding pattern clearly suggested loss of material from bands 15q11.2 and/or 20p13. Absence of clinical abnormalities associated with Prader-Willi/Angelman syndromes lead to the investigation of distal 20p with the subtelomere probe D20S1157(Vysis, Inc.). However, a normal 20p subtelomere signal was evident, prompting the conclusion that the 20p breakpoint was localized in the telomere sequences. Examination of proximal 15q with SNRPN and D15S10 revealed that these loci were also intact. Presumably, the material deleted due to the translocation was confined to the short arm, centromere and proximal pseudogene segment proximal to SNRPN. Duplication of this material has previously been reported as having no clinical effect. This case illustrates the importance of fully characterizing unusual rearrangements with available flanking FISH markers before finalizing the interpretation of their clinical interpretation. Unbalanced structural rearrangements involving proximal 15q are frequently associated with Prader-Willi/Angelman syndromes due to partial deletions. However, assessing band 15q11.2 visually with conventional banding is problematic. In the present case, the patient's phenotype clearly did not support the expected phenotype/karyotype correlation of a known microdeletion syndrome. The alternative clinical interpretation, that of mental retardation/developmental delay due to a presumed terminal deletion of 20p, was also shown to be incorrect by the results of subtelomere FISH.

Molecular cytogenetics characterization of trisomy 13/trisomy 18 mixoploidy in a boy with moderate clinical features. *J. Xu*^{1,2}, *T. Heshka*^{2,3}, *D. Whelan*^{1,2}, *J-X. Cui*⁴, *F-Y. Han*⁴, *Y-G. Xie*⁴. 1) Pathology & Molecular Medicine; 2) Lab Medicine; 3) Pediatrics, Hamilton Health Sciences and McMaster University, Hamilton; 4) Lab Medicine, Memorial University, Newfoundland, Canada.

We present a case with trisomy 13/trisomy 18 mosaicism in a newborn baby boy. The proband was born at 40 3/7 weeks of gestation to a 25 year old G2T2L2. The patient has postaxial polydactyly bilaterally of the hands and of the right lateral toe. The patient also has a prominent nasal bridge, hypertelorism, epicanthic folds, low set ears, a right abducted thumb and hypospadias. Ultrasounds of the head, spine and kidneys were normal. An echocardiogram revealed a patent ductus arteriosus. The patient is presently 4 years old. He can walk with a walker and drink from an open cup. His height and weight are below the 3rd centile. Cytogenetics study of peripheral blood revealed an abnormal male karyotype in all cells; 47, XY,+13[9]/47,XY,+18[21]. This double trisomy mosaicism was confirmed in a repeat blood sample showing 47,XY,+13[15]/47,XY,+18[40] and a skin tissue showing 47,XY,+13[22]/47,XY,+18[28]. The parents have a normal karyotype. A preliminary analysis of DNA polymorphism shows that the extra chromosome 13 was resulted from maternal meiosis I nondisjunction. Further study is underway to determine a) the parental origin and stage of nondisjunction for the extra chromosome 18; and b) mosaicism vs. chimera. This is the 5th case of trisomy 13/trisomy 18 mixoploidy and is characterized by moderate clinical features. The mother went on to have a normal male child. We hypothesize that the mix of these two trisomies might help alleviate lethal effects from each individual trisomy, which might account for the finding of moderate clinical features in our patient.

Opitz Trignocephaly C syndrome in a patient with a 9q34.3 monosomy: phenotype variation by deletion size.

S.A. Yatsenko¹, S.W. Cheung¹, D. Scott¹, M. Tarnopolsky^{4,5}, S. Naidu^{7,8}, G. Bibat⁸, M.J.M. Nowaczyk⁶, A. Patel¹, F. Scaglia^{1,3}, P. Stankiewicz¹, J.R. Lupski^{1,2,3}. 1) Depts of Molecular & Human Genetics; 2) Pediatrics, Baylor College of Medicine; 3) Texas Children Hospital, Houston, TX; 4) Depts of Pediatrics; 5) Medicine; 6) Pathology and Molecular Medicine, McMaster University, Hamilton, Ontario; 7) Johns Hopkins University, Baltimore, MD; 8) Kennedy Krieger Institute, Baltimore, MD.

We identified five unrelated patients with 9q34.3 deletions, including one patient with the clinical diagnosis of Opitz Trignocephaly C syndrome (OTCS). Several individuals with 9q34.3 deletions have been reported recently in association with recognizable facial dysmorphism, mental retardation, speech delay, hypotonia, microcephaly, and early childhood obesity. OTCS is a rare and believed to be autosomal recessive disorder but of unknown etiology; characterized by trigonocephaly, flat, broad nasal bridge with the short nose, an abnormal deeply furrowed palate, polysyndactyly, short limbs, hip dislocation, heart defects, cryptorchidism, hypotonia, and midline brain anomalies. The patients described herein have *de novo* terminal 9q34.3 deletions detected by high-resolution cytogenetic and/or molecular analyses. We mapped the deletions size within overlapping BAC clones by FISH analysis. These deletions showed heterogeneity in the location of the breakpoints and variation in size. We found that, dysmorphic features, **hypotonia, obesity, microcephaly**, delay or absence of expressive speech (HOMS syndrome) observed in the 9q34.3 deletion are characteristic and present in four of our patients, regardless of deletion size. Cardiac defects, seizures, limb and brain anomalies have been detected in patients with larger deletions. The patient with the OTCS has been found to have the largest deletion and the most severe phenotype. Our results suggest that OTCS may represent a complex phenotype due to haploinsufficiency of several genes within chromosome 9q34.3. We propose that 9q34.3 monosomy results in either HOMS syndrome or OTCS depending on the extent of deletion. Critical regions and candidate genes for this newly defined contiguous gene syndrome are discussed.

Congenital anomalies in an infant with a small interstitial deletion on the short arm of chromosome 7. A.

Yenamandra¹, M. Liu¹, E. Holland¹, S. Shelly¹, V.G. Dev¹, M. Cohen², R. Hamid², G.E. Tiller². 1) Genetics Associates, Nashville, TN; 2) Div Med Genetics, Vanderbilt Univ Sch Med, Nashville, TN.

The patient was a female fraternal twin delivered at 33 weeks gestation to a 40 year old G3P2 mother. The male twin was unremarkable, however the patient presented with intrauterine growth retardation, mild dysmorphic features, and a two-vessel umbilical cord. Chromosome analysis of peripheral blood cells revealed 46,XX, del(7)(p14.3p15.2). Chromosome 7 painting did not support a complex rearrangement or translocation. Postnatal evaluation revealed a patent ductus arteriosus, bilateral vesicoureteral reflux, and failure to thrive. At 7 weeks of age, her growth parameters were at the 50th percentile for 34 weeks gestation. Dysmorphic features included microcephaly, patent anterior and posterior fontanelles, flat facial profile with mild frontal bossing, short palpebral fissures and periorbital fullness, upturned nares with flat nasal bridge, smooth philtrum, small lowset pointed ears with prominent antihelix, small mouth and chin with slightly highly-arched palate, umbilical hernia, and slightly prominent clitoris. Thumbs were proximally placed with decreased flexion of the interphalangeal joints; toes 2-4 showed partial syndactyly, were proximally placed, and had a hammertoe configuration. A CT study of the skull failed to demonstrate craniosynostosis.

Five cases have been reported in the literature with deletions of 7p13p15. This case highlights an exceptionally small deletion of 7p which shares a few clinical findings with other patients carrying larger 7p deletions: growth and developmental delay, proximal insertion of thumbs, syndactyly of toes, and absence of significant cardiac or skull anomalies (skull anomalies are observed only in distal deletions of 7p). We propose that the critical region for the common clinical findings we observed lies within 7p14.3 to p15.2.

Pathogenesis of the trisomy 16 placenta. *P.J. Yong*¹, *D.E. McFadden*², *C.D. MacCalman*³, *W.P. Robinson*⁴. 1) MD/PhD Program; 2) Departments of Pathology; 3) Obstetrics and Gynaecology; 4) and Medical Genetics, University of British Columbia, Vancouver, BC.

Trisomy 16 (t16) is the most common trisomy in spontaneous abortion (SA), and is associated with IUGR and preeclampsia (PE) when confined to the placenta in ongoing pregnancies. SA, IUGR and PE have been associated with poor uterine invasion by extravillous trophoblast (EVT) from placental chorionic villi (CV). Thus t16 EVT may be abnormal.

Placentas were obtained from SAs 6-13 wks gestation. Since SAs undergo tissue degeneration before expulsion or surgery, tissue culture was performed. CV explants were cultured on Matrigel, and EVT confirmed by immunohistochemistry (IC). EVT outgrowths from the explants were observed in only 5/20 cases 10 wks, but in 17/30 cases 10 wks ($p = 0.015$). For those cases 10 wks, EVT outgrowths occurred in 7/9 euploid (eu) cases compared to 0/4 t16 cases ($p = 0.021$). Since t16 EVT did not grow, protein expression was assessed in placental fibroblasts from 4 eu cases and 3 t16 cases. Fibroblasts were cultured from collagenase-digested CV explants, with maternal contamination and other cell types excluded by PCR and IC. Protein was extracted at the 3rd passage at 75% confluence, and the expression of 75 protein kinases profiled using a 2D Western blot (Kinexus Inc.). Five kinases (CDK1, CDK7, PKC-, S6K p70, IKK-) were underexpressed, and 2 kinases (PKG1, ERK1) overexpressed, in the t16 cases compared to the eu cases ($p < 0.05$). There was no confounding by gestational age. Of the 3 kinases with genes on chromosome 16 (CK2, PKC-, ERK1), only ERK1 was overexpressed in the t16 cases (~2x higher). A phosphoantibody to T202/Y204 showed ~3x higher levels of phosphorylated (activated) ERK1. In addition, the coefficient of variation (V) of each of the 75 kinases was calculated for the t16 and eu cases: greater variability in protein expression was seen among the t16 cases (mean V: 0.51 vs. 0.12, $p = 0.0015$).

In conclusion, a defect in EVT outgrowth and altered protein kinase expression may be implicated in the pathogenesis of the t16 placenta.

Mosaic X/XX/XXX male with atypical Klinefelter features. C.W. Yu¹, J. Sistrunk², Y. Yang¹, C. Thompson¹, C. Friedrich¹. 1) Dept Preventive Medicine, Univ Mississippi Medical Center; 2) Baptist Medical Center, Jackson, MS.

The estimated incidence of XX males is approximately 1 in 20,000 males (de la Chapelle 1972, 1981; Nielsen and Sillesen 1975). Several hypotheses have been offered to explain the male phenotype in the absence of a normal Y-chromosome in these males. We report a case of mosaic X/XX/XXX male with some features of Klinefelter syndrome and the causes of mosaicism. A 34-year-old white male was referred for infertility study. He had a total testosterone of 289 ng/dL, FSH of 34.5 mIU/ml, LH of 14.9 mIU/ml, and ACTH of 35 picograms/ml. Other than notable childhood asthma, there are no known genetic disorders in his family. His sperm counts showed azospermia and/or minimal sperm present. G-banded blood chromosomes revealed that 42 cells had 46 chromosomes with two Xs, 6 cells had 45 chromosomes with one X, and 2 cells had 47 chromosomes with three Xs. FISH was performed using LSI probes for SRY and Kallmann and alpha satellite DNA probes for X and Y centromeres. For the metaphases with 46 chromosomes, the SRY locus was present only in one of the X chromosomes while Kallmann and DXZ1 were seen in both X chromosomes. For the metaphases with 45 or 47 chromosomes, one copy of SRY, Kallmann and DXZ1, and one copy of SRY and three copies of Kallmann and DXZ1 were seen respectively. No DYZ1 locus was detected in any of the metaphases examined. Parental chromosome study was not available. Cytogenetic and FISH studies revealed that this patient has a normal X and a derivative X chromosome, resulting from a translocation of a partial Yp to the Xp terminal, in a majority of the cells. The breakpoint is around p11.3 for the Y and posterior to the Kallmann locus (p22.3) for the X. Furthermore, a non-disjunction of the normal X chromosome occurred during the somatic cell division to form the 45,X and 47,XXX cell lines. Thus the karyotype for this patient is: 46,X,der(X)t(X;Y) (p22.3;p11.3)/ 45,idem,-X/ 47,idem,+X. The presence of partial Yp material after the X/Y interchange accompanied by the somatic cell non-disjunction and non-random X inactivation in those cells with two or more X chromosomes probably accounts for the atypical features of the Klinefelter syndrome.

A patient with two isodicentric Y chromosomes and radioulnar synostosis. *A.L. Zaslav¹, J. Jacob¹, R. Kazi¹, D. Blumenthal², J. Fox².* 1) Dept Laboratory Medicine, Long Island Jewish Medical Ctr, New Hyde Park, NY; 2) Dept of Peds, Schneider Childrens Hosp, The Albert Einstein College of Medicine, New Hyde Park, NY.

Tetrasomy for the Y chromosome is rare. To our knowledge, only three cases of non-mosaic tetrasomy for the Y have been reported. Here we present a case of non-mosaic tetrasomy Y in a one-month-old male. Echocardiogram was normal. X-ray revealed left radioulnar synostosis. CAT scan of the head showed mild prominence of the Sylvian fissures, frontal temporal subarachnoid space and mild ventriculomegaly. Physical examination revealed radioulnar synostosis, which has been previously reported in phenotypic males with sex chromosome abnormalities. Peripheral blood chromosome analysis of 50 cells with GTG and C-banding revealed a karyotype of 47,X, idic(Y)(q12)x2. This was confirmed by FISH using the DYZ3 Y centromere probe and the Yp11.3, SRY probe recognizing the SRY region of the Y chromosome (Vysis, Downers Grove, IL). The father had a normal karyotype.

To our knowledge, non-mosaic tetrasomy for the Y chromosome has been previously reported in only three cases. There is a wide range of clinical and phenotypic variability among patients with this karyotype. A review of other non-mosaic tetrasomy Y cases and possible correlation between karyotype and phenotype will be attempted. This report will be helpful in determining the phenotype of patients with this rare chromosome abnormality.

A boy with an apparently balanced three-way translocation t(5;8;17) and autism. *L. Zwaigenbaum¹, T. Heshka^{1, 2}, J. Xu².* 1) Pediatrics; 2) Pathology and Molecular Medicine and Lab Medicine, Hamilton Health Sciences and McMaster University, Canada.

We report a 3 year and 8 month old boy with autism and a de novo, apparently balanced complex chromosome rearrangement. He was born following an uncomplicated pregnancy at 37 weeks gestation with a birthweight of 1880g (< 3rd percentile), and required initial support for respiratory distress, hypoglycemia, and feeding difficulties. All developmental milestones were delayed. He first walked at age 2 years, and remains essentially non-verbal at age 5 years. He has poor eye contact, lacks functional communication skills, does not participate in social interaction, and exhibits stereotyped behaviors and repetitive play interests. He meets criteria for a diagnosis of autistic disorder, based on structured clinical history using DSM-IV criteria, and assessment using the Autism Diagnostic Observation Scale at age 3 years. Physical examination did not identify any dysmorphic features. Notably, his younger brother has global developmental delay but not autism. Analysis by G-banding in combination with FISH and SKY revealed that the proband had an apparently balanced 3-way translocation t(5;8;17)(q31.1;q24.1;q21.3). Possibility of microdeletions in Angelman syndrome critical region in 15q11-q13 was ruled out by FISH using probes (GABRB3 and D15S10) and DNA methylation studies. The parents and his brother all had a normal karyotype by routine G-banding. The breakpoints 8q24.1 and 17q21 have been previously reported to be implicated in autistic spectrum disorder (ASD) and autism, respectively. Our case suggests that rearrangements at 5q31.1, 8q24.1 and/or 17q21.3 may predispose to ASD in addition to other clinical features.

Replication timing of different regions of the Y chromosome: A study by FISH using BACs. *S. Dubé^{1, 3}, R. Fetni⁴, N. Lemieux^{1, 2, 3}*. 1) Département de pathologie et biologie cellulaire, Université de Montréal, Montréal, Canada; 2) Département de pathologie, Hôpital Sainte-Justine, Montréal, Canada; 3) Centre de recherche de l'Hôpital Sainte-Justine, Montréal, Canada; 4) Department of pathology of the Montreal Children's Hospital, University McGill, Montreal, Canada.

Recent studies have showed that replication timing, i.e. the time when a locus is replicated, reflects gene expression. A gene which replicates early in S phase will be expressed in the cell, whereas a late replicating gene will not be expressed. Also, actively expressed genes seem to have a loose chromatin structure as opposed to inactive genes that show a more condensed chromatin organization. To date, few loci have been studied according to these two aspects. We hypothesized that a correlation between replication timing and chromatin condensation exists. The first objective of this study is to determine the replication timing of different regions of the Y chromosome. To reach this goal, we are using a FISH replication assay and bacterial artificial chromosomes (BACs) probes covering the Y chromosome. This variant FISH technique can determine the replication time of a DNA sequence in interphase nuclei of unsynchronized normal lymphocytes. An early replicating sequence shows a high percentage of double-dot signals, while a late replicating sequence mostly displays single-dot signals. So far, sequences mapping to bands Yq11.21 and Yq11.222 have been studied and showed a late replication timing. Therefore, these sequences would not be expressed in normal lymphocyte cells. With this project, in addition to determine the replication timing of important genes and regions of the Y chromosome, we want to establish the existence of replication domains and correlate these data with gene expression. Furthermore, we will study the possible link between replication time zones and chromatin organization by analyzing differential compaction of those sequences on the Y chromosome. Consequently, we will be able to see if chromatin structure and replication timing have an influence on the occurrence of preferential DNA rearrangements on the Y chromosome. *Supported by RMGA-FRSQ and the Fondation de l'Hôpital Sainte-Justine.*

Characterization of maternally derived aberration of chromosome 15q in a patient with autism. *D.A. Kwasnicka¹, W. Roberts², M. Li¹, S. Russell¹, S. Choufani¹, S. Scherer^{1, 3}.* 1) Department of Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, ON, Canada; 2) Department of Pediatrics, The Child Developmental Center, Toronto, ON, Canada; 3) Department of Molecular and Medical Genetics, University of Toronto, Ontario, Canada.

Autism is a severe neurodevelopmental disorder characterized by deficits in social interaction, disturbed communication and stereotype routines and interests. Evidence from twin and family studies supports the idea of a strong genetic etiology. Autism has been found in association with other medical conditions such as fragile X syndrome, phenylketonuria, Williams-Beuren syndrome, or neurofibromatosis type 1. Cytogenetic abnormalities in the Prader-Willi/Angelman syndrome (PWS/AS) critical region (15q11-13) have also been described in individuals with autism. Observations of maternal duplications affecting chromosome 15q11-13 in patients with autism and evidence for linkage disequilibrium in this region in autism families indicate the existence of a susceptibility locus. In this study we describe a 6-year-old girl diagnosed with severe autism, overall developmental delay, delayed expressive, and receptive language. The karyotype was designated 47, XX, idic(15)(q13). Parental karyotype was normal. Fluorescence in situ hybridization (FISH) using bacterial artificial chromosome (BAC) clones spanning the long arm of chromosome 15 showed that the patient has additional copy of 15q11-13 region. Molecular analysis of the proband and the parents using polymorphic markers within 15q11-q13 region confirmed FISH results and determined that the extra chromosome 15 material was maternal in origin. Duplication of the 15q11-13 segment represents the most consistent abnormality reported in association with autism. This case report reinforces the hypothesis that additional copies of this chromosome segment may be causally related to autism.

Program Nr: 963 from the 2004 ASHG Annual Meeting

Advanced Paternal Age Affects Recombination. *S.E. Schrump, T.J. Hassold.* Genetics, Case Western Reserve, Cleveland, OH.

Recombination between homologous chromosomes during meiosis I is required for proper chromosome segregation. In the absence of recombination or in situations where recombination is altered, chromosomes may nondisjoin, resulting in aneuploidy. We and others have been interested in knowing whether this factor is linked to the other agents known to be associated with aneuploidy, i.e. increasing parental age. Specifically, does the level of meiotic recombination change with age? While some information on this question is available from humans, data sets are small and the results contradictory. Thus, as a first step toward understanding this relationship, we have initiated studies of recombination and increasing age in the male mouse. Using a novel assay to detect recombination events, we examined the number of exchange events in males of three inbred strains, C57BL/BJ, Spret/EiJ, DBA/2J, in three age groups, young (2-5 months), middle aged (10-13 months), and old (18 months). Preliminary studies indicate a slight, yet significant increase in recombination with increasing age. Likewise, there is a slight increase in the variation of recombination events in these animals with increasing age. While preliminary, these data provide the first evidence to indicate a breakdown in the meiosis I checkpoint as males get older.

Measurement of chromosome specific telomere length on chromatin/DNA fibers. *J. Yan, E. Bouchard, B.Z. Chen, R. Drouin.* Dept Pediatrics/Medical Genetics, CHUS, Sherbrooke, PQ, Canada.

Human telomeres consist of tandem repeats of TTAGGG sequence that extends from 2 to 15 kb. The length of telomeric sequence plays important roles in maintaining chromosome stability. A number of attempts have been made by many investigators to measure the telomere length in different normal and cancer populations. The relative telomere length has been calculated either from certain cell lines in an overall manner using terminal restriction fragments (TRF) analysis or from the measurement of the fluorescence signal intensity on telomeres using quantitative FISH (Q-FISH) technique. However, the TRF does not yield information on individual chromosome ends, and the restriction enzymes used in Southern blot cleave at sites in the subtelomeric DNA that are at variable distance from the beginning of actual TTAGGG repeats. The Q-FISH approach is based on the calculations of the signal intensity of fluorescence, for which the measurement would rely on the hybridization efficiency and would be more or less affected by uneven fluorescence lightness in each single field under the microscope. We have developed a fiber-FISH technique for the direct measurement of individual telomere length. The PNA probe labeled with green for the telomere sequence and the probe specific for the 1q subtelomere sequence labeled with red, which serves as physical length reference, were co-hybridized on the chromatin/DNA fiber preparations. The results showed that the length of measurable telomere and subtelomere signals aligned on such fibers ranged from 0.9-2.9 μ m and 13.8-29 μ m, respectively, according to the stretching degree of the fibers. It implies that 3.4-7.2 Kb/ μ m (average 5.5 Kb/ μ m) of the physical length of the probes hybridized on such fibers. Using this technique, we demonstrated that the mean telomere length in the 1q from a lymphoblast cell line is 8.4 Kb with SD 1.9 Kb. This reflects a precise physical length for a particular telomere and can be used as a reference to determine all other telomere lengths that are measured from metaphase chromosomes by Q-FISH.

Hot spots for ectopic recombination in hominoid evolution: evidence from comparative cytogenetics of human chromosome 3. *Y. Yue*¹, *B. Grossmann*¹, *E. Tsend-Ayush*², *F. Gruetzner*², *M. Ferguson-Smith*³, *F. Yang*³, *T. Haaf*¹. 1) Inst Human Genetics, Mainz Univ Sch Med, Mainz, Germany; 2) Comparative Genomics Group, Australian National Univ, Canberra, Australia; 3) Centre for Veterinary Science, Cambridge Univ, Cambridge, UK.

Comparative FISH mapping of some 150 large-insert clones revealed at least 14 independent evolutionary breakpoints between human chromosome 3 and the genomes of four representative primates. Many rearrangements, i.e. the pericentric inversions leading to orangutan 2, were not simple breakage and reunion events, but involved microduplications and/or microdeletions. The breakpoint regions between human 3 and orangutan 2 contain paralogous sequence blocks, which were duplicated at many subtelomeric regions during hominoid evolution. FISH of fully integrated BAC maps to orangutan, siamang gibbon and silvered-leaf monkey chromosomes combined with precise breakpoint localization by PCR analysis of flow-sorted chromosomes localized three independent rearrangements of the human 3q21.3-syntenic region within a 230 kb BAC contig. Approximately 200 kb of the human 3q21.3 segment were not present on the homologous primate chromosomes, suggesting a genomic DNA insertion into the breakpoint region in the lineage leading to humans and African great apes. The inserted segment represents part of an ancestral duplication. The 3q21.3-syntenic breakpoints in the orangutan and siamang genomes were narrowed down to <5 kb and <13 kb DNA segments, which are enriched with endogenous retrovirus LTRs and other repetitive elements. The three breakpoint regions between human 3p25.1, 3p12.3, 3q21.3 and orangutan 2 as well as their paralogous segments represent breaks of chromosomal synteny between the human, mouse, rat and/or chicken genomes. Collectively our data suggest reuse of short recombinogenic sites in primate and mammalian evolution. Large-scale chromosome rearrangements, microduplications and microdeletions can be considered as different aspects of an inherent instability of these regions. Evidently, genome architecture, in particular low-copy repeats have played an important role in shaping mammalian genomes.

A simple and rapid method of direct CVS preparation for interphase *FISH*. *S. Bahieg*¹, *L. Edelmann*¹, *B. Levy*^{1,2}, *N.B. Kardon*^{1,2}. 1) Department of Human Genetics, Mount Sinai School of Medicine, New York, NY; 2) Department of Pediatrics, Mount Sinai School of Medicine, New York, NY.

In recent years, fluorescence in situ hybridization (*FISH*) on interphase nuclei prepared from fetal cells has been implemented in most cytogenetic laboratories. Laboratories perform this testing most often in response to abnormal ultrasound findings and/or serum screening results or in cases of isolated parental anxiety. Therefore, the assays must be performed without delay and as quickly as possible to ensure the rapid report of results. We developed a simple method for preparing interphase nuclei from small amounts (1-2 mg) of direct CVS. A 50% glacial acetic acid solution was used as an initial dissociating agent, eliminating the need for lengthy collagenase digestion. The dissociated cells were then microfuged at high speed to free the nuclei from the cellular debris followed by fixation in methanol/glacial acetic acid (3:1) with a minimum of three successive fixative changes. Slides were prepared and AneuVysion (Vysis) probes were applied to the nuclei and hybridizations were carried out for 30 minutes and two hours with the X,Y,18 probe set and 13,21 probe set, respectively. This protocol requires 4 hours from receipt of the sample to report of the results. To date, this method has been used in our laboratory to process 104 CVS specimens with 12 aneuploidies detected and 100% concordance with results obtained from GTG banded karyotypes of cultured CVS. Thus, this new method of direct CVS preparation for interphase *FISH* offers a very rapid, inexpensive and highly accurate alternative to traditional methods.

Comparative genomic hybridization microarray analysis: diagnostic considerations to detect common ploidy and sex chromosome anomalies. *B.C. Ballif¹, C.D. Kashork¹, L. Patterson³, R. Saleki¹, E. Rorem¹, K. Sundin¹, B.A. Bejjani^{1,2,3}, L.G. Shaffer^{1,2,3}.* 1) Signature Genomic Laboratories, Spokane, WA; 2) Health Research and Education Center, Washington State University, Spokane, WA; 3) Sacred Heart Medical Center, Spokane, WA.

Chromosome analysis is vital to the understanding of the causes of fetal demise and multiple miscarriages. Autosomal trisomy occurs in ~52% of miscarriages with abnormal karyotypes. Triploidy is the next most frequent anomaly, occurring in ~19% of chromosomally abnormal miscarriages. We recently developed a microarray that contains contigs of three or more BAC clones for 41 subtelomeric regions, 43 pericentromeric regions and 41 known microdeletion syndromes. This microarray is ideal for detecting aneuploidy and unbalanced chromosomes. Among 39 cases with abnormal karyotypes used for validation of our microarray, 11 were derived from products of conception (POC), including seven trisomies, one 45,X, two multiple aneuploidies, and one triploidy with tetrasomy 8. All cases were hybridized to two microarrays using a dye-reversal strategy. In a blinded study, all autosomal single copy gains (trisomies) and losses (45,X) were correctly detected. The microarray did not accurately detect the gain of the X chromosome in a 49,XXX,+2,+15 and only detected the gain of chromosome 8 in the triploidy. During the analysis, we hybridized the DNA from the POCs with DNA from an opposite sex normal control. In doing so, we could not discriminate a trisomy X from a normal XX female, when a normal XY male was used as the control. One component to the analysis of the data is the normalization of control to patient sample ratios. In the case of triploidy, the abnormal 3:2 gain across the genome affects the normalization process by forcing the DNA ratio to 1:1. Therefore, to accurately identify sex chromosome aneuploidies, we have implemented the use of a cell line from a Klinefelter male, 47,XXY, as our control for all microarray analyses. Although the analysis of triploids remain a diagnostic challenge for genomic microarrays, this experience was essential to understand the complexities in analyzing unknown samples in the clinical setting.

Identification of the reciprocal duplication of the NPHP1 gene that causes nephronophthisis. *H. Baris*¹, *B.A. Bejjani*², *B. Ballif*², *C.D. Kashork*², *R. Saleki*², *E. Rorem*², *K. Sundin*², *L.G. Shaffer*², *V.E. Kimonis*¹. 1) Genetics, Children's Hospital Boston, Boston, MA; 2) Signature Genomic Laboratories, Spokane, WA.

Many microdeletions that result in clinically recognizable syndromes are flanked by low copy repeat (LCR) sequences that mediate nonallelic homologous recombination. During this event in meiosis, for each resulting microdeletion, the reciprocal microduplication product is produced. For some microdeletion syndromes, such as DiGeorge syndrome and Smith-Magenis syndrome, the reciprocal duplications result in clinically distinct phenotypes. However, the reciprocal duplications have not been described for many of the remaining syndromes including nephronophthisis, caused by homozygous deletion of the NPHP1 gene at 2q13. Recently, this deletion has also been described in Joubert syndrome in which some patients also suffer from renal failure due to nephronophthisis. We identified an adopted individual with a single copy gain of the NPHP1 gene following microarray analysis using the SignatureChip. The duplication was confirmed with a BAC clone containing the NPHP1 gene. The boy was referred for microarray testing at 12 years of age because of pervasive developmental delay, attention-deficit hyperactivity disorder, obsessive compulsive disorder and behavioral problems. On physical examination we noted small testes of 2ml each with normal penile length, bilaterally adducted thumbs, and dysmorphic features consisting of synophrys and long palpebral fissures. A chromosome analysis and brain MRI were both normal. Ophthalmologic evaluation and renal ultrasound are in progress. This is the first identified case of NPHP1 duplication. It is unclear whether this duplication is related to the clinical phenotype in this patient. We anticipate that other duplications associated with the reciprocal microdeletions will be uncovered through the use of microarrays. Novel syndromes are likely to be identified, and the etiologies of known syndromes will be explained. Microarrays are proving to be a critical adjunct to clinical cytogenetics for identifying submicroscopic rearrangements of clinical importance.

Detection of cryptic deletions by genomic microarray in a patient with a complex four chromosome translocation. *B.J. Baty, J.C. Carey, Z. Chen, B. Issa, B.C. Cowley, E. Aston, T. Maxwell, A.R. Brothman.* Div Med Gen/Dept Pediatrics, Univ Utah Health Sciences Ctr, Salt Lake City, UT.

We report a patient studied as a newborn with prenatal growth deficiency of weight and mildly dysmorphic physical features. Cytogenetic studies revealed a *de novo* two-way, apparently balanced translocation between 6p and 11q, and a three-way translocation with 6q to 7p, 7p to 14q and 14q to 6q. An unrecognized chromosomal imbalance was hypothesized when the proband presented with developmental delay at 15 months. Growth was at the 2nd-5th centile. His only significant health problem was severe cyclic vomiting. Physical findings included bilateral epicanthal folds, low nasal bridge, ptosis, full lips, broad mouth, short fingers, clinodactyly, hypotonia, anal tag, myopia, low frontal hairline, neck webbing, and pectus carinatum. He developed ADHD, aggression, and preverbal behaviors. At 15 years, he was receiving special education services. The above interpretation was confirmed by chromosomal studies [46,XY,t(6;7;11;14)(11qter11q13.5::6p23q23.3::14q32.114qter); 6pter6p23::7p137qter;11pter11q13.5::6q25qter); 14p1314q32.1::6q23.36q25::7p137pter)]. FISH using whole chromosome paint probes helped characterize the specific regions involved in this complex rearrangement. Genomic microarray studies with a Spectral Genomics (Houston, TX) 1 Mb chip revealed deletions at 6p22.3 and 6q23.2, confirmed by FISH probes [nuc ish del(6)(p22.3p22.3)(RP1-130G2-),del(6)(q25.2q25.2)(RP11-535A9-)]. These deletions were close to the breakpoints identified in the initial karyotypic interpretation. Confirming the long suspected imbalance (i.e. deletions) proves the chromosomal basis of the syndrome and eliminates the need for further diagnostic testing. It also confirms the low recurrence risk for the parents, but poses high reproductive risk for the proband. This is an example of the utility of new technology in the characterization of a genetic abnormality. This case also underscores the importance of genomic microarray analysis in the evaluation of patients with suspected unbalanced abnormalities which cannot be discerned by conventional karyotyping.

Construction of a diagnostically useful microarray to identify chromosome imbalance. *B.A. Bejjani^{1,2,3}, C.D. Kashork³, R. Saleki³, E. Rorem³, K. Sundin³, B.C. Ballif³, L.G. Shaffer^{1,2,3}.* 1) Health Research and Education Center, Washington State University, Spokane, WA; 2) Sacred Heart Medical Center, Spokane, WA; 3) Signature Genomic Laboratories, Spokane, WA.

Chromosome analysis is an important component to the diagnosis of congenital anomalies, developmental delay and mental retardation. Routine chromosome analysis identifies aneuploidy and structural rearrangements >5 Mb. Array CGH was developed to increase the resolution of chromosomal studies by using large-insert clones as targets for analysis. We constructed a microarray for the clinical diagnosis of medically significant and relatively common chromosomal alterations. We chose 906 BAC clones for the 41 telomeric regions, 43 pericentromeric regions, and 41 known microdeletion loci. All BACs were evaluated by FISH mapping under constant conditions. FISH revealed that 7% of the clones were mismapped based on map locations obtained from two publicly available databases (58 mapped to the wrong chromosome and 3 mapped to a different locus on the same chromosome), 17% cross-hybridized to other chromosomes, and 10% did not hybridize or showed poor hybridization signals under uniform FISH conditions. Thus, of the 906 clones selected, only 589 (65%) were deemed adequate for arraying on this clinical device. For each clinically relevant locus, at least three overlapping BACs were selected. Additionally, for the microdeletion loci, BAC contigs flanking each locus were chosen. Each BAC was spotted four times on the microarray making it functionally equivalent to >2,000 FISH experiments. This work illustrates that the rigorous assessment of BACs and their use in array CGH is especially important when the microarray is used for clinical diagnosis. Additionally, a targeted array reduces the number of polymorphisms, uninformative or uninterpretable clones and is more appropriate for diagnostic use than whole-genome microarrays at this time. It is anticipated that genomic microarrays will be an important adjunct to the clinical molecular cytogenetic investigation of spontaneous abortions, newborns and children with mental retardation, developmental delay, and congenital anomalies.

Mother to son amplification of a small terminal deletion as a new potential mechanism of familial recurrence in microdeletion syndromes. *F. Faravelli¹, R. Lecce², M. Murdolo², G. Neri², F. Dagna Bricarelli¹, M. Di Rocco³, M. Zollino².* 1) Human Genetics, Ospedale Galliera, Genova, Italy; 2) Istituto di Genetica Medica, facolt di Medicina A. Gemelli, UCSC, Roma, Italy; 3) Pediatria II, Istituto Giannina Gaslini, Genova, Italy.

We report on a instance of familial recurrence of a microdeletion syndrome mediated by mother to son amplification of a small terminal deletion. Two brothers were affected by WHS. The first patient died at 18 years of age. He had a MCA/MR syndrome fully consistent with a WHS diagnosis. Karyotype was normal and molecular cytogenetic analysis was not performed. The youngest brother is now 17 years old. He suffers from severe growth retardation, cleft palate, hypospadias, typical facial appearance, severe mental retardation and seizures. Standard chromosomes were apparently normal. FISH analysis, performed when he was 11 years old, confirmed the diagnosis of WHS (46, XY.ish del (4p) (F26-; IS28-; D4S96-; D4S43-; D4S182-; D4S180 X 2). The deletion spanned about 3 Mb, including both WHS critical region (WHSCR) and WHS critical region 2 (WHSCR-2). The recurrence of phenotype between the two brothers led us to further investigations. A preliminary FISH analysis with the 33c6 probe (D4S43), deleted in the proband, excluded the presence of a cryptic translocation in both parents. A skin biopsy was performed in other to rule out mosaicism for the microdeletion. In this occasion a non mosaic smaller deletion was detected in the mother, spanning about 1.5 Mb from D4S96 to the telomere. Her karyotype was 46, XX.ish del(4p)(F26-; IS28-; D4S96-; FGFR3 X 2; D4S43 X 2). Both WHSCR and WHSCR-2 were fully preserved. Interestingly, she presented with some phenotypic abnormalities (facial dysmorphisms, mild mental impairment, febrile convulsions) but these were not fully consistent with a diagnosis of WHS. We describe the clinical phenotype of the mother in relationship to the small deletion and discuss this undescribed potential mechanism of recurrence of microdeletion syndromes.

Phenotypic description and molecular characterization using QMPSF of a subtelomeric 20p deletion. A.

Goldenberg¹, P. Saugier-Veber^{1, 2}, C. De La Rochebrochard¹, C. Magniette¹, G. Joly-Hélas³, E. Bessenay¹, S. Marret⁴, M. Tosi², T. Frebourg^{1, 2}. 1) Department of Genetics, Rouen University Hospital, 76031 Rouen, France; 2) Inserm U614, Faculty of Medicine, 22 boulevard Gambetta, 76183 Rouen, France; 3) Department of Cytogenetics, Rouen University Hospital, 76031 Rouen, France; 4) Department of Neonatology, Rouen University Hospital, 76031 Rouen, France.

Constitutional subtelomeric imbalances account for approximately 6 % of idiopathic mental retardation (MR). We have developed a new simple molecular genetics assay based on the QMPSF method (Quantitative Multiplex PCR of Short Fluorescent Fragments) to detect and map subtelomeric rearrangements. The telomeric QMPSF is based on the simultaneous amplification under quantitative conditions of short fluorescent genomic fragments specific of each subtelomeric end. Telomeric QMPSF analysis of patients with MR led us to identify a 20pter deletion in a 5 years old girl referred for MR and autistic features. She was the first child of unrelated parents. She walked unaided at the age of 23 months. At the age of 5 years, she presented with moderate mental retardation, social interaction deficiency and moderate facial dysmorphism. She had no malformations and normal growth. The 20pter deletion was also detected in her mother who presented a mild mental disability and similar facial dysmorphic features. This chromosomal imbalance was confirmed by FISH in the index case and her mother. The flexibility of the QMPSF method allowed the design of a new QMPSF, including 4 amplicons covering the 20pter region, and this new QMPSF revealed that this subtelomeric deletion was smaller than 2.3 Mb. This case report constitutes one of the rare descriptions of a 20pter deletion. Additional cases will be necessary to give further delineation of this recognizable phenotype.

Validation of a clinical microarray: identification of chromosome imbalance and polymorphisms. *C.D. Kashork¹, R. Saleki¹, E. Rorem¹, K. Sundin¹, B.C. Ballif^d, L.G. Shaffer^{1,2,3}, B.A. Bejjani^{1,2,3}.* 1) Signature Genomic Laboratories, Spokane, WA; 2) Health Research and Education Center, Washington State University, Spokane, WA; 3) Sacred Heart Medical Center, Spokane, WA.

We have constructed a microarray using 589 BACs covering the 41 telomeric regions, 43 pericentromeric regions, and 41 known microdeletion syndrome loci for use in clinical diagnosis of cytogenetic imbalances. In addition, we selected BACs that flank all of the microdeletion syndrome loci to use as controls for the consistent-sized deletions and to identify larger deletions. We expected this microarray to identify cytogenetic imbalance due to deletions, duplications, aneuploidies, and derivative chromosomes but not mosaicism. We tested this array in a set of blinded experiments on a cohort of 50 phenotypically normal individuals. Even after careful assessment of the BACs through FISH localization prior to constructing the microarray, the array identified deletion/duplication polymorphisms in the 100 normal chromosomes. The polymorphic loci included the pericentromeric regions of 2p, 7q, and 14q, and the subtelomeric regions of 5q, 6p, 14q, and 20p. All polymorphisms detected by the array were confirmed by FISH with a BAC from the appropriate locus. In addition to the analysis of 50 chromosomally normal individuals, we analyzed 39 specimens with known chromosome abnormalities. Eleven of these were in products of conception and are reported elsewhere. Of the remaining 28 specimens, 5 were double segmental imbalances, 3 were common trisomies, one was monosomy X, 4 were telomeric deletions, one was an interstitial duplication, and 14 had interstitial deletions. The microarray detected all of the abnormalities. Thus, the design of our array is ideal for identifying trisomies of any chromosome, known microdeletions and microduplications of the same loci, unbalanced derivative chromosomes, novel deletions/duplications of the pericentromeric regions, and for distinguishing consistent-sized deletions from larger deletions.

Searching for patients with the 22q11.2 duplication syndrome: Confirmation that some patients have phenotypic overlap with DiGeorge/Velocardiofacial Syndrome. A. Lamb¹, R. Kumar^{1,3}, J.E. Pellegrino², D. Chavez², T. Morris¹, P. Challinor¹, J.B. Ravnan¹. 1) Cytogenetics, Genzyme Genetics, Santa Fe, NM; 2) Inst Genetic Medicine, St Peter's Med Ctr, New Brunswick, NJ; 3) Univ Connecticut, Storrs, CT.

Microduplications of the 22q11.2 region had not been observed until Ensenauer et al (AJHG 73:1027-1040,2003) examined interphase cells by FISH with TUPLE1 in patients referred for DG/VCFS. They found 1.5% of unrelated patients had a duplication. To verify this finding and further characterize the phenotype associated with dup22q11.2, a prospective study was performed on 200 cases referred for DG/VCFS testing. FISH analysis on 100 interphase cells was performed. One patient with three copies of TUPLE1 was found (0.5%).

The patient was seen at 22 months and has Tetralogy of Fallot with aberrant subclavian artery, dysphagia, no overt cleft palate, moderate hearing loss, recurrent urinary tract infections with GU reflux, left cryptorchidism, abnormal EEG with seizures, hypotonia, global developmental delays, and hypoplasia of the corpus callosum. He had failure-to-thrive in infancy but currently at the 10%tile for weight and 25%tile for length. There is no documented immune deficiency. Dysmorphic features include: long narrow face, microcephaly, superior placement of eyebrows, bilateral ptosis with normal palpebral fissures, hypertelorism, bulbous nose, abnormal palmer creases. He does NOT have: bitemporal narrowing, brachycephaly, micrognathia, epicanthal folds, ear anomalies, long fingers and toes, or brachydactyly. His appearance is similar to patients in Ensenauer et al.

This study confirms that duplications of the 22q11.2 region can be found by examining interphase cells of patients referred for DG/VCFS. A subset of dup22q11.2 patients are being found due to overlap of features with DG/VCFS, but this does not find the majority of these patients as duplications should be as frequent as deletions. Focusing on the facial features along with LD/DD/MR without other features of DG/VCFS may uncover additional cases. Interphase cells should be examined for referrals for DG/VCFS.

Molecular cytogenetic investigations of multiplex autism families confirm 15q11-q13 duplications as a cause of autism. C. Lese Martin¹, J. Chung², Y. Ilkin², D.H. Geschwind³, D.H. Ledbetter¹. 1) Dept Human Genetics, Emory Univ Sch Med, Atlanta, GA; 2) Dept Human Genetics, Univ of Chicago, Chicago, IL; 3) Dept Neurology, UCLA Sch Med, Los Angeles, CA.

Autism is a neuropsychiatric disorder whose etiology is proposed to have a significant genetic component. Current data estimate that 2-6/1,000 children are affected with an autism spectrum disorder. A collaborative effort, the Autism Genetic Resource Exchange (AGRE), was previously initiated to collect and characterize multiplex families with autism for genetic studies. To cytogenetically characterize this valuable resource, we have used a combination of G-banding and Fluorescence *In Situ* Hybridization (FISH) analyses to examine lymphoblastoid cell lines from a subset of individuals in the AGRE collection. One affected individual per pedigree was analyzed. Of 146 individuals analyzed by G-banding analysis at a 400-550 band level, no abnormalities were identified. Genome-wide subtelomere FISH analysis was carried out to identify any submicroscopic rearrangements of these regions; no subtelomere rearrangements were identified in 128 individuals examined. Since 1-3% of individuals with autism have been shown to carry a duplication of the Prader-Willi/Angelman region on chromosome 15, targeted metaphase and interphase FISH analyses were performed using a clone for the *SNRPN* gene from this region. *SNRPN* FISH analysis was carried out on 148 individuals and two (1.4%) duplications were identified. Additional testing in these two families revealed that the other affected sibling in each family also carried the duplication, which was shown to be inherited from a phenotypically normal mother. Duplication of 15q11-q13 is the only known specific genetic cause of isolated and familial autism. These studies underscore the importance of clinical testing for the 15q duplication in autistic individuals, since the recurrence risk in such families is 50%. Furthermore, this study demonstrates the usefulness of cytogenetic analysis of individuals included in linkage studies, since subjects with chromosome rearrangements can be excluded from such analyses, thus increasing the study's power by reducing heterogeneity.

Development and application of a pericentromeric clone set for exploring genomic instability and architecture.

L.F. May, D. Pressley, D. Johnson, S. Cooper, A. Wong, C. Lese Martin, D.H. Ledbetter. Dept. of Human Genetics, Emory University, Atlanta, GA.

The telomeric and pericentromeric regions of human chromosomes are of great biological and clinical importance. However, their complex, mosaic structures are rich in repetitive duplicated sequences, which have been recalcitrant to whole genome sequencing efforts. Targeted approaches are needed to elucidate their architecture, evolution and role in human disease. We previously reported a set of unique clones for each human telomere. Here we report the development of a set of pericentromeric clones corresponding to the most proximal unique DNA sequence for 43 chromosome arms, excluding the acrocentric p arms. A second clone, 500 kb distal to the first clone was chosen to initiate a molecular ruler for each region. These two clones were positioned in relation to the centromere and each other by interphase FISH. We assayed 112 clones, avoiding clones that showed greater than 10% segmental duplication using the UCSC genome browser. Of these 112 clones, 24% were excluded from analysis: 4 (3.5%) showed unique hybridization signals on the wrong chromosome; 22 (19%) had significant cross-hybridization to other loci by FISH and one showed a signal size polymorphism by FISH. These results demonstrate the necessity of targeted efforts in these regions as clone selection still remains problematic. Our final probe set consists of 85 unique FISH probes (only one unique clone was identified for Yp) that anchor the boundary between the unique and repetitive sequences for each pericentromeric region. We have utilized this probe set to examine 4 marker chromosomes identified during routine prenatal testing. Two marker chromosomes originated from chromosome 13 or 21 and two originate from 14 or 22. None of the 4 patients examined had positive FISH signals on their marker chromosomes suggesting that these markers do not contain euchromatin and may be compatible with a normal phenotype. Continued studies and extension of the molecular rulers will aid in the development of genotype/phenotype correlations that will result in better predictions of the clinical implications for marker chromosomes.

Identification of Chromosome Abnormalities by Array-CGH. *D.L. Pickering, M. Nelson, B.J. Dave, W.G. Sanger.*
University Nebraska Medical Center, Omaha, NE.

Cytogenetic and molecular cytogenetic studies play an important role in the study of mental deficiencies lacking specific clinical landmarks since they may be associated with small chromosome deletions and duplications. However, some chromosome abnormalities are submicroscopic and can only be resolved by specific FISH studies. With increasing genetic information, a growing number of critical chromosome regions need to be examined rendering FISH studies with multiple probes an expensive and time-consuming investigation. Array-CGH is a high-throughput molecular cytogenetic approach that allows for examination of the entire genome for gain or loss of several hundred specific chromosome regions in one assay. To test the reliability of array-CGH for the detection of chromosome abnormalities, we utilized the GenoSensor Genomic Array 300 (Abbott/Vysis, Downers Grove, IL) and examined nine cytogenetically abnormal cases and three cytogenetically normal cases with abnormal phenotypes. Array-CGH accurately identified the regions of deletion and duplication in the nine abnormal cases. Specifically, deletions of 1p36, 3ptel, 7ptel, 7q11.2, 8p22, 15q11.2-q13, 15q26.3, and 22q11.2, duplications of 5p15.2, 8q24.3, and 10p15 and a trisomy 18 were verified. Six of nine abnormal cases involved deletion and/or duplication of one or more subtelomeric regions. Additionally, in one case with der(15)t(8;15), precise breakpoint delineation within an 8Mb region of sub-band 15q26.1 to 15q26.3 was accomplished. The two cases with normal karyotypes were negative for chromosome deletions or duplications and another case with a balanced translocation was also negative for chromosomal gain or loss. Although this array was specific for the abnormalities tested, in eight of the 12 cases a false positive rate of 0.3-1.0% for gain or loss of random clones was noted. This emphasizes the need to confirm array-CGH results with FISH studies. When used in combination with cytogenetics and FISH, array-CGH is a useful tool for detection of subtelomeric and other subtle chromosome deletions and duplications and to help further define breakpoints in unbalanced karyotypes.

Fine mapping of 10qter deletions and duplications using QMPSF: importance of molecular rulers to distinguish deleterious from polymorphic rearrangements. *P. Saugier-Veber^{1,2}, V. Drouin-Garraud¹, A. Goldenberg¹, N. Le Meur^{1,3}, C. Carves¹, A. Rossi⁴, V. Leyer³, G. Joly-Hélas⁵, H. Moirot⁵, E. Bessenay¹, M. Tosi², T. Frebourg^{1, 2}* 1) Department of Genetics, Rouen University Hospital, 76031 Rouen, France; 2) Inserm U614, Faculty of Medicine, 22 Boulevard Gambetta, 76183 Rouen; 3) Department of Cytogenetics, Le Havre Hospital, 76083 Le Havre, France; 4) Department of Genetics, Etablissement Français du Sang, 76235 Bois-Guillaume, France; 5) Department of Cytogenetics, Rouen University Hospital, 76031 Rouen, France.

Constitutional subtelomeric imbalances account for approximately 6 % of idiopathic mental retardation (MR). We have developed a new simple molecular genetics assay based on QMPSF (Quantitative Multiplex PCR of Short Fluorescent Fragments) to detect and map subtelomeric rearrangements. Telomeric QMPSF is based on the simultaneous amplification under quantitative conditions of short fluorescent genomic fragments specific of each subtelomeric end. Telomeric QMPSF allowed us to identify one 10qter deletion and two 10qter duplications in MR patients and five 10qter duplications in normal controls. The 10qter deletion was detected in a 45 years old woman with MR, facial features and growth retardation compatible with previous 10qter deletion descriptions. The flexibility of the QMPSF method allowed the design of a new QMPSF, specific of the 10qter region, in order to estimate the size of each rearrangement. Seven amplicons spanning a 2 Mb region were integrated into this 10qter QMPSF. This analysis revealed that the 10qter deleterious deletion extended over more than 2 Mb. In contrast, the size of the polymorphic 10qter duplications could be estimated to less than 860 Kb. These comparative mappings of 10qter rearrangements using telomeric QMPSF show that deleterious and polymorphic rearrangements can both affect the 10qter region and that the polymorphic rearrangements may be distinguished from the deleterious ones by their size. Thus, because of its flexibility, telomeric QMPSF should facilitate the mapping of such subtelomeric rearrangements, with major implications in genetic counseling.

Deletion mapping in Xp21 for patients with complex glycerol kinase deficiency using Affymetrix GeneChip

mapping 10K array (SNP chip). *C.M. Stanczak¹, Z. Chen¹, M.K. Bedernik², Y-H. Zhang², S.F. Nelson¹, E.R.B. McCabe^{1,2,3}.* 1) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA; 2) Department of Pediatrics, David Geffen School of Medicine at UCLA and Mattel Children's Hospital at UCLA, Los Angeles, CA; 3) Molecular Biology Institute, UCLA, Los Angeles, CA.

Infantile, or complex glycerol kinase deficiency (cGKD), is a contiguous gene syndrome caused by a deletion of *GK*, along with its neighboring genes, *DMD* and/or *NROB1*. Patients with cGKD present with glyceroluria and hyperglycerolemia in association with Duchenne muscular dystrophy and/or adrenal hypoplasia congenita. The purpose of these investigations was to determine whether the Affymetrix GeneChip Mapping 10K Array (SNP chip) could be utilized to detect and map breakpoints in patients with cGKD. The Affymetrix SNP chip is a high-density oligonucleotide array that allows a standardized, parallel interrogation of 11,560 SNPs across the entire genome (except for the Y chromosome). Genomic DNA from 12 primary cell lines from patients with cGKD were analyzed on the Affymetrix platform. We identified deletions with the SNP chip in all 12 cGKD patients with a high degree of confidence. The no call rate and the average perfect-match minus mismatch intensity differed highly significantly (PE-5 for both comparisons) between the entire genome and the deleted regions. These data permitted us to specify minimum and maximum deletion intervals for each patient and these intervals compared well with independent results from PCR analysis and breakpoint sequencing. This study demonstrates the utility of the 10K mapping GeneChips for molecular cytogenetic analysis, beyond the SNP genotyping for which the arrays were initially designed. With 1% of live births (40,000 U.S. neonates annually) having cytogenetic disorders, we envision a significant need for such a platform for rapid, high-throughput, genomic analysis for molecular cytogenetics applications.

Analyses of structural abnormalities involving chromosome 4: Comparison between high-resolution multicolor banding technique and conventional G-banding. *K. Wakui^{1,2}, Y. Sakakibara¹, H. Ohashi³, K. Matsuda⁴, E. Hidaka⁴, T. Katsuyama⁴, Y. Fukushima^{1,2}.* 1) Division of Medical Genetics, Department of Health Science, Shinshu University School of Medicine, Matsumoto, Nagano, Japan; 2) Department of Clinical and Molecular Genetics, Shinshu University Hospital, Matsumoto, Nagano, Japan; 3) Division of Medical Genetics, Saitama Children's Medical Center, Iwatsuki, Saitama, Japan; 4) Department of Laboratory Medicine, Shinshu University Hospital, Matsumoto, Nagano, Japan.

High-resolution multicolor-banding (mBAND) technique was developed in 1999 to provide precise information on intra-chromosomal rearrangements (i.e., inversions, insertions and deletions) and exact break-point mapping (Chudoba et al. [1999], [2004]). We performed FISH analyses using chromosome 4-specific mBAND kit (Xcyte 4) by Isis mFISH/mBAND imaging system (MetaSystems) on the subjects with aberrations involving chromosome 4, identified by conventional G-banding. Xcyte 4 contains 6 region specific partial painting probes of chromosome 4, and each probe is labeled with 1 of 5 different fluorochromes or a combination of them, respectively. **Subject 1:** t(4;14;15)(q25;q31;q26.2), recurrent abortions; **Subject 2:** der(4)(4pter4q27::?:17q2317qter),der(17)(17pter17q21.3::4q284qter), MCA/MR; **Subject 3:** t(3;5;4)(q12.3;q31.3;q27), MCA/MR; **Subject 4:** t(4;6)(p16.1;q21),t(7;10)(p13;q22.3),inv(9)(p24.1;q12), MCA/MR; **Subject 5:** inv dup(4)(:p15.1p16.2::pterqter), MCA/MR. We reinvestigated the breakpoints of abnormal chromosome 4 in each subject, and compared and evaluated the results to conventional G-banding.

Phenotypic findings in patients with subtle terminal deletions detected by subtelomere FISH analysis. *G.D.*

Wenger^{1,2}, J.F. Atkin³, M. Springer¹, M. Millard¹, J.M. Gastier-Foster^{1,2}. 1) Dept. of Laboratory Medicine, Columbus Children's Hospital, Columbus, OH; 2) Dept. of Pathology, Ohio State University, Columbus, OH; 3) Dept. of Pediatrics, Ohio State University, Columbus, OH.

Subtelomere FISH analysis is an effective tool in the investigation of individuals with developmental delay (DD), idiopathic mental retardation, and various congenital anomalies. As these subtle or cryptic rearrangements are detected, it is important to distinguish between normal variants and pathogenetic rearrangements, and to delineate the phenotype associated with the latter. We have identified patients with subtelomeric deletions of 2q, 18p, and 11q. None of these was visible on GTG-banding analysis at 550-600 band resolution. Our patient with a de novo 2qter deletion was a 5 year old with autistic behavior, mild dysmorphism, atypical seizures, and was originally tested at age 3 to rule out Angelman syndrome. Patients with terminal 2q deletions have been reported. Common clinical findings include DD, frontal bossing, depressed nasal bridge, cardiac defects, and hypotonia. An association with autism or Albright hereditary osteodystrophy has also been reported. The patient with 18p deletion had failure to thrive at 8 months of age, dysmorphism, severe DD, cleft palate, and small stature. The biological parents were unavailable for testing. Deletion of 11qter was identified in an 11 month old with DD, dysmorphism, small mouth, and low-set ears, who was originally studied cytogenetically as a newborn to rule out trisomy 8 mosaicism. As increasingly subtle rearrangements are identified by subtelomere or DNA microarray analysis, discrimination of polymorphic variants and characterization of the phenotype represent challenges for the cytogeneticist and the clinician.

Characterization of a rare neocentric marker chromosome using chromosome microdissection. *J. Yu*^{1,2,3}, *Z. Qi*³, *K. Thompson*², *P. Modaff*⁴, *W. Wells*², *L. Meisner*^{1,2}, *R. Pauli*^{4,5}. 1) Dept of Pathology and Lab Medicine; 2) State Lab of Hygiene; 3) Waisman Center; 4) Dept of Medical Genetics; 5) Dept of Pediatrics, University of Wisconsin-Madison.

Chromosome microdissection is a unique technique by which any chromosome fragment within the cytogenetics resolution can be isolated and characterized. It is a powerful tool for clinical diagnosis. We present here an example of using this technique to study a low level mosaic neocentric marker chromosome. The patient was a 10 year old boy referred because of bilateral Perthes disease. In addition, he was noted to have mild developmental delays, attention deficit-hyperactivity, macrocephaly, and asymmetries of the hands and of the legs. He had linear and swirly arrays of irregular skin pigmentation and areas of focal skin atrophy, both distributed in a manner consistent with lines of Blashko. A normal male karyotype was detected in his blood cells. Because the skin pigmentation pattern strongly suggested possible mosaicism, we further analyzed skin biopsy samples. A marker chromosome was found in 4 skin cells. This marker was unstable, being lost in the passage cultures. Microdissection was used to further study this marker in very limited abnormal cells. A single copy of the marker was dissected in four contiguous sections, PCR amplified, labeled with multi-colors and hybridized to normal and patients metaphase cells. The hybridization results demonstrated that the marker was derived from the 3q26.2-qter region and lack of a centromere. Being able to be passed through multiple cell divisions, the marker most likely carried a neocentromere that has partial centromere function. The hybridization further demonstrated that 3q26.2-qter was present as an inverted duplication in the marker; this was confirmed by 3q telomere FISH. The findings greatly assisted the clinical assessment of the patient by providing a detailed and firm identification of the unstable marker that was most likely the cause of the abnormal phenotype. Our studies further demonstrated the necessity of using chromosome microdissection to completely analyze chromosome abnormalities that could not be confirmed by traditional methods.

Program Nr: 983 from the 2004 ASHG Annual Meeting

Clinical abnormalities in a girl with random X-inactivation and duplication of Xp11.1-p11.4. *D.S. Bonner, A.N. Meyer, J.E. Wiley, K.R. Schmidt.* Dept Pediatrics/ Genetics, E Carolina Univ, Brody Sch Med, Greenville, NC.

This report describes a 15 month-old female with abnormal clinical findings and *de novo* partial Xp duplication. She has mild dysmorphic features, a congenital heart defect, developmental delays (especially in the area of speech), and mild general muscular hypotonia. The cytogenetic analysis revealed a duplication of band p11.3 in the short arm of one of the X chromosomes (46,X,dup(X)(p11.2p11.4), with the normal and duplicated X chromosomes randomly inactivated. It has been postulated that cytogenetic or molecular replication studies alone cannot distinguish between phenotypically normal and abnormal females. In most females with structurally abnormal X chromosomes, the abnormal chromosome is inactivated and they are free from abnormal clinical findings. Some females with dup(X) chromosomes exhibit developmental defects because of random X-inactivation. A review of the literature did not reveal any similar case with this size duplication. This patient appears to be a first case of a female bearing this small duplication of Xp with random X-inactivation and may help to further define the location of genes important for development. There are several genes for mental retardation thought by linkage to lie within this band.

DEVELOPMENT AND VALIDATION OF CHROMOSOME MICROARRAY ANALYSIS (CMA) FOR CLINICAL DIAGNOSIS. *S. Cheung, W. Yu, C. Shaw, J. Li, Z. Ou, E. Brundage, S. Yatsenko, L. Cooper, S. Trilochan, P. Furman, A. Patel, P. Stankiewicz, W. Cai, J. Lupski, C. Chinault, A. Beaudet.* Department of Human and Molecular Genetics, Baylor College of Medicine, TX.

We have developed a second generation of BAC-based microarray at Baylor College of Medicine for clinical diagnosis of genetic disorders by comparative genomic hybridization (CGH). This array contains 380 FISH-verified clones that span genome regions implicated in over 40 known human genomic disorders. The array contains subtelomeric clones for the 41 clinically relevant human chromosome telomeric regions. The new array has multi-clone replication for each disease, with an average of 3-4 clones representing each deletion or duplication syndrome, and 4 or more clones for subtelomeric regions. The applicability of the chromosomal microarray in detecting copy number changes in the disease specific regions and subtelomeric regions was tested in a blinded fashion by hybridizing total genomic DNA from 25 patients to this array. A novel software package implemented in the R statistical programming language was developed for normalization, visualization, and inference. The overall results from the expanded array have been completely consistent with known cytogenetic and FISH abnormalities. Overall we find this to be a specific, sensitive and rapid approach for detecting chromosome imbalances. Two major advantages are the ability to test for a wide range of duplication and deletion syndromes without the need to rely on clinical suspicion to order specific FISH tests and the ability to detect duplications that might be undetected by metaphase FISH. The main limitation of this array is its inability to detect chromosome changes such as balanced translocations, inversions or low levels of mosaicism. However, a significant number of cryptic rearrangements, duplications or deletions may go undetected by typical chromosome analysis. Therefore, we conclude that the use of CMA together with standard cytogenetics can significantly improve diagnostic precision. We have now completed analysis of 55 prospective samples, and eight months experience offering the CMA test will be presented.

A de novo trisomy of 22pter-22q11.22 in a child with Ebstein's anomaly. R.A. Conte¹, L.A. Cannizzaro¹, V.R. Pulijaal¹, D.T. Walsh¹, D. Wei¹, M. Zohouri¹, T. Zhou¹, A.R. Deshikar¹, L. SanMarco¹, P.A. Levy², C. Walsh², K.H. Ramesh¹. 1) Pathology, Montefiore Medical Center/Albert Einstein Col. Med., Bronx, NY. 10461; 2) Pediatrics, Montefiore Medical Center, Bronx, NY. 10461.

A 7 year old Hispanic female with Ebstein's anomaly including tricuspid atresia, pulmonary atresia, mild mental retardation, asthma, decreased urine output and dysmorphic features:(slightly brachycephalic head, frontal bossing, hypoplastic midface, feet with mild pes planus, clubbing of fingers and hypertelorism) was referred for peripheral blood cytogenetic and FISH studies to rule out velocardiofacial syndrome. Neurological exam revealed mild hypotonia. Her dysmorphic features could not be categorized into any well-described syndrome. She was born at term bw:6lb 6oz to a 22-year-old G2 mother. Initially, FISH with N25 (D22S75)(22q11.2) and TUPLE1(22q11.2) loci probes, each with (ARSA) control (22q13.3), detected a third copy of N25 (D22S75) and TUPLE1 loci , on a deleted supernumerary chromosome 22 [SC22]. Additional FISH analysis using 22 wcp, 22q subtelomere (MS607) and centromere 22 (D22Z1) probes, in conjunction with GTG banded chromosomes, determined the karyotype to be: 47,XX,+del(22)(q11.22)[25].ish +del(22)(q11.22)(D22Z1+,wcp22+,N25+,TUPLE1+, ARSA-,MS607-)[120]. The parent's peripheral blood chromosomes were normal. Based on these findings the patient has a de novo chromosome abnormality of trisomy 22pter-22q11.22. It is believed that parental origin of SC22 does not have a strong influence on the progeny's phenotype since imprinting of chromosome 22 has not been reported. SC22s usually do not produce deleterious effects when their composition is noneuchromatic in nature. However, the amount of euchromatin that is trisomic, as a result of the SC22, plays a significant role in the phenotype. Additional molecular studies are warranted to further delineate this SC22 that may shed more light on the genotype/phenotype correlates involving Ebstein's anomaly in this child.

FISH Analysis for Prader-Willi Syndrome: Diagnostic Significance of Diminished Signal Intensity. *L. Dong, C. Wilczewski, L. Mak, B. White, J. Neidich, A. Anguiano.* Quest Diagnostics Nichols Institute, San Juan Capistrano, CA.

Prader-Willi syndrome (PWS) is a common dysmorphic syndrome characterized by hypotonia and feeding problems in infancy, followed by obesity, polyphagia, short stature, hypogonadism, behavioral disorders, and cognitive impairment. PWS is caused by molecular alterations of the SNRPN gene (15q11-q13) via microdeletion, duplication, uniparental disomy, and imprinting mutations. Approximately 70% of cases are detectable by FISH probes specific for the PWS SNRPN region. We present two cases: a 4-day-old female and a 3-month-old female, in which the clinical indication for FISH and cytogenetic analysis was hypotonia and feeding difficulties. Conventional cytogenetic studies for both patients were normal, with no visible deletion or duplication at 15q11-q13. A commercially available set of FISH probes (Vysis) that included a PWS-specific probe on chromosome 15 (SNRPN region [15q11-q13]) and two control probes (CEP 15 [15p11.2] and PML [15q22]) was used. In both cases, one of the chromosome 15 SNRPN regions consistently had a diminished signal. Follow-up studies were performed using proximal and distal probes adjacent to the SNRPN locus: D15S11 and D15S10, respectively. Both studies exhibited equal intensity on the target regions. Therefore, the FISH studies were reported as ish 15q12(SNRPN dim). Further investigation by methylation-specific PCR (MSPCR) of both cases showed an abnormal methylation pattern consistent with a clinical diagnosis of PWS. The probe manufacturer indicated that the 125Kb SNRPN probe preparation was sonicated into smaller 200-1000 bp fragments to allow for more efficient hybridization. This suggested that the observed diminished signal is likely due to a partial deletion within the SNRPN probe, leading to an alteration of the methylation pattern on 15q12. In conclusion, for SNRPN region FISH studies, when both signals are present, but one signal is consistently diminished, an additional test such as MSPCR is required to complete the evaluation.

Genomic array analyses of an unbalanced chromosome 18 translocation in a patient with psychosis. C.

Drazinic^{1,3,5}, A. Ercan-Sencicek¹, L. Gault¹, F. Hisama⁴, H. Zheng³, M. Qumsiyeh², J. Conroy⁶, D. McQuaid⁶, J. Cubells^{3,5,7}, M. State^{1,2}. 1) Child Study Center, Yale University, New Haven, CT; 2) Department of Genetics, Yale University, New Haven, CT; 3) Department of Psychiatry, Yale University, New Haven, CT; 4) Department of Neurology, Yale University, New Haven, CT; 5) Department of Psychiatry, VA Connecticut Healthcare System, West Haven, CT; 6) Department of Cancer Genetics, Roswell Park Cancer Institute, Buffalo, NY; 7) Department of Genetics, Emory University, Atlanta, GA.

BACKGROUND: Array-based copy number analysis has recently emerged as an efficient means of mapping certain complex chromosomal abnormalities. Here we compare two such techniques in the evaluation of a 45 year-old female with dysmorphic features, mental retardation, psychosis, and an unbalanced chromosome 18p translocation.

METHODS: Patient genomic DNA was analyzed using both GeneChip 10K SNP Arrays (Affymetrix) and BAC-arrays provided by Roswell Park Cancer Center (RPCI) consisting of 6,000 probes with an average spacing of 0.5 Mb. Subtelomeric FISH with commercially available probes (Vysis) was used to confirm the origin of the translocated material. **RESULTS:** The patient's G-banded karyotype was read as 46, XX, der(18)t(18;?)(p12;?). Subtelomeric FISH confirmed the extra material was of chromosome 5 origin. SNP arrays mapped the duplication on chromosome 5p telomeric to position 23.630 Mb (July freeze; <http://genome.ucsc.edu>). BAC arrays placed the boundary at 25.320 Mb. The 18p deletion was mapped to an interval telomeric to either position 8.352 Mb (BAC array) or 8.437 Mb (SNP array). **CONCLUSIONS:** Array-based techniques are a rapid means of mapping difficult-to-characterize copy number changes, though at present they do not eliminate the need for traditional fine-mapping. Single hybridizations using either method defined a 25 Mb duplication on 5p and an 8.4 Mb 18p deletion. Interestingly, case reports and linkage analyses have implicated both chromosomal regions in psychosis. Further investigations of patients with such symptoms and cytogenetic abnormalities involving these intervals may help clarify the relative contributions of these loci to our patient's psychiatric presentation.

Constitutional t(8;22)(q24.1;q11.2): Prevalence and Clinical Significance. *S. Gupta¹, J. Joshi¹, R. Perrone¹, J. Gallo², S.L. Allen², P. Koduru¹.* 1) Dept. of Lab. Medicine, and; 2) Div. of Hematology & Oncology, North Shore Univ. Hospital, NY.

A reciprocal chromosome translocation (RCT) may be heritable or acquired; the latter are often associated with cancer. The most frequently reported heritable RCT is the t(11;22). t(8;22) has been reported in three different families (Godde-Salz et al 1982; Mark and Sigman 1999; Keung et al 2004). Although the positional relationship is not known, the 22q11.2 region has been a common site for rearrangements both in constitutional changes and in tumor related changes. We report a patient with t(8;22) ascertained because of thrombocytopenia. A 54 year male with a history of idiopathic thrombocytopenic purpura for 5 years developed worsening thrombocytopenia. His WBC was 12,000/uL, hgb was 15.2 g/dl, hct was 44.1, platelets were 36,000/ul, and differential count revealed 5% blasts. Flow cytometry demonstrated normal myeloid antigen pattern. Bone marrow aspirate and biopsy revealed increased megakaryocytes, erythroid hyperplasia, and absent iron stores. Chromosome analysis of a 24h cultured BM cells showed a t(8;22) (q24.1;q11.2); this was present in PHA stimulated PB cultures also. Therefore, the t(8;22) was a constitutional change in this patient. FISH study with cMYC, BCR, TUPLE1 and ARSA probes showed normal signal pattern; but BCR had moved to the 8q+ chromosome, cMYC had moved to the 22q- chromosome, TUPLE-1 was present on the 22q- chromosome, whereas the ARSA had moved to the 8q+ chromosomes. These findings suggest that the break at 22q11.2 occurred in-between TUPLE-1 and BCR genes, and the break at 8q24.1 occurred proximal to the cMYC locus. This is the second report of a patient with t(8;22) ascertained following the development of an autoimmune disease. A previous patient diagnosed with myasthenia gravis, leukocytosis and thrombocytosis has been found to have a t(8;22) (Keung et al 2004). Although certain constitutional changes such as del(13q), t(3;8), del(11p), have been reported to be associated with increased risk for cancer development, it is premature to consider whether the t(8;22) contributes to the development of autoimmune disease in carriers.

A second reported case of a female with dup (X)(q21.3-q24): case report and review of the literature. *K.C. Herman¹, P.N. Rao², R.E. Falk¹*. 1) Medical Genetics Institute, Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) Department of Pathology and Laboratory Medicine, UCLA Medical Center, Los Angeles, CA.

We report a 22-month-old Hispanic female with global developmental delay, hypotonia, joint laxity, poor feeding, failure to thrive, and minor dysmorphic features. Cytogenetic analysis performed shortly after her birth revealed an abnormal female karyotype consistent with segmental duplication of the long arm of the X chromosome from band q21.3 to q24. The duplication was confirmed by whole chromosome painting of the X chromosome. Cytologically, the morphology of the X chromosomes suggested random X-inactivation, but specific X-inactivation studies have not been completed.

A review of the literature found one other case of interstitial duplication of Xq with similar breakpoints, reported by Carozzo et al (*Am J Med Genet.* 72:329-34, 1997). This female infant presented with developmental delay, hypotonia, intrauterine growth restriction and subsequent short stature. However, the reported dysmorphic features were quite different than those seen in our case. This child was found to have random X-inactivation, an unusual finding as most reported cases of females with dup(X) have skewed X-inactivation. An MRI study obtained at 20 months revealed findings suggestive of hypomyelination. The gene involved in Pelizaeus-Merzbacher disease, PLP, is located at Xq22, within the region duplicated in this child. FISH testing confirmed duplication of the PLP gene.

The evaluation of our patient is on-going. However, her neurologic features are similar to the previously reported child. Also, considering the cytologic appearance of random X-inactivation, this may represent a second case of unexpected random X-inactivation in a female with dup(Xq). Possible explanations for this phenomenon have been hypothesized, including impaired cell selection mechanisms, a lethal mutation on the normal X chromosome, and interference with the mechanism leading to the preferential inactivation of the abnormal X chromosome.

Array-based comparative genomic hybridization facilitates identification of breakpoints of der(1)t(1;18) in a child presenting with mental retardation and clinical features of autism. *P.A. Lennon¹, C.A. Bacino¹, M.A. Curtis², C. Lim², Z. Ou¹, M.L. Cooper¹, A. Patel¹, S.W. Cheung¹.* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Pediatrics, University of Arkansas for Medical Sciences College of Medicine, Little Rock, AR.

Duplications involving 18q rearrangements produce clinical phenotypes ranging from severe, as seen in trisomy 18, to milder, as seen with a smaller duplication involving only 18q2118qter. To this date, no duplication of 18q has been reported involving only the distal 18q2318qter. We report dup(18)(q23qter) as well del(1)(p36.3) which were detected via subtelomere fluorescent in situ hybridization (FISH) and array-based comparative genomic hybridization (array-CGH) during the cytogenetic analysis of a 7 1/2 year old female with a der(1)t(1;18)(p36.3;q23). Thus, this patient has a combination of abnormalities which include duplication 18q phenotypic anomalies as well as features often seen in del(1)(p36) syndrome. At birth, a large anterior fontanelle and mild clinodactyly of both 5th fingers were noted. On clinical exam at age 7 1/2 she had dysmorphic features which included a pointed chin, a broad nose with a flat nasal bridge, mild hypertelorism and a midface hypoplasia. These findings are typical for the clinically recognizable del(1)(p36) phenotype. She also had an open mouth and widely-spaced teeth. She had a history of chronic ear infections superimposed to a moderate bilateral sensorineural hearing loss. Dextrocardia was previously diagnosed at birth. Global developmental delay was evident and she displays features seen in the autistic spectrum disorders. Molecular characterization of this novel der(1)t(1;18)(p36.3;q23) involves determining the precise chromosomal breakpoints, which may yield insight into this compounded phenotype as well as into subtelomere healing. These breakpoints have been elucidated using array-CGH and FISH, and will be presented.

A Referral Center for Prenatal FISH Study in Taiwan First Year Experience. *C.C. Lin¹, Y.C. Li², L.J. Hsieh¹, C.P. Chen³, T.M. Ko⁴, C.C. Tzeng⁵, M.L. Yang⁶, J.S. Fang⁷, M.S. Li⁴, L.S. Tzeng⁸, Y.J. Pan⁹, S.K. Lin⁶, F.J. Tsai¹.* 1) Dept Medical Research, China Medical Univ Hosp, Taichung, Taiwan; 2) Dept Life Sci, Chung Shan Med Univ, Taichung, Taiwan; 3) Mackay Memorial Hosp, Taipei, Taiwan; 4) Kos Obs/Gyn Clinic and M.S. Li Obs/Gyn Taipei/Taichung, Taiwan; 5) Chi-Mei Med Ctr, Tainan, Taiwan; 6) Vet General Hosp Taipei/Taichung Taiwan; 7) Tai-An Hosp, Taichung, Taiwan; 8) Natl Taiwan Univ Hosp, Taipei, Taiwan; 9) Lin Shin Hosp, Taichung, Taiwan.

Several large series of prenatal interphase FISH have been reported. Much lesser population data were available for prenatal diagnosis using FISH-based full karyotyping analysis. Since 2003, a referral center for FISH-based study has established to offer prenatal FISH analysis for clinical cytogenetic laboratories in Taiwan. We reported here the experience for the first year of such service. There were 10 cytogenetics laboratories using the service with a total of 19 samples or fixed cells submitted for FISH-based analysis. This represented 0.26% of total number of prenatal cytogenetic cases (7,143) performed in those laboratories. All referral cases were requested for full karyotype FISH study including 9 (47%) cases of de novo marker chromosomes, 3 (16%) cases of suspected microdeletion syndromes (2 cases for DiGeorge syndrome and 1 case for Williams syndrome) and 7 (37%) cases of undetermined structural aberrations. The chromosome origins of all marker chromosomes were identified by SKY except for 1 case which was identified by FISH with Y-specific probe DYZ3. 3 of the markers (33%) were derived from the chromosome 22. No deletion was detected in all 3 cases suspected of having microdeletion syndromes. Among structural aberrations identified, 4 cases involved extra chromosomal material of various origin, 1 case of isochromosome, and 2 cases of cryptic reciprocal translocations. The identifications of chromosome origin and structural rearrangements may be important for genetic counseling to couples undergoing prenatal testing. The study was supported by grants from The Bureau of Health Promotion, Taiwan (BH92-GC03-1) and from NSC, Taiwan (NSC 91-2320-B-040-037).

Two novel cases of duplications with cryptic gain or loss of the IgH gene. *P. Papenhausen¹, J. Tepperberg¹, I. Gadi¹, L. Wisniewski¹, P. Jayakar², U. Lichter-Konecki³, S. Sparks³.* 1) Dept Cytogenetics, Labcorp of America, Res Triangle Pk, NC; 2) Miami Children's Hospital, Clinical Genetics, Miami, FL; 3) Children's National Medical Cntr, Div of Genetics, Washington, DC.

A 22 mo old female was referred for cytogenetic evaluation secondary to failure to thrive (ht&wt at the 3rd percentile) and mild speech delay. A mosaic peripheral blood karyotype revealed 35% of the cells had an added segment at 9p23 and 65% were normal. Ancillary FISH studies showed tandem 9p subtelomere positivity representing a predictable terminal 9p duplication, but with an intervening G-band negative "spacer" inconsistent with distal 9p G-banding. Sequential WCP-FISH revealed an insertion from chromosome 14. Both the light band color and the nature of the IgH gene suggested that it may be a candidate region for the insert and gene specific FISH confirmed the compound mosaic partial trisomies for 14q32.2-q32.3 and 9p23-pter.

The second case was a 7mo old male referred for cytogenetics and subtelomere FISH due to a VSD/ASD, dysgenesis of the corpus callosum, hypotonia and DD. The pregnancy was complicated by oligohydramnios, IUGR and premature birth at 33wks. G-banded karyotypes showed a subtle "swelling" of the 14q32 band which was deleted of the subtelomere in the FISH analysis. No subtelomere of any chromosome was noted in that analysis consistent with many distal inverted duplications in the literature. Additional gene specific FISH for the IgH gene showed that it was part of the terminal deleted segment and 14 WCP showed that the added segment was from chr 14 and consistent with a duplication. The duplicated segment was then presumed to be 14q32.1-q32.2. The transposability of the IgH gene may be associated with the etiology of the structural alterations in both of these cases, resulting in the distal duplications. Clinical comparisons with similar cases will be presented. Competence of CGH chip analysis in revealing the overall imbalance in these cases will be reported.

Deletion of 22q11.2 associated with a jumping translocation. *D.L. Persons¹, X.Y. Wang¹, D. Collins², T. Arthur¹, S. Hagemeister¹, J. Ragona¹, B. Davoren¹, T. Troyer¹, R.N. Schimke².* 1) Department of Pathology and Laboratory Medicine; 2) Department of Internal Medicine, University of Kansas Medical Center, Kansas City, KS.

Jumping translocations are rare chromosomal rearrangements that are defined as translocations involving the same portion of a donor chromosome and various recipient chromosomes in different cell lines of a single person. Only a limited number of cases (approximately 24) involving constitutional jumping translocations have been reported in the literature. Four of the reported cases involved chromosome 22; three of which had a clinical history consistent with deletion of 22q11.2. Fluorescence in situ hybridization (FISH) was not performed to verify a deletion at the molecular level in these cases. We report a six-year-old male who presented with velopharyngeal incompetency. He was without the classical facial features of velocardiofacial syndrome (VCFS). Parathyroid hormone and calcium levels were normal and an echocardiogram was unremarkable. Chromosomal analysis revealed three different cell lines, each containing an unbalanced translocation involving the long arm of chromosome 22 from q11.2 to qter. In the majority of cells (87%), chromosome 22 was translocated to 11p15.5; two minor populations contained translocations of 22q11.2 to 6q27 (10%) and 4p16.3 (3%). FISH using a DNA probe specific for the DiGeorge/VCFS critical region (TUPLE1) at 22q11.2 confirmed that 100% of 35 metaphases examined had the deletion. In addition, subtelomere probes for 11p and 6q were present in all metaphases examined and were not rearranged. Parental cytogenetic studies and FISH studies for deletion 22q11.2 were normal. This is the first case where deletion of 22q11.2 associated with a jumping translocation was verified using FISH.

Postnatal detection of nonmosaic tetrasomy 18p in an infant with multiple congenital abnormalities, characterized by G-banding and FISH. A. Piurek¹, J. Meck¹, E. Zafer¹, N. Scribanu², D. Boles¹. 1) ObGyn, Georgetown University Hospital, Washington, DC; 2) Pediatrics, Georgetown University Medical Center, Washington, DC.

Tetrasomy 18p was identified postnatally in a newborn infant by high-resolution karyotype analysis and confirmed by FISH. The pregnancy was uncomplicated; prenatal tests were normal, except for a low baseline fetal heart rate and maternal hyperemesis gravidarum. Multiple congenital anomalies and dysmorphic features were observed at birth including: bilateral talipes equinovarus; slanted palpebral fissures; retromicrognathia; adducted thumbs; capillary hemangiomas on the forehead and occiput; small, low set and rotated ears; prominent nose; short neck; bilateral transverse palmar creases; hypertonicity; grade II/VI heart murmur; and both atrial and ventricular septal defects. The proband's mother and maternal uncle also had VSDs at birth. Heart valve defects, feeding difficulties, hypertonicity, short neck, craniofacial deformities, low set ears and hand/foot deformities have been reported previously by others as well (Takeda et al., 1989, Pinto et al., 1998). G-band analysis revealed a small supernumerary metacentric chromosome that appeared to consist of 18p material in all cells. FISH was performed using probes specific to the telomeres and centromere of chromosome 18. All metaphases examined had 18p telomere probe signals on each end of the supernumerary chromosome. The centromere also appeared to be enlarged indicating duplication of the centromeric region. Proximal 18q11.2 is also believed to be duplicated based on the G-band appearance of the supernumerary chromosome. The karyotype was 47,XY,+idic(18)(q11.2).ish idic (18q11.2)(18ptelx2, D18Z1x2). Parental bloods were karyotypically normal. A two month follow up was significant for several ear infections and severe bilateral hearing loss. The patient has neck and right arm contractures, similar to a report by Pinto et al. (1998). The feeding problems have resolved; weight is now at the 50th percentile. Subsequent pregnancies in the parents will be monitored with prenatal genetic testing in the unlikely event of gonadal mosaicism.

Monte Carlo Simulations in Clinical Cytogenetics: Modeling the Detection of Abnormal Cell Subpopulations. *K. Shera*¹, *G. Bonnet*¹, *C.A. Shera*². 1) Cytogenetics Studio, Santa Fe, NM; 2) Harvard Medical School, Boston, MA.

The American College of Medical Genetics has proposed quality standards and guidelines for clinical cytogenetic analysis (ACMG, 2003). For specimens of peripheral blood or bone marrow, the ACMG recommends that a minimum of 20 metaphase cells be evaluated, and in many US clinical cytogenetics laboratories, evaluation of 20 cells constitutes a routine clinical cytogenetic analysis. When test sensitivity is 100%, a 20-cell analysis is sufficient to exclude mosaicism or an abnormal clonal subpopulation of approximately 15% with 95% confidence (Hook, 1977). A larger sample is required to: (1) rule out lower levels of mosaicism or clonal abnormality, or (2) maintain power when test sensitivity is less than 100%, as in cancer or molecular cytogenetic analysis. How large a sample is large enough? In statistical terms, a cytogenetic analysis represents a simple random sample of size n , drawn from the total population of cells collected from the patient under study. We used Monte Carlo simulation, a powerful stochastic method, to model the random sampling of cell populations harboring different proportions of chromosomally abnormal cells, while varying test sensitivity and sample size. For a test of a defined sensitivity, we determined the sample size required to detect a given abnormal cell subpopulation, assuming a variety of sampling distributions. When test sensitivity was 85% (as in some FISH analyses), exclusion of a clonal abnormality of 20% required analysis of 300 cells; a 200-cell analysis failed to detect the clone between 9-16% of the time, depending on the variance in test sensitivity. Our study highlights the fundamental role of sample size in quality clinical cytogenetic analysis. As a practical aid to the clinical cytogenetics lab, we present a series of Monte Carlo detection curves, simple tools for estimating the minimum sample size required to reliably detect a given abnormal cell subpopulation when using a test of a known sensitivity, or conversely, the confidence level attained in excluding that subpopulation when a defined number of cells is analyzed. The detection curves are applicable to both conventional and molecular cytogenetic analysis.

Newborn with diaphragmatic hernia and single cell with marker chromosome: think Pallister-Killian syndrome.

S.L. Wenger¹, M. Schmidt¹, A.C. Obringer². 1) Dept Pathology, West Virginia Univ, Morgantown, WV; 2) Dept Obstetrics and Gynecology, West Virginia Univ, Morgantown, WV.

The infant was born at 30 weeks gestation to a 33-year-old female. During the pregnancy, an ultrasound at 24 weeks identified a diaphragmatic hernia. The stomach was in the thoracic cavity medial to the heart. Polyhydramnios, bilateral short femurs and a left renal cyst were also present. The patient received genetic counseling and declined amniocentesis. A fetal echocardiogram at 25 weeks was within normal limits. The mother had a history of poorly controlled type 1 diabetes. Family history was significant for a maternal uncle who died at 3 years of age with a congenital heart defect, and two paternal half-nephews with congenital deafness. The mother was hospitalized at 29 weeks with preterm labor. Nine days later the fetal membranes ruptured and a Cesarean section was performed due to fetal heart distress. The birth weight of the male infant was 1240 g, with APGAR scores of 4/5/6 at 1, 5, and 10 minute, respectively. A peripheral blood sample was drawn for chromosome analysis. The newborn died on the second day of life due to respiratory distress syndrome. The karyotype was normal with 1 of 20 cells containing a small metacentric marker chromosome, thought to be an isochromosome 12p. The marker was confirmed as being an isochromosome 12p using an alpha-satellite FISH probe for chromosome 12 in interphase cells. An autopsy was not performed on the patient. Paraffin slides on the umbilical cord and placenta were obtained to examine other tissue. The percentage of interphase cells with the isochromosome 12p was 43% in peripheral blood with more than twice as many signals in non-stimulated cells (68%) versus stimulated cells (24%). In umbilical cord cells, 35% contained 3 signals, similar to 30% in the placenta. To our knowledge, this is the third reported case that has examined paraffin slides to determine or confirm mosaicism in multiple tissues for Pallister-Killian syndrome.

Automated detection of metaphase chromosomes in FISH and routine cytogenetics. *P. Yanala^{1,2}, T. Lu², F. El-Ghussein^{1,2}, C. Zhao², D. Medhi^{1,2}, Y-P. Wang², J. Knopp², J.H.M. Knoll¹, P.K. Rogan^{1,2}.* 1) Children's Mercy Hospital, Schools of Medicine and; 2) Computer Science and Engineering, University of Missouri-Kansas City.

We present an integrated, automated microscopy system that has been designed to assist the cytogeneticist in rapidly selecting the optimal metaphase spreads for routine cytogenetic or FISH analyses. After the boundaries of the coverslip are localized, slides are raster-scanned and either DAPI-stained or GTG-banded metaphase cells are distinguished from other objects at low magnification. Autofocusing at both low and high magnification maximizes contrast across features in the image based on Brenner's Sharpness Measure. Procedures for determining the optimal focal position could be expedited at low power, based on the fact that focal planes of adjacent fields of view are nearly identical. The metaphase detection algorithm has a specificity of 98% and sensitivity of 54%. The centroids of these metaphase cells are relocated and recentered at high power magnification (100X objective), and, for FISH, DAPI and probe images are captured using automated exposure controls that are customized for each channel. Metaphase images are ranked using a content-based classification system trained on features extracted from chromosome spreads. The ranking procedure differentiates metaphase cells with limited chromosomal overlap from incomplete or poorly spread metaphases. This algorithm has an average precision of 88% with an 80% recall rate relative to ranking by an experienced cytogeneticist. Multichannel images are uploaded to a modified version of the web-based Open Microscopy Environment, where they are merged and indexed for subsequent retrieval or recapture. The integrated expert system (a) substantially increases the throughput: allowing many more probes to be analyzed in the same time frame; (b) mitigates fluorescent bleaching due to prolonged light exposure; (c) efficiently manages large volumes of cytogenetic data; and (d) potentially reduces errors due to eye strain, thereby improving identification of chromosomal abnormalities.

Recurrent sites for new centromere seeding. *M. Ventura*¹, *S. Weigl*¹, *L. Carbone*¹, *M.F. Cardone*¹, *D. Misceo*¹, *M. Teti*¹, *P. D'Addabbo*^{1,2}, *A. Wandall*³, *E. Bjork*⁴, *P.J. de Jong*⁵, *X. She*⁶, *E.E. Eichler*⁶, *N. Archidiacono*¹, *M. Rocchi*¹. 1) Dept Dapeg Sez Genetica, Univ Di Bari, Bari, Italy; 2) Center for Research into Molecular Genetics Fondazione CARISBO, Institute of Histology and General Embryology, University of Bologna, Bologna, Italy; 3) Dept. of Medical Genetics, Panum Institute, Copenhagen, Denmark; 4) Department of Molecular Medicine, Karolinska Institutet, Stockholm Sweden; 5) Children's Hospital Oakland Research Institute, Oakland, CA; 6) Department of Genetics, Case Western Reserve University School of Medicine, Cleveland, OH.

Using comparative FISH and genomics, we have studied and compared the evolution of chromosome 3 in primates and two human neocentromere cases on the long arm of this chromosome. Our results show that one of human neocentromere cases maps to the same 3q26 chromosomal region where a new centromere emerged in a common ancestor of the Old World monkeys approximately 25-40 million years ago. Similarly, the locus where a new centromere was seeded in great apes ancestor was orthologous to the site where a new centromere emerged in New World monkeys ancestor. These data suggest the recurrent use of longstanding latent centromeres and that there is an inherent potential of these regions to form centromeres. The second human neocentromere case (3q24) revealed unprecedented features. The neocentromere emergence was not accompanied by any chromosomal rearrangement that usually trigger these events. Instead, it involved the functional inactivation of the normal centromere, and was present in an otherwise phenotypically normal individual who transmitted this unusual chromosome to the next generation. We propose that the formation of neocentromeres in humans and the emergence of new centromeres during the course of evolution share a common mechanism.

Hidden 45, X/47, XXX/47, XX, del(Y)(p?)/46, XX mosaicism associated with True Hermaphroditism (TH). *K. Nieto¹, S. Kofman-Alfaro¹, R. Alvarez¹, Y.R. Pena², I. Palma¹, L. Erana², L.M. Dorantes², G. Queipo¹.* 1) Dept. Genetics, Hospital General de Mexico, Mexico City, Mexico; 2) Intersex Clinic. Hospital Infantil de Mexico-Federico Gomez, Mexico City, Mexico.

True hermaphroditism (TH) is an unusual form of sex reversal, characterized by unequivocal testicular and ovarian elements in the same individual. Approximately 60% TH have a 46, XX karyotype, 33% are mosaics with a second cell line containing a Y chromosome, while the remaining 7% are 46, XY. The Sex determining gene *SRY*, is present in only 10% of true hermaphrodites with a 46, XX karyotype, therefore in the remaining 90%, mutations at unknown X-linked or autosomal sex determining loci have been proposed as factors responsible for testicular development. TH presents considerable genetic heterogeneity with several molecular anomalies leading to the dual gonadal development in a single subject. In 1998, gonadal *SRY* mosaicism was proposed in 3 sporadic 46, XX TH *SRY*- negative in blood leukocytes but positive in gonadal tissue and in 2002 the presence of hidden mosaicism for Y-derived sequences was confirmed as an alternative mechanism to explain TH etiology in some cases. Here we report a new TH case in which a hidden mosaicism for the Y and X chromosome was detected by PCR and FISH in peripheral blood and gonadal tissue, supporting the fact that hidden mosaicism is associated with TH and that molecular analysis of gonadal tissue should be done in all 46, XX cases.

A sub-microscopic duplication of Xq27.1 including the *SOX3* gene is associated with hypopituitarism. M.

*Cundall*¹, *K. Woodward*¹, *K. Woods*², *J. Turton*², *R. Palmer*³, *T. Otonkoski*⁴, *M.T. Dattani*². 1) Clinical and Molecular Genetics Unit, Institute of Child Health, London, United Kingdom; 2) Centre for Paediatric Endocrinology, Biochemistry, Endocrinology and Metabolism Unit, Institute of Child Health, London, United Kingdom; 3) N.E. London Regional Cytogenetics Laboratory, Great Ormond Street Hospital for Children NHS Trust, Queen Square, London, United Kingdom; 4) Department of Endocrinology, Hospital for Children and Adolescents, University of Helsinki, Finland.

Recent studies have implicated *SOX3* in the etiology of X-linked hypopituitarism. Sox3 belongs to the B1 subfamily of Sox transcription factors and marks neuroepithelial progenitor and stem cells from the earliest stages. Expansion of a polyalanine tract within *SOX3* has been implicated in X-linked mental retardation associated with isolated GH deficiency (IGHD), and interstitial duplications encompassing *SOX3* at Xq26.1-q27.3 have been associated with variable GHD and hypopituitarism. To date, the smallest duplication identified spans 9Mb.

We screened a cohort of males with hypopituitarism and identified a family in which 2 siblings (variable hypopituitarism with absent infundibulum and anterior pituitary hypoplasia) have been shown to harbour a sub-microscopic duplication of 690kb on chromosome Xq27.1. Increased dosage of *SOX3* was confirmed by interphase FISH using a BAC probe containing *SOX3*. The chromosome rearrangement in this family is small and was not identified by standard chromosome analysis, and we have shown that the duplication is tandem in nature. The extent of the duplication has been characterised by interphase FISH in this family using further probes from the region and the duplication breakpoints have been identified.

The duplicated region in this family included just the *SOX3* gene and two novel uncharacterised genes. This, to our knowledge, is the smallest duplication described to date. Since *SOX3* has already been associated with hypopituitarism we suggest that increased dosage of this gene is the primary cause of the pituitary abnormalities in this family.

Evidence Of Preferential Meiotic Segregation In Two Balanced Translocations. *J. Cuzzi*¹, *C.G. Petersen*², *A.C. Laus*¹, *A.L. Mauri*², *R.L.R. Baruffi*², *J.G. Franco Jr*², *L. Martelli*¹. 1) Genetics Department, University of Sao Paulo, Ribeirao Preto, Sao Paulo, Brazil; 2) Human Reproduction Centre, FMSJ, Ribeirao Preto, Sao Paulo, Brazil.

Chromosome translocations are associated with aneuploid gametes, which may be responsible for embryos with unbalanced karyotypes, first trimester abortions, fetal losses or liveborns with a chromosomal syndrome. Preimplantation genetic diagnosis (PGD) is an early form of prenatal diagnosis, which makes possible to detect hereditary genetic diseases in human embryos. In this study, we present the PGD results in two young couples, with normal phenotype, presenting recurrent abortions. In the first one (couple A), the spouse was the carrier of robertsonian translocation involving chromosomes 13 and 14, with karyotype 45,XX,der(13;14)(q10;q10) and in the second (couple B), she was the carrier of reciprocal balanced translocation involving chromosomes 7 and 18, with karyotype 46,XX,t(7;18)(q31;q22). Our objective was to establish a molecular cytogenetic diagnosis, to indicate the transfer of euploid embryos. In Couple A, seven embryos were biopsied and 6 nuclei were submitted to fluorescent in situ hybridization (FISH) technique, using 14q telomeric and LSI 13q14 probes. All nuclei showed 2 signals (compatible with normal or balanced karyotype) corresponding to chromosome 14, but presented aneuploidy of chromosome 13, three of them being monosomic and two trisomic. In Couple B, five embryos were biopsied and 5 blastomeres were obtained and submitted to FISH technique, using 7q and 18q telomeric probes. All nuclei showed 2 signals related to chromosome 18, but presented aneuploidy of chromosome 7, three of them being trisomic and one monosomic and the diagnosis was inconclusive in one blastomere. Therefore, the transfer of the embryos was not indicated in both cases. Our results in both patients make evident a mechanism of preferential meiotic segregation where all oocytes were abnormal for one of the involved chromosomes in the translocations. PGD was able not only to select the embryos, but also to define the risk for the offspring, fetal losses and the birth of an affected child.

Molecular cytogenetics analysis for diferencial diagnosis of lissencephaly. *A.C. Laus¹, A.C. Santos², S.A. Santos¹, J.F. Cuzzi¹, E.S. Ramos¹, L.R. Martelli¹.* 1) Genetics, University of São Paulo, Ribeirão Preto, São Paulo, Brazil; 2) Radiology, University of São Paulo, Ribeirão Preto, São Paulo, Brazil.

Classical or type I lissencephaly (LIS) is a malformation characterized by smooth cerebral surface (cortical agyria-pachygyria) originated by incomplete neuronal migration during embryonic development. LIS can be described in two forms: Miller-Dieker Syndrome (MDS) and Isolated Lissencephaly Sequence (ILS). MDS consists of lissencephaly, characteristic facial abnormalities, sometimes associated to other birth defects, and almost 100% of the patients present deletion of LIS1 gene, located to 17p13.3. The ILS main finding is the cortical malformation, without other abnormalities. This type can be associated with alterations in LIS1 or DCX gene, located to Xq22.3-q23, which encodes proteins associated with neuronal movement. The aim of this study was to perform molecular cytogenetic analysis of the short arm of chromosome 17 in ten patients with lissencephaly to determine the diferencial diagnosis and to provide adequate genetic counseling to their families. We have performed routine cytogenetic and molecular cytogenetic analysis in patients presenting lissencephaly confirmed by magnetic resonance image. The cytogenetic studies included GTG high resolution banding; for the FISH protocols we have used specific probes located to 13.3 and 11.2 regions and telomeric region of the short arm of chromosome 17. The results did not show any numerical or structural chromosomal abnormalities and any deletion in 17p13.3 region nor in the tel17p region. The protocol was useful to exclude the diagnosis of Miller-Dieker syndrome in all patients and to formulate the diagnosis of X-linked lissencephaly in one family, changing the recurrence risks for the families. According to the literature lissencephaly results from complex genetic and biochemical mechanisms. In our study we have analyzed just the 17p13.3 and telomeric regions. Therefore, we suggested that other mechanisms, as intragenic mutation in LIS1 gene undetected by FISH, alterations in DCX gene, alterations in PAFAH1B2 or PAFAH1B3 subunits or even some environmental factors could explain the cortical malformation.

Molecular Cytogenetic Anchors for the Zebrafish Genome. *C. Lee*^{1,2}, *H. Stern*^{1,2}, *C.D. Belair*^{2,3}, *Y. Zhou*^{2,3}, *B.H. Paw*^{2,3}, *L.I. Zon*^{2,3}, *A. Smith*¹. 1) Department of Pathology, Brigham & Woman's Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Children's Hospital, Boston, MA.

The zebrafish, *Danio rerio*, is an important model organism for studying vertebrate development, cell biology and cancer. The zebrafish genome is organized into 25 pairs of chromosomes that are difficult to unequivocally identify solely on the basis of classical cytogenetic methods that rely on chromosome size, morphology and dark-and-light banding patterns. Systematic mapping of large-insert clones to metaphase chromosome spreads from wildtype zebrafish will provide molecular cytogenetic anchors for the zebrafish genome, which in turn could be integrated with the well-developed linkage maps. We have now mapped a total of 74 BAC clones, containing genomic DNA inserts of an average of 170 kb. Each clone has been end-sequence verified prior to FISH-mapping. Flanking z-markers serve as reference points for relative positioning of these clones on the various available linkage maps. With the exception of the chromosome corresponding to linkage group 4, three clones were identified for each chromosome: one near each chromosome end (telomere) and one near the primary constriction (centromere). The apparent presence of a substantial amount of heterochromatin on the long arm of the linkage group 4 chromosome has precluded identification of a specific near-telomeric probe for this chromosome region. These DNA probes are extremely useful for assessing chromosome translocations, ploidy and genomic instability in mutants and tumor material. These molecular cytogenetic anchors also refine current zebrafish linkage maps, providing a framework that underlies the correct assembly of the DNA sequence of the zebrafish genome.

Program Nr: 1004 from the 2004 ASHG Annual Meeting

Numerical chromosomal anomalies of the tissues involved in neural tube defects (NTD). *D.R. Lucon, D.P. Cavalcanti.* Perinatal Genetics Program, Dept. Medical Genetics, UNICAMP, Campinas, Sao Paulo, Brazil.

Chromosomal anomalies have been described in a number of children displaying neural tube defects. Interphasic FISH was suggested to be an appropriated tool analyzing criptomosaicism in malformed babies. In a recent paper it was reported chromosomal variation in neurons of both, developing and adults mammalian nervous system. The purpose of this study was to investigate tissue involved in neural tube defects (TINTD) applying interphasic FISH technique. We report the results of the investigation from 13 cases of children presenting neural tube defects (NTD). In the studied samples, cytogenetical and karyotype analysis were performed from peripheral lymphocytes. Also, analysis of the TINTD by conventional karyotype and interphasic FISH were realized. Standard procedures for cytogenetics analyses were employed. At least 15 metaphases from lymphocytes and 15 from the TINTD for each case were studied by GTG banding. Interphasic FISH analysis was performed using the multiprobe system (Cytocell), and from each case, at least 300 nucleous were accounted. With the purpose of defining the confidence limit, a control sample was taken from peripheral lymphocytes of 10 clinically normal newborns. The results showed four mosaicisms: three tetraploid/diploid cases and one monosomy 6. The monosomy 6 and one case of $4n/2n$ were detected only by the interphasic FISH of the TINTD. It was also detected a probable pseudomosaicism represented by a monosomy 8. The conclusions are that 7.7 % chromosomal numeric anomalies were found in lymphocytes from peripheral blood, 15,4% in TINTD by conventional cytogenetics, and 25% in TINTD by interphasic FISH. These results suggest that numerical anomalies could be very common in tissues involved in neural tube defects. Moreover, these results suggest that further studies with neural tissues in humans are fundamental to clarify the relationship between chromosomal numerical anomalies and nervous tissues. (Supported by FAPESP, 98/16006-6).

Program Nr: 1005 from the 2004 ASHG Annual Meeting

Breakpoint analysis of a balanced reciprocal t(3p;10p)translocation in a Bardet-Biedl syndrome patient. *H.L. May-Simera, P.J. Scambler, P.L. Beales.* Molecular Medicine Unit, Institute of Child Health, London, United Kingdom.

Bardet-Biedl syndrome (BBS) is a heterogeneous disorder with primary features that include age-related retinal dystrophy, obesity, polydactyly, renal dysplasia, reproductive tract anomalies and cognitive impairment. Eight loci have been found to be causative for the disease (*BBS1-8*), for which seven have been cloned. Recent evidence suggests that aspects of the BBS phenotype may result from defective ciliogenesis/basal body function. We identified a female Iranian BBS patient with a paternally inherited balanced reciprocal translocation t(3;10)(p13;p15.3) in whom we have excluded mutations in known BBS genes. Given the coincidental G-banding karyotype localisation of the breakpoint in 3p13 with the published linkage interval for *BBS3* (3p13-12), we performed FISH analysis on EBV transformed PBL to determine if breakpoints are associated with gene disruption. The 3p breakpoint mapped outside the locus for *BBS3*, but localised within an incomplete region of the genome sequence. Although we can exclude this region from *BBS3* we cannot yet rule out the possibility of an additional disease-related gene at 3p14. Likewise, the breakpoint on 10p potentially disrupts two candidates, one of which is directly involved with microtubule assembly and intracellular transport. We report results of our translocation mapping approach in an attempt to identify a novel BBS gene.

Analysis by fluorescence in situ hybridization (FISH) of the relation between gonosomal aneuploidy and the results of assisted reproduction in men with severe oligospermia. *M. MEHDI, M. BENCHAIIB, B. SMATTI, J.F. GUERIN.* Laboratory of Biology of reproduction, Faculty of Medicine, University Claude BERNARD, Lyon, France.

OBJECTIVE: The aim of this study was to analyze the frequency of sex chromosome aneuploidy in human spermatozoa of severe oligozoospermic men undergoing intracytoplasmic sperm injection (ICSI), in order to evaluate the impact of these chromosomal anomalies on the results of the ICSI. **MATERIALS AND METHODS:** Fluorescent in situ hybridization (FISH) with direct label fluorescence DNA probes specific for chromosome X, Y and 18, was performed on decondensed spermatozoa from fresh ejaculates of 12 patients with severe oligozoospermia undergoing ICSI. A total of 500 spermatozoa were analyzed per chromosome per probe per donor. **RESULTS:** The rate of gonosomal aneuploidy was significantly increased in the patients compared with the case in the normal donor (respectively 3,5 and 0,8%). The sex-chromosomal anomalies due to the I meiosis (XY) are less important than the anomalies due to the II meiosis (XX or XY), but the difference was not statistically significant. There was a negative correlation between the rate of aneuploidy and the percentage of spermatozoa with normal morphology ($r = -0,71$; $p < 0,05$). The correlation was negative between the percentage of gonosomal aneuploidy and the rate of fertilization ($r = -0,7$; $p < 0,001$). In conclusion, our results suggest an increased rate of gonosomal aneuploidy in the patients with oligozoospermia compared with the normal population. This aneuploidy, although it decreases the rate of fertilization, doesn't seem to affect the rate of segmentation, nor the embryonic quality.

Program Nr: 1007 from the 2004 ASHG Annual Meeting

Sperm aneuploidy in the male partners of the couples with Bad Obstetric History. *Z.M. Patel, A. Meka, H.M. Gawde, S.R. Menon.* NIRRH/GRC, Indian Council Medical Research, Jehangir Merwanji Street, Parel Mumbai, India.

Approximately 15% of all conceptions end in spontaneous abortions in the first trimester and 60% of it bear chromosomal abnormalities. Of the various vital factors involved, sperm aneuploidies may be one. Thus, the objective of this research was to investigate the relationship between sperm aneuploidy and spontaneous abortions (simultaneously looking into other factors). The study also aims at looking into correlation between sperm morphology, count and aneuploidies. 20 semen samples (200000 cells) from male partners of the couples with 2 or more abortions, were analyzed for aneuploidies for chromosomes 13, 21, 18, X, and Y using multicolor LSI (13,21) and CEP (18, X&Y) FISH probes. FISH analysis showed marked deviation from normal only in 5 patients of the 20 analyzed. The mean frequency of total disomic sperm (X-X, X-Y, Y-Y, 13-13,21-21) was 14.65 per 10^4 cells (range 1- 190), frequency of total diploid sperm was 10.1 per 10^4 cells (range 7-175) and frequency of total nullisomic sperm was 10.75 per 10^4 cells (range 1-75). Details of sperm count and percentage of abnormal forms were also obtained wherever possible and they were analyzed for correlation. The analysis reveals no correlation between aneuploidies and sperm morphological abnormalities as well as between aneuploidies and sperm count. Our study suggests that sperm morphology and count in themselves are not sufficient to rule out the role of sperms in spontaneous abortions.

Developmental Genome Anatomy Project (DGAP): In Search of Genes Critical for Human Development. *F. Quintero-Rivera*^{1,4}, *G.A. Bruns*^{2,4}, *D.J. Donovan*³, *R. Eisenman*², *H.L. Ferguson*³, *D.J. Harris*^{2,4}, *A.W. Higgins*^{3,4}, *A.H. Ligon*^{3,4}, *H.G. Kim*^{1,4}, *K.M. Kocher*⁴, *W. Lu*^{3,4}, *R.L. Maas*^{3,4}, *S.D. Moore*^{3,4}, *N.T. Leach*^{3,4}, *R. Peters*³, *B.J. Quade*^{3,4}, *I. Saadi*^{3,4}, *R.E. Williamson*⁴, *C.C. Morton*^{3,4}, *J.F. Gusella*^{1,4}. 1) Massachusetts General Hospital, Charlestown, MA; 2) Children's Hospital, Boston, MA; 3) Brigham & Women's Hospital, Boston, MA; 4) Harvard Medical School, Boston, MA.

DGAP (<http://dgap.harvard.edu>) represents an integrated approach to finding genes important in human development by studying individuals who have apparently balanced chromosomal rearrangements and congenital anomalies. Our progress to date includes ascertainment of 160 cases, 71 FISH-mapped breakpoints, and localization of 48 breakpoints from 33 cases within single BAC clones. Candidate genes have been identified in 23 cases and breakpoints cloned in 7 cases. Of 13 breakpoints analyzed in detail, 9 reside within the intron of a gene, none is within an exon, one occurs within a 3' UTR, and 3 are present in putative non-genic regions with the breakpoint in the other derivative chromosome disrupting a known gene. Microdeletions, insertions and duplications involving a few nucleotides have been detected in 6 cases and presently are interpreted not to be of pathological significance. Evaluation of possible conserved non-genic sequences in these introns is being studied in addition to assessing of candidate genes. Mutational analyses of patients with phenotypes similar to a DGAP case are being performed in 8 cases. Knock-out mouse models of 6 candidate genes from 5 DGAP cases are being created; chimeric mice have been obtained for all 6 genes and breeding for germline transmission is underway. As the number of mapped cases increases, the DGAP database will provide a resource to predict clinical severity of *de novo* balanced chromosomal rearrangements diagnosed pre- and post-natally. Because it is currently not possible to make such clinical prognoses, this database will be a valuable contribution in the improvement of genetic counseling and subsequent decision-making. DGAP investigators thank the many geneticists worldwide who make this project possible.

22q11 rearrangements in different patients groups. *M. Kriek¹, K. Szuhai², S. White¹, S. Kant¹, J. Knijnenburg², J. Dauwerse¹, C. Rosenberg², J. den Dunnen¹, M. Breuning¹.* 1) Center for Human and Clinical Genetics, Leiden University Medical Center, Leiden, Netherlands; 2) Molecular Cell Biology, Leiden, Netherlands.

The 22q11 region contains 4 highly homologous sequences, known as low copy repeat sequences (LCR). Despite the difference in size and organisation of the repeats, the overall sequence identity is 97-98 %. This homology predisposes for unequal recombination between the different LCRs. Different genomic disorders caused by rearrangements within 22q11, are characterized by an enormous variation in clinical features with no obvious relation between the size of the genomic imbalance and the severity of the clinical characteristics. To investigate 22q11 alterations in different patients groups, we have screened 96 adult patients diagnosed with Tetralogy of Fallot (TOF) as well as 220 mild to severe developmental delayed (DD) patients with a normal karyotype using Multiplex Amplifiable Probe Hybridisation (MAPH) and Multiplex Ligation-dependent Probe Amplification (MLPA). Seven deletions of 22q11.2 were diagnosed among the TOF patients (7.3%), a figure similar to that reported by other studies. The screening of DD patients resulted in the detection of 2 alterations; in one case a duplication of 22q11.2, and in the other a more complex chromosome rearrangement. By MAPH analysis, we demonstrated a deletion on 22q11.1 and a duplication on 22q11.2. Additional arrayCGH analysis revealed a second deletion on chromosome band 22q12 in the same patient. Since Fluorescent In Situ Hybridisation (FISH) experiments had already excluded the patients presenting a typical 22q deletion phenotype from our samples, the number of alterations detected is rather high (~1%). The limited number of described duplications on 22q11.2 is probably due to a combination of phenotypic diversity and difficulty of diagnoses by FISH analysis on metaphases. MLPA represents a better technical alternative for diagnosing copy number changes in 22q11, as it simultaneously detect deletions and duplications. Moreover, in contrast to FISH experiments, MLPA can target small rearrangements and does not depend on dividing cells for analysis.

Variation in meiotic recombination frequencies among human males. *F. Sun*^{1,2}, *K. Trpkov*³, *A. Rademaker*⁴, *E. Ko*², *R.H. Martin*^{1,2}. 1) Dept Medical Genetics, Alberta Children's Hosp, Calgary, AB, Canada; 2) Department of Medical Genetics, University of Calgary, Calgary, Canada T2N 4N1; 3) Department of Pathology, Rockyview Hospital, Calgary, Canada T2V 1P9;; 4) Cancer Center, Biometry Section, Northwestern University Medical School, Chicago, USA, 60611-4402.

Meiotic recombination (crossing over) is essential for the segregation of homologous chromosomes and formation of normal haploid gametes. Little is known about patterns of meiotic recombination in human germ cells or the mechanisms that control these patterns. The aim of this study was to determine the extent of variation in the frequency of recombination in human males and to uncover any variables contributing to this variation. Newly-developed immunofluorescence techniques, based on the detection of MLH1 (a DNA mismatch repair protein) foci on synaptonemal complexes (SCs) at prophase of meiosis, were used to examine recombination in human spermatocytes. The mean number of MLH1 foci per cell in 11 donors was 48.0 with range from 21 to 65. Remarkable variation in the recombination frequency was noted among 11 normal individuals: the mean frequencies of chromosomal recombination foci ranged from a low of 42.5 to a high of 55.0 exchanges. Donor age did not contribute to this variation. There was no correlation between this variation and the frequency of gaps (discontinuities) or splits (unpaired chromosome regions) in the SCs. The mean percentage of cells with gaps was 35% (range 20-58%) and with splits was 7% (range 0-37%). In our observations of more than 20,000 autosomal SCs, the proportion of bivalents without a recombination focus was 0.3%. Thus, achiasmate chromosomes appear to be rare in human male meiosis.

Interstitial Deletions of Chromosome 6q: Genotype-Phenotype Correlation of Three Patients Utilizing Array Comparative Genomic Hybridization. *O. Klein¹, P. Cotter¹, A. Zanko¹, M. Gilats¹, C. Epstein¹, F. Conte¹, D.*

Albertson², D. Pinkel², K. Rauen¹. 1) Dept. of Pediatrics, UCSF, San Francisco, CA; 2) Dept. of Laboratory Medicine, UCSF, San Francisco, CA.

Interstitial deletions of chromosome 6q are relatively rare, with approximately 50 cases reported. Phenotypic variation is due to differences in size and location of the segmental aneuploidy. Here, we report three new patients with interstitial deletions of chromosome 6q characterized by array CGH. Patient 1 had a conventional karyotype 46,XY,del(6)(q15q16.2) and had craniofacial dysmorphism including brachycephaly, downslanting palpebral fissures and low-set, dysplastic ears. He also had retinitis pigmentosa and strabismus. Patient 2 had a karyotype 46,XY,del(6)(q16.2q21). He had IUGR, and craniofacial dysmorphism included brachycephaly, hypotelorism with downslanting fissures and dysplastic ears. The patient also had a visual abnormality, minor hand and foot anomalies, truncal obesity and delayed myelination on brain MRI. Patient 3, whose conventional karyotype was 46,XY,del(6)(q15q16.2), had low-set ears, a visual abnormality, minor hand and foot anomalies, truncal obesity and diabetes insipidus. All patients were developmentally delayed. To define the molecular breakpoints and deletion size, array CGH analysis was performed. Deleted regions were as follows: Patients 1 and 2 had minimal deletions of 6 Mb involving 6q16.2q21 and 8.8 Mb involving 6q16.2q21, respectively. Patient 3 had the largest deletion of 11.3 Mb spanning 6q15q21. All three had developmental, ear and eye anomalies, suggesting genes for brain and craniofacial development in 6q16.2q21, the deleted region common to the patients. Furthermore, gene(s) for discordant features, such as diabetes insipidus, may reside at 6q15, the monosomic region unique to Patient 3. In two of three cases, the molecular breakpoints differed from those indicated by conventional karyotyping, demonstrating the enhanced resolution of array CGH. The improved characterization of segmental aneuploidy by array CGH may impact the prediction of a patient's phenotype and prognosis, as well as provide finer mapping of candidate genes for specific malformations.

Phenotypic features in a boy with trisomy of 16q22-qter due to paternal Y;16 translocation. A. Talarski^{1,2}, F. Tsien², E. Morava³, M. Marble^{1,2}. 1) Genetics, LSU Health Science Center, New Orleans, LA; 2) Children's Hospital of New Orleans, New Orleans, LA; 3) UMC Nijmegen, The Netherlands.

The incidence of Y;autosome translocation in newborns is approximately 1/10,000, with the long arm of chromosome Y most frequently involved. Most patients with either unbalanced or apparently balanced Y-autosome translocations are infertile, usually due to disruption of one of the DAZ genes in the azoospermia factor (AZF) region in the euchromatic area of the Y chromosome long arm. We report an 8-year old patient with partial trisomy of the long arm of chromosome 16. High resolution chromosome analysis revealed an unbalanced Y;16 translocation [46,X,der(Y)t(Y;16)(q12;q22)pat], which was confirmed by fluorescence *in situ* hybridization (FISH) using whole chromosome paint probes for chromosomes Y and 16. The patient was noted to have craniofacial anomalies including a prominent forehead, thin upper lip, and smooth philtrum. He also had growth deficiency and mental retardation. The father, a balanced Y;16 translocation carrier, has apparently normal fertility since the Y chromosome breakpoint is in the heterochromatic region distal to the DAZ genes. He has no dysmorphic features. There have only been a few published reports of trisomy for 16q22-qter. In these previous cases, phenotype/cytogenetic correlations have been difficult to assess due to the overlapping effects of the other involved chromosome. In contrast, since the translocation breakpoint in our patient involves Y heterochromatin, it is likely that the patient's phenotype is reflective of true 16q22-qter trisomy. Analysis of additional cases of trisomy 16q will help to further delineate the trisomy 16q phenotype.

IS THE PRADER-WILLI SYNDROME PHENOTYPE RELATED TO MOLECULAR MECHANISMS? A STUDY OF 75 PATIENTS. *M.C. Varela¹, F. Kok², N. Setian³, C.A. Kim⁴, C.P. Koiffmann¹*. 1) Human Genome Study Center, Department of Biology, Bioscience Institute, University of Sao Paulo, Sao Paulo, SP, Brazil. email: mcvarela@ib.usp.br; 2) Child Neurology Service, Dept of Neurology, Univ of Sao Paulo School of Medicine; 3) Endocrinology Unit, Childrens Institute, Univ of Sao Paulo School of Medicine; 4) Childrens Institute, Univ of Sao Paulo School of Medicine.

Prader-Willi syndrome (PWS) can result from either a 15q11-q13 paternal deletion, maternal uniparental disomy (UPD), or imprinting mutations. We describe here the phenotypic variability detected in 51 patients with different classes of deletions and 24 patients with UPD. Diagnosis was made by methylation pattern analysis of exon 1 of the SNRPN-SNURF gene and by microsatellite profiling of loci within and outside the 15q11-q13 region. Although no statistically significant differences could be demonstrated between the two main classes of PWS deletion patients, it was observed that Class I (BP1-BP3) patients acquired speech later (4 years 4 months) than Class II (BP2-BP3) patients (3 years 3 months). Comparing the clinical pictures of our patients with UPD with those with deletions, we found that: UPD children presented lower birth length and started walking earlier, at age 2 on the average, whereas in deletion patients the average was 2 years and 5 months; deletion patients presented a much higher incidence of seizures (45%) than UPD patients (7.14%); the mean maternal age in the UPD group was higher than in the deletion group. No statistically significant differences could be demonstrated between the deletion and the UPD group with respect to any of the major features of PWS (neonatal hypotonia, poor sucking and failure to thrive in the postnatal period, delayed psychomotor development and facial features). In conclusion, our study did not detect significant phenotypic differences among Class I and Class II PWS deletion patients, but it demonstrated that seizures were six times more common in patients with a deletion than in those with UPD. This finding might be accounted for by haploinsufficiency of genes related with seizures (as GABRB3) in the deleted region. Supported by: FAPESP, CEPID, CNPq.

Recurrent Trisomy 21: Four Cases in Three Generations. *J.L. Gair¹, R. Rupp¹, L. Arbour¹, R. Jiang¹, H. Bruyere², W.P. Robinson¹.* 1) Dept. of Medical Genetics, University of British Columbia, Vancouver, BC Canada; 2) Dept. of Pathology, University of British Columbia, Vancouver, BC, Canada.

While gonadal mosaicism can lead to recurrence of trisomy 21 for a single couple, recurrence of free trisomy 21 in multiple members of a single pedigree has rarely been reported. We hereby present an unusual pedigree with four cases of Down syndrome (DS) born to four separate women related through three generations of one family. The mothers were aged 18, 21, 29 and ~30 at the time of the births. G-banded karyotypes in two of the mothers of DS individuals were normal and karyotypes of all of the DS individuals showed free trisomy 21. Microsatellites spanning chromosome 21 were typed in this family to determine if any regions were shared in common among the mothers of the DS children. The centromeric and telomeric regions of chromosome 21 could be excluded from being shared, and of those tested, only the markers D21S215 and D21S258 (21q11.2) and D21S1440 (21q22.3) were potentially shared. Two members of the pedigree including one DS mother carried supernumerary alleles at markers 2503J9TG, D21S369 and D21S215, which span the region from 21p - 21q11.1. The level of meiotic recombination on chromosome 21 was unusually high in this family as well. FISH using a centromeric probe for chromosome 21 did not reveal a novel location which rules out a cryptic translocation. We hypothesize that there is a complex rearrangement involving the centromeric region that disrupts the function of the centromere and leads to nondisjunction of chromosome 21 in this family. This is currently being tested with multicolour FISH using BAC probes on either side of the centromere.

Paternally derived 15q12-q13 duplication associated with Autism Spectrum Disorder. *M. Smith, M. Hanouni, M.A. Spence, J.J. Gargus, M.A. Lerner.* Dept. Pediatrics, Univ. California Irvine, Irvine, CA.

Studies by Cook et al., Huang et al., (1997) concluded that 15q duplications that arise on a maternal chromosome and contain the Prader Willi Angelman (PWA) syndrome critical region, lead to manifestations of autism spectrum disorder (ASD). There are a few reports of subjects with paternally derived duplications of chromosome 15q that include the PWA region who manifest developmental problems (Mohandas et al 1999) or ASD (Roberts et al., 2002). We describe studies on a female subject who had hypotonia, developmental and speech delay: walked at 15 months, did not use simple phrases until the age of 3 years. She had difficulty learning to read. Multisensory reading instruction and individualized learning assistance was provided from age 7- 15 years. At 12 years she met criteria for autism in 3 domains: Social interaction, Communication, Repetitive behaviors and interests. Cumulative CARS Score: 30.5 (Mildly Autistic). Assessment at 17 years revealed short stature, minimal dysmorphism and motor co-ordination problems. Cognitive assessment revealed superior verbal and normal performance IQ, normal reading skills and dyscalculia. Cytogenetic studies revealed an interstitial duplication of 15q12-q13. Plasma levels of lactate, pyruvate and ammonia were normal. Skin fibroblast activities of mitochondrial respiratory complexes 2-4 were normal. In these parameters she differs from patients with ASD and 15q inverted duplication that we reported (Filipek et al., 2003). Analysis with 8 different Bac clones showed that the interstitial duplication includes the PWA region between breakpoints BP2 and BP3. Analysis of polymorphic micro- satellite markers revealed that proband has three alleles at each of the following loci: D15S122, GABRB3, D15S1002 and GABRA5. At each of these loci the patient inherited two alleles from her father and one allele from her mother. We conclude that paternally derived duplications of the PWA region may lead to manifestations consistent with autism spectrum disorders. Furthermore the molecular lesion potentially sub-localizes critical regions involved in the metabolic and developmental components of the 15q duplication ASD syndromes.

In vitro assessment of the genotoxicity of benzo-a-pyrene using the trypan blue exclusion test, the sister chromatid exchanges (SCE) and the electron microscopy in situ end-labeling (EM-ISEL) tests on human blood lymphocytes.

F. Fortin^{1,4}, N.-R. Azizieh¹, C. Viau², N. Lemieux^{1,3,4}. 1) Département de pathologie et Biologie Cellulaire and; 2) Santé environnementale et santé au travail, Université de Montréal, Montréal, PQ, Canada; 3) Département de pathologie and; 4) Centre de recherche, Hôpital Sainte-Justine, Montréal, PQ, Canada.

Benzo-a-pyrene (BaP) is a polyaromatic hydrocarbon (PAH) compound, listed by the International Agency for Research on Cancer (IARC) as a probable human carcinogen. It is used as a model for the carcinogenicity of the 20 PAHs listed as priorities by the IARC. PAHs are produced during the incomplete combustion of organic matters, where hundreds of different compounds are emitted simultaneously, making it hard to assess the effects of the exposition to carcinogenic PAHs in the workplace or in the general environment. In our study, human cultured lymphocytes were exposed in vitro to different concentrations of BaP dissolved in DMSO, 0,1g/ml, 1g/ml and 10g/ml, for 24 hours. Cells obtained from 5 different donors, selected following the same criteria, were harvested 24 hours after the end of the exposition and assessed for viability, SCE and EM-ISEL. The viability test showed no cytotoxic effects, attesting that our doses are suitable for genotoxic studies. A significant increase in the mean number of SCEs per cell was found in the cells exposed to 10g/ml of BaP. A significant increase in the amount of DNA single-strand breaks (clastogenic effect) was present in the cells exposed to a lower dose (1g/ml of BaP). Our data show that, in the same experimental conditions, a genotoxic effect of BaP is detected at a dose lower with EM-ISEL test than the minimal genotoxic dose found with the SCE test. Apart from that, we detect a clastogenic effect of BaP at lower doses and shorter exposition times, when compared to similar studies reported in the literature. Pursuing this study on a larger number of participants will allow us to determine if a variation in the genotoxic response following exposure to benzo-a-pyrene exists between individuals.

Preimplantation genetic diagnosis (PGD) for chromosome translocations: Strategies for probe selection. *J.-C. Wang, A. Hajianpour, R. Habibian.* Genzyme Genetics, Pasadena, CA.

Couples with balanced translocations are at risk for spontaneous abortions or abnormal liveborns as a result of unbalanced meiotic segregants. Application of PGD can decrease the risk of these adverse outcomes by selectively transferring only normal or balanced embryos. Various strategies have been employed using combinations of FISH probes. These include chromosome paint probes, centromeric probes, subtelomeric probes, other unique sequence probes, and probes spanning or flanking translocation breakpoints. The latter probes, while most specific, require custom development and are impractical for most labs. A complete set of chromosome-specific subtelomeric probes is now available commercially. Unbalanced translocations can be detected using two subtelomeric probes labeled with different fluorophores, making PGD feasible in most cytogenetics labs. However, two-probe hybridization can not detect all types of unbalanced segregants. With 2:2 and 3:1 segregations, there are 14 different products. Of the 12 unbalanced products, some can result in viable fetuses. It is imperative that these potentially viable products be detected by PGD. Intuitively, the probes to be used are the subtelomeric probes located at the two translocated segments. This will detect all but the two adjacent-2 segregants. Although most adjacent-2 products are exceedingly unbalanced, fetuses can occasionally survive to term when translocation segments are extremely large. Furthermore, virtually all unbalanced liveborns of carriers of the most common reciprocal translocation in humans, t(11;22)(q23.3;q11.2), have tertiary trisomy due to 3:1 segregation. Therefore, probe selection needs to be individualized to avoid transfer of undetectable unbalanced embryos that can result in viable fetuses. It will be shown that probes can be selected that will detect both adjacent-1 and -2 segregants but specifically miss two of the eight 3:1 segregants, or detect all but adjacent-1 segregants. Alternative probe sets can also be used depending on the availability of differentially labeled probes, as long as the two undetectable segregants are not compatible with long term fetal survival.

Pregnancy outcome following prenatal diagnosis of 46,XX,dup(9)(q22.3q32): first case report. *M. Do¹, H. Lin², M. Thangavelu¹, K. Chan³, D.B. Rogers¹.* 1) Genzyme Genetics, Orange, CA; 2) Harbor-UCLA Medical Center, Torrance, CA; 3) Magella Medical Group, Torrance, CA.

We report a case of an 11-month old girl with a partial duplication of chromosome 9q diagnosed prenatally. The mother was seen for genetic counseling because of an abnormal expanded AFP screening test (positive for Down syndrome). Ultrasound at 18 weeks was unremarkable and she underwent an uneventful amniocentesis. The fetal karyotype revealed extra material on the long arm of one chromosome 9 homolog. Further cytogenetic analyses revealed the karyotype to be *de novo* 46,XX,dup(9)(q22.3q32). Fluorescence in situ hybridization confirmed the karyotype. Following further genetic counseling, the mother elected to continue the pregnancy. Pregnancy complications included oligohydramnios and reduced movement at 39 weeks. Labor was induced, and a viable SGA female infant was delivered. Remarkable features at birth included a 31-week head circumference, facial hypertelorism, large set ears and possible cardiac malposition. Postnatal peripheral blood chromosome analysis confirmed the prenatal diagnosis. Following minor feeding problems the infant went home after 3 days. At four months and eleven months, the infant demonstrated poor postnatal growth, persistently falling under the 5th percentile for both weight and height. She was found to have microcephaly, low frontal hairline, bulging forehead, arched eyebrows, upslanted palpebral fissures, hypertelorism, upper lip over lower lip/probable retromicrognathia, fifth finger clinodactyly, and a cardiac murmur. Evaluation of gross and fine motor skills, cognitive and language at eleven months indicated that the infant was developing within the normal range. This child manifests a number of features documented in previous reports of partial trisomy 9q, including facial dysmorphism, microcephaly and pre- and postnatal growth delay. However, this is the first report of normal development in what appears to be a duplication of a unique segment of the long arm of chromosome 9.

Second Trimester Trisomy 22: Cytogenetics and Ultrasound Findings. *S.A. Ebrahim^{1,3}, M. Treadwell^{2,3}, A.N. Mohamed^{1,3}.* 1) Department of Pathology, Cytogenetics Laboratory; 2) Department of Obstetrics and Gynecology, Hutzel Hospital; 3) Wayne State University, Detroit, Michigan.

Trisomy 22 usually presents in cases of early spontaneous abortions and is a rare finding in the second and third trimester fetuses. A 29 year-old gravida 4, para 3, VIP 0, female was referred for genetic counseling and amniocentesis due to anomalies detected on ultrasound scan. Ultrasound revealed a growth-retarded fetus (15 weeks by ultrasound and 20 4/7 weeks by last menstrual period). Diffuse skin edema was noted. The upper and lower extremities remained in a flexed position throughout the exam. There appeared to be an underdevelopment of the right side of the heart. FISH on uncultured amniocytes showed no evidence of numerical abnormality for chromosome 13, 18, 21, X, and Y. Subsequent chromosome analysis of cultured amniocytes revealed a 47,XX,+22[20]. The trisomy 22 colonies were distributed in five independently established cultures. The patient was counseled regarding these findings, and opted to continue the pregnancy. Subsequent ultrasound two weeks later revealed new onset non-immune hydrops with ascites now present. The previously noted persistent flexion of the extremities was still apparent. The cardiac defect appeared most consistent with an unbalanced endocardial cushion defect with a large ventricular septal defect. At 20 weeks gestation the pregnancy is still ongoing.

MOLECULAR CHARACTERIZATION OF TWO CONSTITUTIONAL RINGS DERIVED FROM ONE CHROMOSOME 22 DETECTED DURING PRENATAL DIAGNOSIS. *M. Gadjji¹, K. Krabchi¹, M. Ferland¹, S. Cote², M. Perigny³, P. Langis⁴, R. Drouin¹.* 1) Dept of Med Genet & Dept of Pediatrics, CHUS, Univ. de Sherbrooke, Sherbrooke, Qc, Canada; 2) Cytogenet Lab, CHUL, CHUQ, Qc, Canada; 3)) Sce de Path, Hp. St-Francois d'Assise, CHUQ, Laval Univ., Qc, Canada; 4) Sce de Radiologie, Hp. St-Francois d'Assise, CHUQ, Laval Univ , Qc, Canada.

Introduction: Several cases of ring chromosome 22 have been described in the literature. We present the first case of two constitutional rings derived from one chromosome 22. **Objective:** Cytogenetic and molecular genetic characterization of two rings chromosome 22 identified during prenatal diagnosis. **Methods:** A 39 year-old, gravida 4, para 2, abortion 1 woman had amniocentesis performed at 16 3/7 weeks of gestation for AMA. Conventional and molecular cytogenetic studies of the fetal and parental cells were performed to allow the diagnosis. Microsatellites analyses were performed to elucidate the parental origin and the genetic pathogenesis. **Results:** The fetus had two rings chromosome 22 with three breakpoints: one located at the centromere (22q10), another one at the band 22p11.2 and the third one at the band 22q13.31. The distal parts of the chromosome were lost. Then, it resulted two rings: one constituted by joining the end of band 22p11.2 and a portion of the centromere leading to a small ring; the other by joining the second part of the centromere and the end of band 22q13.31 leading to a larger ring. The male fetus presents the following karyotype: 47,XY,r(22)(p10p11.2),+r(22)(q10q13.31). The parental karyotypes were: 46,XX,16qh+ (mother); and 46,XY,inv(9)(p11q12)(father). The probands chromosome aberration occurred de novo from the maternal chromosome. The breakpoint is localized between the microsatellite markers D22S1170 (22q13.31) and D22S922 (22q13.32). At the autopsy, the fetus showed slight clinical features. The number of fetal nucleated blood cells detected in peripheral maternal circulation, showing positive signals for Y chromosome and DiGeorge/VCF probes with absence of ARSA control probe signal was 10 cells per ml. **Conclusion:** Despite the haploinsufficiency of many active genes, the fetus showed very slight congenital malformations.

Further characterization of a 46,X,abn(X)/45,X karyotype detected prenatally. *P. Koduru¹, S.D. Batish³, S. Dittmar¹, C. Moore², L. Mehta², S. Gupta¹.* 1) North Shore Univ. Hospital, Manhasset, NY; 2) Schneider Children's Hospital at NSUH; 3) Ahena Diagnostics, Inc., Worcester, MA.

Precise diagnosis and characterization of genomic imbalance in patients with sex chromosome abnormalities may help in the evaluation of phenotype, genetic counseling and clinical follow up. We report here use of cytogenetics, FISH and molecular studies in characterizing a psu dic(X) in a newborn girl. Amniocentesis was performed on a 36 y.o., G1P1 woman for reasons of maternal age. FISH on AF cells detected one signal for the X chromosome in 94.3% cells and two signals in 3.7% cells. Chromosome analysis showed mosaicism for two cell lines, mos 46,X,dup(X)(?q24q26)[3]/45,X[42]. The pregnancy was continued and at 37 weeks of gestation a non-dysmorphic baby girl was born. Renal sonogram was normal, she had a small atrial septal defect. Blood chromosome analysis from the newborn confirmed the prenatal findings. FISH study with probes for X- paint, centromere and subtelomere regions was performed. The WCP probe painted the whole abn(X), suggesting that the structural alteration involved only the X. X-centromere probe detected one signal in 62.58% nuclei and three signals in 37.42% nuclei. The Xp subtelomeric probe hybridized to the p-arm of the normal X and to both ends of the abn(X). The Xq subtelomeric probe did not show signal on the abn(X), but hybridized to the q-arm of the normal X. These findings suggest that the abn(X) lost a part of the distal region of Xq, but had duplication of the short arm. Therefore, the karyotype of this abnormal line was 46,X,abn(X).ish psu dic(X) (pter->q22.1::q22.1->pter)(tel Xp+ +,DXZ1+ +,tel Xq-). Chromosome analysis on mother was normal. DNA studies with polymorphic markers at Xq27.3(FMR1) and Xq12(AR) showed heterozygosity at both loci suggesting the presence a of 46,XX cell line not detected by cytogenetic methods. This implies that the abnormality was post-zygotic in origin. Despite the mosaicism for XX/dup(Xp)/X cell lines, the majority of cells are 45,X. Therefore, the infant is predicted to have some features of Turner syndrome, and appropriate follow-up is planned.

Mosaic marker i(21q) resulting in tetrasomy 21 identified through an integrated prenatal screen (IPS) positive for Down Syndrome. *E. Mak-Tam*¹, *M. Care*¹, *D. Chitayat*², *J. Furnival*¹, *P. Griffin*¹, *A. Summers*¹, *P. Wyatt*¹. 1) Genetics Program, North York General Hospital, Toronto, Ontario, Canada; 2) The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto, Ontario, Canada.

A 39 year old G2P1 woman of Indian background presented at our Genetics Clinic for a positive Integrated Prenatal Screen (IPS). The risk was 1 in 70 for the baby to have Down Syndrome. Her family history was negative. The amniotic fluid chromosome result showed a female fetus with an extra small metacentric marker in 30% of cells examined. The marker appeared to be i(12p) by GTG Banding. However FISH analysis identified the marker to be an i(21q), resulting in mosaic tetrasomy 21. The karyotype was 47,XX,+i(21)(q10)/46,XX. Parental chromosomes were normal. Level II ultrasound and cardiac screen were normal. The patient terminated the pregnancy. While we are still awaiting the final autopsy report, the external examination showed dysmorphic features not particularly in keeping with a diagnosis of Down Syndrome. Mosaic i(21q) is rare. Early reports (1980s) were likely misdiagnosed cases of mosaic tetrasomy 12p (Pallister-Killian Syndrome). To our knowledge two prenatal cases have been reported previously and only one (Nagarsheth and Mootabar 1997) was confirmed with FISH. This pregnancy resulted in a live-born with features of Down Syndrome. Due to the rarity and the controversy with the few reported live-born cases, the clinical picture of mosaic tetrasomy 21 is not well defined. Our case is of interest because it was detected through a positive IPS screen for DS and to our knowledge it is only the second prenatal case confirmed by FISH. The autopsy findings will add to the clinical picture of mosaic tetrasomy 21. A review of the literature and the autopsy findings will be presented.

Dynamic differential expression of *Paraoxonase-1 (Pon1)* in murine liver. L. Parker-Katirae^{1,2}, K. Nakabayashi¹, S.W. Scherer^{1,2}. 1) Genetics and Genomic Biology, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Medical and Molecular Genetics, University of Toronto, Toronto, Canada.

Differential allelic expression of specific genes, characterized by a preference for one allele in a non-parent of origin manner has been observed in maize, mouse and humans. This phenomenon has also been implicated in disease pathogenesis. We describe the expression pattern of murine *Paraoxonase-1 (Pon1)*, a gene involved in lipid metabolism and implicated in the formation of atherosclerotic lesions. *Pon1* is member of a family of at least three genes that are found in a cluster on chromosome 5 and 7 in mouse and human, respectively. Previous studies have shown that *Pon2* and *Pon3* display preferential maternal expression in mouse. *Pon1* is adjacent to *Ppp1r9a*, a gene recently shown to be imprinted in both human and mouse. Using quantitative methods, we measured the expression of *Pon1* in liver at different stages of embryonic development using F1 hybrid crosses between C57BL/6J (B) and CAST/Ei (C), and C57BL/6J (B) and JF1/Ms (J). At the same time, SNaPshot analyses were performed to quantify the frequency of both parental alleles. At 12.5 days post coitum, a frequency of 61% and 89% of the C allele was observed in BxC and CxB crosses, respectively. The frequency of the J allele was measured at roughly 95% in both JxB and BxJ. However, at P0, the frequency of the C allele decreased to approximately 24% in BxC and CxB hybrids, whereas the frequency of the JF1/Ms was an average of 62% in JxB and BxJ livers. We concluded that *Pon1* shows a non parent-of-origin allelic preference in its expression, with variations throughout development. To our knowledge, this is the first case of a dynamic differential allelic expression pattern documented to date.

Congenital diaphragmatic hernia in WAGR syndrome: additional evidence that *WT1* plays an important role in diaphragm development. *D.A. Scott*^{1,2}, *M.L. Cooper*¹, *P. Stankiewicz*¹, *A. Patel*¹, *L. Potocki*^{1,2}, *S.W. Cheung*¹. 1) Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Texas Children's Hospital, Houston, TX.

WAGR (Wilms tumor, Aniridia, Genitourinary anomalies and mental Retardation) syndrome is a contiguous gene deletion syndrome involving *WT1*, *PAX6* and possibly other genes on chromosome 11p13. *WT1* is required for normal formation of the genitourinary system and the high incidence of Wilms tumor and genitourinary anomalies found in patients with WAGR are attributed to haploinsufficiency of this gene. It has been hypothesized that *WT1* also plays an important role in the development of the diaphragm. During mammalian embryonic development, *WT1* is expressed in the pleural and abdominal mesothelium that helps to form the diaphragm and mice that are homozygous for a deletion in the mouse homolog of *WT1* have diaphragmatic hernias. Case reports describing congenital diaphragmatic hernias in infants with Denys-Drash and Frasier syndromes, both of which are caused by mutations in *WT1*, provide additional support for this hypothesis. We report an infant with aniridia, bilateral cryptorchidism, vesicoureteral reflux, and a right-sided diaphragmatic hernia. G-banded chromosome analysis revealed a deletion of 11p13-p15.3. Breakpoint regions were refined by FISH and deletion of the WAGR critical region, including *WT1*, was confirmed. A complete description of this patient's cytogenetic abnormality will be provided. A review of the medical literature identified a second patient with a deletion of 11p13, a left-sided congenital diaphragmatic hernia, and anomalies that may be consistent with a diagnosis of WAGR including bilateral microphthalmia, a small penis, bilateral cryptorchidism, and a hypoplastic scrotum. These cases support the hypothesis that *WT1* plays an important role in diaphragm development and suggest that deletions of *WT1* may predispose individuals to develop congenital diaphragmatic hernia.

DNA damage detection by comet assay in personnel occupationally exposed to ionizing radiation. Evidences of adaptative response. A. Corona-Rivera¹, T.A. Garcia-Cobian¹, I. Ceja-Andrade¹, R. Troyo-San Roman¹, E. Castillo-Corona², L. Bobadilla-Morales¹. 1) Lab de Genetica Humana, Univ Guadalajara, CUCS, Guadalajara, Mexico; 2) Instituto Jaliscience de Cancerologia.

Ionizing radiation is a known genotoxic agent due to the induction of breakages in the DNA strand. The hospital personnel occupationally exposed to ionizing radiation (POE) do not have to exceed annual dose of 50 mSv. The detection of low dose biological effect of ionizing radiation in POE is based on the improvement of methods to detect genome integrity damage. Our goal was to evaluate comet assay as suitable biomonitoring tool in POE exposed to low doses of ionizing radiation. The study group was constituted by 7 POE from radiotherapy and nuclear medicine, and controls matched by age and sex. Comet assay was performed from blood samples in four conditions: uncultured cells unirradiated and irradiated to 1.5 Gy, and cultured cells (72 hs) unirradiated and irradiated to 1.5 Gy. 50 images from condition were captured, visual analysis by categories proposed by Avishai (2003) was used. In POE group annual registered dose was below to 10 mSv. Damage differences were not observed in unirradiated cell conditions in POE versus controls. With respect to irradiated cells, comparison POE versus control in 72 h cultures, were not observed differences. With respect to the evaluation of comet assay in uncultured conditions was observed: (1) in unirradiated blood samples the POE group showed a non significant increase of damage versus controls, (2) in irradiated blood samples differences were not observed between POE and controls, (3) in POE comparison basal versus irradiated, was observed damage increase only in category III comets, and (4) in control comparison basal versus irradiated, significant increase of damage was observed in all the measurements. These results suggest the existence of activation of damage repair mechanisms and adaptative response in POE. Comet assay is able to detect acute damage. Such method is suitable as biomonitor to the effect of low dose radiations in risk groups.

***FMR1* repeat length in premature ovarian failure and mothers of trisomy.** K. Bretherick¹, M. Fluker^{2,3}, M. Stephenson³, W. Robinson¹. 1) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Genesis Fertility Center, Vancouver, BC, Canada; 3) Department of Obstetrics and Gynaecology, BC Children's and Women's Hospital, Vancouver, BC, Canada.

Advanced maternal age is the only known risk factor for having a trisomic pregnancy. Reduced follicular pool size or physiologic changes in aging ovaries may be responsible for the increase in risk with age. Premature ovarian failure (POF) is the occurrence of menopause before the age of 40 and can be due to either ovarian follicular depletion or dysfunction. It is therefore possible that genetic factors that predispose to POF are also associated with an increased risk of having a trisomic conceptus. The most significant single gene association with POF is with *FMR1* premutation size alleles (60 repeats), which are found in up to 7% of women experiencing POF. We therefore examined *FMR1* repeat length by fluorescent PCR and chemiluminescent Southern Blot in 196 women who had experienced a trisomic pregnancy, 47 women with POF, and 107 control women. We found no premutation size alleles in our population of trisomy mothers, and the allele distribution of this group did not differ significantly from that of the control population. Our sample of 47 POF women had 2 premutation size alleles, a result consistent with that in the literature. Interestingly, there was an excess of alleles 33 repeats in our POF population as compared to controls (18.1% in POFs vs 7.5% in controls, $p=0.006$), a finding that has not been previously reported. This excess of alleles 33 repeats was not present in our sample of trisomy mothers. We assessed *FMR1* repeat length weighted by X chromosome inactivation ratio in our POF and control populations. While *FMR1* repeat size weighted by inactivation ratio was also associated with POF ($p=0.01$), it was not more significant than repeat size alone. In conclusion, our results suggest that the *FMR1* gene is not associated with an increased risk for trisomic pregnancy. However, the unexpected finding that *FMR1* alleles of 33 repeats may be associated with an increased risk of POF is of potential clinical importance.

Disruption of DMD and deletion of FACL4 causing developmental delay, hypotonia, and multiple congenital anomalies. *S. Bhat*¹, *S. Ladd*¹, *K. Schmidt*², *C.E. Schwartz*¹, *B.R. DuPont*¹, *R.E. Stevenson*¹, *A.K. Srivastava*¹. 1) J. C. Self Research Institute of Human Genetics, Greenwood Genetic Center, Greenwood, SC; 2) Department of Pediatrics, East Carolina University, Greenville, NC.

Defects in genes located on the X-chromosome are responsible for the causation of mental retardation (MR) in males. Several X-linked syndromic and nonsyndromic MR genes have been identified utilizing X chromosomal rearrangements associated with MR. We have studied a 3-year-old boy with limited speech, growth failure, hypotonia, microcephaly, multiple congenital anomalies, significant developmental delay and a karyotype reported to be 46, Y, inv(X)(p11.4q13). He also had ASD and VSD that were surgically repaired. The brain magnetic resonance imaging was normal. The molecular analysis of the inversion breakpoints allowed us to locate the Xp-breakpoint in the Duchenne Muscular Dystrophy (DMD) gene. Several known genes mapped within the second breakpoint region at the Xq13, but none was found to be inactivated. FISH analysis using a probe from the Xq13 region led us to suspect the presence of an additional chromosomal rearrangement, telomeric to the Xq13 inversion breakpoint. We identified a deletion at Xq22.3. Using FISH and STS analyses, we mapped the deleted region between markers DXS1413 (cen.) and DXS456 (tel.). RT-PCR analysis further confirmed the deletion of GUCY2F, NXT2, KCNE1L, and FACL4 genes. Deletion of these genes has previously been reported in a contiguous gene deletion syndrome, ATS-MR (OMIM #300194), and mutations of FACL4 have been identified in patients with nonsyndromic XLMR. These findings will assist in developing an adequate care strategy for the patient who is likely to develop classic DMD due to the loss of DMD expression, and MR due to deletion of the FACL4 gene. It remains to be seen if the absence of a gene from the deleted region may have also contributed to the development of the ASD and VSD observed in the patient.

Fragile X Syndrome: Screening strategies in Indian context. *S. Padma, K.R. Manjunatha, S.R. Girimaji*, G.K. Chetan, S. Roy, E. Venkataswamy, S. Balu.* Department of Human Genetics & Psychiatry*, National Institute of Mental Health & Neurosciences (NIMHANS), Bangalore-560029, India.

Fragile X syndrome represents the most common inherited cause of mental retardation, second only to Down's syndrome with a prevalence of approximately 1 in 4000 males and 1 in 8000 females. The key clinical features of the fragile X-syndrome in males are mental retardation, elongated triangular face, lop ears and macro-orchidism. The fragile X syndrome was the first disease shown to be associated with "dynamic mutations" caused by an amplification of an unstable CGG repeat sequence located at the 5' untranslated region of FMR1 gene. A fragile site at the distal long arm of the X chromosome (FraXq 27.3) is the hallmark cytogenetic feature of the syndrome. AIM: This study was aimed to facilitate both cytogenetic and molecular genetic screening of fragile X syndrome in Indian population for the analysis of the mutation. SUBJECTS AND METHODS: Fifty subjects with fragile X syndrome clinical features, were studied. Cytogenetic and molecular genetic analysis using lymphocyte culture, PCR and Southern technique, were done. The PCR method provided rapid and reliable results for the identification of fragile X negative and positive patients. The PCR-positive cases were confirmed by the CGG repeat expansion on Southern blot analysis with a positive cytogenetic result, their methylation status was also known which helps in finding out the mosaic individuals. CGG polymorphism in normal individual was studied using radioactive PCR and the most frequent repeats in Indian population was found to be 31 in the present analysis. CONCLUSIONS: The cytogenetic and molecular genetic techniques improves diagnostic accuracy and allows to verify the normal condition of FRAXA locus, identify carriers, detect complete mutations and also mosaics in fragile X syndrome for giving proper genetic counseling in fragile X families who are at high risk of having the affected gene. With fragile X syndrome being such a complex condition, national screening would need to be considered for families before a child is conceived so that an informed choice can be made. Report of a 46,X,t(X;1)(q22.1;p34.1) female with short stature, dysmorphic features and multiple congenital anomalies. *R.K. Pettman¹, C. Lee³, J.P. Welch³, M. Ludman^{1,2}, S. Dyack^{1,2}.* 1) Medical Genetics, IWK Health Centre, Halifax, NS, Canada; 2) Department of Pediatrics, IWK Health Centre & Dalhousie University; 3) Department of Pathology & Laboratory Medicine, IWK Health Centre.

We present a 4-year-old female with short stature, dysmorphic features including downturned corners of her mouth and epicanthic folds, and multiple congenital anomalies including an ASD, left cystic kidney, umbilical hernia, prominent fingertip pads, bilateral colobomas and talipes. This constellation of features is not known to be those of an identifiable syndrome. Cytogenetic studies revealed a balanced de novo translocation 46,X,t(X;1)(q22.1;p34.1). X-inactivation studies were performed twice and revealed the derivative X chromosome containing XIST being inactivated in at least 10% of the cells, resulting in a partial functional disomy Xq and a possible partial monosomy 1p. X-inactivation is typically non-random in balanced X:autosome translocations, with inactivation of the intact X chromosome. Random X-inactivation with X:autosome translocations have been reported. Most had an X-chromosome breakpoint between Xq28->Xqter, while our probands breakpoint was more proximal at Xq22.1. Four reported cases with a breakpoint in proximal Xq had incomplete skewing of X-inactivation with the derivative X inactivated in only 2-5% of cells. This patient had a significantly greater inactivation ratio than these reported cases. The possible contributors to the development of this phenotype include disruption or deletion of a gene, or genes, at the translocation breakpoint(s), partial monosomy 1p and functional disomy Xq22.1->Xqter. Review of the literature made a disruption or deletion less likely. Some of our patient's features have each been reported in partial monosomy 1p, but they are not often found in the same individual. Males with duplications involving Xq display a consistent phenotype, which includes many of our patient's features. This suggests that partial monosomy 1p may play a role in the development of this phenotype; however, it is more likely that functional disomy Xq in a proportion of her cells is the major contributor to the development of this unusual phenotype.

A novel satellite DNA family generated by microdissection of Y-chromosome of Indian muntjac (*M. muntjac vaginalis*). Y.C. Li¹, Y.M. Cheng², L.J. Hsieh², S.J. Liao², S.Y. Chang², C.C. Lin². 1) Chung Shan Medical Univ, Taichung, Taiwan; 2) China Medical Univ Hosp, Taichung, Taiwan.

Cytogenetically, the Indian muntjac is the most fascinating mammalian species with only 6 chromosomes in female and 7 chromosomes in male. Extensive tandem fusions and few centric fusions occurred in the ancestor species with $2n=70$ resembling the *Mazama gouazoubira* and *Hydropotes inermis* which karyotype were thought to have resulting the present-day Indian muntjac karyotype. The different chromosome number between male and female of the species is due to the fact that the X-chromosome centric fusions with autosome 3 to forming the X+3 chromosome and therefore the female have two X+3 chromosomes. The male on the other hand has one X+3 chromosome, an unfused chromosome 3 and a Y-chromosome, thus having one more chromosome than the female. Satellite DNA appeared to play an important role in karyotypic evolution of the mammalian species by promoting chromosomal rearrangement. In this study, we isolated a DNA clone, designated MMV-0.4 using a chromosome microdissection technique from the Y-chromosome of Indian muntjac. By screening microclones constructed from DOP-PCR products initially generated from 15 whole Y chromosome, with cervid satellite I, II and IV, a microclones (IM-Y5-7) negative for all three satellite DNAs was obtained. The size of the clones is 426-bp and appeared to contain a ~400-bp monomer. Southern blot analysis showed tandem repetitive nature of the clone with polymeric ladder signal of ~400-bp. No similar sequence of the clones have been deposited in the GenBank data base suggesting that they could belong to a new cervid satellite DNA family with monomer size ~400-bp. The clone hybridized specifically to the heterochromatin portion of the Y chromosome and the pericentric region of the chromosome 3 of the male Indian muntjac as demonstrated by FISH. The solely present of MMV-0.4 in the Y-chromosome and chromosome 3 could provide a mechanism for the formation X+3 chromosome (by close association of the X-Y and chromosome 3) of the Indian muntjac. The study was supported by grants from the NHRI (NHRI-EX92-9207SI) and from the NSC (NSC92-2320-B-040-048), Taiwan.

Familial Subtelomere Rearrangement Determined via Multiplex Ligation-Dependent Probe Amplification (MLPA) and Fluorescent In-situ Hybridization (FISH). *H. Rishag, D. Cohn, K. Lee, S. Skinner, M.J. Friez, B.R. DuPont.* Greenwood Genetic Center, Greenwood, SC.

A 9 year-old white male was noted to have developmental delay with autistic features. He was the product of a twin pregnancy with premature labor and delivery at 34 weeks gestation. He failed to grow during the last 2 weeks of the pregnancy while his fraternal twin continued a normal growth pattern. In the newborn period he had feeding problems, reflux, dependent edema, and colic. Surgery was done for an atrial septal defect, bilateral inguinal hernias, and bilateral strabismus. By 2 years of age, he exhibited global developmental delays, withdrawn behavior, and limited dysarthric speech. Dysmorphic features included: plagiocephaly, low posterior hairline, hypoplastic midface, smooth philtrum, posteriorly rotated and low set ears, upslanting palpebral fissures, long eye lashes, telecanthus, thin lips, single transverse palmar crease on the right and bridged palmar crease on the left hand, stiff fingers and slight bilateral 5th finger clinodactyly. He was noted to have an extensive family history for mental retardation and birth defects. Furthermore, his mother has had four 1st trimester miscarriages. High resolution chromosome analysis revealed an apparently normal male karyotype. However, subtelomere analysis, done by multiplex ligation-dependent probe amplification (MLPA), revealed abnormal findings consistent with a duplication of the subtelomeric region of chromosome 4p. FISH showed the additional 4p material to be on the end of the p arm of chromosome 22, ish der(22)t(4;22)(p16.3;p13)(D4S3360 +). Parental FISH analysis revealed the mother to have a balanced form of the translocation. Further studies on additional family members will be discussed, as well as, the use of MLPA as a diagnostic tool for identifying subtelomere deletions and duplications in combination with FISH based-testing.

Transcription factor gene expression changes and interaction networks in regenerating inner ear hair cells. *S. Bashiardes, D. Hawkins, R. Veile, V. Bhonagiri, M. Warchol, M. Lovett.* Washington University, School of Medicine, St. Louis, MO.

Much of human hearing loss is caused by loss of auditory hair cell (HC) function. Mammals cannot regenerate these essential mechano-electrical transducers of sound. However, birds have retained the ability to regenerate HCs from surrounding supporting cells. We have conducted the first large scale study of gene expression on chicken HCs as they regenerate. Pure sensory epithelia (SE), consisting of HCs plus supporting cells, were damaged with either neomycin or laser treatment. As the HCs regenerated, the cultures were sampled at various timepoints. Changes in gene expression were compared to undamaged control cultures on a microarray that interrogates the vast majority of transcription factor (TF) genes. These experiments involved multiple biological samples and hundreds of microarray comparisons. Gene expression changes in SEs from the cochlea (auditory HCs) and the utricle (vestibular HCs) were measured, allowing us to identify changes that were specific to the treatments, to the SE type, or that were common to both. For example, 30 TF genes were reproducibly found to change during utricle HC regeneration. Among these were members of known pathways such as Jun/Fos and Hedgehog signaling, as well as members of unknown pathways such as Cebpg. We identified 77 genes that are specific to cochlea HC regeneration, including Foxh1, Znf174 and Hoxc10. Interestingly, only 5 TFs show similar changes in both SE types under all treatments and timecourses. These experiments were also conducted on neomycin damaged mouse SE to identify TF changes that occur in an SE that is incapable of regenerating. To test the relevance of specific TFs, we employed RNAi on regenerating SEs to knockdown specific TFs and measure the effect on regeneration, as well as on the expression of all other TFs. RNAi on over a dozen TFs indicates that 3-fold knockdowns can be routinely achieved, and that most of these do not appreciably affect regeneration. However, specific TF knockdowns do arrest regeneration. In these ways we have begun to identify the important TF pathways in avian HC regeneration.

Large scale gene expression profiles of early mouse inner ear development. *S. Sajan, M. Lovett.* Department of Genetics, Washington University, St Louis, MO.

Hearing loss affects ~30 million Americans, one-third of those being between the ages of 21 and 65. Environmental factors play a role, but up to half of all hearing loss is attributable to some form(s) of genetic abnormality. Sensorineural deafness, deafness due to damage to the sensory hair cells and/or the nerves of the inner ear, is the most common type of hearing loss. The inner ear contains the auditory (cochlea) and the vestibular organs which detect sound and movement, respectively. These structures contain many cell types including hair cells, the mechanosensory transducers of sound or motion. However, only a handful of genes are known to play a role during inner ear development, partly because these structures are small, complex and inaccessible. The majority of inner ear developmental genetics has yet to be explored. To expand our understanding of this important organ and to obtain a base line measurement of normal gene expression, we micro-dissected inner ears from mouse embryos at stages E9 to E15 in half-day intervals (covering the earliest discernible structures of the inner ear up until the development of true hair cells). Gene expression profiles were derived using mouse Affymetrix gene chips. Two litters per developmental stage were obtained, the structures were dissected and duplicate gene-chips were hybridized. Genes were selected that were reproducibly differentially expressed by at least 1.5-fold between any two stages, and self-organizing maps created to identify genes with similar expression patterns. Approximately 600 genes were differentially expressed across the time course, of which 10% had previously been shown to be expressed in the inner ear. Genes with high expression at early stages (E9-E9.5) included *Dachshund 2*, *Choroidermia*, *Kinesin family member 1B*, and *NeuroD6*. Among those that are highly expressed later at E13.5 and beyond are *GATA3*, *FGF-20*, *Aryl hydrocarbon receptor*, *Neuronatin*, and *Otogelin*. Many of these observations have been validated by quantitative-PCR and/or in-situ hybridizations. This study provides new candidate pathways for further investigation in inner ear development and the genetics of hearing loss.

Frizzled Wnt receptor gene expression strongly associated with initiation of hematopoietic stem cell neural-transdifferentiation in vitro. *H. Hao, P. Wooley.* Orthopedics Surgery, Wayne State University, School of Medicine Detroit, MI.

Hematopoietic stem cell (HSC), an alternative source to provide pluripotent precursors, have been recognized to give rise to osteocytes, chondrocytes, hepatocytes, endothelial, adipose, pancreatic islet cells as well as neural cells. Our previously reported results indicate neural cells can be generated from HSC. However, the major genes that initiate and govern final cellular phenotypes remain unknown. To gain molecular understanding of neurogenesis of HSC, gene expression profiles were analyzed using cDNA microarray representing 11000 mRNAs in non-induced HSC (CD34+) and neural-transdifferentiated cells (nestin+) from the same hematopoietic isolate. The significant alterations in Wnt/Frizzled (Fz) gene expression levels were confirmed by reverse transcription PCR. Genes that differently expressed in nestin+ and CD34+ cells were identified. Wnt/Fz (40) and adhesion molecule (56) genes were up-regulated respectively (2 to 4 times increased in CD34+ cells). In nestin+ cell, Fz gene transient alteration strongly related to the neural induction media exposure. The up-regulated Wnt/Fz signal transduction related genes such as beta-catenin and dishevelled were also detected. However, Fz gene expressions were decreased and diminished after differentiated neural cell maker genes were present. This data is first time to suggest that the Wnt signaling pathway is critical for stem cell transdifferentiation, which will require functional testing. Our studies, therefore, provide not only a molecular basis to understand biological processes of stem cell transdifferentiation but also a useful model to explore the mechanism of Fz-beta-catenin expression in neurogenesis from atypical tissue source.

Analysis of neural-specific conditional deletions to identify the role of the paired-like transcription factor PITX2 in basal ganglia disorders. *D.M. Martin*^{1,2}, *J.M. Skidmore*¹, *A.M. Sciafani*¹, *P.J. Gage*³. 1) Pediatrics; 2) Human Genetics; 3) Ophthalmology, University of Michigan, Ann Arbor, MI.

The *Pitx* genes *Pitx2* and *Pitx3* are paired-like homeobox transcription factors expressed in the mammalian subthalamic nucleus and substantia nigra, respectively. These brain regions are part of the basal ganglia brain circuitry that controls movements. In mice, *Pitx2* is required for normal differentiation of subthalamic nucleus neurons, whereas *Pitx3* regulates survival of mesencephalic dopaminergic neurons. In mice, complete loss of *Pitx3* is associated with a Parkinsonian phenotype, whereas *Pitx2* deficiency is embryonic lethal, precluding analysis of the *Pitx2*^{-/-} neurological phenotype at later embryonic timepoints. Here we report a conditional deletion of *Pitx2* in the mouse central nervous system using Nestin-Cre transgenic mice. The Nestin-Cre transgene is expressed in neural progenitors in the brain, in the pituitary, and in craniofacial regions coincident with *Pitx2* expression. *Pitx2*^{flox/-}; Nestin-Cre transgenic mice are viable to e18.5, but are reduced in size and do not survive beyond the immediate postnatal period. Mutant embryos have an elongated nose, displaced eyes, fused mouth, and kinked tail. *Pitx2* mRNA and protein in the subthalamic nucleus are absent in *Pitx2*^{-/-} embryos, and reduced in *Pitx2*^{flox/-}; Nestin-Cre transgenic embryos, suggesting partial Cre-mediated recombination of *Pitx2* in developing subthalamic nucleus neurons. Ongoing analysis of these and other neural-specific *Pitx2* deficient mice will help define molecular mechanisms of *Pitx2*-mediated neuronal differentiation in developing subthalamic nucleus neurons, and clarify the role of *Pitx2* in movement and movement disorders.

PITX2 and LMX1B interactions in the developing mammalian subthalamic nucleus. *J.M. Skidmore¹, D.M. Martin^{1,2}*. 1) Pediatrics, University of Michigan, Ann Arbor, MI; 2) Human Genetics, University of Michigan, Ann Arbor, MI.

Understanding the mechanisms of regional specialization in the developing neuroepithelium is a central issue in developmental neurobiology. In the embryonic mouse forebrain and hindbrain, transcription factors including *Dlx*, *Pax*, and *Engrailed* genes function to specify distinct neuronal identities with specific neurotransmitter and anatomical phenotypes. *Pitx2*, a paired-like homeodomain transcription factor, is expressed in discrete regions of the developing mammalian brain. *Pitx2* is likely to have a role in regional specialization of distinct neuronal populations, given the recently identified requirement for *Pitx2* for normal development of neurons in the murine subthalamic nucleus (STN), a key component of basal ganglia and a target for deep brain stimulation in Parkinson's disease. The mechanisms regulating *Pitx2*-mediated STN development are not known. Here we report an analysis of STN gene expression in midgestation wildtype and *Pitx2* mutant mouse embryos, aimed at identifying potential downstream targets of *Pitx2* in this brain region. We found that *Pitx2* co-localizes at the cellular level with *Lmx1b*, a LIM-homeodomain transcription factor that also specifies *Pitx3*-expressing mesencephalic dopaminergic neurons in the developing mouse substantia nigra. We detected loss of LMX1B protein in the developing STN of *Pitx2* mutant embryos, indicating a potential genetic interaction between these two transcription factors. LMX1B expression is preserved in other brain regions of PITX2 overlap in *Pitx2* mutant mouse embryos, suggesting regionally specific interactions of *Pitx2* and *Lmx1b* in the STN during brain development. Ongoing studies will help clarify the precise molecular genetic pathways by which *Pitx2* and *Lmx1b* confer STN neuronal differentiation and lineage specification.

Role of Notch signaling in early skeletal development. *F. Engin*¹, *G. Zhou*¹, *Y. Chen*¹, *T. Honjo*², *H. Zheng*³, *B. Lee*^{1,4}. 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston , TX; 2) Department of Medical Chemistry, Graduate School of Medicine, Kyoto University, Kyoto, Japan; 3) Huffington Center of Aging, Baylor College of Medicine, Houston , TX; 4) Howard Huges Medical Institute, Houston, TX.

Evolutionary conserved Notch genes regulate cell fate determination, differentiation, proliferation and apoptosis in multiple developmental pathways. Defects in Notch pathway have been implicated in a variety of human diseases such as T cell leukemias, a type of cerebral arteriopathy (CADASIL), and a common form of congenital heart disease (Tetralogy of Fallot). However, the role of Notch signaling in early skeletal development is still poorly understood. Mutations of the ligands of Notch signaling in humans cause skeletal patterning defects including Alagille syndrome with abnormal butterfly vertebrae, and spondylocostal dysostosis characterized by vertebral defects, rib abnormalities, short trunk and dwarfism. We performed in vitro and in vivo studies to elucidate the function of Notch signalling during chondrogenesis. In transient transfection studies, Notch1 intracellular domain (NICD) was able to activate a type II collagen (Col2a1) reporter construct by itself, as well as synergistically with SOX9. Presenilin 1 and 2 (PS1/PS2) liberate the NICD from the membrane. Interestingly, a chondrocyte specific double knock out of (PS1/PS2) showed that these mice appeared to be normal at birth, but then gradually exhibited shortened axial and appendicular skeletons, without obvious segmentation defects. Transgenic mice over-expressing Notch1 ICD in chondrocytes die shortly after birth due to severe chondrodysplasias reminiscent of the Sox5/6 double knock out. Histology analyses of these mice suggest that chondrogenesis was initiated but chondrocyte proliferation and maturation was severely blocked. To further understand the underlying molecular mechanism, we are currently performing analyses of chondrocyte specific markers on these transgenic mice. In conclusion, our data strongly suggest that Notch signaling has an important role during chondrogenesis perhaps by regulating the proliferation of this cell population.

***ITSN1* is essential for early brain development as shown in the *Itsn1* knockout mouse.** X-N. Chen, Y.W. Brown, J.R. Korenberg. Med Gen Inst, Cedars-Sinai Med Cntr, UCLA, Los Angeles.

ITSN1 maps to chromosome 21 and encodes a scaffolding protein regulating clathrin coated vesicles, some forms of receptor mediated endocytosis, mitogenic signaling and dendritic shape through its role in cdc42-mediated control of the actin cytoskeleton. We previously showed that the *Itsn1* deficient mouse exhibits dysgenesis of the cerebral cortex, absent midline brain structures and hippocampal malformation, which mirrors CNS defects in human deletion 21. We now show that these defects originate in early embryogenesis, are accompanied by prenatal mortality and implicate a dosage dependent role for *ITSN1* in CNS morphogenesis. We determined the viability and brain structures of *Itsn1* homozygous (-/-), heterozygous (+/-) and normal littermates (+/+) from E10.5 through P3. These included 91 embryos, 103 neonates, and 220 adult mice from 142 *Itsn1*^{+/+}, 209 *Itsn1*^{+/-}, and 63 *Itsn1*^{-/-}. We found the expected ratio of 1:2:1 from E10.5 to 15.5. Due to possibly decreased fitness in the *Itsn1*^{+/-}, the ratio of *Itsn1*^{-/-} to *Itsn1*^{+/+} was used as a more sensitive indicator of demise. This decreases to 0.6 at E16.5 (n=32), to 0.5 at P1 (n=38), to 0.3 at P3 (n=65) and to 0.31 in the adult (n=220). This suggests that *Itsn1* deletion causes embryonic lethality and increased neonatal and postnatal mortality. Using Hematoxylin & Eosin staining and immunohistochemistry with antibodies for Reelin and Dcx, we examined the development and numbers and distribution of Cajal-Retzius cells and radial organization of Dcx-positive elements of the preplate (PP), cortical plate (CP) of cortex. We observed abnormalities in the *Itsn1*^{-/-} vs the *+/+* from E13.5 including: 1) disoriented and malpositioned mitotic cells in all embryonic stages examined; 2) reduced number, abnormal distribution and morphology of Cajal-Retzius cells in the PP and CP; 3) increased Dcx-positive radial columns. Taken together, these results suggest that *Itsn1* deficiency adversely affects the migration and differentiation of Reelin- and Dcx-positive neurons and, combined with previous results (Pucharcos et al. 1999) that these cortical processes are mediated largely by the ubiquitously expressed short form of *ITSN1*.

Conservation of the visual system from flies to humans: *Drosophila* homologs of *Chx10*, a human microphthalmia gene essential for eye development. *T. Erclik*^{1,2}, *V. Hartenstein*³, *H. Lipshitz*^{1,2}, *R. McInnes*^{1,2}. 1) Developmental Biology, HSC, Toronto, ON; 2) Molecular and Medical Genetics, UofT, Toronto, ON; 3) MCD Biology, UCLA, Los Angeles, CA.

Chx10 encodes a homeodomain (HD) and CVC domain containing protein and is essential for mammalian eye development. In the mouse eye, *Chx10* is expressed in neuroretinal progenitor cells and bipolar interneurons. In mice, *Chx10* mutations lead to a hypocellular neuroretina, absent bipolar interneurons, microphthalmia and blindness; in humans, *Chx10* mutations cause an orthologous phenotype. We are using the powerful genetics of *Drosophila* to facilitate the dissection of the *Chx10* mammalian regulatory pathway. We have identified two *Drosophila* homologs of *Chx10*, *dChx1* and *dChx2*, which are >80% identical to *Chx10* in the HD and CVC domain. *dChx1* and *dChx2* map to the X chromosome where they are located 33 kb apart.

dChx1, but not *dChx2*, is expressed in the optic lobe of the fly embryo. In later stages of *Drosophila* development, *dChx1* and *dChx2* are co-expressed in the optic lobe. The fly optic lobe contains a class of interneurons that synapse with the retinal photoreceptor axons. Remarkably, *dChx* expression in these optic lobe interneurons suggests that fly visual system interneurons are orthologous to the *Chx10*-dependent bipolar interneurons in mammals. To determine whether the *dChx* genes are expressed in these fly optic lobe interneurons, we will use confocal microscopy to visualize the synaptic contacts of membrane labeled *dChx* neurons. We have identified the *dChx* optic lobe enhancer in a 9 kb fragment upstream of *dChx1* and are using this fragment to drive a membrane bound reporter.

To establish that the *dChx* genes are essential for visual system interneuron development in the fly, we have generated lethal loss-of-function mutants for *dChx1* and *dChx2* using transposon based deletions. Genetic screens will be performed to identify genes that enhance or suppress *dChx* mutant phenotypes. These genes and their mammalian homologs are likely to be members of a remarkably conserved genetic cascade regulating eye development from flies to vertebrates.

Molecular profiling of the transcriptomes of synthetic astrocytes differentiated from embryonic stem cells in vitro. A. Guha^{1,2}, D. Kamnasaran^{1,2}. 1) Surgery(Pediatric Neurosurgery), Hospital For Sick Children, Toronto, Ontario, Canada; 2) Surgery (Neurosurgery), Western Hospital, University of Toronto, Toronto, Ontario, Canada.

The pluripotency of Embryonic stem cells is determined by the ability to differentiate into derivatives of the three germ layers. We have determined an optimal protocol for the in vitro synthesis of astrocytes from murine embryonic stem cells harboring wildtype and p53 (+/-) genetic backgrounds. Immunocytochemistry with the best known marker for astrocytes, GFAP, showed expression in over 90% of cells. The majority of the astrocytes displayed morphologies similar to Type 1 astrocytes. cDNA microarray analyses on Affymetrix arrays were performed to provide detailed molecular profiling of the transcriptomes of these synthetic astrocytes. After normalizing and scaling of the data, the transcriptomes of synthetic astrocytes with wildtype or p53 (+/-) genetic backgrounds were found to be very similar ($r = 0.89$), with only 18 genes differentially expressed ($P < 0.001$). Immunocytochemistry showed these astrocytes were absent for the expression of OLIG2, NESTIN and OCT4, consistent with the microarray data. The transcriptomes of our synthetic astrocytes were compared to the published transcriptomes of in vivo astrocyte cultures established from various murine embryonic, post natal and adult brain sections (PNAS 101(22):8384-9). We calculated the extent of similarity (Pearsons correlation coefficient (r), $P < 0.001$) with possible astrocyte specific genes identified by having an expression pattern similar to GFAP, and the use a Recursive-Supervised Machine (R-SVM) class prediction analysis. Wildtype synthetic astrocytes were found most similar to astrocytes from the adult Corpus callosum ($r=0.281$), while synthetic p53 (+/-) astrocytes were most similar to astrocytes from the Cortex (P2) ($r=0.212$), by comparison with 325 astrocyte specific markers having expression similar to GFAP. By comparison with 156 astrocyte specific markers identified by R-SVM analysis, both wildtype and p53 (+/-) synthetic astrocytes were found to be most similar to astrocytes from the Cortex (P2) ($r=0.287$, $r=0.315$).

Program Nr: 1041 from the 2004 ASHG Annual Meeting

Characterization of *Prdm8*, a novel putative retinal transcription factor gene. C.C. Jung, I. Chau, R.R. McInnes.
Program in Developmental Biology, Hospital for Sick Children, Toronto, Ontario, Canada.

In mice and humans, disruptions to over 20 retinal transcription factors have been shown to result in developmental eye defects or retinal degenerations. We are interested in the molecular and genetic events underlying mammalian retinal development and maintenance, namely, the role of transcriptional regulators in guiding these processes. *PRDM8* (*PR-domain containing 8*) maps to 4q21 and is a putative transcription factor identified in a retinal cDNA screen for developmental regulatory molecules. *Prdm8* encodes a SET domain and several C2H2 zinc finger motifs. The SET domain is an evolutionarily conserved motif found among proteins that regulate chromatin structure. Disruption of SET domains often leads to impaired development or cancer. *Prdm8* homologues are found among all vertebrates genomes sequenced to date. In the adult mouse, full-length *Prdm8* is expressed abundantly in the retina and hippocampus, with smaller abundant mRNAs also in testis. *Prdm8* is broadly expressed in tissues that will contribute to the CNS and PNS. In the developing retina, antibody staining appears to be confined to post-mitotic cells. Preliminary results indicate that the Prdm8 protein is found in a perinuclear distribution in adult rod photoreceptors, whereas it is homogeneously distributed within nuclei of other retinal cell types. Based on expression data and homology to a family of developmentally important proteins, we predict that *Prdm8* may be required for neuronal development and that it may be influencing cell fate by regulating neuronal differentiation and/or maintenance. To identify the essential roles of *Prdm8* in the developing and mature brain, we have constructed loss-of-function *Prdm8* mouse mutants. To better understand the role of Prdm8 within the cell, a Yeast 2-hybrid screen is being performed to identify Prdm8 interacting proteins while a biochemical approach is being carried out to determine whether Prdm8 participates in histone modifications. These studies will define the role of *Prdm8* in the developing and mature retina, and address the significance of the heterogeneous nuclear distribution of Prdm8 among different classes of retinal neurons.

CNS-specific FGFR3 K644E transgenic mice: gene expression profile. *T. Lin*¹, *S.B. Sandusky*¹, *H. Xue*², *A.M. Heitman*¹, *M.S. Rao*², *C.A. Francomano*¹. 1) Laboratory of Genetics, NIA, NIH, Baltimore, MD; 2) Laboratory of Neurosciences, NIA, NIH, Baltimore, MD.

The K644E mutation in mouse FGFR3 results in constitutive activation of the receptor and is the cause of the neonatal lethal skeletal dysplasia, Thanatophoric dysplasia type II (TDII). Previously, we generated central nervous system (CNS)-specific TDII mice referred to as TDII-N. These mice demonstrated asymmetric changes in cortical thickness, dilated lateral ventricles, disorganized hippocampi, and cerebellar abnormalities, all of which correlate with brain abnormalities observed in human TDII patients. FGFR3 signaling operates along three pathways: PI-3 kinase, Ras-MAPK, and STAT signaling. To better understand gene regulation within and beyond these pathways, we examined brain RNA from both E12.5 and P0 TDII-N with cDNA microarray and RT-PCR assays. The expression pattern of several genes is altered in TDII mice when compared to WT littermates. Among these genes, an especially interesting one is Stat3, a key component in the STAT pathway that is involved in cell apoptosis regulation. Deletion of Stat3 is reported to increase cell proliferation in the myeloid lineage. Stat3 was found to be down-regulated in both embryo and P0 CNS. Lif interacts with Stat3 in primary neural progenitors and is also down-regulated in TDII E12.5 CNS. In the MAPK pathway, Mapk14 is up-regulated in E12.5 brain but down-regulated in P0 brain. Mapk14, also known as p38, is a member of the stress-activated protein kinase class of MAPKs, and plays a critical role in cell cycle control. We are currently quantifying additional genes that showed significant changes in microarray data. These include genes in FGFR3 and Stat1 signaling pathways as well as genes known to be important in cell cycle regulation and the developmental process of osteogenesis.

A mouse model for Amish lethal microcephaly. *M.J. Lindhurst¹, A. Chen¹, R.L. Nussbaum¹, D.M. Bodine², L.G. Biesecker¹.* 1) GDRB, NHGRI/NIH, Bethesda, MD; 2) GMBB, NHGRI/NIH, Bethesda, MD.

Amish lethal microcephaly (MCPHA) comprises severe microcephaly, a congenital malformation of the brain, increased urinary -ketoglutarate, and premature death. It is inherited in an autosomal recessive pattern. Previously, we reported a missense mutation in the *SLC25A19* gene encoding a mitochondrial membrane deoxynucleotide carrier, DNC, which segregates with the disease and alters a highly conserved amino acid. Functional analysis of the mutant protein using an *in vitro* transport assay revealed that nucleotide transport activity was lost. To understand how loss of function of this protein results in MCPHA, we have created a knockout mouse that has lost three exons of the *Dnc* gene. Homozygous mutant embryos fail to develop past 11.5 days p.c. Mutant embryos are small and most fail to complete neural tube closure in the mid and hindbrain portion of the embryo resulting in disorganization of developing brain structures. The neural folds have ruffled edges with convolutions extending into the neural tube of the trunk and tail. In addition, 10.5 day mutant embryos had very few erythrocytes in the circulation, indicating that yolk sac erythropoiesis requires DNC. Preliminary functional analyses of mitochondria from cultured cells isolated from 10.5 day embryos were unremarkable. Immunohistochemistry to both mitochondrial HSP70 and subunit I of the cytochrome C oxidase complex was normal in mutant cells. Quantitative PCR assays showed no change in mitochondrial DNA levels from whole embryos, yolk sacks or embryonic fibroblasts that were homozygous mutant. The presence of functional mitochondria in DNC deficient embryos indicates that DNC is not required to synthesize mitochondrial DNA or produce mitochondria. We hypothesize that MCPHA may be the result of the disruption of an undescribed non-mitochondrial function of DNC.

Imaging gene expression and anatomy in the developing human brain. *S. Lindsay¹, S. Sarma¹, M. Scott¹, J. Kerwin¹, J. Sharpe², T. Strachan¹, D. Davidson², L. Puellas³, S.C. Robson⁴, R.A. Baldock².* 1) Institute of Human Genetics, Univ Newcastle upon Tyne, Newcastle on Tyne, United Kingdom; 2) MRC Human Genetics Unit, Western General Hospital, Crewe Road, Edinburgh, United Kingdom; 3) Dept. of Morphological Sciences, Faculty of Medicine, University of Murcia, Spain; 4) School of Surgical and Reproductive Sciences, University of Newcastle, Newcastle on Tyne.

Disorders involving abnormal brain development are common and can be severe. Identifying underlying causative genes and their expression patterns is important because it may reveal the tissue/cell type affected, genes which can potentially interact and possible targets for therapeutic interventions. Although the mouse is a powerful model system, there are differences between human and mouse transcriptomes [e.g. 1,2] and there is a clear need to study gene expression directly during human development. The MRC-Wellcome Human Developmental Biology Resource (HDBR) is a collection of intact, staged and karyotyped human fetuses, ranging from 4-12 weeks of development. The HDBR is held at the Institute of Human Genetics, Newcastle and the Institute of Child Health, London and developmental material is available to the international scientific community.

With material from the HDBR, we have used optical projection tomography [3], to generate 3D models of all stages of human development from Carnegie Stage 12 (CS12; 26 days of development) to CS23 (56 days of development). In addition to providing a means of analyzing and interpreting anatomical changes, our 3D models act as a framework onto which gene expression patterns are mapped. Visualizations of the 3D models and a prototype gene expression database are available on the web (<http://www.ncl.ac.uk/ihg/EADHB/>). The EADHB will be a valuable tool for neuroanatomical and gene expression studies of human development and is immediately useful as an educational resource for both clinicians and scientists. 1.Clement-Jones et al [2000] *Hum Mol Genet* 9: 695-7022. 2. Fougrousse et al [2000] *Hum. Mol. Genet.* 9: 165-1733. 3.Sharpe et al [2002] *Science* 296: 541-545.

Hippocampal hypocellularity during early development in the Ts65Dn mouse, an animal model of Down Syndrome. *H. Lorenzi, R.H. Reeves.* Dept Physiology, School of Medicine, Johns Hopkins University, Baltimore, MD.

Down syndrome (DS) is caused by trisomy of human chromosome 21 (HSA21). It is the most frequent genetic cause of mental retardation, affecting one in 800 live born human beings. Currently there are several animal models for DS. The Ts65Dn mouse is trisomic for the distal end of mouse chromosome 16 containing homologs of nearly half of the genes located on HSA21. Both DS patients and Ts65Dn mice have cognitive impairments involving hippocampal functions. In particular, Ts65Dn mice perform worse than euploid littermates in tasks that require spatial or working memory, such as the spatial version of the Morris Water Maze or the Radial Maze. The aim of this work is to study the hippocampus of Ts65Dn mice and their euploid littermates in early development and adulthood. We performed a quantitative study of the volume and number of neurons in the hippocampus of young (6 days old) and adult (3 months old) mice using unbiased stereology. Six-day old Ts65Dn mice presented a significant reduction in the number of granule cells (5.66×10^5 vs. 7.06×10^5 , $p=0.03$) and a non-significant 14% reduction in the number of pyramidal cells (9.34×10^5 vs. 10.8×10^5 ; $p=0.14$) compared to their euploid littermates. Accordingly, Ts65Dn mice showed a significant 19.4% decrease in the volume of the pyramidal cell layer (6.41×10^8 mm³ vs. 7.94×10^8 mm³, $p=0.04$) and a non-significant 14% reduction in the volume of the granule cell layer (1.68×10^8 mm³ vs. 1.95×10^8 mm³, $p=0.24$). We also identified an 18.2% reduction in the number of mitotic cells in the hilum, the region where granule cell precursors divide to generate the internal granule cell layer. Hypocellularity of the Ts65Dn hippocampus has origins early in development may contribute to the cognitive deficits in these mice.

Evidence that PDGF signaling is disrupted in human anomalies of the pulmonary veins. *S.B. Bleyl¹, Y. Saijoh¹, S.E. Klewer², J.C. Carey¹, G.C. Schoenwolf¹*. 1) University of Utah, Salt Lake City, UT; 2) University of Arizona, Tucson, AZ.

We mapped a gene for a congenital heart defect called total anomalous pulmonary venous return (TAPVR) to chromosome 4q12 in large Utah kindreds and identified two patients with missense mutations in the gene encoding the platelet derived growth factor receptor alpha (PDGFRA) and on a small paracentric inversion in the region. In TAPVR, the pulmonary vein fails to migrate to the left atrium during remodeling of the embryonic heart stalk. To examine the role PDGF signaling molecules play in TAPVR we examined their expression in the heart stalk of normal chick embryos using whole mount and section in situ hybridization. We found asymmetric expression of PDGFRA and its ligand PDGFA in the proliferating mesenchyme surrounding the developing pulmonary vein. Asymmetric proliferation of mesenchymal cells and differential left-right growth in the heart stalk are thought to be necessary for the displacement of the pulmonary vein to the left atrium. Based on our expression and genetic data, we hypothesize that right-sided expression and function of PDGFRA in the developing heart stalk is required for normal pulmonary vein development. In support of this hypothesis, we have observed TAPVR in chick embryos treated in ovo with specific PDGFRA function blocking agents. The effects of these agents on pulmonary vein development were assessed using vascular casting and 3D serial reconstructions. These studies will advance our understanding of the role of PDGF signaling during pulmonary vein and embryonic heart development and will provide insight about the role of PDGFRA in the pathogenesis of TAPVR.

Retinoid Antagonist in the Mouse: A New Experimental Model for Transposition of the Great Arteries. D.

*Cipollone*¹, *F. Amati*², *G. Calcagni*³, *M. Biancolella*², *G. D'Amati*⁴, *G. Novelli*², *G. Siracusa*¹, *B. Marino*³. 1) Public Health and Cell Biology, Tor Vergata University, Rome, Italy; 2) Biopathology, Tor Vergata University, Rome; 3) Pediatrics, University of Rome La Sapienza; 4) Experimental Medicine University of Rome La Sapienza.

The morphogenetic mechanisms responsible for transposition of the great arteries (TGA) are still largely unknown, also because this malformation is very difficult to be experimentally reproduced. Retinoic acid (RA), the active metabolite of vitamin A, is an essential molecule for heart formation. The aim of the present study was to test the effect on murine heart morphogenesis of BMS189453 an antagonist of all RA receptors. It was administered at 5 mg/kg body weight (twice, at 10 h interval) to pregnant female mice at 6.5 (group 1), or 7.5 (group 2), or 8.5 (group 3) dpc. At birth the anatomical features were evaluated by stereomicroscopic examination. All mice of group 1 presented viscerio-atrial situs solitus with D-loop of the ventricles. The thymus was normal in 8 cases (80%) and ipoplastic in 2 cases (20%). Only 4 neonates (40%) presented TGA. 22 neonates (mothers treated at 7.5 dpc) presented viscerio-atrial situs solitus with D-loop of the ventricles. The thymus was abnormal in all but one mouse (absent in 5 cases); 6 mice (23%) had other types of extracardiac malformation, such as meroanencephalia. 15 mice (68%) presented various types of cardiac defects: 12 with TGA (54%) 2 with Truncus (9%) and 1 right aortic arch (5%). 20 neonates of group 3 presented normal cardiovascular anatomy, but altered thymus morphology. Resorbtion of the embryos due to the toxic action of the substance decreased significantly from 6.5 dpc to 8.5 dpc. All control mice presented normal extracardiac and cardiovascular anatomy. Conclusions: TGA can be consistently reproduced in the mouse by administration of a competitive antagonist of RA at 7.5 dpc that corresponds to 18 days of pregnancy in humans. This new experimental model for cardiac defects can be used for further dissection of the early molecular mechanisms of RA action, i.e. using microarray techniques and can be used in evaluating the function of genes related to RA.

Cells expressing a mutant of DNA polymerase are susceptible to chromosomal aberrations induced by an alkylating agent. *S. Mehra, S. Banerjee.* Department of Cancer Biology, Cleveland Clinic Foundation, Cleveland, OH.

Eukaryotic DNA polymerase (pol) is a DNA repair enzyme in base excision repair pathway (BER) and meiosis. Both wild-type (WT) and pol proteins are expressed in primary breast and colorectal tumors. A complex of truncated pol (pol) and X-ray cross complementing group 1, XRCC1 acts as a dominant-negative mutant. In this study, we investigated the potential role of pol in maintenance of chromosomal integrity. We used three cell lines derived from mouse embryonic fibroblasts of pol knockout and WT mice: (1) pol null cell line $-/-$, 19.4 (2) WT pol $+/+$, 16.3 and (3) pol $-/+$, 19.4P expressing pol (established in our laboratory). The cell lines were cultured and treated during the exponential growth with various doses (10nm to 100nm) of N-methyl-N-nitrosourea (MNU) for 1 hr and allowed to recover. Colcemid (50ng/ml final concentration) was added and after 3 hrs, cells were harvested, treated with hypotonic solution, fixed and stained by Giemsa. A minimum of 100 metaphases were examined for chromosomal aberrations such as radials, chromatid breaks and translocations. The average number of chromosome aberrations per cell was significantly enhanced in 19.4 cells treated with 25 nm MNU compared to the pol and WT cells. 19.4P cells were more resistant than 19.4 cells but still less resistant than 16.3 as the chromosome breaks could only be seen after treatment with 50nm and 100nm of MNU. 16.3 cells showed chromosomal aberrations when MNU concentration was increased to 100nm MNU. 19.4 cells were remarkably more sensitive to low doses of MNU than pol or WT. This may be due to an error-prone BER caused by pol deficiency leading to chromosomal aberrations.

Folic acid deficiency and/or methylenetetrahydrofolate reductase deficiency induce adverse reproductive outcome and congenital heart defects in mice. *D. Li¹, L. Pickell¹, Y. Liu¹, Q. Wu¹, J. Cohn², R. Rozen¹*. 1) medical genetics, Montreal Children's Hospital Research Institute, Montreal, QC, Canada; 2) Institut de Recherches Cliniques de Montreal, Montreal, QC, Canada.

By virtue of its importance for protein and nucleotide synthesis and methylation reactions, folate may crucially impact embryonic development. Methylenetetrahydrofolate reductase (MTHFR) is a key enzyme in folate metabolism. Clinical reports suggest that folate deficiency and mild MTHFR deficiency may be associated with pregnancy complications and birth defects. To further investigate this hypothesis, we fed *Mthfr* $+/+$ and $+/-$ female mice a control diet (CD) or folic acid deficient diet (FADD) post-weaning. Plasma homocysteine levels in CD-treated $+/-$ dams and FADD-treated dams ($+/+$ and $+/-$) were found to be at least 2-fold higher than those in CD-treated $+/+$ dams. On gestational day (GD) 14.5, a significant increase in the rate of embryonic resorption and delay, indicative of fetal loss and intrauterine growth retardation (IUGR), was observed in these hyperhomocysteinemic mice, compared to CD-treated $+/+$ dams. Of the viable embryos, no congenital heart defects (CHD) were found in embryos from CD-treated $+/+$ dams. In contrast, 6.5% from CD-treated $+/-$ dams, 23.1% from FADD-treated $+/+$ dams and 16.2% from FADD-treated $+/-$ dams showed CHD. These defects included ventricular septal defects, double outlet right ventricle and endocardial cushion defects. Most of the affected embryos also showed hypoplasia of the myocardium and a few embryos had heart failure. Examination of embryonic *Mthfr* genotype demonstrated no consistent correlation with IUGR or with heart defects. Our findings show that low maternal folate status and decreased maternal MTHFR increase the incidence of pregnancy complications and a range of CHD, supporting the benefit of folic acid supplementation.

Program Nr: 1050 from the 2004 ASHG Annual Meeting

Expression of Irf6 and Tgfb3 mRNA in murine palate epithelium is not affected by dioxin. *B. Schutte, S. Goudy, M. Malik.* Dept Pediatrics, Univ Iowa, Iowa City, IA.

Isolated cleft lip and palate is a common disorder with a complex etiology. An ideal, genetically simple, model to study clefting is Van der Woude Syndrome (VWS). Interferon Regulatory Factor 6 (IRF6) is the transcription factor responsible for VWS and is expressed in the medial edge epithelium (MEE) on the leading edge of the palate just prior to palatal fusion. This pattern of expression is similar to Tgfb3, a growth factor that is necessary for palate development. In mice that lack Tgfb3, the palate fails to fuse, in part, because the MEE fails to dissolve. The failure of the MEE to dissolve is also seen in clefts induced by 2,3,7,8-tetrachlorodibenzo-p-dioxin (dioxin). Previous studies have shown that dioxin increases the level of TGFB3 protein in human palate cultures while the amount of mRNA decreases slightly. However, palate fusion in mice is 200 times more sensitive to dioxin, and the effect of dioxin on Tgfb3 and Irf6 in the MEE in the murine model is unknown. In this study we treated murine palates with dioxin in culture to study the effect on Tgf3 and Irf6 mRNA production in the MEE. As expected, palate cultures in dioxin-containing media did not fuse. Using Laser Capture Microdissection, we specifically removed the MEE from the palate shelves. Following dioxin treatment, we found no apparent difference in TgfB3 and Irf6 mRNA when compared to control palate cultures using RT-PCR. We conclude that dioxin-induced cleft palate is not caused by down regulation of transcription of TgfB3 or Irf6. Future studies will elucidate whether dioxin affects Irf6 function, possibly by inhibiting post-translational activation.

Control of enteric nervous system differentiation by endothelin 3 and SOX10. *N. Bondurand*^{1, 2}, *D. Natarajan*¹, *A. Barlow*¹, *N. Thapar*¹, *N. Lemort*², *V. Pachnis*¹. 1) Division of Molecular Neurobiology, National Institute of Medical Research, London; 2) Inserm U468, Hôpital Henri Mondor, Creteil, France.

Hirschsprungs disease (HSCR), or congenital aganglionosis, is a common disease of newborns affecting approximately 1 in 4500 live births. HSCR is characterised by failure of enteric ganglia to form, usually in the distal part of the colon; this results in lack of peristalsis and intestinal obstruction in the affected segment of the gut, which, if left untreated leads to death. Several genes encoding transcription factors and signalling molecules have been shown to play key roles in enteric nervous system (ENS) development. Among these are the G-protein coupled receptor-B, its ligand endothelin3 (ET3), and the transcription factor SOX10. To understand the mechanisms by which these factors control cell differentiation during enteric development, we previously developed a primary culture system which allows us to isolate, expand and follow the differentiation of multipotential progenitors of the murine ENS (i.e, EPCs) (Bondurand et al., *Development*, 2003, 130: 6387-6400). Here we report the use of this system to study SOX10 function in ENS neurogenesis: we demonstrate, using retrovirus infection, that constitutive SOX10 expression inhibits overt neuronal differentiation of these EPCs. On the basis of these results and previous observations showing that ET3 inhibits neuronal differentiation in mixed ENS cultures, we decided to test the possibility of an interaction between ET3 and SOX10. To this end, we performed a series of in vitro assays based on our culture system and in vivo experiments making use of spontaneous or induced mouse models of these genes (i.e, the lethal spotted, dominant megacolon and Sox10^{-/-} mice). Altogether, our results point out the existence of a genetic interaction between these two genes and indicate that ET3 is likely to operate upstream of SOX10 to contribute to the maintenance of multipotent progenitors and the regulation of ENS differentiation.

Comparison of Gene Expression Patterns Induced by Different C-terminal Isoforms of RET. *S.M. Myers, S.D. Andrew, D.S. Richardson, L.M. Mulligan.* Dept Pathology, Queen's Univ, Kingston, ON, Canada.

The proto-oncogene *RET* encodes a receptor tyrosine kinase that is involved in development of the kidney and neural crest lineages. Alternative splicing of the gene leads to three distinct C-terminal RET isoforms, RET9, RET43 and RET51. Functional differences between isoforms has been suggested by phenotypic differences in animal models expressing only single RET isoforms and by different isoform requirements for neuronal survival in culture. A difference in the onset of isoform transcripts during early human embryonic kidney development has been shown. These data suggest that each isoform may stimulate expression of a unique spectrum of target genes. In previous studies, we have used cDNA expression arrays to show that a broad range of genes may be modulated by both RET9 and RET51. However, we were not able to directly compare quantitative and qualitative differences in gene expression associated with each RET isoform. Here, we have used a doubly inducible RET isoform expression system in embryonic kidney 293 cells that allows us to regulate both RET expression and RET receptor dimerization and downstream signalling. We have used cDNA gene expression arrays to compare the nature and extent of relative gene expression induced by each of the RET isoforms. We have identified 67 genes with increased expression in the presence of one or all three RET isoforms. In preliminary analyses, we have confirmed 33 of these genes by qRT-PCR and, in some cases, by western blotting. Our data suggest that similar genes are modulated in response to each RET isoform and that few, if any, genes show a unique isoform specific induction pattern. It seems likely that RET isoform specific functional roles may be cell type specific or related to quantitative differences in target gene expression.

FOXL2 function in human and mouse development. *M. Uda*¹, *C. Ottolenghi*², *L. Crisponi*¹, *M. Deiana*¹, *M. Marongiu*¹, *A. Meloni*¹, *J.E. Garcia*², *A. Forabosco*³, *A. Cao*¹, *D. Schlessinger*², *G. Pilia*¹. 1) Istituto di Neurogenetica e Neurofarmacologia, Consiglio Nazionale delle Ricerche, c/o Ospedale Microcitemico, Via Jenner s/n, Cagliari, Italy 09121; 2) Laboratory of Genetics, National Institute on Aging, Baltimore, Maryland, USA 21224; 3) Medical Genetics, Department of Mother and Child, University of Modena and Reggio-Emilia, Policlinico, Via del Pozzo 71, Modena, Italy 41100.

FOXL2 mutations cause gonadal dysgenesis or premature ovarian failure (POF) in women, as well as eyelid/forehead dysmorphology in both sexes (the Blepharophimosis-Ptois-Epicanthus Inversus Syndrome, BPES). To understand better the role of the winged-helix forkhead transcription factor FOXL2 in development, we created homozygous mice lacking *Foxl2*. Males and females are smaller than wild type and show distinctive craniofacial morphology with upper eyelids absent, resembling features of human BPES. Furthermore, in mice as in humans, sterility is confined to females. Although heterozygous females were able to reproduce, preliminary results indicate subfertility, in at least one of three mice strains utilized. Phenotype analysis found that in addition to some skeletal dysmorphology, severe anomalies were confined to eyelids and ovary. Ovarian follicle development was abrogated at the primordial follicle stage. We are currently evaluating malformations further at different stages of mouse development, and have begun complementary biochemical approaches. To detect interacting proteins we carried out yeast two-hybrid screens with cDNA libraries from human adult ovary and 17.5 dpc mouse embryo, and have developed a FOXL2-specific antibody for immunoprecipitation studies in cells expressing FOXL2 from a transfected cDNA. Three putative interacting proteins are being characterized, providing tools to help identify target genes for FOXL2 in the critical follicle development that determines female reproductive lifespan.

Isolating New Genes In Adrenal Development. *S. Ching, E.R.B. McCabe, E. Vilain.* Dept Human Genetics, Univ California, Los Angeles, Los Angeles, CA.

In humans, abnormal development of the adrenal gland leads to severe adrenal insufficiency which is often fatal if untreated. Adrenal Hypoplasia Congenita (AHC) is an inherited disorder in which the development of the adrenal cortex is defective. It can be inherited as either an X-linked or autosomal recessive disorder, each characterized by a distinct histopathology. X-linked AHC is characterized by the cytomegalic persistence of fetal adrenal cortex that fails to differentiate into the adult zone. Affecting approximately 1 in 12,500 births, only about half of these cases can be explained by a mutation in the gene DAX-1, an unusual member of the orphan nuclear receptor superfamily, suggesting that there are additional genes involved in adrenal development. The purpose of these studies is to identify other genes involved in adrenal development, and therefore, candidates for cases of AHC not associated with DAX-1 mutations. During adrenal development in rodents, there is a period of dramatic reorganization of the adrenal cortex between 13.5 dpc and P0. We therefore isolated RNA from the adrenals of female mice at these timepoints to be used as probes for microarrayed genes and ESTs. Analysis of the microarray data produced a list of differentially expressed genes, from which several were chosen for further analysis. *Fzd2* and *SFRP2*, two genes involved in Wnt signaling, showed respective 4.0-fold and 13.9-fold increases between 13.5 dpc and P0. RT-PCR confirmed that there were highly significant differences in mRNA transcript levels between these two timepoints. *Fzd2* is a transmembrane receptor which binds to Wnt protein at the cell surface and transmits the signal intracellularly via cGMP and increasing levels of intracellular calcium. *SFRP2* modulates Wnt signaling by binding to extracellular Wnt proteins and preventing them from binding to Fzd receptors located at the cell surface. These results suggest that Wnt signaling may play a previously uncharacterized role in adrenal development.

A novel gene for truncus arteriosus type 1. *K. Heathcote¹, P. Syrris², C. Dalageorgou¹, M. Guy¹, M. Khetyar¹, L. Abushaban³, C. Braybrook⁴, P.J. Scambler⁴, M. Patton¹, A. Crosby¹, N.D. Carter¹.* 1) Clinical Developmental Science, St George's Hospital Medical School, London, United Kingdom; 2) Cobbold Laboratories, University College, London, United Kingdom; 3) Cardiology Department, Chest Hospital, Code 13110, Kuwait; 4) Molecular Medicine Unit, Institute of Child Health, London, United Kingdom.

We identified a large consanguineous family which contained six individuals affected with truncus arteriosus, a failure of the pulmonary artery and aorta to septate during cardiological development. Echocardiograms confirmed type 1 truncus arteriosus in the three living affected individuals and no cardiac abnormalities in their parents. A homozygosity mapping approach was employed to identify the locus involved. The locus mapped to a 6cM region of homozygosity on 8p21, with a maximum LOD score of 2.92 at D8S1820 (Mapmaker/Homoz).

Candidate genes in this region were sequenced, including all cardiac expressed genes and all novel genes. A novel gene was identified on the Ensembl database which is the human homolog of mouse *Nkx2.6*, a gene encoding a homeobox transcription factor expressed in the sinus venosa and the myocardium of the outflow tract in the developing mouse heart. A Phe151Leu mutation was identified in the homeodomain of this gene. All three affected individuals were homozygous for this mutation and all parents who had had an affected child were carriers of the mutation. In the mouse the *Nkx2.6* gene is expressed during embryonic development and not in the adult. We have not detected expression of the gene in human heart samples from adults, or in second trimester heart samples. Expression analysis is currently underway using a human embryonic heart northern blot.

The closely related transcription factor *Nkx2.5* is involved in septation of the heart chambers and is expressed at a similar time in mouse embryonic development. Mutations in human *Nkx2.5* have been associated with septal defects. Therefore it appears that the human homolog of mouse *Nkx2.6* is a good functional candidate gene that may play a role in septation of the cardiac outflow tract.

Expression of the IL-1 family gene in mouse preimplantation embryos and precursors of embryonic stem cells.
R.L.C. Tavares^{1,3}, S.H. Kim¹, Z.S. Sun², V. Freitas³, Z. Rosenwaks¹, K. Xu¹. 1) The Center for Reproductive Medicine and Infertility, Cornell University, New York, NY, USA; 2) Department of Pediatrics, Cornell University, New York, NY, USA; 3) Escola Paulista de Medicina, UNIFESP, Sao Paulo, SP, Brazil.

Genes of the IL-1 (Interleukin-1) family have been described as participating in cross talk between preimplantation embryos and endometrium during implantation, but their role in embryonic stem cell culture is still not clear. Our purpose was to study IL-1 family gene expression during mouse embryo development and throughout the conversion of the inner cell mass (ICM) to embryonic stem cells. We used the OCT-4 as a marker of the totipotential state of the ICM. Eighteen zygotes retrieved from 6 to 7-week-old mice were cultured in M16 medium under mineral oil, with 15 (83%) reaching the blastocyst stage. Two zona-free blastocysts were used as a positive control for Oct-4 expression. The remaining 13 blastocysts were cultured in 4 well dishes, previously prepared with 0.1% gelatin and 0.6 ml of conventional embryonic stem cell feeder medium. The medium was changed daily, and after 4 days, six inner cell mass outgrowths (ICM-O) were removed. Each was loaded individually into a 0.5 ml PCR tube for the RT-PCR. All RT-PCR and PCR reactions were run with negative controls. PCR products were analyzed by electrophoresis. Gene expression of OCT-4, b-actin and Interleukin-1 receptor antagonist (IL-1ra) was successfully detected using SuperScript First-Strand Synthesis System for RT-PCR. Our results showed that all 6 ICM-O samples were positive for OCT-4 and b actin, confirming that the cells analyzed were totipotential. One of the six ICM-Os was also positive for IL-1ra. The results suggest that the IL-1 family gene is expressed in totipotential mouse embryonic cells and may be involved in the process of conversion toward their becoming stem cells. Further experiments including other genes of the IL-1 family and more passages of ICM-O during the establishment of embryonic stem cell culture may provide more information for efforts to elucidate the mechanisms of cellular differentiation and implantation process in mouse.

Genomic, cDNA, and Embryonic Expression Analysis of the Zebrafish Ortholog of *IRF6*, the Causative Gene in Van der Woude and Popliteal Pterygium Syndromes. *J. Ben*¹, *E.W. Jabs*^{2,3}, *S.S. Chong*^{1,2}. 1) Pediatrics, Ob/Gyn, and Lab Medicine, National Univ Singapore & Hospital, SINGAPORE; 2) Pediatrics, McKusick-Nathans Institute of Genetic Medicine & Center for Craniofacial Development and Disorders, Johns Hopkins Medicine, Baltimore, USA; 3) Medicine, Plastic Surgery, Johns Hopkins Medicine, Baltimore, USA.

Mutations in the *Interferon Regulatory Factor 6 (IRF6)* gene have been identified in the autosomal dominant clefting disorders Van der Woude and popliteal pterygium syndromes. The *IRF* gene family consists of nine members encoding transcription factors that share a highly conserved helix-turn-helix DNA-binding domain and a less conserved protein-binding domain. Most IRFs regulate the expression of interferon- and - after viral infection, but the function of *IRF6* remains unknown. Using initial sequence information from a 5 prime EST, coupled with 5 prime and 3 prime RACE experiments, we have isolated a full length zebrafish *irf6* cDNA. It contains an open reading frame encoding a 492 amino acid protein, and a GT-rich 3 prime untranslated region. The encoded protein has a Smad-IRF interaction motif and a DNA-binding domain. Genomic analysis indicates that the zebrafish *irf6* gene consists of nine exons, of which four coding exon splice junctions are highly conserved with other vertebrate species. Using probes from the 5 prime untranslated region and upstream promoter of *irf6*, the gene was mapped to linkage group 22 using a radiation hybrid mapping panel. By *in situ* hybridization analysis of whole mounts and cryosections, we demonstrate that *irf6* is present as a maternal transcript, suggesting an important if not essential role in the early embryo. During gastrulation, *irf6* was expressed at forerunner cells. No expression was observed at the early somite stages. At the 17-somite stage, distinct expression was observed in the otic placode and Kupffers vesicle. During the pharyngula and hatch periods, *irf6* was expressed at the olfactory and otic placodes, and epithelial tissues of endodermal origin such as the mouth, pharynx and intestine. In 5-day old larvae, *irf6* was also expressed in the pharyngeal arch.

Human Developmental Disorders: Categories of Genes. *G.A. Bruns^{1,2}, R.E. Eisenman¹*. 1) Genetics Div, Children's Hosp, Boston, MA; 2) Dept of Pediatrics, Harvard Medical School, Boston, MA.

The OMIM Morbid Map was sequentially searched for inherited disorders with known gene mutations not associated with pathway enzymopathy to assess the different types of genes underlying developmental disorders. From more than 300 disorders meeting criteria and evaluated to date, the genes involved in 100 disorders with developmental phenotype were categorized. When mutation in a gene is associated with more than one syndrome, that gene was tabulated only once. Among the disorders evaluated, transcription factor mutations are the most common at 19 percent. These include: 5 HOX; 2 Forkhead family; 2 SOX family; 2 GATA binding protein genes; and loci for 4 tissue specific transcription factors. Sixteen mutations involve structural proteins, including members of the troponin-tropomyosin complex and IF filaments. There are 6 mutations of cell adhesion or gap junction proteins; 6 of fibroblast growth factors and FGF receptors; 4 of signal transduction molecules; 3 of receptor or protein tyrosine kinases/phosphatases; and 2 of Notch related cell fate decision proteins. Four disorders are due to alterations in solute carrier (SLC) loci and 3 to mutation in ATP binding cassette (ABC) proteins. Organelle trafficking protein and nuclear envelope protein alterations accounted for 4 and 2 disorders, respectively. Two mutations involve genes for members of the helicase superfamily; 3 loci encode neural cell neurotrophic or neural cell restricted proteins; 2 involve a GDP/GTP exchanger or RAS family GTPase activating protein; and 1 specifies a histidine triad family member. In 8 disorders, the mutation involves a novel protein, most with significant homology in lower organisms. The remainder, currently, are single category entities. The distribution of these mutations reflects the disorders evaluated to date, with additional analysis in progress. However, alterations in loci specifying transcription factors, signaling molecules and structural proteins are prominent. Although a significant fraction of loci in mammals are limited to higher Eukaryotes, the vast majority of those underlying the developmental disorders evaluated here encode sequences of ancient origin.

Changes in gene expression associated with NSDHL loss of function in mouse embryonic fibroblasts. D.

Cunningham¹, D. Swartzlander¹, S. Liyanarachchi², R. Davuluri², G.E. Herman^{1,3}. 1) Human and Molecular Genetics, Children's Research Institute; 2) Division of Human Cancer Genetics, Comprehensive Cancer Center; 3) Dept. of Pediatrics, The Ohio-State University, Columbus, OH.

Seven human disorders of post-squalene cholesterol biosynthesis have been described. Common features include growth and mental retardation, major malformations, skeletal defects, and increasing severity with prenatal lethality for disorders involving earlier steps in the pathway. We are using microarray analysis in a mutant mouse model to unravel the pathogenesis of these disorders. Initial studies have focused on *Bpa*^{1H}, a null allele of the X-linked *Nsdhl* gene encoding a sterol dehydrogenase involved in cholesterol biosynthesis. Heterozygous *Bpa*^{1H} females have skin and skeletal abnormalities with a distribution reflecting random X-inactivation, while hemizygous male embryos die before E9.5. To obtain a large, homogeneous population of *Bpa*^{1H} cells, we generated doubly heterozygous females carrying a *Bpa*^{1H} X chromosome and an X expressing a GFP transgene that undergoes random X-inactivation. Embryonic fibroblasts were cultured from *Bpa*^{1H} and wild type (wt) female embryos, and >99% pure populations of GFP-negative cells were isolated by FACS. Labeled cDNAs from parallel cultures of sorted *Bpa*^{1H} or wt cells grown in normal or lipid-depleted sera (LDS) were hybridized to microarrays containing 22,000 mouse genes. Among 44 genes that showed higher expression (p-value < 0.001) in the *Bpa*^{1H} vs wild type cells when grown in LDS, 12 function in cholesterol biosynthesis, 7 are involved in fatty acid synthesis, 2 (*Srebp2*, *Insig1*) encode sterol regulatory proteins and 2 (*Ldlr*, *StarD4*) are lipid transporters. Of the 21 remaining genes, 16 are known genes, some of which have been previously implicated in cholesterol homeostasis or lipid-mediated signaling (*Map17*, *Ctsd*, *Epb7.2*, *Mdk*), and 5 are anonymous cDNA clones. Further characterization of the expression patterns and functions of these novel genes may reveal additional roles of cholesterol in development.

Program Nr: 1060 from the 2004 ASHG Annual Meeting

X-linked genes differentially regulated during testis and ovary maturation. *J.E. Garcia, D. Schlessinger, C. Ottolenghi.* Laboratory Genetics, NIA/NIH, Baltimore, MD.

Sex chromosomes carry some genes that are sex-determining and can be modified in expression by gene dosage mechanisms. Several groups, starting with Rice (1984), have hypothesized that X-chromosome-enriched genes should be either male- or female-specific, but not both. In invertebrates, the X-chromosome was shown to be enriched in female-specific genes, but reports for mammalian systems have been conflicting concerning the degree to which sex-specific genes are on the X, and if so, which sex is selectively represented. To clarify the situation, we used *in silico* and experimental analyses (RT-PCR, Real time-PCR, and *in situ* hybridization). Genome-wide EST mapping was consistent with an enrichment of either male- or gonad-specific genes on the X chromosome. Arguing in favor of gonad rather than male specificity, genes reported to be selectively expressed in adult testis are consistently found to be expressed in the newborn ovary as well. Our results modify previous suggestions in two categorical ways: 1) Rices hypothesis that is, that the X chromosome is enriched in genes with sexually dimorphic expression is not supported; and 2) some enrichment does occur for a group of genes that are expressed early in development in both male and female gonads, and are then specifically turned off at later stages of ovarian differentiation. This suggests a previously undetected mechanism, possibly related to progression through meiosis, that differentially regulates a cohort of sex-related genes in maturing mouse ovary and testis.

SUMO modification of the Chx10 microphthalmia transcription factor is dependent on Pias1. *A. Huang¹, R.L. Chow^{1,2}, B. Muskat¹, R.R. McInnes¹.* 1) developmental biology, hospital for sick children, toronto, Ontario, Canada; 2) Department of Biology, University of Victoria, PO Box 3020, Station CSC, Victoria, BC V8W 3N5, Canada.

The homeodomain transcription factor Chx10 is essential for the normal development of the human eye. Loss of Chx10 function in humans and mice leads to microphthalmia and blindness. We hypothesized that proteins that associate with Chx10 are also likely to be required for eye formation, and that identification of these Chx10 partners will provide insight into other hereditary ocular defects. Using the yeast two-hybrid screen, we identified the protein inhibitor of activated STAT1 (Pias1) as a Chx10-interacting protein. Pias1 is a nuclear receptor coregulator and is also known to function in protein SUMO modification as a small ubiquitin-like modifier E3 ligase. Direct protein-protein interactions between Chx10 and Pias1 were confirmed by glutathione s-transferase (GST) pull-down and co-immunoprecipitation. Immunohistochemical analysis of mouse retinas revealed that Chx10 and Pias1 colocalize in cells of the inner nuclear layer. Furthermore we found that SUMO modification of Chx10 in 293 cells is dependent on Pias1. Although Pias1 can physically interact with two naturally occurring Chx10 splice variants (19 and -19), Chx10 sumoylation was observed only in the Chx10(-19) variant. The Chx10 splicing event results in the presence or absence of a 19 amino acid stretch within the CVC domain, a highly conserved region adjacent to the homeodomain that contains the sumoylation consensus sequence, MKTE. Mutation analyses established that the MKTE sequence is essential for SUMO conjugation to Chx10(-19). In summary, we have identified Pias1 as a Chx10-interacting protein required for the splice variant-specific SUMO modification of Chx10. Current studies will determine how Pias1 interaction and SUMO modification affect both the transcriptional activity of Chx10 and its biological function in retinal development. Post-translational SUMO modification of Chx10 is likely to play an important role in normal eye development and may represent an important regulatory mechanism for other hereditary ocular diseases.

Investigating the Effects of NSDHL Deficiency on Placental Development. *F. Jiang¹, D. Cunningham¹, L. Humphries¹, G. Herman^{1, 2}.* 1) Center for Molecular and Human Genetics, Columbus Childrens Research Institute, Division of Human Cancer Genetics, Comprehensive Cancer Center, Columbus, OH; 2) Department of Pediatrics, The Ohio State University, Columbus, Ohio.

The *Nsdhl* gene, located on X-chromosome, encodes a sterol dehydrogenase involved in cholesterol biosynthesis. Mutations in this gene cause the male lethal phenotype in bare patches (Bpa) mice and human CHILD syndrome. Affected male mouse embryos die in mid-gestation and demonstrate a thinner, more compact and less vascularized labyrinth layer of the fetal placenta. To further characterize the placental defects, in situ hybridization was performed to examine the expression of placental markers, including giant cell markers pII and pIII, trophoblast marker 4311 and labyrinth markers *dlx3*, *mash2*, and *gcm1*. The results suggest that the mutant placentas are generally delayed and do not maintain *mash2* expression in the labyrinth layer as early as 9.5 dpc. More striking is the dramatic reduction in the number of fetal blood vessels in affected male placentas. In situ hybridization of allantois and endothelium markers indicates that there is a failure of invasion of extraembryonic mesoderm which normally forms the endothelial lining of blood vessels in the fetal labyrinth. Our previous data have shown that there is no significant difference in cholesterol or total sterol levels between normal and affected embryos, suggesting that the defects observed are not caused by a lack of sterols. We hypothesize that NSDHL deficiency is disturbing one or more signaling pathways in the developing placenta, resulting in the defects observed. Sonic hedgehog (Shh) is processed normally in mutant immortalized fibroblasts grown in normal or delipidated medium. *Ptch-lacZ* mice have been crossed with Bpa mice to examine in vivo hedgehog signaling via its receptor Patched. The expression pattern suggests an overall delay in development in embryos carrying the mutant *Nsdhl* allele. We are also performing Shh and Wnt signaling assays on normal and mutant cultured fibroblasts to see if NSDHL deficiency affects the cellular response to Shh and Wnt signaling.

Brachydactyly caused by loss of function of *sFrp2* signaling. *R. Morello, T. Bertin, K. Preuss, P. Hermanns, Y. Chen, B. Lee.* Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX.

We have examined potential components of the Wnt signaling pathway during joint and limb development. *sFrp2* belongs to the secreted frizzled related family of proteins that share a cysteine-rich domain (CRD) with the Wnt family of receptors, called frizzled. Since Wnt molecules bind the CRD domain of the frizzled receptors, the sFrps proteins can function as soluble receptors for Wnt thereby modulating its downstream signaling. *sFrp2* is highly expressed during mouse embryonic development of the eye, brain, neural tube, craniofacial mesenchyme, kidney, joints, testis, pancreas and sub-epithelial structures. We found that during mouse limb bud development, *sFrp2* is expressed in perichondrium of the digits at E13.5, in all limb joints and mesenchymal tissue surrounding them at E15.5 and then in mesenchyme lining ossified diaphyses of autopod elements. We generated *sFrp2* knock-out mice via homologous recombination. From F1 crosses we obtained *sFrp2* null mice at the expected mendelian ratios at weaning. *sFrp2*^{-/-} pups are grossly indistinguishable from their WT counterparts and thrive into adulthood. Both histological and functional analyses at 10 weeks of age have not showed any morphological defects or alteration of the organs analyzed. However, skeletal preparations of newborn mutant pups have revealed brachydactyly of the distal skeletal elements of the limb (including a delayed ossification in the second phalanx of the digits). Moreover, a selective hind-limb syndactyly, involving usually the 3rd and 4th digit, was also observed. The pattern of brachydactyly is reminiscent of brachydactyly type E in humans. These data point to the importance of Wnt signaling in the regulation of chondrocyte proliferation, perhaps similar to Tgfb signaling via GDF5 in humans and mice. Current studies are aimed at elucidating the mechanisms underlying the brachydactyly defect and the first demonstration of Wnt signaling-mediated regulation of interdigital mesenchymal apoptosis.

The role of LGL1 in alveolar development and recovery from arrested alveolar growth. *K. Nadeau*^{1,3}, *R. Jankov*^{4,5,6,7}, *K.A. Tanswell*^{4,5,6,7}, *N.B. Swezey*^{5,6,7}, *F. Kaplan*^{1,2,3}. 1) Dept Human Genetics, McGill U, QC, Can; 2) Dept. of Pediat, McGill U, QC, Can; 3) Mtl Child's Res Inst, QC, Can; 4) Lung Biol and Can Insts for Health Res Group in Lung Dev; 5) Hosp for Sick Child Res Inst, TO, ON, Can; 6) Dept. of Physiol, U of Toronto, ON, Can; 7) Dept. of Pediat, U of Toronto, ON, Can.

Bronchopulmonary dysplasia (BPD), a leading cause of morbidity in preterm infants, is characterized by inhibited lung growth and alveolarization. We cloned LGL1, a glucocorticoid-induced, developmentally regulated gene in lung mesenchyme, and showed that reduction of Igl1 inhibits lung branching. Maximal fetal expression of LGL1 is concordant with the onset of alveolar septation and augmented surfactant production. Beginning in late gestation and continuing after birth, secreted Igl1 is imported by epithelial cells. We therefore hypothesized that Igl1 would have an additional role in alveolarization. We report increasing expression of LGL1 mRNA and Igl1 protein from postnatal day (PN) 7 to PN 14. We show that at PN7, Igl1 concentrates at the tips of budding 2nd alveolar septa, suggesting that Igl1 may be required for postnatal alveolarization. Interestingly, at PN14 concentration of Igl1 at septal tips was restricted to the lung periphery, where post-septation alveolarization is believed to occur. We showed that LGL1 expression is severely reduced in two rat models of impaired alveolarization (BPD) generated by exposure of newborn rats to 60% O₂ for 2 wks or 95% O₂ for 1 wk. Recovery of animals exposed to 95% O₂ was associated with normalization of Igl1 levels. Surprisingly, when accelerated lung growth in recovering animals is prevented following injection of a soluble FGF receptor-1 (sequesters FGF-2), Igl1 levels rapidly increase. This suggests a potential regulatory feedback link between Igl1 and FGF-2, a key growth factor of lung development. We speculate that Igl1 is important for normal alveolarization, that deficiency of Igl1 contributes to the arrested alveolar partitioning observed in BPD, and that recovery is associated with normalization of Igl1 levels.

Nr0b1 is expressed and functional in the early embryo, but not in the extra-embryonic visceral endoderm. K.

*Niakan*¹, *E.C. Davis*², *M. Jiang*³, *D.B. Dehart*⁴, *K.K. Sulik*⁴, *E.R.B. McCabe*^{1,2}. 1) Depts of Hum Genet; 2) Pediatr; 3) Molec and Med Pharmacol, David Geffen Sch of Med at UCLA, LA, CA; 4) Dept of Cell and Dev Biol, UNC, Chapel Hill, NC.

The cytomegalic form of adrenal hypoplasia congenita is an X-linked disease caused by mutations in NR0B1, which codes for DAX1. Failure to create a conventional knock-out mouse model led us to hypothesize that Nr0b1 is expressed earlier than predicted and with a novel function. Previously we reported Nr0b1 expression in ES cells and preimplantation embryos. Our purpose was to identify Nr0b1 expression and map its patterns throughout murine embryonic development and to investigate a functional role for Nr0b1 in early embryos. Immunohistochemistry, in situ hybridization and western blots were used to determine Nr0b1 expression in mouse embryos from E3 through E12. Expression of the following steroidogenic proteins was investigated: progesterone, estrogen (and) and androgen receptors; Wilms tumor 1; steroidogenic factor 1; and cytochrome P450_{sc}. Nr0b1 expression was confirmed by quantitative RT-PCR. ES cells were treated with Nr0b1-targeted siRNAs; the phenotype observed was confirmed using a known inhibitor of Nr0b1 expression and the cells stained with Nr0b1 antibody. Nr0b1 expression was observed at a critical boundary throughout embryonic development; specifically, it distinguishes between the embryo and its extra-embryonic visceral endoderm. Expression was also found in polar bodies, hypothesized to determine polarity in embryos. Nr0b1 did not appear to function in the steroidogenic pathway at this early developmental stage, as determined by absence of steroidogenic proteins. By utilizing siRNA knock-down in ES cells and observing differentiation of treated cells, we demonstrated functional relevance of Nr0b1 in early development. Based on the expression observed in embryonic development and the differentiation induced with loss of Nr0b1 expression, we hypothesize that Nr0b1 is critical in early embryonic development and plays a role different from that in steroidogenesis.

LGL1 transgenic mice have accelerated newborn alveolarization. *L. Oyewumi*^{1,2}, *F. Kaplan*^{3,4}, *N.B. Swezey*^{1,2,5}. 1) Lung Biol Research, Hosp Sick Children, Toronto, ON, Canada; 2) Dept Physiology, Univ of Toronto, Toronto, ON, Canada; 3) Dept Human Genetics, McGill Univ, Montreal, QC, Canada; 4) Dept Pediatrics, McGill Univ, Montreal, QC, Canada; 5) Dept Paediatrics, Univ of Toronto, Toronto, ON, Canada.

We previously cloned LGL1, a glucocorticoid- induced, developmentally regulated gene in rat lung mesenchyme. We have provided evidence that LGL1 plays an important role in lung branching morphogenesis during early gestation, based on the effects of oligodeoxynucleotide-induced reduction of LGL1 expression and of exogenously supplied recombinant lgl1 protein. Moreover, we found that lgl1 may be important for normal alveolarization, that deficiency of lgl1 is associated with the arrested alveolar partitioning observed in a hyperoxic rat model with some features of bronchopulmonary dysplasia, and that recovery is associated with normalization of lgl1 levels. We report here studies of a mouse expressing transgenic LGL1 driven by the (mesenchymal) h-versican promoter. Increased copies of the LGL1 transgene cause developmental changes in alveolarization of the postnatal mouse lung. At post-natal day (PND) 1 the structural maturation of the transgenic lung is accelerated, characterized by a marked increase in mesenchymal and secondary septal thinning and an increased number of sprouting secondary septa. By PND 4, sprouting secondary septa are numerous and the airspaces are smaller than non-transgenic littermates. Immunohistochemistry for elastin (a marker of secondary septal formation) was used to identify alveolar myofibroblasts within alveolar walls and septa. At this time, transgenic mice have more elastin expression at the tips of airspace septa. By PND 14, the two groups are indistinguishable in all these respects. We propose that LGL1 regulates the development of alveolar structures during postnatal lung development.

Human pre-implantation development characterized by unique transcript modulation. *R. Raja*¹, *A. Dobson*², *M. Abeyta*², *R. Reijo Pera*². 1) Arcturus Bioscience, 400 Logue Avenue, Mountain View, California 94043; 2) Center for Reproductive Sciences; Department of Obstetrics, Gynecology and Reproductive Sciences; Departments of Physiology and Urology; Programs in Human Genetics, Cancer Genetics, and Development and Stem Cell Biology; University of California at San Francisco (UCSF), San Francisco, California 94143.

Human development is dependent upon a cascade of events following fertilization. Unfortunately, knowledge of these critical events in humans is remarkably incomplete. Although hundreds of thousands of human embryos are cultured yearly at infertility centers throughout the world, the vast majority fail to develop in culture or following transfer to the uterus. We used a high sensitivity linear amplification methodology combined with DNA microarray analysis to characterize global patterns of gene expression in single human oocytes and embryos through the first three days of embryonic life. Using real-time RT-PCR, we verified the expression of several genes in healthy oocytes and embryos and then examined expression in embryos with arrested development. Our results provide the first global analysis of human preimplantation transcript profiles, and demonstrate that RNA can be linearly amplified from single oocytes and embryos for analysis using cDNA microarrays. We will summarize the results of our study and discuss future direction for our understanding of molecular mechanisms underlying human pre-implantation development.

A potential role for the interferon response pathway in epithelial cell fate during palate development. *N.K. Rorick*¹, *S.L. Goudy*², *M.I. Malik*³, *J.L. Mihm*³, *C.A. D'Alencon*⁴, *R.A. Cornell*⁴, *B.C. Schutte*^{1,3}. 1) Genetics PhD Program, Univ Iowa, Iowa City, IA; 2) Otolaryngology, Univ Iowa, Iowa City, IA; 3) Pediatrics, Univ Iowa, Iowa City, IA; 4) Anatomy and Cell Biology, Univ Iowa, Iowa City, IA.

Genetic variation in Interferon Regulatory Factor 6 (*IRF6*) causes Mendelian forms and confers risk toward complex forms of cleft lip and palate. *IRF6* is a member of the IRF family of transcription factors. Although best known for mediating the Type I interferon response following a viral infection, several *Irf* transcription factors have been shown to regulate cell proliferation, differentiation and death. These cellular processes are also necessary to determine the cell fate of the epithelium located at the medial edge of the fusing palates in normal development. Previous studies show that stimulation of maternal immunity reduces the frequency of teratogen-induced clefts in mice. We hypothesize that the interferon pathway regulates the cell fate of the medial edge epithelium and that *IRF6* mediates this response. We performed Laser Capture Microdissection and RT-PCR to quantify gene expression in the medial edge epithelium and gel-shift assays to determine DNA binding activity for *Irf6*. We observed that *Irf6* mRNA is expressed in the medial edge epithelium, and is consistent with a role for *Irf6* in determining their cell fate. Also, like other *Irf* transcription factors, we observed that *Irf6* binds the consensus Interferon Stimulatory Response Element, a site that is often located in the promoters of the Type I interferon and interferon-stimulated genes. Additional expression studies show that *Ifna*, but not *Ifnb*, is expressed in the medial edge epithelium. These results are consistent with involvement of part of the interferon pathway in palate development. Finally, whereas several other *Irf* members are expressed in the medial edge epithelium, *Irf5*, the paralog most similar to *Irf6*, is not. In zebrafish, there is partial but not complete overlap of *Irf5* and *Irf6* expression, suggesting that the phenotype caused by mutations in *IRF6* may be restricted to the palate because *IRF5* provides redundant function in other tissues.

Comparative expression patterns of Tbx1, FoxG1b/BF1 and Dlx5 transcription factors during human craniofacial development. *D. Sanlaville, H. Etchevers, M. Clément-Ziza, G. Goudefroye, S. Audollent, E. Detrait, T. Attié-Bitach, M. Vekemans.* Dept Genetics and INSERM U393, Hôpital Necker Enfants Malades, 149 rue de Sèvres, 75743 Paris Cedex 15, France.

We examined the spatiotemporal expression patterns of Tbx1, FoxG1b (also known as BF1) and Dlx5 in normal human embryos obtained from voluntary interruptions of pregnancy, in accordance with ethical guidelines established by French law, using *in situ* hybridization. All three transcription factors are members of gene families with highly conserved DNA-binding domains, for which these and other members have been shown to increase functional specificity through protein-protein interactions. In addition, they all interact genetically with FGFs 8 or 10. In order to see if Tbx1, FoxG1b and/or Dlx5 colocalized during human craniofacial development, we hybridized specific riboprobes to embryonic sections at chosen stages between Carnegie stage (C) 8 and C19. FoxG1b is expressed very strongly at C10 (22 days) in rostral cephalic mesenchyme of mesodermal origin, while Dlx5 is found in the neural folds at the cephalic but not trunk level. During C11-C12 (24-27 days), FoxG1b and Dlx5 are observed in overlapping domains of the prosencephalon. All three factors are expressed in the pharyngeal arches, in the endoderm (FoxG1b, Tbx1) and in neural crest/mesodermal mesenchyme (Tbx1, Dlx5), particularly around the dynamic heart outflow tract connection to the caudal branchial arches, the secondary heart field. At later stages, FoxG1b is maintained in the ventral prosencephalon up to the infundibulum; Dlx5 is seen in the same region but extends caudally into the hypothalamus and distally into the olfactory nerve. Tbx1 and Dlx5 are expressed in similar domains of the otic vesicle and its derivative parts of the inner ear. All three factors also had unique expression domains during embryogenesis. These patterns are consistent with possible physical interaction between Dlx5, Tbx1 and/or FoxG1b during cephalic development, hypotheses that will be tested using functional assays.

Molecular identification of genes and pathways involved in skeletogenesis by EST sequence analysis and functional studies. *S. Schlaubitz*^{1,2}, *C. Stelzer*², *B.U. Zabel*², *B. Lee*¹. 1) Dept. of Mol. and Human Genetics and Howard Hughes Medical Institute, Baylor College of Medicine, Houston, TX/ USA; 2) Mol. Genet. Lab., Childrens Hospital, Mainz/ Germany.

An EST-sequencing project was initiated to identify so far undescribed genes in poorly understood pathways related to skeletogenesis. On the basis of 5000 EST clones generated from a human cDNA library of pooled fetal cartilage tissue we obtained sequence data which were compared to the non-redundant Genbank/ EMBL/ DDBJ and dbEST databases using the Ensembl Genome Browser and the EST identification task ESTsweep provided by the HUSAR group in Heidelberg/ Germany as well as the UCSC Genome Bioinformatics browser. An extensive examination of the data obtained by this approach revealed that 77% of EST sequences match to known genes/ mRNAs, 10% to genomic sequences, whereas 9.5% still match to anonymous ESTs (3.5% were contaminations). We scanned these anonymous ESTs for domains by using the SMART browser of EMBL in Heidelberg/ Germany and started to characterize the most interesting clones by Northern Blot analysis with RNA from human, murine and rat cell lines and tissues. Additional RT-PCR and in-situ hybridizations on whole mouse embryos and sections were used as tools to characterize the expression pattern of these genes during development. One of these genes matches a hypothetical protein that shows an interesting expression pattern at different embryonic stages and in northern blot analysis of RNA from different cell lines. Its expression is temporally and spatially restricted. At E13.5, it is expressed in proliferating chondrocytes. By E17.5, it is also strongly expressed in the inner cortex of long bones. Its expression was found in a cell line of murine hypertrophic chondrocytes (MCT, both 32 and 37C), but was absent in murine fibroblasts. Further experiments may help us to understand its involvement in bone pattern formation, growth and development as well as ossification and homeostasis of the skeleton. This gene as well as others within this library may represent candidate genes for skeletal dysplasias as well as for complex disorders (osteoarthritis/ osteoarthrosis and osteoporosis).

Confirmation of a locus on chromosome 5q for a 46 XY Sex Reversal phenotype. *G. Sivapalan, K. Kalidas, Y. Adjei-Gyamfi, S. Sivakumaran, M. Patton, A. Crosby.* Medical Genetics Res, SGHMS, London, United Kingdom.

Genetic sex is determined by inheritance of either an X or Y chromosome. Sex reversal occurs when an individual is genetically one sex but phenotypically the other. There are a number of genes known to play a role within the sex-determining pathway including DAX1 and SOX9. A novel locus on chromosome 5 has also been recently identified in a single family, although the causative gene is as yet unidentified. We investigated a four generation family with multiple individuals affected by XY sex reversal. These individuals are phenotypically female with complete gonadal dysgenesis. Linkage analysis excluded an X-linked mode of inheritance but detected linkage to the recently identified chromosome 5 locus, confirming that a gene for this condition resides in this region. A number of candidate genes are located within this region and are currently under investigation including the gene *FST* which encodes follistatin, a regulator of cell differentiation involved in embryogenesis.

Identification and analysis of Gli3 regulated genes in the murine embryonic limb and face. *C. Wicking, K. Lammerts van Bueren, B. Wainwright, E. McGlinn.* Inst for Molecular Bioscience, University of Queensland, Brisbane, Australia.

Limb and craniofacial defects are amongst the more common features of human dysmorphology syndromes, and evidence suggests the molecular mechanisms governing the development of each of these structures are highly conserved. Using the mouse as a model we have undertaken a microarray screen to identify genes dysregulated in the anterior region of the limb of the polydactylous mutant *extra-toes*. This mutant arose through sporadic deletion of the gene encoding the Gli3 transcription factor, which in the limb is the primary mediator of the secreted morphogen Sonic hedgehog. Mutation of *GLI3* in humans results in a spectrum of developmental disorders including Greig's cephalopolysyndactyly and Pallister-Hall syndrome, both of which involve limb defects. Recent evidence suggests that Gli3 is pivotal to correct anterior-posterior patterning of the limb and is central to specifying digit number and identity. As a result of our microarray screen we have identified a number of both known and novel genes whose expression is altered as a result of *Gli3* loss in the mouse limb. A number of these have been validated by whole mount in situ analysis in the limb, and several show striking expression alterations. Some of these genes also show altered expression domains in the developing face of *Gli3* mutants, providing further support for the molecular conservation of limb and face development. The genes identified in this screen potentially encode missing molecules in the hierarchies governing limb and facial development, and may ultimately prove to contribute to disorders involving these structures.

Inactivation of the Huntingtin disease gene (Hdh) impairs early patterning and primitive streak progression.

J.M. Woda¹, P. Hilditch-Maguire¹, T. Calzonetti¹, M.P. Duyao^{1,2}, V.C. Wheeler¹, M.E. MacDonald¹. 1) Molecular Neurogenetics, Massachusetts General Hospital, Charlestown, MA; 2) Ardaís Corporation Lexington, MA 02421.

Huntington's Disease, a dominantly inherited neurodegenerative disorder, is caused by a mutation in the huntingtin protein that results in an expanded polyglutamine segment in its N-terminus. Currently, the normal function of huntingtin, a novel 365kDA HEAT domain protein, is unknown. Previous studies have shown that inactivation of the mouse huntingtin gene (Hdh) results in early embryonic death. Expression of huntingtin in the extraembryonic tissues is sufficient to rescue this phenotype in chimeric embryos. To understand the underlying defect in huntingtin deficient embryos, we have examined embryonic patterning and morphogenesis in these embryos. Here, we demonstrate huntingtin is required for node formation and normal primitive streak progression. Additionally, in the absence of huntingtin, posterior restriction of growth factors such as nodal and FGF-8 fails and these factors are ectopically expressed throughout the epiblast. Transient goosecoid expression is also altered, resulting in ectopic goosecoid expression in the posterior epiblast at late streak stages. This failure in posterior restriction does not reflect a loss of anterior/posterior polarity, as normal expression of markers of the anterior epiblast and anterior visceral endoderm (AVE) is observed and the primitive streak and its derivatives are formed in these embryos. Impaired regionalization does not appear to be a result of loss of extraembryonic signal expression, as evidenced by the normal expression of nodal antagonists in the AVE and other extraembryonic signaling molecules in huntingtin deficient embryos. Taken together, these results suggest that huntingtin is essential for normal node formation, primitive streak progression and regionalization in the developing embryo. Support: Hereditary Disease Foundation, NINDS grant NS32765.

Pathophysiology of syndromic combined pituitary hormone deficiency due to a LHX3 defect in light of LHX3 and LHX4 expression during early human development. *M. SOBRIER*¹, *T. ATTIE-BITACH*², *I. NETCHINE*³, *F. ENCHA-RAZAVI*², *M. VEKEMANS*², *S. AMSELEM*¹. 1) Genetique Moleculaire et Physiopathologie,INSERM U468, Hopital Henri Mondor, CRETEIL, France; 2) Handicaps Genetiques de l'Enfant, INSERM U393, Hopital Necker-Enfants malades,PARIS, France; 3) Explorations Fonctionnelles Endocriniennes, Hopital Trousseau, Paris, France.

The pathophysiology of combined pituitary hormone deficiency (CPHD) is just beginning to be elucidated, with mutations in genes encoding transcription factors expressed at different stages of pituitary development. Among them, the two closely related genes, LHX3 and LHX4, are believed to share redundant biological properties. The patients with a LHX3 mutation display a CPHD phenotype, associated with a rigid cervical spine and anteverted shoulders. These latter features, not reported in *Lhx3*^{-/-} and *Lhx4*^{-/-} mice nor in patients with a LHX4 defect, prompted us to study the molecular consequences of a previously identified LHX3 23-bp deletion and to determine the LHX3 and LHX4 expression patterns during early human development. This deletion, which results in the skipping of one coding exon, would lead to a protein with no transcriptional capability. Using in situ hybridization, we show that LHX3 and LHX4 are expressed in the developing pituitary and along the rostro-caudal length of the spinal cord; here, both transcripts are detected in the ventral part giving rise to motoneurons and interneurons. However, whereas LHX3 is expressed at all stages studied, LHX4 expression is transient, and, at 6 weeks of development, is much stronger at the caudal than at the cervical level, thereby suggesting that the extrapituitary anomalies result from a LHX3-dependent neurological defect that is not rescued by the closely related protein LHX4. Overall, these data, which shed light on the pathophysiology of a human developmental disorder, disclose the absence of redundancy between LHX3 and LHX4 during the early stages of human development.

Scd1ab-Xyk: A new allelic asebia model due to a CCC trinucleotide insertion in exon 5 of stearyl-CoA desaturase 1. X. Kong^{1,2,5}, L. Bu^{1,2}, S. Zhou³, M. Jin², J. Sundberg⁴, H. Jiang^{1,2}, M. Qian^{1,2}, Y. Shi^{1,2}, G. Zhao², L. Scd1ab-Xyk: A new allelic asebia model due to a CCC trinucleotide insertion in exon 5 of stearyl-CoA desaturase 1
Abstract We found a spontaneous, autosomal, recessive mutant mouse, which arose on the outbred Kunming mice, suffering from skin and hair defects. By haplotype analysis and direct sequencing of PCR products, we describe this mutation as a new allelic asebia one with a naturally occurring mutation in Scd1 (a CCC trinucleotide insertion at nucleotide position 835 in exon 5). This mutation introduces an extra proline residue at position 279 of the Scd1 protein. The mutant mice, originally designated km/km but now assigned Scd1ab-Xyk (hereafter abbreviated abXyk/abXyk), have a similar gross and histologic phenotype as reported in characterized allelic mutations of asebia (Scd1ab, Scd1abJ, Scd1ab2J, and Scd1tm1Ntam). Histological analysis showed they were also characterized by hypoplastic sebaceous glands and abnormal hair follicle. In a cross of Kunming- abXyk/abXyk with ABJ/Le-abJ/abJ mice, all the progeny had the same phenotype indicating these were noncomplimentary and therefore allelic mutations. Comparing with other four allele mutants, this Scd1ab-Xyk carries the mildest change in Scd1 leading to the dysfunction of the Scd1 protein. So this new mutant mouse is a good model not only for studying the human scarring alopecias, which are characterized by hypoplastic sebaceous glands, but also for studying the function and structure of Scd1 protein.

***Tbx1* in the pharyngeal pouch endoderm is required for VCFS/DGS relevant organogenesis.** *J.S. Arnold¹, U. Werling², E.M. Braunstein¹, J. Liao¹, W. Edelmann², B.E. Morrow¹.* 1) Molecular Genetics, Albert Einstein College of Med, Bronx, NY; 2) Cell Biology, Albert Einstein College of Med, Bronx, NY.

Velo-cardio-facial syndrome/DiGeorge syndrome is associated with hemizygous 22q11.2 deletions and characterized by cardiovascular defects, thymic and parathyroid gland hypoplasia or aplasia and craniofacial defects including mild facial dysmorphism, outer and middle ear defects, velopharyngeal insufficiency and submucous cleft palate. Mouse model studies have found *Tbx1*, a gene mapping to the region of synteny to 22q11.2, to be responsible for this syndrome. *Tbx1* is required for embryogenesis and is expressed in multiple interactive tissues during development of the pharyngeal apparatus. Mice heterozygous for a null mutation in *Tbx1* develop mild cardiovascular defects; homozygous *Tbx1* ^{-/-} embryos die at birth with severe congenital defects stemming from abnormal pharyngeal arch (PA) development, including a single outflow tract, thymus and parathyroid aplasia, missing muscles of mastication, absent outer and middle ears and hypoplastic inner ears as well as cleft palate. *Tbx1* is expressed in the pharyngeal pouch endoderm and non-neural crest mesoderm of the PAs and in the otic vesicle. In order to determine the role of *Tbx1* in each interacting tissue during embryonic development, we have conditionally inactivated *Tbx1* in the pharyngeal pouch endoderm and in the otic vesicle epithelium using the Cre/LoxP system. Conditional ablation of *Tbx1* in the *Foxg1* domain causes a severe pharyngeal phenotype including neonatal lethality, thymus and parathyroid aplasia, cleft palate and craniofacial defects. Inactivation of *Tbx1* in the otic vesicle results in absent outer and middle ears and hypoplasia of the inner ear. Overall, *Tbx1* conditional mutants do not differ significantly from the previously described homozygous null mutants. These results underlie the importance of endodermal and otic vesicle driven *Tbx1* expression and suggest that signaling from these structures is critical for proper development of the embryo. We are currently inactivating *Tbx1* in the mesenchyme of PA1-2 to determine its separate role(s) in craniofacial development.

Somitic origin of side population cells in skeletal muscle. *J. Schienda*¹, *S. Jun*¹, *J. Epstein*³, *C. Tabin*², *L. Kunkel*¹, *G. Kardon*². 1) Genomics, Children's Hospital Boston, Harvard Medical School, Boston, MA; 2) Dept of Genetics, Harvard Medical School, Boston, MA; 3) Cardiovascular Division, University of Pennsylvania, Philadelphia, PA.

Within adult skeletal muscle resides a population of cells, side population (SP), which is obtained via FACS analysis of Hoechst dye exclusion. SP cells are a heterogeneous population that contain cells which can radioprotect lethally irradiated mice after intravenous injection and can actively participate in the formation of skeletal myotubes during regeneration. The developmental origin of these cells within the SP population has been controversial. Various researchers have proposed that they are of hematopoietic, vascular or somitic origin. We have examined the potential for somitic origin of the SPs in the chick and mouse. We have labeled chick somitic cells early in development (E2-3) with either replication-defective retroviruses or via quail-chick chimeras (replacing chick somites with quail). Mouse somitic cells were labeled via a Pax3 Mcre x Z/EG transgenic system. SPs were isolated from limb skeletal muscle at ages E14-17 and 5 weeks, respectively, and were found to contain retrovirally-labeled, quail or GFP⁺ cells. When co-cultured with primary myoblasts, these somitic SPs were induced to differentiate into functional myotubes. These results show that the somites are a probable source of adult skeletal muscle-derived SP cells.

Foxc2 is Expressed in Lymphatic Vessels and Other Tissues Associated with Lymphedema-Distichiasis

Syndrome. *S.L. Dagenais*¹, *R.L. Hartsough*¹, *R.P. Erickson*², *M.H. Witte*^{2,3}, *M.G. Butler*¹, *T.W. Glover*^{1,4}. 1) Human Genetics, U. of Michigan, Ann Arbor, MI; 2) Pediatrics, U. of Arizona, Tuscon, AZ; 3) Surgery and Pathology, U. of Arizona; 4) Pediatrics, U. of Michigan.

Mutations in FOXC2 cause hereditary lymphedema-distichiasis (LD) syndrome. LD is an autosomal dominant disorder typically characterized by pubertal lymphedema, and distichiasis, or double row of eyelashes. Less penetrant phenotypes include tetralogy of Fallot, cleft palate, ocular and renal abnormalities. Previous reports showed *Foxc2* expression in mesenchyme of developing heart, kidney and bone. However, its role in the lymphatic system was not characterized, and the basis for lymphatic disease in LD has been unknown. We have conducted a study of *Foxc2* expression during mouse development using immunohistochemistry, and have examined its expression in lymphatics and other tissues associated with LD. We found *Foxc2* expression in lymphatic endothelial cells (LEC) throughout lymphatic development. At E9.5-E10.5, we detected *Foxc2* in cardinal vein endothelial cells, coinciding with the embryonic age and site where lymphatic development is initially detected. We found *Foxc2* in LECs of the jugular lymph sac, and as lymphatic development progresses, it is expressed in the thoracic duct, lymphatic collectors and capillaries. In adult mice, we detected *Foxc2* in lymphatic vessels in the mesentery and skin. We also found that *Foxc2* is expressed embryonically in glomerular podocytes and developing eyelids. We did not detect *Foxc1*, a *Foxc2* paralog, in lymphatics. *Foxc2* nullizygous mice die between E12.5 to a shortly after birth due to heart and skeletal defects. We found that *Foxc2* nullizygous embryos have a lymphatic vasculature; however, lymphatic dilation was seen in an E18.5 embryo. These studies show that *Foxc2* is expressed throughout lymphatic development, suggesting an important role in their development. Also, we can closely correlate expression in various other developing tissues and cell types that exhibit abnormalities in some LD syndrome patients. The exact role of FOXC2 in development of lymphatics and these other tissues should shed light on the pathogenic mechanisms involved in this disorder.

A morpholino based screen for developmental eye defects in zebrafish. *B.R. Bill, A. DeLuca, M.A. Pickart, B.E. Warman, E. Mendenhall, S.C. Ekker, L. Schimmenti.* Depts. of Molecular, Cellular, Developmental Biology and Genetics; Pediatrics and the Arnold and Mabel Center for Transposon Research, University of Minnesota, Minneapolis, MN.

Introduction: We are participating in a large multilaboratory zebrafish screen using reverse genetics to facilitate gene discovery. Our laboratory screens for zebrafish phenotypes that resemble human developmental eye defects, such as microphthalmia, anophthalmia and coloboma. Morpholino oligonucleotides are used to generate loss-of-function phenotypes from sets of genes enriched for predicted secreted proteins or hematopoietic stem cell development. Embryos are screened at 2 and 3 days for gross morphologic defects in eye development specifically optic cup formation, optic fissure closure, pigment localization, and size. **Results:** We are characterizing a phenotype specific to a morpholino against the 5' end of a conserved secreted protein SP2009. By 2 days post fertilization (dpf), the morpholino-injected embryos have larger pupils and microphthalmic eyes compared to wildtype siblings. The penetrance of the phenotype increases with increasing morpholino dose suggesting specificity. The gene product affected by morpholino SP2009 is the zebrafish homolog of the -1-microglobulin bikunin precursor (AMBP) gene. Experiments designed to confirm the specificity of the phenotype to AMBP are underway. We have also discarded a number of phenotypes that appear to be characterized by a disruption of the ventral eye; we believe that this abnormality may largely be due to a common toxicity of the morpholino or a secondary phenotype due to defects in critical developmental processes. Determination of phenotype specificity is an important consideration and possible limitation in the use of morpholino screens for ocular defects. **Conclusion:** The identification of specific eye developmental abnormalities due to defects in conserved genes opens the door to analysis of function and provides candidate genes for human developmental eye defects.

Construction and Screening of Developmentally Staged, Full-Length, Early Embryo Mouse cDNA Libraries for the Identification of Novel Developmental Genes. *D. Konecki, N. Zhou, E. Roessler, M. Muenke.* Medical Genetics Branch, NHGRI/NIH, Bethesda, MD.

The specific interests of our laboratory reside in the study of human genetics disorders (i.e. holoprocencephaly, HPE) resulting from midline and laterality defects occurring early in the development of the human brain. To date mutations in six genes of the more than twenty loci determined to be associated with HPE have been shown to give rise to this disorder. To aid in the identification of additional genes associated with HPE and disorders with similar or related phenotypes, we have constructed and are in the process of screening several early mouse embryo cDNA libraries. These libraries were constructed from gestational time points 7.5 dpc and 9.5 dpc with mRNA isolated from CD-1 mice. SMART technology (Clontech) was implemented in the generation of cDNA cloning material, while TOPO cloning methodologies (Invitrogen) and electroporation were utilized for the production of recombinants. CDNA insert material was sized by agarose gel electrophoresis prior to cloning to be in the size classes of 0.5-1.0 kbp, 1.0-3.0kbp, or 3.0-20 kbp. At the present time, templates from 2016 recombinants have been purified and sequenced using an ABI 3100 Genetic Analyzer. Following editing and trimming to remove vector sequences and long poly(A) tracts, the sequences were submitted for BLAST analysis against the NR Sequence Database established and maintained by the NCBI, resulting in the identification of 64 novel sequences, with no significant sequence homology in the database. Additionally, 52 sequences with polyadenylation signals and poly(A) tracts were detected with >95% homologies only to finished mouse BAC sequences. These and other novel and known genes of interest will be investigated by whole mount in situ hybridization against wild-type (CD-1) and sonic hedgehog (Shh) homozygous and heterozygous mutant embryos of 9.5 dpc gestational age to help identify transcripts involved in the Shh developmental pathway. Other functional screens are currently being assessed to aid in the classification of these previously unknown transcripts.

Cloning and expression of a DAX1 homologue in Zebrafish. *Y. Zhao*¹, *Z. Yang*², *J.K. Phelan*³, *D. Wheeler*⁴, *S. Lin*², *E.R.B. McCabe*^{1,3}. 1) Dept Hum Genet, David Geffen Sch Med at UCLA, LA, CA; 2) Dept Mol, Cell and Dev Bio, UCLA, LA, CA; 3) Dept Pediat, David Geffen Sch Med at UCLA, LA, CA; 4) Human Genome Seq Cen, Baylor Coll Med, Houston, TX.

DAX1 is an unusual orphan nuclear receptor. Mutations in human DAX1 cause X-linked adrenal hypoplasia congenita (AHC), and duplications result in dosage-sensitive-sex reversal. DAX1 is expressed in all regions of the hypothalamic-pituitary-adrenal-gonadal (HPAG) axis. To understand better the roles of DAX1 in the normal HPAG axis development, we use zebrafish as a model organism. We report here the isolation and characterization of a DAX1 homologue in the zebrafish embryo. The isolated DAX1 cDNA clone encodes 264 amino acid residues, including the conserved 3 ligand-binding motif; but the 5 region lacks the unusual repeat motif of the DNA-binding-like domain in mammals. The putative zebrafish DAX1 protein has 50.3% identity and 65.5% similarity with the human DAX1 protein over the 3 region. Stronger identity (65.5%) exists with the tilapia DAX1 over the full-length protein sequence. Genomic sequence analysis indicates that the cloned DAX1 homologue is conserved in gene structure as well: the fish DAX1 is composed of two exons and a single intron, with highly conserved exon-intron boundaries. To explore the expression pattern of this putative DAX1 ortholog, we performed whole mount *in situ* hybridization on zebrafish embryos at various developmental stages. Expression of DAX1 was first detected in the hypothalamus at around 28 hours post fertilization (hpf). Later, a novel expression domain for DAX1 appeared in the fin buds at around 30 hpf. Expression in both locations peaked at 36 hpf. Interestingly, weak and transient expression of this gene was observed in the adrenal at around 31 hpf. Based on the conserved gene structure, the significant protein homology and the shared expression profile, we propose that the cloned DAX1 homolog could be involved in the HPAG axis development in zebrafish. Characterization of the mechanisms of DAX1 action in zebrafish will inform our understanding of the pathogenesis of developmental disorders involving human HPAG, including AHC.

siRNA mediated knockdown of the Survival of Motor Neuron (Smn) protein in cell culture and in transgenic mice. *R. Kothary*^{1,2,3}, *P. Côté*¹, *Y. De Repentigny*¹, *D. Shafey*^{1,2}. 1) Molecular Medicine Program, Ottawa Health Research Inst, Ottawa, ON, Canada; 2) Department of Cellular and Molecular Medicine, University of Ottawa, Ottawa, Ontario, Canada; 3) Department of Medicine, University of Ottawa, Ottawa, Ontario, Canada.

Spinal muscular atrophy (SMA) is a neurodegenerative disorder characterized by the degeneration of the -motor neurons in the spinal cord. The loss of these neurons causes proximal, symmetrical limb and trunk muscle weakness that progresses to paralysis and ultimately to death. To get a better understanding of the various steps in the pathogenesis of SMA, different knock out and transgenic approaches have been employed to generate suitable mouse models. These mouse models resemble the more severe type of human SMA, but it would be beneficial to generate mice with intermediate and mild phenotypes. In the present study, we describe the use of the short interference RNA (siRNA) approach to selectively reduce *Smn* expression in cell culture and transgenic mice. Double stranded siRNA constructs were targeted to different regions of murine *Smn* and cloned into the psiRNA-hH1neo (from Invivogen) expression vector. This placed the siRNA constructs under the regulation of an RNA polymerase III promoter. The siRNA constructs were transfected into C2C12 muscle cells and *Smn* protein knockdown was achieved. Subsequent to this, we microinjected the siRNA constructs into mouse embryos to derive transgenic founder embryos and mice. Preliminary experiments indicate that the siRNA approach works well in this *in vivo* context. Knockdown of *Smn* protein levels has been observed and we are currently addressing the effect this has on embryonic development particularly as it pertains to the nervous system.

Generating zebrafish models of human muscle disease. *J.R. Guyon¹, S.J. Jun¹, M. Thorne¹, L.S. Steffen¹, E.D. Vogel¹, N. Hsia², G. Ackermann³, Y. Zhou², B. Paw³, L.I. Zon², L.M. Kunkel¹.* 1) Division of Genetics, Childrens Hospital - Boston and the Howard Hughes Medical Institute, Boston, MA; 2) Division of Hematology/Oncology, Childrens Hospital - Boston and the Howard Hughes Medical Institute, Boston, MA; 3) Division of Hematology, Department of Medicine, Brigham & Womens Hospital, Boston, MA.

While many dystrophy associated genes have been identified in mammals, an understanding as to how these genes/proteins contribute to disease pathology is incomplete. To help identify additional proteins involved in the pathogenesis of muscular dystrophy, we have initiated an early pressure screen in zebrafish to genetically isolate additional animals showing symptoms of disease. To date, we have crossed 27 ENU treated males with wildtype females to generate a stock of 2,500 females, each heterozygous for approximately 25 different gene encoding mutations. These females are now being screened using the Early Pressure (EP) technique to generate gynogenetically diploid embryos. Our previous embryonic knockdown experiments have shown that zebrafish embryos lacking either dystrophin or -sarcoglycan are relatively inactive, show decreased muscle organization, show decreased muscle birefringence, and have difficulty inflating their swim bladders. These phenotypic characteristics are now being used to select for muscle mutants with a preference towards those with muscular dystrophy. To date, we have screened 300 of our proposed screen of 600 females and have selected almost 60 potential mutants showing obvious muscle abnormalities or other interesting phenotypes. For example, we have identified potential mutants showing defects in muscle birefringence, muscle organization, left/right patterning, tail structure and pigmentation defects. In order to verify the phenotype, the selected females are now being crossed with wildtype males and the offspring incrossed to see if we can recapitulate the phenotype. The causative mutations for the verified muscle mutants will then be identified using established positional cloning techniques whereas collaborations will be sought to investigate the genetic mechanism for the other interesting mutants.

Developmental defects and impaired short-term synaptic plasticity in Af5q31 mutant mice. *Y. Gu¹, E.J. Weeber^{3,4}, B.A. Antalffy², D. Armstrong², J.D. Sweatt³, D.L. Nelson¹.* 1) Dept Molec & Human Genetics,; 2) Dept of Pathology; 3) Division of Neuroscience, Baylor College of Medicine, Houston, Texas 77030; 4) Current Address: Department of Molecular Physiology and Biophysics, John F. Kennedy Center for Human Development Research, Vanderbilt University Medical Center, Nashville, TN 27232-0615.

Af5q31 is one member of the AF4/FMR2 family, which function as transcription factors. Mutations in FMR2 result in fragile X E mental retardation in humans. There are no reports about simple mutations involved with other members of this family in humans although leukemia has been associated with fusion of MLL gene to AF5q31, AF4 and LAF4, all members of this family except FMR2. To understand the functions of AF5q31, we deleted exon 2, which contains the start codon, in mouse ES cells and developed an Af5q31 mutant mouse model. Several interesting phenotypes have been found in this mutant mouse model, including more than 50% embryonic lethality. This early embryonic lethality is associated with inability of some Af5q31 mutant blastocysts to develop embryos and demonstrates the importance of AF5q31 in the initial embryonic development. This phenotype is not observed with FMR2 and AF4 knockout models; an LAF4 mutant mouse model is not yet reported. The surviving AF5q31 mutant mice exhibited abnormal hair patterns in later life and reduced paired-pulse facilitation in the hippocampus. The abnormal hair patterns result from a shorter catagen stage of hair follicle development cycles; apoptosis plays a role in this stage of hair follicle development. This is the first time demonstrated that functions of AF4/FMR2 family are involved with cell differentiation and apoptosis in vertebrates. Expression of several candidate Af5q31 targets including Sp, TGFbeta and Abl families, has been examined in the Af5q31 mutant mice, and changes were found in several members of Sp family including Sp1 and Zinc 46, a novel member of Sp family, but not in TGFbeta and Abl families.

Anti-sense transcription plays an important role in gene regulation during spermatogenesis. *W.Y. Chan^{1,2,3}, S.M. Wu¹, L. Ruszczyk¹, V. Baxendale¹, E. Law¹, M. Dym³, O.M. Rennert¹.* 1) Laboratory of Clinical Genomics, NICHD/NIH, Bethesda, MD; 2) Departments of Pediatrics, Georgetown University, Washington, DC; 3) Department of Cell Biology, Georgetown University, Washington, DC.

There are numerous examples of anti-sense transcripts in prokaryotes and viruses. On the other hand, only a few examples of anti-sense transcripts in eukaryotes have been reported. A recent computational analysis identified 2,500 pairs of putative sense-antisense transcripts out of 60,770 full-length mouse cDNA (~8%). No example of sense-antisense transcript pairs in eukaryotic germ cell development has been reported. Serial Analysis of Gene Expression (SAGE) was used to profile the expressed genes in mouse type A spermatogonia, pachytene spermatocytes and round spermatids. Sixty two confirmed differentially expressed genes identified in the three types of germ cells with appreciable number of SAGE tags in each were examined for the presence of anti-sense transcripts. Forty two genes showed the presence of anti-sense transcription (65.5%). Of these 42 genes, 35 had overlapping sense-anti-sense transcripts (SAT). Nine of these genes had more than one SAT pairs. Twelve genes had non-overlapping anti-sense bidirectional transcription pairs (NABT). Seven genes had both SAT and NABT. The presence of anti-sense transcripts of selected genes were confirmed by orientation specific RT-PCR and gel electrophoresis. Alignment of the amplified anti-sense transcripts with the genomic sequence of the genes allowed localization of the anti-sense transcripts to exons and introns. 5' and 3' RACE analysis of the anti-sense transcripts and nucleotide sequencing of the cloned fragments were used to examine the size and genomic structure of the anti-sense transcripts of three selected genes, namely, Uba52, Prm2 and Ppp1cc, respectively. Results showed that besides intronic and exonic sequences of the functional gene, anti-sense transcripts could also be derived from pseudogenes. This study showed that anti-sense transcription is a common phenomenon during germ cell development. Anti-sense transcripts can be derived from exons and introns of the functional sense transcript as well as from pseudogenes.

A gene-trap mouse model suggests Nirg1, related to SPG6 involved in spastic paraplegia, functions as a transporter in brain synaptogenesis and renal excretion. J-H. Chai, Q-C. Yu, K. Talbot, E. Pearson, Y. Huang, R.D. Nicholls. University of Pennsylvania, Philadelphia, PA.

A superfamily of *NIPAI/2*-related genes (*NIRGs*) encodes putative 9-transmembrane (TM) domain transporters in species ranging from mammals to bacteria. Human and mouse have six *NIRGs*, with one subfamily including *NIPAI*, mutated in spastic paraplegia type 6. To characterize the other subfamily, we focused on *NIRG1* mapping to human chromosome 1p35-p36 and mouse chromosome 4. Mouse *Nirg1* expression is high in brain, kidney, heart, skeletal muscle, and embryos. We identified a gene-trap (Gt) mouse model with a *geo* insertion in intron 11 of *Nirg1*. Interestingly, a polymorphic 7079-nt IAP element, present in C57BL/6J but absent in 129/Sv, maps ~200-nt from the Gt insertion. Multiplex RT-PCR in heterozygous Gt ES cells (129/129, IAP -/-) vs. brain and liver in heterozygous F₁ mice (B6/129, IAP +/-) suggests that the IAP upregulates *Nirg1* with no effect of the Gt on expression. The Gt allele may be hypomorphic as it expresses all 9-TM domains (exons 2-11) but not the highly conserved C-terminus, which may have a specific function. Intercrossing of Gt F₁ heterozygous (+/-) mice showed non-Mendelian inheritance, with -/- and +/+ homozygotes found at only 20% expected levels in neonates, E7 and E11, with no decrease in litter size. Using X-gal staining, *Nirg1-geo* was detected in -/- and +/- Gt F₂ mice with no signal in +/+. *Nirg1-geo* staining is strong in certain brain regions with a high density of synapses, particularly in mossy fiber terminals of the hippocampal formation and the molecular and granule cell layers of the cerebellum. In kidney cortex and medulla, *Nirg1-geo* is detected in ascending and descending loops of Henle and collecting ducts, in the apical brush border region. Three types of kidney pathology are observed in adult Gt -/- mice: the parietal layer of Bowman's capsule is composed of cuboidal epithelial cells, the glomerulus is also underdeveloped, and many tubules appear dilated, in some instances lacking the regular apical brush border. These data suggest that *Nirg1* is a transporter involved in neuronal synaptic transmission and renal hypertonic urine excretion.

Characterization of Mouse Models for Two Craniosynostosis Syndromes, Apert and Saethre-Chotzen. *Y.L. Wang, R. Xiao, A.J. Iacovelli, D.L. Huso, E.W. Jabs.* Johns Hopkins University, Baltimore, MD.

The neurocranium is normally developed by the process of intramembranous ossification with differentiation of mesenchymal stem cells to osteoblasts without an intermediate cartilaginous stage. Abnormal development can result in craniosynostosis, the premature fusion of cranial sutures. Two autosomal dominant craniosynostosis syndromes are Apert syndrome caused by gain of function mutations of fibroblast growth factor receptor 2 (FGFR2) and Saethre-Chotzen syndrome caused by loss of function of the TWIST gene. To elucidate the pathogenesis of these conditions, transgenic mouse models were designed with mutations analogous to those found in humans. Analysis of the *Fgfr2* S252W/+ mice revealed nascent cartilaginous islands at developing sagittal sutures at E18 and P1. *Sox9* and collagen type II, shown to regulate chondrogenesis, were expressed in the cartilaginous islands. Immunohistochemical and in situ hybridization analyses showed that the expression of Ki67, alkaline phosphatase (ALP), and osteopontin mRNA were increased in the mutant sagittal suture compared with that of wild type. The results indicate that the *Fgfr2* S252W/+ mutation leads to abnormal cell fate determination as mesenchymal cells improperly differentiate into chondrocytes and there is increased proliferation and differentiation of cells in the osteoblastic lineage. Analysis of the *Twist* +/- mice showed increased bone formation and premature ossification in the coronal sutures at E16, E18, and P1. The mutant mice have increased ALP and osteopontin expression, indicating that *Twist* plays a role in suppressing osteoblast differentiation. TUNEL staining revealed increased apoptosis of osteoblast in the mutant coronal suture, signifying that *Twist* may also be involved in the control of osteoblast survival. These studies show that the pathogenesis of craniosynostosis is different for the sagittal and coronal sutures in these two syndromes even though mutations in TWIST and FGFR2 may affect components of the same molecular pathway. Development of the sutures is a complex and delicate balance of several processes involving proliferation, differentiation, and apoptosis.

A role for ATRX in retinal development. *N.G. Bérubé*^{1,2}, *M. Jagla*³, *V. Wallace*³, *D. Picketts*³. 1) Department of Paediatrics and Biochemistry, University of Western Ontario, London, Canada; 2) Child Health Research Institute, London, Canada; 3) Ottawa Health Research Institute, Ottawa, Canada.

ATRX is a component of a large protein complex that exhibits chromatin remodeling activity. ATRX gene mutations in humans cause aberrant methylation of repetitive elements. Affected individuals suffer a multitude of developmental defects that result in mental retardation, delayed motor milestones, as well as urogenital, skeletal, and cardiac abnormalities. The visual and auditory systems are also affected in a subset of cases. The cellular and molecular events that are altered by ATRX mutations and that lead to these developmental defects have not yet been resolved. Using a conditional loss-of-function approach, we show that ATRX is required for the normal development of the murine retina. Loss of ATRX in the retina causes ectopic differentiation of a subset of retinal progenitors accompanied by increased cell death during the embryonic period. Using cell-type specific markers, we observed that the proportion of cell types in the mature retina was perturbed. The number of amacrine cells was greatly reduced and horizontal cells were misplaced within the inner nuclear layer. These results suggest that normal ATRX activity is required for the differentiation and survival of a restricted subset of retinal progenitors during the embryonic period and that loss of ATRX consequently influences the fate and number of different cell types in the mature retina.

Gene-trapping of a tetraspan-like protein disrupts lens fiber cell development in mice. *A. Shiels, J. King, D. Mackay, S. Bassnett.* Ophthalmology/Visual Sciences, Washington Univ Sch Medicine, St Louis, MO.

The human gene for lens intrinsic membrane protein 2 (LIM2) encodes a distant relative of the peripheral myelin protein-22 (PMP22)/epithelial membrane protein (EMP)/claudin (CLDN) sub-family of the tetraspan superfamily of integral membrane proteins. Mutations in LIM2 and its murine counterpart (Lim2) have been linked with autosomal recessive and dominant forms of lens opacities (cataracts), respectively. To gain further insights about loss of Lim2 function we have generated Lim2-deficient mice from a bank of gene-trap embryo stem cells. Genomic PCR amplification and sequencing showed that the gene-trap vector had disrupted intron 3 of Lim2 resulting in a null allele as verified by reverse-transcript (RT)-PCR amplification and sequencing, RNA blotting, immunoblotting and immunofluorescence microscopy. Mice homozygous for the gene-trap (Lim2Gt/Gt) presented with congenital cataracts when the eyes opened on postnatal day 14 (P14). At three weeks of age (P21), Lim2Gt/Gt lenses displayed a discrete opacity centered in the fetal nuclear region. In contrast, heterozygous lenses (Lim2+/Gt) did not develop similar opacities until around 24 weeks of age, however at P21, Lim2+/Gt lenses displayed an optically disturbed nuclear region centered along the optical axis. When crossed with mice transgenic for green fluorescent protein (GFP) expression in all tissues, Lim2Gt/Gt/GFP mouse lens fiber cells underwent normal loss of nuclei and other organelles but failed to develop a characteristic syncytial core region that is believed to facilitate macromolecular diffusion thereby enhancing lens transparency. These results suggest that heterozygous loss of Lim2 is sufficient to induce cataracts in mice and that this functionally enigmatic tetraspan plays a dosage-dependent junctional or adhesive role in establishing the unique refractive architecture of the crystalline lens.

Mediolateral Patterning of the Face; a new mechanism to understand Hypotelorism. *D. Cordero*¹, *M. Tapadia*², *W. Gaffield*³, *J.A. Helms*². 1) Albert Einstein Col Medicine, Bronx, NY; 2) Stanford University School of Medicine, Palo Alto, CA; 3) Western Research Center, US Department of Agriculture, Albany CA.

Recent breakthroughs in molecular and developmental biology have greatly influenced our traditional concepts of how a patient's phenotype correlates with their genotype. Engrained in our clinical acumen is the concept that facial dysmorphologies such as hypotelorism are a consequence of underlying brain anomalies. While the architectural design of the brain certainly plays a role in conditions such as hypotelorism, growing evidence indicates that regions of the brain act as signaling centers, which influence mediolateral and proximodistal patterning of the face. We have investigated the function of one of these signals encoded by Sonic Hedgehog (Shh). Chick embryos exposed to the steroidal alkaloid cyclopamine, which specifically inhibits Shh signaling, develop marked hypotelorism if the treatment occurs prior to Shh induction in the forebrain neuroectoderm. Embryos exposed to cyclopamine at slightly later stages, after Shh induction in the forebrain neuroectoderm, also develop hypotelorism but of a lesser degree. Our analyses revealed an important difference between these two experimental groups, however: in the former case, facial hypotelorism was accompanied by a collapse in mediolateral expansion of the forebrain whereas in the latter case, facial hypotelorism arose independent of brain morphology. Molecular analysis showed that the phenotypic presentation of hypotelorism in the first case is the result of an underlying patterning defect in forebrain neuroectoderm and in the other case was the result of a patterning defect in facial ectoderm. Collectively, our data provides new insights into the molecular mechanisms of how the brain can act as a molecular semaphore, controlling patterning of the face. These studies challenge our traditional views of the etiologies of craniofacial anomalies, and open the door to new strategies to ameliorate or prevent these anomalies.

Williams Syndrome: evidence from atypical deletion links GTFII-I and GTFII-IRD1, with posterior cortical structure and neural functions. *J.R. Korenberg¹, M. Appelbaum², U. Bellugi³, X-N. Chen¹, D. Mills⁴, A. Reiss⁵, F.E. Rose³, L.S. Salandanan¹, A.F. Simon¹, G.M. Yao¹.* 1) Med Gen Inst, Cedars-Sinai, UCLA, Los Angeles, CA; 2) Dept Psych, UCSD, San Diego, CA; 3) Salk Inst Cog Neurosci, San Diego, CA; 4) Emory Univ, Atlanta, GA; 5) Dept Psych Behav Sci, Stanford Univ of Medicine, Stanford, CA.

Williams Syndrome (WS) is a neurodevelopmental disorder caused by a deletion of chromosome 7q11.23. Individuals exhibit striking peaks and valleys in neurocognition that include deficits in visuospatial processing along with relatively preserved language and face processing. These features are associated with distinct variations in neuroanatomy and physiology. In an effort to identify their genetic origins, we have compared 2 atypical cases to WS and to control populations at a highly integrative level, combining studies of molecular structure, volumetric magnetic resonance imaging (MRI), cognition, and event-related potentials (ERPs). We used multicolor FISH with a panel of 45 BACS, PACS and cosmids, PCR of somatic cells hybrids and quantitative Southern blots to identify 80 adults with typical deletions, and 2 adult males with overlapping atypical deletions (one from FKBP6 to CYLN2, and the 2nd from CLDN4 through GTFII-I). Brain structure was determined through MRI studies. Cognition was determined by standard tests and brain electrophysiology by ERPs analyses. Such an approach allowed us to compare the data obtained with the two atypical cases to the distribution for normal and WS subjects. We propose that decreased expression of 2 transcriptional regulators, GTFII-IRD1 and GTFII-I, but not of FZD9, is related to a distinct subset of WS features that includes posterior cerebral variation, visuospatial processing, and abnormal neural activity for face processing. The results of this study begin to define pathways linking gene expression with human cognition.

Increased plasticity of genomic imprinting in brain is due to genetic and epigenetic factors. A.K. Naumova^{1,2,4}, S. Croteau¹, D. Roquis³, M.-C. Charron², D. Frappier⁴, D. Yavin¹, T.J. Hudson^{2,3,4,5}. 1) Department of Obstetrics and Gynecology, McGill University, Montreal, PQ, Canada; 2) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 3) Genome Quebec and McGill University Innovation Centre, Montreal, Quebec, Canada; 4) The Research Institute of the McGill University Health Centre, Montreal, Quebec, Canada; 5) Department of Medicine, McGill University, Montreal, Quebec, Canada.

Expression of imprinted genes was examined in the brains of mice derived from crosses between C57BL/6 and MOLF/Ei strains. Imprinting of *Igf2r*, *Kcnq1*, *Gtl2*, and *Dlk1* varied among different individuals. As three of these genes are implicated in cell-cell signaling or cell-environment interactions, variation in their imprinting, may influence a wide range of biological processes from cell differentiation to behavior. To elucidate the mechanisms underlying the inter-individual imprinting variation in the brain we focused our effort on the paternally expressed gene *Dlk1* located within the imprinted region of distal chromosome 12. We present evidence that *trans*- and *cis*-acting genetic factors of MOLF/Ei origin facilitate the reactivation of the normally silent maternal allele of *Dlk1*. We mapped one of the *trans*-acting factors to the proximal region of mouse chromosome 7. Reactivation of the maternal allele was also associated with hypermethylation of the maternal copy of the intragenic (IG) DMR, which is the imprinting control region for the *Dlk1* -*Gtl2* domain. Thus, our data suggest that the imprinting status of *Dlk1* in the brain results from interplay between genetic, epigenetic and stochastic factors.

Sexually dimorphic expression in mouse brain of x-linked genes that escape inactivation. *J. Xu, R. Bijlani, A.P. Arnold.* Dept. of Physiological Sci. and Lab of Neuroendocrinology at the Brain Res. Inst., UCLA, Los Angeles, USA.

In mice some X-linked genes escape X-inactivation; most have a Y-linked homologue thought to ensure the dosage balance between the two sexes. To test whether the expression of X escapees is higher in females and X and Y partner genes are expressed in parallel, we examined three such X-Y gene pairs, *Eif2s3x/y*, *Utx/y* and *Jarid1c/d* (aka *Smcx/y*), which have been suggested to be involved in translation initiation, protein-protein interaction, and transcriptional regulation respectively. Using Northern blots, we first confirmed that all three X escapees were expressed at a significantly higher level in the neonatal and adult female brains than in male brains (with the exception of *Jarid1c* in neonates). To determine if the female bias in brain expression is due to the X chromosome dosage effect rather than the sex difference in sex hormones such as estrogens, we used a transgenic mouse model in which there are four genotypes: XX and XY females (with ovaries) and XX and XY males (*Sry* transgene causes testicular development). As expected, XX females and XX males expressed all three genes significantly higher than the two XY genotypes, indicating the XX bias in expression of the three X escapees is a result of sex chromosome complement. Is the sex difference for X escapees compensated by their Y homologues? Previous results suggested differences in expression pattern for *Eif3s3x/y* and *Smcx/y*. However, we found the X and Y partners were expressed in a similar distribution when we examined the regional pattern of expression in adult mouse brain sections with *in situ* hybridization. *Eif2s3x/y* were expressed more highly in brain regions such as hypothalamus, dentate gyrus in hippocampus and habenular nucleus relative to neighboring area. *Utx/y* were found to be highly expressed in brain regions including hippocampus, hypothalamus and cerebellum. The expression pattern of *Jarid1c* and *Jarid1d* was more uniform throughout the brain. A potential sex difference in expression of these X-Y gene pairs suggests a novel mechanism for sexual differentiation of the brain and behavior. (Supported by NS043196 and HD43942.).

Analysis of DNA methyltransferases in Beckwith Wiedemann Syndrome. *E. Algar*^{1,2,3}, *A. Sridhar*². 1) Dept Hematology & Oncology, Royal Children's Hospital, Melbourne, Australia; 2) University of Melbourne, Dept. of Paediatrics, Parkville, Australia; 3) Murdoch Children's Research Institute, Royal Children's Hospital, Melbourne, Australia.

The Beckwith Wiedemann Syndrome (BWS) is an overgrowth disorder in which imprinting mutations affect two centres within 11p15.5, IC1 and IC2. IC1, a 5' region within *H19* is normally methylated only on the paternal chromosome, however 10% of BWS cases acquire maternal methylation at this site. IC2, also known as *KvDMR1/LIT1*, is located 600Kb centromeric to IC1 within an intron of *KCNIQ*, and is normally methylated only on the maternal chromosome. 45% of BWS cases have lost methylation at IC2. Imprinting mutations at IC1 and IC2 are respectively associated with aberrant expression of the 11p15.5 genes *IGF2* and *CDKN1C*.

Mouse models have implicated the DNA methyltransferases *dnmt1* and *dnmt3l* in maternal methylation at the *h19/igf2* locus and indirectly to *cdkn1c* expression in the oocyte and developing embryo. We hypothesize that aberrant expression or function of these genes may therefore underlie the pathogenesis of human BWS. We are screening 100 cases, with either a clinical or molecular diagnosis of BWS, by direct sequencing for evidence of mutations within exonic or regulatory regions of *DNMT1* and *DNMT3L*. To date we have identified four patients with an ARG to CYS change at codon 97 within the DMAP binding domain of *DNMT1*, however this change was also present in unaffected controls. Another patient has a HIS to ARG change at *DNMT1* codon 136. Work is continuing on the analysis of *DNMT1* and *DNMT3L* in patients and controls.

The chromatin remodeling protein Tip60 interacts with FANCD2 in the repair of DNA interstrand crosslinks. *J. Hejna¹, L. Mathewson¹, A. Sobeck², A. Hemphill¹, C. Faulkner¹, M. Matkovic¹, S. Stone², M. Hoatlin^{1,2}, R. Moses¹.* 1) Molec & Med Genetics, Oregon Health & Science University, Portland, OR; 2) Molecular Medicine, Oregon Health & Science University, Portland, OR.

Fanconi anemia (FA) is one of several autosomal recessive diseases characterized by genomic instability and a predisposition to cancer. FA cells are particularly sensitive to DNA interstrand crosslinks (ICLs), manifesting increased cell death and chromosome breaks and radials compared to normal cells. Interactions between various FANC proteins and other proteins implicated in DNA repair have been described, including FANCA and BRCA1; FANCG and BRCA2; BRCA2 and RAD51; and FANCD2 and BRCA2. While the molecular functions of the FANCD2 protein are unknown, its post-translational modification by mono-ubiquitylation in response to treatment with DNA crosslinking agents is required for function of the FA pathway and normal ICL repair. In order to identify additional FANCD2-interacting proteins, we conducted a yeast two-hybrid (Y2H) screen, using FANCD2 as bait. A human fetal brain cDNA library, cloned into the Y2H vector pACT2, was probed with a subclone of FANCD2 encoding amino acids 55-971. Of 2×10^6 colonies screened, one FANCD2-interacting clone, isolated twice independently, was the histone acetyltransferase Tip60, suggesting the involvement of chromatin remodeling in ICL repair. The interaction was confirmed in HeLa cells by colocalization of FANCD2 and Tip60 in nuclear foci, and by co-immunoprecipitation. In addition, siRNA depletion of Tip60 sensitized an immortalized human fibroblast cell line (GM639) to killing by the ICL agent mitomycin C. The results support a model with chromatin remodeling, involving the interaction of Tip60 and FANCD2, as a central requirement for ICL repair.

Program Nr: 1096 from the 2004 ASHG Annual Meeting

Promoter hypermethylation and epi-genetic silencing in retinoblastoma. *C.P. Pang, K.W. Choy, D.S.P. Fan, D.S.C. Lam.* Ophthalmology & Visual Sci, Chinese Univ Hong Kong, Hong Kong, China.

Identification of DNA hypermethylation is an efficient alternative approach for detection of disease associated genes and could have diagnostic applications in cancers. We have shown that promoter hypermethylation that silences expression of the DNA repair gene MGMT is a causative factor of retinoblastoma. To delineate the possible roles of DNA hypermethylation in retinoblastoma, we examined a series of 30 retinoblastoma tissue specimens from sporadic and unrelated patients, and 2 retinoblastoma cell lines (Y79 and WERI-Rb1) by methylation-specific PCR analysis of genes RB1, p14ARF, p15 INK4b, p16INK4a, VHL, MGMT, MLH1, and RASSF1, which were frequently hypermethylated in human cancers. Results of our investigation indicated that aberrant methylation of the MGMT locus was present in a subset (15%) of retinoblastoma tumors, MLH1 in 67% and RASSF1 in 82%. Promoter hypermethylation was associated with null protein expression of all these genes. No hypermethylation on the p14ARF, p15 INK4b, p16INK4a VHL and RB1 genes. was found on tumor DNA. Our study and a report by Harada et al. 2002 both demonstrated that epigenetic silencing as an alternative mechanism by which cancer-related genes are inactivated in retinoblastoma. DNA methylation is associated with the loss of gene function in retinoblastoma. We further propose that epigenetic silencing of multiple cancer related genes may play an important role during development and/or progression of retinoblastoma.

Large-scale chromosome conformation and genome regulation: analysis of the Fragile X locus. *J. Dekker, T. Tabuchi, N. Gheldof.* Dept PGFE, Univ Massachusetts, Worcester, MA.

Large-scale chromosome conformation is emerging as a major regulator of genome activity [1]. Several human diseases, notably cancer and neurological disorders can be caused by changes in chromosome conformation. However, little is known about large-scale chromosome organization and how it modulates genome activity.

We analyzed the Fragile X site to better understand formation of silent chromatin. The Fragile X site contains the FMR1 gene, which is silenced in patients suffering from Fragile X Syndrome, a common form of inherited mental retardation. Silencing is the result of trinucleotide repeat expansion in the first exon, which induces epigenetic changes in the surrounding chromatin. The spatial organization of silent chromatin and the size of the affected region are not known in detail. We analyzed large-scale chromosome conformation of the Fragile X site using 3C technology [2, 3]. 3C (Chromosome Conformation Capture), a relatively new technology that we originally developed, is used to detect interactions between genomic loci revealing the spatial organization of a genomic region. We find that local trinucleotide repeat expansion has large-scale effects on chromatin conformation. A region of at least 250 kb displays increased compaction. Interestingly, the level of compaction fluctuates throughout this region, suggesting the presence of sequence elements that play a role in spreading of silent chromatin.

We are part of the new ENCODE consortium initiated by the National Human Genome Research Institute (<http://www.genome.gov/ENCODE/>). The goal of this consortium is to identify all functional elements in the human genome. We use 3C technology to identify interacting elements involved in transcription and chromosome morphogenesis and have devised a general strategy for 3D structural annotation of human genomic regions.

Maternal duplication of chromosome 11p15 in a young girl with growth retardation and dysmorphic features.

J.L. Lauzon, K. Anderson, J.E. Chernos, D.R. McLeod. Department of Medical Genetics, University of Calgary and Alberta Children's Hospital, Calgary, Alberta, Canada.

Paternal duplication of the short arm of chromosome 11 is a well-described cause of Beckwith-Wiedemann Syndrome (BWS). The chromosomal region of 11p15 harbours many imprinted genes. Dysregulation of the expression of imprinted growth-related genes found in this region are thought to be responsible for the overgrowth phenotype and risk of malignancy seen in individuals with BWS. We describe a 17 month-old girl with growth retardation, dysmorphic features who has three copies of 11p15, two of which are of maternal in origin. Our patient was born to a healthy 31 year-old mother at 36 weeks gestation. Symmetrical intra-uterine growth restriction was noted on prenatal ultrasound. Her birth weight was 1.84 kg(3rd percentile). Physical features included a prominent forehead, hypertelorism, low-set ears, up-slanting palpebral fissures, and 5th finger clinodactyly. She was found to have an ectopic non-functioning left kidney, right nephrocalcinosis and a small spleen. In the neonatal period, she had periodic breathing and required oxygen therapy. She has failure to thrive and is G-tube fed. Her hearing is decreased on the left and she has strabismus. Initial chromosome analysis revealed a karyotype of 46,XX,add (10)(q26) at 500-550 band resolution. Further characterization using fluorescent in situ hybridization showed a karyotype of 46,XX,add(10)(q26).ish der(10) t(10;11)(q26.3;p15.1)(WCP 11+, tel 10q-, tel 11p+). BAC probes for the regions 10q26.3 and 11p15.2 showed two and three signals respectively. Microsatellite repeat analysis identified the duplicated material of chromosome 11p to be of maternal origin. There are three other published cases of maternal duplication of chromosome 11p15 and all have growth retardation. Our findings are consistent with the proposed model that growth-promoting genes on chromosome 11 are paternally expressed and growth-suppressing genes are maternally expressed. A dysregulation of the maternally expressed growth-suppressing genes such as H19 and p57^{KIP2} may to responsible for the growth retardation seen in patients with maternal duplication 11p15.

Disruption of epigenetic regulatory elements and chromosomal aberrations in patients with Beckwith-Wiedemann syndrome. *A.C. Smith^{1,2}, J.A. Squire², C. Shuman¹, R. Weksberg¹*. 1) Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Institute of Medical Sciences, Dept. Laboratory Medicine and Pathobiology, University of Toronto, Toronto, Canada.

Beckwith-Wiedemann syndrome (BWS) is characterized by somatic overgrowth, macroglossia, omphalocele, and tumor predisposition. It is associated with dysregulation of gene expression of an imprinted gene cluster on chromosome band 11p15. The 11p15 region is divided into two domains each controlled by an imprinting centre for each domain. Imprinting centres can be differentially methylated and associated with anti-sense transcripts that can regulate the expression of neighboring genes in cis over large distances up to one megabase. The KCNQ1 differentially methylated region (DMR2) is found within intron 10 of KCNQ1 in Domain 2. DMR2 also contains the promoter for KCNQ1OT1, a paternally expressed, untranslated anti-sense transcript, which is believed to suppress the expression of nearby genes on the paternal chromosome e.g. KCNQ1 and CDKN1C. About 50% of patients with BWS have a loss of methylation at DMR2 and biallelic expression of KCNQ1OT1. A variety of other genetic and epigenetic molecular alterations comprise the other 50%.

We have 7 translocation or inversion patients (3 with BWS, 4 without) that have breakpoints within 500kb of DMR2. We expected that translocations and inversions associated with BWS would disrupt the imprinting centre in Domain 2; however, we found that BWS patients with translocations have normal DMR2 methylation and expression of KCNQ1OT1. Our data suggest that there are as yet unidentified mechanisms that can cause BWS and its associated tumors. Thus, we hypothesize that physical disruption of the region and regulatory signals other than DMR2 methylation and KCNQ1OT1 transcription in Domain 2 can alter imprinted gene expression in cis. In this regard, we are currently assessing allele specific expression of the imprinted genes in Domain 2. The results of this investigation will further elucidate the mechanisms of epigenetic control on chromosomal region 11p15.

Genomic analysis of human neocentromeres. *A.L. Alonso¹, M. Paziienza¹, F. Cheung¹, J. Tepperberg³, J. Engelen², P. Papenhausen³, M. Ventura⁴, M. Rocchi⁴, P. Warburton¹.* 1) Mount Sinai, New York, NY; 2) Academic Hopspital, Maastricht; 3) LabCorp, NC; 4) University of Bari.

Neocentromeres are new human centromeres that are devoid of alpha satellite DNA and have arisen ectopically in chromosome arms, permitting their genomic position to be precisely mapped onto the underlying DNA sequence. In order to provide insight into epigenetic mechanisms for neocentromere formation, we have performed genomic analysis of multiple neocentromeres from bands 8q21, 13q21, and 13q32. Chromosome 13q represents a neocentromere hotspot, containing 13 (18.5%) of the 70 cases thus far described, with 4 cases in 13q21 and seven cases in 13q32. To position 13q neocentromeres, we used ChIP on a CHIP assays with antibodies to CENP-A, the centromere-specific histone H3, and screened contiguous genomic BAC microarrays spanning 13q21 (11.4Mbp) and 13q32 (14Mbp). Human 13q21 neocentromeres may represent the reemergence of ancestral centromeres, since centromeres in several old world monkeys correspond to human chromosome band 13q21. The CENP-A binding domain of a 13q21 neocentromere was localized to a 280kb domain, which was several Mbp distal to the old world monkey centromeres. An ~11mb 13q21 neocentric ring chromosome also maps distal to the old world monkey centromeres. The CENP-A chromatin of three neocentromeres that all cytologically localized to band 13q32 was found to form on distinct genomic sequences of 130kb, 215kb and 275kb within a 7mb region. CENP-C, a constitutive centromere protein, also colocalized to the 130kb CENP-A domain. A unique neodicentric chromosome 8, with an inactivated endogenous centromere and a neocentromere in band 8q21, was found fortuitously in a phenotypically normal male. 2 similar recently observed neodicentric chromosomes 3 and 4 represent an emerging class of novel chromosome variants. Molecular cytogenetic comparison of the 8q21 neodicentric chromosome to a neocentric ring 8q21 chromosome showed that they do not share a common neocentromere site. Overall, these studies show a remarkable plasticity in the genomic position of neocentromeres, and support a sequence-independent epigenetic model for neocentromere formation.

Epigenetic Variegation in Long DNA Palindromes. *A.G. Cote^{1,2}, S.M. Lewis^{1,2}*. 1) Genetics and Genomic Biology, Hospital for Sick Children, Toronto, Canada; 2) Department of Molecular and Medical Genetics, University of Toronto, Toronto, Canada.

DNA palindromes are perfect inverted repeats with two-fold rotational symmetry and have the ability to form hairpins and cruciform structures by intrastrand base-pairing. These arrangements are unstable in the genome and are frequently rearranged. It is postulated that they are substrates for chromosomal deletions, insertions, gene amplification, and translocations, but the mechanism responsible for palindrome instability is unknown nor have any factors been identified that affect this process. The Line 78 mouse bears a 15.4kb perfect palindromic transgene that rearranges at a high rate in somatic cells. We report that the degree of DNA methylation of the Line 78 palindrome can vary between completely isogenic cell lines in culture. Variegating patterns of methylation do not correlate with the acquisition of a central palindrome modification event, where the differences in methylation are observed in a number of cell lines that all harbour an intact, unmodified palindrome. Cell lines carrying a fully methylated or an undermethylated Line 78 palindrome will be analyzed to determine if there exists a relationship between DNA methylation and instability of long palindromes. The Line 78 palindrome's rate of rearrangement will be assessed for each cell line to determine if variations in the palindrome's pattern of DNA methylation are associated with significant differences in the rate of rearrangement.

A fraction of mouse minor satellite DNA is favoured for centromere function on a mini-chromosome in human, mouse and chicken cells. *M.H. Shen¹, K. Zeng¹, J.I. de las Heras¹, A. Ross¹, H. Cooke¹, J. Yang².* 1) Chromosome Biology, MRC Human Genetics Unit, Edinburgh, Scotland, United Kingdom; 2) Institute for Stem Cell Research, University of Edinburgh, West Mains Road, Scotland, Edinburgh EH9 3JQ, UK.

Centromeres are required for faithful segregation of chromosomes in cell division. It is not clear how the centromere sites are specified on chromosomes in vertebrates. We have previously introduced a mini-chromosome, named ST1, into a variety of cell lines including human HT1080, mouse LA9 and chicken DT40. This mini-chromosome, segregating faithfully in these cells, contains mouse minor and major, and human Y alphoid satellite repeats. In this report, we examine the requirement of DNA sequences for centromere function of ST1. After determining the organisation of the satellite repeats, we investigated the centromere location on this mini-chromosome by combined analysis of immunocytochemistry and FISH. Centromeric proteins were consistently co-localised with the minor satellite repeats and the CENP-B boxes embedded in these repeats in all the three cell lines. When chromatin fibres were highly stretched, centromeric proteins were only seen on a small portion of the minor satellite repeats. These results demonstrate that a fraction of the minor satellite repeats is fully competent in centromere function not only in mouse but also in human and chicken cells while the human Y alphoid DNA on this mini-chromosome is disfavoured for centromere activity. These findings suggest a sequence favour model for possible mechanisms specifying a centromere site upon the establishment of hybrid cell lines.

Heterogeneous distribution of methylated histone H3 and macroH2A in heterochromatin of the human inactive X chromosome. *C.M. Valley, B. Chadwick, H.F. Willard.* Inst Genome Sciences/Policy, Duke University, Durham, NC.

In female mammalian cells, one X chromosome is transcriptionally silenced to equalize X-linked gene expression between the sexes. Several features distinguish the inactive X chromosome (Xi) from the active X (Xa), including late replication in S-phase, trimethylation of lysine 9 on histone H3 (H3TrimK9), and association with both XIST RNA and the histone variant macroH2A. To explore the cytological, molecular and genomic distributions of these features, we have used immunocytochemistry, analysis of late replication, and chromatin immunoprecipitation (ChIP) to detect both H3TrimK9 and macroH2A in human primary cell lines. Cytologically, macroH2A and H3TrimK9 appear enriched on the Xi, but occupy separate territories at interphase and metaphase in alternating bands that are both spatially and temporally distinct. The latest replicating regions on the Xi are associated with H3TrimK9, but not macroH2A, while regions replicating in mid-S phase are associated with macroH2A and with XIST RNA, but not H3TrimK9. To examine their composition at a higher resolution and to better understand their relationship on the Xi, we next determined the enrichment of macroH2A and H3TrimK9 on the Xi. Over 120 informative X-linked SNPs were identified in a female cell line and examined by ChIP in combination with a quantitative assay to discriminate the Xi and Xa alleles. The resulting profile revealed a ~2- to >10-fold enrichment of either macroH2A or H3TrimK9 on the Xi for the majority of SNPs and correlated with their location in either a macroH2A- or a H3TrimK9-associated band, confirming the cytological data. However, a few SNPs gave intermediate or reverse patterns, suggesting an additional level of heterogeneity at the molecular level. We conclude that the composition of facultative heterochromatin on the Xi is more complex and heterogeneous than previously believed. Extension of this analysis to additional SNPs at high density and correlation with both the underlying DNA sequence and the Xi expression profile should provide insights into the chromosomal and genomic basis for X inactivation.

A role for genomic imprinting in male sexual orientation. *S. Bocklandt*¹, *C.E. Roselli*², *S. Horvath*³, *M.G. DuPree*³, *E. Vilain*¹, *D.H. Hamer*³. 1) Dept Human Genetics, David Geffen School of Medicine, UCLA, Los Angeles, CA; 2) Department of Physiology and Pharmacology, OHSU, Portland, OR; 3) Laboratory of Biochemistry, National Cancer Institute, NIH, Bethesda, MD.

Genomic imprinting of X-chromosome genes could lead to sex-specific gene expression, and is therefore a candidate mechanism for the regulation of sex specific traits, such as sexual orientation. Since X-inactivation and genomic imprinting share several molecular mechanisms, we measured X-inactivation in mothers of gay men to test the role of imprinted X genes in sexual orientation. We analyzed X chromosome inactivation in 96 mothers of gay men and 105 control women matched for age and ethnicity. Skewing was assayed in white blood cell DNA at the androgen receptor gene and at the fragile X locus. We found a significant difference ($p=0.004$) in X chromosome skewing between the two groups. The mothers of gay men showed a bimodal distribution in which 14% displayed extreme skewing (more than 90% inactivation of one chromosome). The control women showed a normal distribution in which less than 3% had extreme skewing. Analysis of mouthwash samples showed a high correlation between skewing in blood and buccal cells. Daughters of mothers with extreme skewing were analyzed, and only 1/24 was skewed, indicating that it is not caused by an X chromosome mutation. In order to identify the exact mechanisms of genomic imprinting in sexual orientation, we undertook two complimentary approaches, based on linkage and expression profiling. A full genome linkage scan was performed on 146 gay brother pairs. Significant linkage to 10q26 was found on the maternal allele only, indicating a maternally expressed, paternally silenced, imprinted gene involved in sexual orientation. Micro array expression analysis of cell lines from gay and straight men and their families was performed. In addition, cross species micro array hybridization was performed on the anterior hypothalamus and amygdala of male oriented and female oriented rams. Candidate genes derived from a combination of human and sheep data have been identified. Together, these data suggest that genomic imprinting influences male sexual orientation in mammals.

Methylation-specific MLPA: a novel method for the methylation status of multiple CpG sites of tumor-suppressor genes. *A.O.H. Nygren^{1,2}, S. Guerrero Caballero^{1,2}, H.M. Duarte¹, R.N.C.P. Vijzelaar¹, G. Pals², J.P. Schouten¹, A. Errami¹.* 1) MRC-Holland, Amsterdam, Netherlands; 2) Department of Clinical Genetics, VU Medical Center, Amsterdam, Netherlands.

We have developed a novel method, methylation specific Multiplex Ligation-dependent Probe Amplification (MS-MLPA), to detect CpG methylation and copy number of up to 26 genes in a single reaction. This method combines digestion of genomic DNA with methylation-sensitive restriction enzymes and MLPA. The methylation sensitive probes have a design similar to that of ordinary MLPA probes except that the sequence detected by the MS-MLPA probes contains a recognition sequence for the methylation sensitive restriction enzymes HpaII or HhaI. Upon digestion with one of these enzymes, probes of which the recognition sequence is unmethylated will not generate a signal. In contrast, a probe signal will be detected if the site is methylated. This method is very easy to use and requires only 20 ng of DNA. Furthermore, it has the advantage to study simultaneously several genes in contrast to existing methods that only allows the study of one gene or locus at a time. In addition, we show that this technique can be applied successfully to establish the methylation status in tumor DNA obtained from paraffin-embedded tissue samples. To prove that MS-MLPA is a powerful technique for the detection of methylation changes of promoter regions, we used MS-MLPA in DNA samples of patients with Prader-Willy and Angelman syndrome.

Epigenetic and molecular genetic findings in Russian Rett syndrome cohort: linking the epigenetics to MECP2 gene mutations. *S.G. Vorsanova¹, I.Y. Iourov², V.Y. Ulas¹, L. Villard³, L. Gianti⁴, M.-L. Giovanucci-Uzielli⁴, Y.B. Yurov².* 1) Molecular Cytogenetics, Institute of Pediatrics, Moscow, Russian Federation; 2) National Center of Mental Health RAMS, Moscow, Russia; 3) INSERM U491, Faculte de Medecine, Marseille, France; 4) University of Florence, Florence, Italy.

We have screened 39 females and 1 male with Rett syndrome (RTT) for the MECP2 mutations and 84.6%; (33 from 39) of them were found to have a MECP2 mutation. The boy studied had a R270X mutation. We have studied X-inactivation in these 39 females. The incidence of skewed X-inactivation was 41% (16 from 39). This value is significantly higher than for control group (6.5%, $p < 0.001$). We have also analyzed X chromosome inactivation patterns in another 31 RTT patients not screened for MECP2 mutation. Skewed X-inactivation was determined in 10 (31.1%) RTT girls being significantly different from control group and insignificantly different from RTT females screened for MECP2. Therefore the total incidence of skewed X-inactivation in RTT females studied is estimated as 37% (26 from 70). We have also carried out the study of preferentially inactivated chromosome X determination by assessing the X-inactivation in RTT females and their mothers. About 33% had a maternal X chromosome to be preferentially inactivated. This analysis allowed us to determine genotype-phenotype correlations. The more severe forms of the disease were observed in cases with preferentially inactivated maternal X chromosome and milder forms were associated with preferentially inactivated paternal X chromosome. We have proposed two hypotheses explaining skewed X-inactivation higher incidence in RTT. Firstly, the unstable transcription of some X-linked genes could be caused by MECP2 mutations and lead to X-inactivation skewing. Secondly, MeCP2 is known to be involved in repression of LINE-1 expression. The abnormal expression of these elements located on chromosome X may also lead to skewed X-inactivation. These assumptions should be carefully tested. However the data obtained is clearly indicating the relation of this epigenetic phenomenon and MECP2 mutations.

X-chromosome inactivation and premenopausal breast cancer. *J.P. Struewing¹, M.A. Pineda¹, M.E. Sherman², L.A. Brinton², J.M. Lissowska³, M. Garcia-Closas².* 1) Lab of Population Genetics, and; 2) Hormonal and Reproductive Epidemiology Branch, National Cancer Institute, Bethesda, MD; 3) Division of Cancer Epidemiology and Prevention, Cancer Center and M. Sklodowska-Curie Institute of Oncology, Warsaw, Poland.

Each cell of a female fetus randomly inactivates one X-chromosome during embryogenesis, resulting in a population of cells that express roughly equal quantities of transcripts from maternally and paternally derived X-chromosomes. Skewed X-chromosome inactivation is present if most or all of the transcripts are derived from only one of the parental X-chromosomes. A trinucleotide-repeat in the androgen receptor gene (*AR*) on the X-chromosome is highly polymorphic and methylation at two CpG sites near the repeat correlates with silencing. This allows one to assess skewed inactivation by comparing relative peak heights for the polymorphism in DNA digested with a methylation-specific restriction enzyme and undigested DNA. Skewed X-inactivation in lymphocytes has been associated with increased risk of ovarian cancer in a US study and with early-onset breast cancer in a Norwegian study. The recent observation of the involvement of the BRCA1 protein in normal X-chromosome inactivation further highlights the possible involvement of skewed X-chromosome inactivation in breast cancer. We are assessing the association between skewed X-chromosome inactivation and breast cancer by testing lymphocyte DNA of a subset of 585 subjects enrolled in a population-based case-control study from Warsaw and Lodz, Poland using the *AR* assay. Subjects include 305 premenopausal invasive breast cancer patients (mean age 46 years, 80% below age 50) and 280 age-matched controls. Preliminarily, among 362 heterozygous women tested to date, 27.4% (n=46) of cases and 26.8% (n=52) of controls showed skewed X-chromosome inactivation. Using a more stringent cut-point for categorizing a sample as skewed, cases were slightly less likely to show skewing (5.8%) than were controls (7.6%). Based on preliminary, unadjusted analyses, there appears to be no difference in skewed X-chromosome inactivation between pre-menopausal breast cancer cases and controls.

A novel deletion in the Prader-Willi imprinting center narrows the critical region. *H. Dong, M. Whitney, P. Kuipers, D. Driscoll.* Dept. of Pediatrics and Molecular Genetics & Microbiology, University of Florida, Gainesville, FL.

Angelman (AS) and Prader-Willi (PWS) syndromes are complex neurobehavioral conditions involving the loss of expression of imprinted genes in a 2 Mb region on human chromosome 15q11-q13. AS is due to loss of maternal-only expressed genes and PWS is due to the loss of paternal-only expressed genes from this region. The 2 Mb imprinted domain is under the control of a bipartite imprinting center (IC) comprising two distinct regulatory regions. Several unique PWS microdeletion families have narrowed the critical region for PWS to a 4.3 kb area including the SNURF-SNRPN promoter, CpG island and exon/intron 1. The AS smallest region of overlap (SRO) has been narrowed by patients with microdeletions to an 880 bp sequence 35 kb upstream of the PWS-SRO. The PWS-SRO has a strong DNase I hypersensitive site specific for the paternal allele and 6 evolutionary conserved (human-mouse) sequences that are potential transcription-factor binding sites.

In this study we describe a unique PWS patient with an IC deletion that further narrows the distal boundary of the IC critical region. Multiple restriction enzyme digests and Southern blots revealed a 24 kb deletion. PCR primers were designed to allow us to sequence the proximal and distal breakpoints, which revealed that the distal breakpoint is 385 bp into intron 1 of the SNURF-SNRPN gene. DNA methylation analysis of MKRN, PW71 and SNURF-SNRPN demonstrated a maternal uniparental pattern. Expression analysis showed loss of expression of MKRN3, NDN, SNURF-SNRPN and IPW that is consistent with PWS. We are currently in the process of evaluating histone modifications in the AS/PWS region in this unique PWS-IC deletion patient to correlate with our expression and DNA methylation results.

Our findings are important since they narrow the PWS-SRO to 4.1 kb and delineate the exact sequence of the proximal and distal breakpoints of this IC microdeletion. These data should provide a foundation for a better understanding of the genesis of IC microdeletions and the mechanisms involved in the imprinting process in the AS/PWS region.

Association of the Polymorphism IGF2/ApaI with birth weight and body mass index. *M.V.M. Gomes¹, M.R. Soares^{1,2}, C.R. Marcondes¹, A. Pasqualim-Neto², R.B. Lobo¹, E.S. Ramos¹.* 1) Department of Genetics, FMRP-USP, Ribeirão Preto, São Paulo, Brazil; 2) University Center Barão de Mauá, Ribeirão Preto, São Paulo Brazil.

Insulin-like growth factor II (IGF-II) has a high degree of sequence homology with insulin and plays a key role in mammalian growth, influencing fetal cell division and differentiation and possibly metabolic regulation. The gene IGF2 is subject to parental imprinting and only expressed from the paternal allele. Studies using pigs have implicated the *Igf2* gene in fat deposition. In humans the ApaI polymorphism at the exon 9 of the IGF2 has large been associated with alteration involving weight and obesity predisposition. In the present study we examined the association of IGF2/ApaI genotype with body index mass (BMI) in healthy volunteers (95 men and 199 women; 18-30y) and correlated the results with the birth weight (BW) of the subjects. Blood sample were obtained for DNA extraction and RFLP-PCR. Normal distribution for BMI and BW was showed by Kolmogorov-Smirnov normality test. The highest value of BW in the genotype groups (AA=3.87kg, AG=4.68kg and GG=4.95kg) could indicate a gradual increasing in the weight related to the presence of allele G. The genotype was statistically significant (p.05) for BW but the effect of the sex did not (p.23). The existence of other sources of variations in BW, which were not controlled in this experiments, was indicated by the low R-square of the model (R²=0.03). There is no evidence of statistically significant differences between the least-square means of each genotype, for both BW and BMI (AA: BW=3.21 and BMI=22.66; AG: BW=3.30 and BMI=23.06; GG: BW=3.42 and BMI=23.76), by the Tukeys pos hoc tests (=0.05). No statistically significant correlation (p.05) were observed between BW and BMI in each genotype group. Nevertheless a statistically significant correlation (p.023) and equal .33 was observed between BW and BMI in GG subjects whose BW was higher than 3.5 kg (n=47). Although the IGF2 genotype was not significantly associated with BMI and BW, there was a non-significant trend for babies with the GG genotype to be heavier than those with the AA genotype.

Quantitative analysis of mosaic DNA methylation in patients with Angelman syndrome. *H. Nazlican¹, M. Zeschnick¹, U. Claussen², S. Michel², G. Gillessen-Kaesbach¹, S. Gross¹, C. Lich¹, S. Boehringer¹, B. Horsthemke¹, K. Buiting¹.* 1) Universitätsklinikum Essen, Institut für Humangenetik, Essen, Germany; 2) Institut für Humangenetik, Universität Jena, Germany.

In a small group of patients with Angelman syndrome (AS) the disease is due to an imprinting defect. Among 92 such patients, 11 patients (12%) were found to have an imprinting center (IC) mutation, whereas in 81 patients (88%) no mutation could be detected. The presence of a faint maternal band detected by methylation specific PCR analysis of the *SNRPN* locus in one third of non IC mutation patients suggests that these patients are mosaic for an imprinting defect that occurred after fertilization. In one patient studied, somatic mosaicism was proven by methylation analysis of cloned fibroblasts. X inactivation studies of these clones suggest that the imprinting defect occurred before the blastocyst stage, when the maternal genome undergoes global demethylation. To quantify the degree of methylation at the *SNRPN* locus, we developed a novel quantitative real time PCR-based assay (TaqMan) based on bisulfite treated DNA. We used two primers that bind to DNA sequences unaffected by differential DNA methylation and two minor groove binding probes specific for the unmethylated and the methylated allele, respectively. A standard curve was constructed by mixing varying amounts of DNA from a patient with Prader Willi syndrome with uniparental disomy (two methylated gene copies) and a patient with AS with a typical deletion (one unmethylated gene copy). In 24 patients tested, the percentage of normally methylated cells ranged from 1-32%. A genotype-phenotype correlation suggests that patients with a higher percentage of normally methylated cells tend to have milder clinical symptoms than patients with a lower percentage.

ANALYSIS OF EPIMUTATION IN THE 15q11-13 IMPRINTED DOMAIN IN AUTISM. *M. Shinawi*¹, *R. Wagle*¹, *T. Sahoo*¹, *R.J. Schroer*², *R. Stevenson*², *A.L. Beaudet*¹. 1) Dept Molec Human Genetics, Baylor Col Medicine, Houston, TX 77030; 2) Greenwood Genetic Center, South Carolina 29646, USA.

The genome wide linkage studies have failed so far to identify major autism-related loci suggesting that many loci might contribute to the etiology of autism. We have proposed that there may be an epigenetic component to the etiology of autism. The maternally inherited duplication of 15q11-q13 among autistic patients indicates gene-dosage and parent-of-origin effects in this domain. In previous studies, we showed increased sharing for the paternal haplotypes at *D15S817*. We hypothesized that epigenetic and genetic factors may cause autism by altering the expression of principal imprinted genes in 15q11-q13 and that a pre-zygotic or post-zygotic imprinting defect (imprint-switch failure) in the imprinting center of the domain 15q11-q13 could be the cause of some of the cases of autism. To determine the grandparental origin of the imprinted PWS/AS domain, we genotyped fathers and mothers from the AGRE, NIMH, and South Carolina Autism Project (SCAP) collections by means of analysis for the *HpaII/MspI* RFLP in intron 1 of *SNRPN* and analyzed the informative families by a combined RFLP/ methylation-specific PCR analysis of the *SNRPN* locus. The AGRE and NIMH samples were mostly sib pairs and the SCAP samples mostly isolated cases. By analyzing 172 autistic individuals, there was no statistically significant difference in the overall sample for whether the 15q11-q13 domain was inherited from the grandmother vs. grandfather on the paternal side or for the grandmother vs. grandfather on the maternal side. There was a borderline significance favoring inheritance from the paternal grandmother ($P = 0.05$) and from the maternal grandmother ($P = 0.01$) in the SCAP group, but it is unlikely that both would be significant, and neither was found for the NIMH or AGRE groups. Considering the inherently greater risk for a chromosome that must switch imprint vs. not switch, it may be appropriate to further evaluate the risk of imprint defects inherited from the paternal grandmother in sporadic cases of autism.

Molecular mechanism of reciprocal imprinting of the mouse *Grb10* gene during brain development. Y.

Yamasaki^{1,2}, *T. Kayashima*¹, *H. Soejima*³, *T. Ohta*⁴, *H. Masuzaki*², *T. Ishimaru*², *T. Mukai*³, *N. Niikawa*¹, *T. Kishino*⁴.

1) Dept. of Human Genetics and; 2) Obstetrics and Gynecology, Graduate School of Biomedical Sciences, Nagasaki Univ; 3) Dept. of Biomolecular Sciences, Saga Univ. Faculty of Medicine; 4) Division of Functional Genomics, Center for Frontier Life Sciences, Nagasaki Univ. Japan.

The mouse *Grb10* is an imprinted gene with tissue-specific and promoter-specific expression. In most tissues, *Grb10* is expressed exclusively from the major promoter of the maternal allele, whereas in the brain it is expressed predominantly from the brain-specific promoter of the paternal allele. Such reciprocally imprinted expression in the brain and other tissues is thought to depend on the alternative usage of promoters and insulator activity on the differentially methylated region (DMR). To investigate the mechanisms of brain-specific *Grb10* imprinting, we focused on epigenetic modifications in neuronal cells in the brain. *Grb10* expression, DNA methylation and histone modifications were separately analyzed in neurons, glial cells and fibroblasts by using primary cortical cell cultures. RT-PCR analysis demonstrated that imprinted paternal expression of *Grb10* in the brain was promoter-specific for neurons but not for glial cells and fibroblasts, which showed reciprocally maternal expression same as in other tissues. Methylation analysis of putative CpG islands revealed that the DMR in the brain-specific promoter region was detected not only in neurons, but in glial cells and fibroblasts, while other CpG islands including in the major promoter were not methylated in the cultured cells. Histone modifications in DMR was analyzed by chromatin immunoprecipitation(ChIP) assay. Neurons were associated with paternal-allele-specific high acetylation of H3 and H4 and dimethylation of K4 and preferentially maternal-allele-dominant dimethylation of K9, although hypoacetylation of H3 and H4 was detected in glial cells and fibroblasts. These data indicate that reciprocally imprinted *Grb10* expression in the brain depends on neuron-specific histone modifications related to the lineage determination of neural stem cells, but not to DNA methylation.

Loss of AGG Interruptions from Gray-Zone FRAXA (CGG)_n Tracts: Mapping Tract Length Changes & Deletion Breakpoints. *K. Nichol Edamura*¹, *C.E. Pearson*^{1,2}. 1) Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Molecular & Medical Genetics, University of Toronto, Toronto, Ontario, Canada.

Fragile X syndrome (FRAXA) can be caused by either a deletion or a point mutation within the non-repeating region of the FMR1 gene, or more commonly by large expansions of the CGG repeat tract within the FMR1 promoter. The genetic instability of the FRAXA (CGG)_n repeat is sensitive to the length, purity and CpG methylation of the repeat tract. Tracts 25 pure CGG repeats can be unstably transmitted. Tracts that are 40-60 repeats long can be consistently inherited without mutations while in other families the same tract lengths can frequently lead to length changes. The different genetic instabilities of these Gray-Zone tract lengths is attributed to the presence or absence of AGG interruptions. Thus, expanded tracts that are interrupted with AGG are more stable than pure tracts of similar lengths. It has been suggested that loss of the AGG interruptions, by some yet unknown process, may be a precursor to expansion.

Through the use of bacterial and SV40 primate replication systems it was possible to study the effect of replication and CpG methylation upon repeat stability, as well as the sequence integrity, of a FRAXA clone with an interrupted gray-zone allele length of (CGG)₉AGG(CGG)₉AGG(CGG)₃₂ flanked by non-repeating genomic sequence. The presence of AGG interruptions increased the stability of the CGG repeat during replication, regardless of CpG methylation status. Deletions were predominantly limited to the repeat tract. However, rare deletion events involving the loss of repeats as well as the non-repeating flanking sequence 5' of the CGG tract were observed in CpG methylated templates replicated in primate cells. Interestingly, the 5 breakpoints of these deletions mapped to the deletion hotspots identified in some FRAXA patients. These results may explain the observation of FRAXA patients harboring deletions into the region flanking the CGG repeat, as well as upon how AGG interruptions might be lost.

Up-regulated genes after demethylation corresponds to regions of recurrent chromosomal breakpoints and fragile sites In Osteosarcoma. *K. Al-Romaih^{1,3}, I. Braude^{1,3}, J. Bayani³, P. Marrano³, G. Lim³, S. Selvarajah^{1,2}, B. Beheshti³, P. Thorner^{1,2}, M. Zielenska^{1,2}, J. Squire^{1,3}.* 1) Department of Laboratory Medicine and Pathobiology, University of Toronto, Toronto, Canada; 2) Department of Pediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, Canada; 3) University Health Network, Ontario Cancer Institute, Princess Margaret Hospital, Toronto, Canada.

A large number of translocations take place in Osteosarcoma (OS) and often the breakpoints occur in regions of the genome containing fragile sites (FS). It has also been suggested that FS regions may be subject to epigenetic modification during tumorigenesis. This prompted us to profile epigenetic change in OS and to determine whether differential methylation of specific loci also corresponded to the regions of high chromosomal rearrangements in this tumor. We employed expression gene-chip, and CpG island arrays to identify chromosome regions corresponding to differential gene expression in human OS cell lines U2OS and MG63 and normal human osteoblasts after treatment with the de-methylation agent 5-aza-2deoxycytidine. We also correlated the regions of changes in gene expression to chromosomal FS. Our data show that up-regulated genes, and areas of differential expression, after de-methylation, map to the same specific chromosome regions recurrently rearranged in human OS cell lines. We also found closer correlation between regions of up-regulated genes after 5Aza-dc treatment and FS (cytobands 1p36, 1q12.32, 2p13, 6p22-23, 9p21, 14q23-24). This study provides further support for the role of epigenetic modification at distinct chromosomal regions of the OS genome. Significantly, the concordance between areas of the genome that are subject to differential methylation, and the location of recurrent chromosomal rearrangements and FS suggests that differentially expressed genes, associated with oncogenesis may cluster to distinct chromosomal domains that have a propensity to undergo translocation during tumor progression.

Program Nr: 1115 from the 2004 ASHG Annual Meeting

Gene inactivity leads to permanent silencing of the *RARB2* tumor suppressor gene. *G. Bistulfi, M. Ren, S. Pozzi, G. Somenzi, N. Sacchi.* Cancer Genetics, Roswell Park Cancer Institute, Buffalo, NY.

In cancer cells genes become silenced in association with repressive epigenetic changes such as histone modifications and DNA hypermethylation. This is the case for the tumour suppressor gene retinoic acid receptor beta 2 (*RARB2*) that mediates the action of retinoic acid (RA), the bioactive derivative of vitamin A. *RARB2* is the target gene of another RA-receptor, RAR alpha (*RARA*). In the absence of RA, a *RARA*-RXR heterodimer binds to a RA-responsive element (beta RARE) and along with co-activators maintains the beta- RARE-containing chromatin region in a poised, transcriptionally permissive state. Upon RA binding to *RARA*, additional co-activators, histone acetyltransferases, and ATP-driven chromatin remodeling activity are recruited at *RARB2* in a stepwise fashion leading to *RARB2* transcription. Cancer cells are often RA resistant because of *RARB2* silencing. *RARB2* silencing has been traced to repressive modifications including DNA hypermethylation and histone modifications. We hypothesised previously that an aberrant *RARB2* inactive status can attract repressive histones and DNA changes, leading to permanent silencing (Sirchia et al., 2000; 2002). We tested this hypothesis by impairing *RARA* by using both genetic and pharmacological strategies. Abrogation of *RARB2* transcriptional activity was paralleled by the induction of histone and DNA and modifications at *RARB2*. Loss of *RARB2* was concomitant with in vitro tumour phenotypic changes and RA resistance. Acknowledgements: This work was supported by US Army IDEA DAMD17-02-1-0432 Award, RPCI Alliance Foundation and AROCC Foundation.

Analysis of DNA Methylation in the FSHD Syndrome-linked *D4Z4* Repeat with a New Highly Specific Probe. *M. Ehrlich*¹, *K. Jackson*¹, *M.E. Ballestas*¹, *G. Jiang*¹, *S. Winokur*², *V. Vedanarayanan*³. 1) Depts. of Biochemistry and Human Genetics, Tulane Medical School, New Orleans, LA 70112; 2) Dept. of Biol.Chem., Univ. of Cal., Irvine CA 92697; 3) Dept. of Neurol., Univ. of Miss., Jackson MS 39601.

Facioscapulohumeral muscular dystrophy (FSHD) is characterized by the shortening of an array of 3.3-kb tandem repeats called *D4Z4*. Though this array is on the subtelomeric regions of both 4q and 10q, only shortening of the 4q array is associated with the disease. The presence of many *D4Z4*-like sequences elsewhere in the genome has interfered with methylation analysis of *D4Z4* by Southern blotting. Therefore, we tested subfragments of the 3.3-kb repeat to try to find a hybridization probe that is specific for the *D4Z4* sequences on chromosomes 4 and 10. By Southern blot analysis of DNA from monochromosomal human-rodent somatic cell hybrids (SCH), we demonstrated that a 1-kb subfragment of *D4Z4* has high specificity for the *D4Z4* repeats on chromosomes 4 and 10. In contrast, when we tested PCR primer-pairs from six different subregions of *D4Z4* for amplification of a panel of SCH DNAs, none was specific for chromosomes 4 and 10. Using the 1-kb *D4Z4* subfragment as a hybridization probe, we analyzed *D4Z4* methylation at CpG methylation-sensitive sites for *SmaI* and *EagI* in various control tissues, including skeletal muscle biopsy samples. All of these DNAs showed much methylation at *D4Z4*, which contains an unusually high CpG content (73% CpG). However, an appreciable amount of signal was also in lower-molecular-weight restriction fragments. There were similar patterns of methylation at *SmaI* sites in two control and two FSHD skeletal muscle biopsy samples and in control and FSHD myoblast cell strains, whose cell type was confirmed by desmin staining. Several control and FSHD lymphoblastoid cell lines showed moderate hypomethylation in *D4Z4* compared to the other samples. This new hybridization probe will be useful not only for *D4Z4* methylation analysis, but also for analysis of 4q or 10q-specific *D4Z4* transcripts and nuclease sensitivity of *D4Z4* chromatin. This research was supported in part by NIH Grant R21 NS43794.

RASSF2A, a member of the RASSF family of putative tumour suppressor genes, is inactivated in colorectal and lung cancer by promoter hypermethylation. *L. Hesson¹, M.D. Vos², D. Morton¹, E.R. Maher¹, G.J. Clark², F. Latif¹.*
1) Medical & Molecular Genetics, University of Birmingham, Birmingham, United Kingdom; 2) Department of Cell and Cancer Biology, National Cancer Institute, National Institute of Health, Rockville, Maryland, USA.

The RASSF1A tumour suppressor gene, located at 3p21.3, is frequently inactivated by promoter region hypermethylation in a variety of human cancers including lung, breast, kidney, neuroblastoma and glioma. RASSF2, located at 20p13, is an additional RASSF member identified using in silico BLAST searches. RASSF2 has three isoforms designated RASSF2A, RASSF2B and RASSF2C. All three proteins contain a C-terminal Ras-association domain. Recently, we have shown RASSF2A protein to be a novel pro-apoptotic K-Ras effector that induces cell cycle arrest. RASSF2A was expressed in all tissues examined including lung. Since expression of RASSF2A is frequently downregulated in tumour cell lines we examined the RASSF2A CpG island for promoter hypermethylation. RASSF2A CpG island was hypermethylated in 56% breast, 45% SCLC, 100% NSCLC, 78% colorectal, 20% neuroblastomas, 67% glioma and 88% kidney tumour cell lines. Loss of or downregulated RASSF2A expression was shown in methylated lung and colorectal tumour cell lines and expression was restored after treatment with a demethylating agent. In primary tumours 44% NSCLC and 70% colorectal tumours underwent RASSF2A CpG island hypermethylation. Allele loss also occurs at the 20p13 region in around 30% of methylated NSCLC tumours. Growth suppression analysis of colorectal cell lines by RASSF2A and functional analysis using yeast two-hybrid assay is currently underway. Our results demonstrate that RASSF2A is inactivated in human cancers by CpG island hypermethylation. Furthermore our data warrants investigation of other RASSF family members for possible epigenetic inactivation and functional analysis.

X chromosome inactivation patterns in elderly females aged over 70 years. *I.Y. Iourov¹, L. Villard², S.G. Vorsanova³, I.A. Demidova³, S.A. Shalnova⁴, M.A. Shkolnikova³, A.M. Olferiev⁴, Y.B. Yurov¹.* 1) Molecular Genetics, National Center Mental Health, Moscow, Russian Federation; 2) INSERM U491, Faculte de Medecine, Marseille, France; 3) Institute of Pediatrics and Children Surgery Russian Ministry of Health, Moscow, Russia; 4) Center of Preventive Medicine, Ministry of Health, Moscow, Russia.

X chromosome inactivation is a transcriptional silencing of one X chromosome in mammalian females. This phenomenon leads to X-linked gene dosage compensation. In females the mean contribution from each parental chromosome X is 50%. However due to randomness of this process some deviation from the mean contribution is noticed. The study of X chromosome inactivation patterns in normal females showed conflicting results. Particularly higher percentage of elderly females with skewed X-inactivation was observed. These results have led to propose the hypothesis about age dependence of X chromosome inactivation patterns. Therefore it is of great interest to investigate X chromosome inactivation patterns in elderly females. In this study we have analyzed X-inactivation patterns in 40 female aged from 74 to 85 years (mean age 78 years). The control group was 36 females (mean age 30 years). The most common AR-assay (the study of methylation patterns of HpaII site of human androgen receptor gene (HUMARA) by quantitative PCR) to determine X-inactivation patterns was used. The age dependence of X-inactivation was not observed. We have detected skewed X-inactivation in three women among 40 (7.5%) elderly females comparing to two women among 36 (5.5%) females from control group. The difference was not found to be statistically significant ($p > 0.4$). We made a suggestion that higher incidence of skewed X-inactivation in elderly females revealed by previous studies could occur due to some experimental ambiguities as a heterogeneity of groups studied (in some studies females having relatives with genetic abnormalities associated with skewed X-inactivation patterns were included) and the difference of X chromosome inactivation skewing determination. We conclude that present study does not show X chromosome inactivation to be age dependent.

The dactylaplasia phenotype is suppressed by the silencing of its mutational retrotransposon. *H. Kano*¹, *H. Kurahashi*², *T. Toda*¹. 1) Division of Functional Genomics, Department of Post-Genomics and Diseases, Osaka University Graduate School of Medicine, Osaka, Japan; 2) Division of Molecular Genetics, Institute for Comprehensive Medical Science, Fujita Health University, Aichi, Japan.

Dactylaplasia, characterized by missing central digital rays, is an inherited mouse limb malformation that is clearly dependent on a two-locus interaction between *Dac* and *mdac*. The dactylaplasia phenotype depends on the genotype at the mutated locus, *Dac*, and also requires homozygosity for a recessive allele at another unlinked locus, *mdac*. Two independent *Dac* mutations in the *dactylin* gene on mouse chromosome 19 have been identified from different strains. Both mutations found in the *Dac* locus were insertions and were named *Dac1* and *Dac2*. However, little is known about the interaction between *Dac* and *mdac*. We therefore focused on the property of the unknown recessive alleles, *mdac* (which permits expression of *Dac*) and *Mdac* (which inhibits expression). We first cloned these insertions of 7,486bp for *Dac1* and 7,473bp for *Dac2*. The insertions were long terminal repeat (LTR) retrotransposons and were 99.6% identical. Most transposons are thought to be maintained in a silent state. Bisulfite sequencing revealed that CpG dinucleotides in the LTRs of mice carrying the *Mdac* allele were hypermethylated, although those of mice carrying only the *mdac* allele were hypomethylated. We also carried out ChIP analysis on nucleosomes of the LTR region and found that hypermethylated LTRs consisted of inactive chromatin, whereas hypomethylated LTRs consisted of active chromatin. In addition, these epigenetic changes caused by *Mdac* were limited to the 5LTR region. Our results indicate that some types of LTR retrotransposons are silenced by *Mdac*, leading to chromatin inactivation and DNA methylation at their 5LTR regions. Dactylaplasia will contribute to our understanding of the hosts defense mechanism for suppressing and silencing such retrotransposons.

Epigenetic implications in schizophrenia: site-specific cytosine methylation in S-COMT promoter on 22q11. B.C.

Murphy¹, R.L. O'Reilly², S.M. Singh¹. 1) Biology (Division of Medical Genetics) University of Western Ontario, London, Ontario, Canada; 2) Psychiatry, University of Western Ontario, London, Ontario, Canada.

The COMT gene on chromosome 22q11 remains a strong candidate gene for schizophrenia susceptibility due to its chromosome location and protein function. Further, the identification of a Val/Met polymorphism in exon 4 has been assessed in individuals with schizophrenia with conflicting results. We hypothesized that the COMT gene association with schizophrenia may not involve genetic alterations, rather the allele specific activity alterations could be brought about by epigenetic changes (epi-alleles) and may involve methylation. We have tested this hypothesis by examination of methylation profile of the human S-COMT promoter using sodium bisulfite. This genomic region overlaps with the MB-COMT coding region, includes 56 cytosines. The analysis of 31 adult brain regions and 51 individual blood samples suggests that the methylation is restricted to the CpG dinucleotides only; four sites (6, 17, 51 and 53) are completely methylated while two site (23 and 27) are partially methylated and differ from sample to sample. For example site 27 is partially methylated in three blood sample and five brain regions while site 23 is partially methylated in all samples with one exception. The exception being a blood sample from a schizophrenia patient with predominant negative symptoms. Interestingly, three pairs of monozygotic twins discordant for schizophrenia showed no differences in methylation in this region. The results offer three conclusions. It may be possible to use blood DNA in methylation studies. The results rule out a role for DNA methylation in the S-COMT promoter in discordance of MZ twins for schizophrenia. Finally, complete methylation of cytosine 23 in one case of schizophrenia may suggest that it may represent one, but not a common cause of this heterogeneous and complex disease. Financial support for this research was provided by Ontario Mental Health Foundation and the Bill Jefferies Schizophrenia Endowment Fund.

Microarray- based large scale profiling of DNA methylation. *A. Schumacher*¹, *P. Kapranov*², *J. Flanagan*¹, *Z. Kaminsky*¹, *A. Assadzadeh*¹, *P. Yau*³, *C. Virtanen*³, *N. Winegarden*³, *T. Gingeras*², *A. Petronis*¹. 1) The Krembil Family Epigenetics Laboratory, Centre for Addiction and Mental Health, 250 College St, Toronto, ON, Canada M5T 1R8; 2) Affymetrix, Inc. 3380 Central Expressway Santa Clara CA 95051, USA; 3) The Microarray Centre, The Ontario Cancer Institute, 610 University Avenue, Toronto, ON, Canada M5G 2M9.

We describe a microarray technology that enables DNA methylation profiling of large chromosomal regions. The technology consists of two steps: i) enrichment of methylated- and unmethylated- DNA fractions, and ii) hybridization of the enriched DNA-fractions on high-density arrays. For the enrichment procedure, genomic DNA is treated with methylation sensitive and insensitive restriction enzymes, ligated to universal adaptors, and subjected to polymerase chain reaction that preferentially amplifies either unmethylated or methylated DNA fragments. Amplification products are then hybridized to microarrays to detect DNA methylation differences between tester and control samples. Various aspects of the technology including replicability, informativeness, sensitivity, and the minimal amount of template DNA, among others, were investigated using a microarray containing ~400 oligonucleotides that represent ~100 kb of genomic DNA and also a 12,192 element- containing CpG island microarray. Epigenetic profiling at the chromosome-wide scale is demonstrated using high-density chr 22 microarrays that consists of 337,256 probe pairs. The method represents a valuable tool in studying epigenetic variation in normal and pathological conditions over large genomic fragments. The principles developed in this work in addition to the availability of high-resolution microarrays for all human chromosomes will make profiling of DNA methylation of the entire human genome a routine procedure.

Program Nr: 1122 from the 2004 ASHG Annual Meeting

Analyses of epigenetic DNA modification in the human genome. *Y. Tamura, H. Kunugi, K. Kaneko, H. Hohjoh.* Nat. Inst. Neuroscience, NCNP, Kodaira, Tokyo, Japan.

Epigenetic genome modification such as DNA methylation appears to be involved in the regulation of gene expression, chromatin structure and genomic imprinting, and also associated with various diseases. The level of such a modification on the genome is difficult to determine and still poorly understood. In this study we established a method, by which the relative levels of DNA methylation at a methylation sensitive restriction enzyme site in genomic DNA can be determined. This method depends on methylation sensitive restriction enzymes and a real-time PCR. Using the method, we attempted to investigate the levels of DNA methylation at a methylation sensitive enzyme (BssH II) site in the human REELIN (RELN) and dopamine D2 receptor (DRD2) genes. Results indicate that the levels of DNA methylation at a BssH II site in the RELN gene vary among individuals, whereas the levels of DNA methylation at a BssH II site in the DRD2 gene appear to be similar among them. These observations suggest that genes undergoing either similar or different levels of DNA methylation among individuals are present in the human genome.

Molecular mechanisms for Myotonic Dystrophies (DM) 1 and 2: the role of RNA CUG and CCUG-binding proteins. *L.T. Timchenko*¹, *E. Salisbury*², *B.G.H. Schoer*³, *C. Schneider-Gold*⁴, *N.A. Timchenko*². 1) Dept Cardiovascular Sci, Baylor Col Medicine, Houston, TX; 2) Huffington Center on Aging, Baylor Col Medicine, Houston, TX; 3) Friedrich-Baur-Institute, LMU, Munich D-80336, Germany; 4) Neurochirurgische Universitaetsklinik, Wuerzburg 97080, Germany.

DM1 is a neuromuscular disease caused by an untranslated CTG repeat expansion on chromosome 19q. A new type of DM, DM2, is associated with an untranslated tetranucleotide CCTG repeat expansion on chromosome 3q. In DM1, CUG repeats affect two distinct families of CUG RNA-binding proteins, CUGBP1 and MNBL, contributing to the myotonia, insulin resistance, muscular dystrophy and delay of muscle differentiation and development. Since GC-repeats are present in CUG and CCUG repeats, the same RNA GC-binding proteins might be affected in both diseases. We found that CUGBP1 activity and protein levels are elevated in both DM1 and DM2. This observation suggests that, in DM2 patients, CCUG repeats might disrupt specific CCUG-binding proteins. To identify novel CCUG RNA-binding proteins, we used a combination of chromatography columns (HPLC). We have purified to homogeneity a Mega Protein-Protein Complex (MPPC) that specifically interacts with long CCUG repeats. Detailed analysis of this complex shows the MPPC has a molecular weight 1 million Dalton and consists of 10-12 proteins. UV cross-link determined three RNA-binding proteins within this complex. Immunoblotting with monoclonal antibodies revealed that one of the CCUG binding proteins is CUGBP1. Protein sequencing of the other components of the MPPC is on the way to determine a biological role of the complex in normal cells and examine if this function is affected in DM2. Investigations of RNA binding proteins in DM1 using a CUG riboprobe also identified high molecular weight CUGBP1-protein-protein complexes that bind preferentially to CUG repeats. These data are consistent with the hypothesis that expanded RNA CUG and CCUG repeats might destroy biological functions of multimeric protein-protein complexes leading to the complex phenotype of DM1 and DM2 diseases.

Withdrawal from the cell cycle in FSHD myoblasts. *D.A. Figlewicz, Y. Hong, I. Coltas.* Dept Neurology, Univ Michigan, Ann Arbor, MI.

Facioscapulohumeral dystrophy (FSHD) is an autosomal dominant disorder resulting from deletion of 3.3 kb ("D4Z4") repeats on chromosome 4q35. In recent years, our attention has focused on studies of FSHD myoblasts, which display an aberrant phenotype in both the undifferentiated and differentiated states. FSHD myoblasts upregulate the cyclin dependent kinase inhibitor, p21, divide less robustly, and leave the cell cycle and fuse more readily than controls. While p21 is upregulated downstream of MyoD and initiation of the myogenic differentiation program in control myoblasts, we have determined, using real-time PCR, that the p21:MyoD ratio is nearly 3 fold elevated in FSHD myoblasts. This suggests that a pathway other than normal differentiation may be responsible for withdrawal from the cell cycle in FSHD myoblasts. Recent identification of D4Z4-binding proteins has suggested a new direction for study. The D4Z4-binding proteins include YY1, a member of the Class I polycomb protein complex. Acetylation of members of the Class I polycomb complex leads to activation of the Class II group of polycomb group proteins, which localize to the surface of condensed chromatin domains. Perhaps the functionally most important member of this group is the polycomb protein Bmi1. Not only is Bmi1 association with chromatin and heterochromatin inversely related to progression of the cell cycle, it has been shown to promote proliferative capacity in several cell types, including human fibroblasts. Nothing is known about the potential role of Bmi1 in control of myoblast proliferation. We quantitated expression levels of Bmi1 in undifferentiated control and FSHD myoblasts; Bmi1 expression is significantly decreased in FSHD myoblasts. Bmi1 in other cell types suppresses the expression of tumor suppressor protein p16. We are currently investigating whether p16 mRNA and/or protein levels are altered in undifferentiated FSHD myoblasts.

Program Nr: 1125 from the 2004 ASHG Annual Meeting

Etiology of epigenetic gene silencing in cancer cells. *M.Q. Ren, S. Rossetti, G. Bistulfi, S. Pozzi, G. Somenzi, N. Sacchi.* Cancer Genetics, Roswell Park Cancer Institute, Buffalo, NY.

In non-embryonic normal cells DNA methylation of cytosine of the dinucleotide sequence CpG is distributed globally in the genome with exception of CpG islands. In contrast, aberrant hypermethylation of CpG islands that have been associated with loss of transcription of genes essential for crucial biological functions has been detected in virtually every type of cancer. DNA hypermethylation in cancer cells is likely the tip of the iceberg of hierarchical epigenetic changes in somatic cells. We hypothesize that aberrant gene inactivity can attract hierarchical chromatin repressive changes (at both histone and DNA level) ultimately leading to profound gene downregulation and stable gene silencing. To test whether aberrant gene inactivity can attract repressive chromatin changes at both histone and DNA level we used different somatic cell systems and induced aberrant transcriptional repression of target genes of a) nuclear receptors and b) fusion proteins. Induction of aberrant transcriptional repression led to both repressive histone modifications and DNA hypermethylation with consequent gene downregulation and stable gene silencing. These epigenetic changes were concomitant with biological changes indicative of tumor progression.

Epigenetic consequences of genetic abnormalities in leukemia. *S. Rossetti*¹, *A.T. Hoogeveen*², *N. Sacchi*¹. 1) Cancer Genetics, Roswell Park Cancer Institute, Buffalo, NY; 2) Erasmus Medical Center, Rotterdam, The Netherlands.

Leukemia chromosomal abnormalities often result in the production of aberrant fusion proteins. The translocation t(16;21)(q24;q22) often associated with therapy-related acute myeloid leukemia (AML) and myelodysplastic syndrome (MDS) leads to the ectopic production of the AML1-MTG16 fusion protein. This protein retains the DNA binding domain of AML1, a transcription factor crucial for normal hematopoiesis, and most of the functional domains of MTG16, encoding a transcriptional corepressor able to recruit histone deacetylase (HDAC) activity. For this reason, we hypothesized that AML1-MTG16 can aberrantly regulate AML1 target genes by inducing repressive epigenetic modifications of histone tails. To test this hypothesis, we used a cellular system (32D cells) where AML1-MTG16 induces block of granulocytic differentiation and inhibition of cell proliferation and we examined the chromatin associated with AML1-target genes. AML1-MTG16 expression in 32D cells results in down regulation of the endogenous *Mpo* and *Csf1r*, two AML1-target genes, which are relevant in the myelogenesis process. Interestingly, by using chromatin immunoprecipitation analysis the regulatory regions of the *Csf1r* locus were found significantly hypoacetylated at both histone H3 and H4. These results establish a mechanistic link between a myeloid-specific fusion protein and aberrant epigenetic regulation of a myeloid differentiation gene.

Chromatin remodelling is involved in the pathogenesis of the Mandibuloacral Dysplasia (MADA). *F. Gullotta¹, G. Lattanzi², A.M. Nardone¹, M.R. D'Apice¹, I. Filesi³, C. Capanni², P. Sabatelli², G. Scarano⁴, S. Biocca³, N.M. Maraldi², G. Novelli¹.* 1) Biopathology, University of Tor Vergata, Rome, Italy; 2) Cell Biology and Electron Microscopy, Rizzoli Orthopedic Institute, Bologna, Italy; 3) Neuroscience, University of Tor Vergata, Rome, Italy; 4) Division of Medical Genetics, Gaetano Rummo Hospital, Benevento, Italy.

Chromatin remodelling influences DNA and histone modifications, which are responsible of chromatin structure and thereby gene expression, DNA methylation, replication, recombination, repair, apoptosis and senescence. Several evidences have established the relationship between epigenetic changes and the molecular pathogenesis of many monogenic diseases involving chromatin remodelling. The Mandibuloacral Dysplasia (MADA, OMIM 248370) is caused by mutation in LMNA-encoding lamin A/C. Lamins exert a profound influence in the maintaining the structural integrity of the nuclear lamina and on the organization of heterochromatin within the nucleus. We examined the nucleus morphology, the cytoarchitecture, the chromatin organization and the distribution of its associated proteins in fibroblast cell lines from 3 MADA patients carrying the R527H homozygous mutation. Nuclear alterations mostly consisting with focal absence of peripheral heterochromatin, invaginations of the nuclear envelope or thin papillary projections, were observed in MADA cells. A different distribution pattern of heterochromatin protein 1 (HP1) and histone H3 methylated at Lysine 9 (Me9H3) were found in nuclei from MADA patients compared to controls. The interplay between heterochromatin and lamin A is likely to involve the nuclear lamina protein all along its maturation process. To verify this hypothesis, we studied the redistribution of heterochromatin during lamin A precursor processing. We detected a reduced rate of lamin A precursor maturation with a significant accumulation of pre-lamin A in MADA cells. This suggests that pre-lamin A plays a major role in peripheral heterochromatin organization, likely interacting with silenced hyper-methylated chromatin and strongly supports a major role of the chromatin in the pathogenic pathway of MADA and possibly other laminopathies.

Tissue-specific shifting of early-late replication zone borders: a general mechanism for higher-order gene regulation. *R.S. Hansen, B. Huse, T.K. Canfield, K.R. Varadarajan, S.M. Gartler.* Medicine/Medical Genetics, Univ. Washington, Seattle, WA.

The genome is composed of a number of large replication time zones that correspond to the classical R and G chromosome bands. Using a bromodeoxyuridine-based molecular replication timing assay, we examined replication timing patterns in several cell types for STS markers in two late-replicating G band regions, Xq27 and 11p15.4, and in their flanking early-replicating R bands. Although cytogenetically determined replication banding patterns are thought to be constant over tissue type, we found that the molecularly defined borders of the corresponding replication time zones differed between cell types. These border shifts of one to several megabases correlate with cell type-specific expression of a subset of genes in the interborder region such that these genes have the classic pattern of early replication in expressing cells and later replication in nonexpressing cells. The beta globin gene cluster on 11p15.4, for example, is within a large chromosomal segment of late replication in nonexpressing cells of about 1 Mb in size. In expressing erythroleukemia cells, this band shows a dramatic shift in early-late replication border locations in that the entire zone shifts to early replication. Thus, either one or both of the replication borders is altered in expressing cells so as to advance replication of the entire band. Gene regulation by border shifting is also seen in fragile X syndrome in that we previously found *FMRI* repression to be associated with a variable border shift that always brings the gene into a large zone of very late replication that is normally proximal. The general phenomenon allows for an efficient way to package genes that are near replication time zone borders into a late-replicating, repressive domain, and suggests that tissue-specific genes depending on late replication for full repression might be preferentially located near replication borders. We speculate that replication border shifting, if general, could have implications for higher-order gene regulation, genome organization, and abnormal epigenetic states associated with disease.

The effect of the Z-DNA structure of genomic retroelements in major psychosis and stressed chickens on the experimental design of epigenetic studies. *P.X. Kan^{1,2}, X.G. Yang², D.J. Zhang², Z.L. Xie³, S.C. Wang², W.Y. Huang².*

Elucidation of the causes of schizophrenia (SCH) and bipolar disorder (BD) remains to be the main challenge to psychiatric researchers. Despite strong evidence of the importance of hereditary factors in SCH and BD as well as significant effort to identify disease genes, the progress in the field of molecular psychiatric genetics has been quite slow. This work is dedicated to the exploration of the role of epigenetic (epiG) factors in major psychosis. One of the key functions of epigenetic modification of the genome of eukaryotic cells is to suppress transcriptional activity of the retroelements. Examples of retroelements are human endogenous retroviruses (HERV) sequences, Alu elements and long interspersed nucleotide elements (LINE), among others, which as a rule are hypermethylated. There is evidence from schizophrenia (SCH) and other human complex diseases that some of the genomic retroelements become transcribed in the affected tissues. Our goal was to screen DNA samples from post-mortem brain tissues of individuals who were affected with major psychiatric illness for retroelements that were located in the hypomethylated fraction of the genomic DNA. The HERV sequences in the hypomethylated fraction of brain DNA were below the detection level. Over 100 Alu sequences were cloned, sequenced, and mapped to the human genome. The results were, however, not consistent. The possibility is that the HERV sequences might locate in the DNA breakpoint region with Z-DNA structure in high salt solution. The human postmortem brain genomic DNA was severely degraded. The comparison of postmortem brain genomic DNA between human and chickens showed that the degree of degradation of brain genomic DNA increase with postmortem interval. Better experimental design is required to produce consistent result in epigenetic studies.

Transcriptional Regulation of ETn Elements: Active Mobile Mutagens in the Mouse. *I.A. Maksakova*^{1,3}, *D.L. Mager*^{1,2}. 1) Terry Fox Laboratory, BC Cancer Agency, Vancouver, BC, Canada; 2) Department of Medical Genetics, UBC; 3) Genetics Graduate Program, UBC.

Novel insertions of endogenous retroviruses (ERVs) account for up to 10% of spontaneous mutations and numerous cases of cancer in mice. Our research focuses on the early transposons (ETns), a class of mouse ERVs highly transcribed during early mouse embryogenesis and in undifferentiated cells. Flanked by long terminal repeats (LTRs), ETns do not contain retroviral open reading frames (ORFs), but remain transcriptionally active, inducing insertional mutations. ETns have a close relative in the mouse genome, a full-length ORF-possessing mouse ERV, MusD. There is at least twice the copy number of MusD compared to ETnII elements; however, ETnII elements account for almost 30 times more transcripts, despite the fact that ETnII and MusD LTRs, carrying transcription control elements, are closely related. The objective of this research is to determine the factors responsible for the difference in transcription level between ETnII and MusD elements and to elucidate the reason for preferential embryonic expression of ETns. Reporter gene assays demonstrate that ETnII LTRs exhibit greater promoter ability in comparison to MusD LTRs, and their activity in undifferentiated embryonic carcinoma P19 cells is considerably higher than in differentiated NIH/3T3 cells. Electrophoretic mobility shift assay (EMSA) utilizing DNA probes specific to the only region of significant divergence between ETnII and MusD LTRs confirms that different transcription factors (TFs) bind this region. Deletion experiments helped identify an 80 bp region responsible for high LTR promoter efficiency in P19 cells, confirmed by EMSA to bind Sp1 and Sp3 TFs. Southern blotting suggests lower methylation levels of ETnII LTRs in P19 cells compared to NIH/3T3 cells. In conclusion, differences in the LTRs of ETnII and MusD elements seem to account for differences in their expression level. Both types of LTRs harbour cis-acting elements responsible for their preferential transcription in undifferentiated cells. Finally, the embryonic pattern of ETn expression appears to be influenced by both methylation and TF regulation.

Possible epigenetic protective factor for FSHD identified in the Black South African population. A. Olckers^{1,2}, A. Van der Merwe^{1,2}. 1) Centre for Genome Research, North-West University, Pretoria, South Africa; 2) DNAbiotec (Pty) Ltd, Pretoria, South Africa.

Facioscapulohumeral muscular dystrophy (FSHD) is the third most common inherited disorder of muscle after Duchenne and Myotonic dystrophy, with a prevalence of at least 1 in 20,000. FSHD is characterised by progressive weakening and atrophy of the face, shoulder-girdle and upper arm, although other skeletal muscles may also become involved with progression of the disorder. This disorder has a highly variable phenotypical presentation with weakness occurring from infancy to late life, but generally in the second decade of life. The FSHD phenotype segregates as an autosomal dominant trait. A deletion of an integral number of 3.3 kb repeats on chromosome 4q35, localised at the D4Z4 locus, was reported to cause FSHD. Translocation events between chromosomes 4q35 and 10q26, also harbouring similar 3.3 kb repeat units, have been detected via the presence of Bln I sites within the 10q26 repeats. In this study the D4Z4 locus was investigated for the first time on a molecular level in the Black South African population. The translocation frequency between chromosomes 4q35 and 10q26 was evaluated via the Bln I / Bgl II dosage test. The Eurasian population harbours an excess of 4-on-10 fragments and this excess was postulated to be a significant, if not the major predisposing factor that gives rise to the FSHD-type deletion. The predisposed population thus has individuals that are more susceptible to FSHD. An enrichment of 10-on-4 was observed in the Black South African population. It was postulated that this enrichment is an epigenetic protective factor for FSHD, since no FSHD case has been reported in this population to date. It was further hypothesised that the absence of FSHD cases in this population is due to this enrichment. As a consequence, the excess / enrichment of specific translocation profiles in different populations is an additional factor that affects the aetiology of FSHD within specific populations. We acknowledge the donation of the p13E-11 probe by S.M. van der Maarel and R.R. Frants, Dept. of Human Genetics, Leiden University Medical Centre, The Netherlands.

A powerful biological, clinical and diagnostic method to evaluate X-chromosome inactivation by RNA FISH. *T. Kubota*¹, *T. Nakamura*², *M. Mimaki*³, *H. Ohashi*⁴, *M. Tsukahara*⁵, *S. Yamamori*². 1) Epigenetic Medicine, Fac Med, Univ Yamanashi, Yamanashi, Japan; 2) Mitsubishi Kagaku Bio-Clinic Lab, Inc., Tokyo, Japan; 3) Saitama Child Med Ctr, Saitama, Japan; 4) Natl Inst Neuroscience, NCNP, Tokyo, Japan; 5) Fac Health Sciences, Yamaguchi University Sch Med, Ube, Japan.

X-chromosome inactivation (XCI) is a genetic phenomenon in females in which one of two X chromosomes is randomly inactivated. DNA methylation-based assays have recently been used to evaluate XCI in various genetic diseases. However, these assays detect abnormal XCI indirectly utilizing DNA methylation, and they are not capable of assessing XCI at each cell level. Here we show a new expression-based direct and cell-level XCI method using RNA FISH with XIST (X-chromosome inactive specific transcript) DNA probe. In this method, one XIST RNA signal derived from the inactive X chromosome was obtained in the nucleus of each cell of a normal female, and the RNA signal was merged with one of two XIST DNA signals from the two X chromosomes. By this method, we demonstrated that 1) two of three X had an XIST RNA signal in a XXX patient and three of four X had an XIST RNA signal in a XXXXY patient, indicating that Lyon's hypothesis can be visualized, 2) a 46,X,i(Xq)(10) patient showed no XIST RNA signal on the normal X whereas two XIST RNA signals on the i(X), suggesting that XIST gene is not inactivated by intrinsic XIST transcript from another XIST gene in cis, 3) a ring X Turner syndrome [46,X,r(X)] patient with severe mental retardation (MR) had no XIST RNA signal in all cells (i.e. complete functional X disomy), whereas a patient with the same karyotype but with less severe MR had some XIST RNA-positive cells signal (i.e. partial functional X disomy). These results indicate that the RNA FISH-based XCI assay will be an alternative powerful biological, clinical and diagnostic tool.

Analysis of concordance of X-inactivation patterns in haematopoietic and non-haematopoietic tissues of neonates and elderly females. *S. Provost¹, V. Bolduc¹, MP. Dube², C. Belisle¹, M. Gingras¹, P. Chagnon¹, L. Busque¹.* 1) Research Center, Maisonneuve-Rosemont Hospital, University of Montreal, Montreal, Canada; 2) Montreal Heart Institute, University of Montreal, Montreal, Canada.

Studies have shown that there is great variability of X-inactivation patterns in different tissues of a same individual. The incidence of inactivation skewing is generally greater in haematopoietic cells than in other tissues (epithelial cells, muscle, glandular tissue). One likely explanation is that as women age, the incidence of X-inactivation skewing in blood cells increases (acquired skewing phenomenon, Busque *et al*, Blood, 1996) and deviates from the initial X-inactivation pattern common to all tissues. To test this hypothesis, we compared the concordance of X-inactivation patterns between epithelial and blood tissues in cohorts of neonates and elderly females. Blood samples and buccal epithelium cells from 350 neonates and 648 females aged 55 years and over were analyzed for X-inactivation status using the HUMARA assay. In neonates, the incidence of skewing (using a criteria >3:1) was similar for blood and epithelial cells (10.6% and 7.7% respectively). Furthermore, the intra-individual correlation of X-inactivation ratios considering the direction of skewing was very strong ($r=0.71$, Pearson, $p<0.01$). In contrast, the incidence of skewing in the elderly cohort was significantly higher for blood cells than for epithelial cells (47.3% and 13.3%). The correlation between these two tissues in the elderly cohort was much lower ($r=0.59$, Pearson, $p<0.01$). These results suggest that the incidence of non-random X-inactivation at birth is low and concordant in different tissues. The concordance of X-inactivation patterns is lost over time as blood cells become progressively skewed, explaining the generally reported intra-individual discordances. The low and similar incidences of skewing in epithelial cells of neonates and elderly females suggest that skewing in this tissue is stable over time and correspond to the initial body-wide skewing. This also suggests that the increased incidence of skewing documented in blood cells of elderly females is acquired and specific to haematopoietic cells.

Analysis of 2,903 single base substitutions from the coding regions of 118 alternatively spliced genes associated with human disease. *F. Ma*¹, *L. Chen*², *H. Huang*², *J. Li-Ling*³, *X. Ji*^{4,5}, *Q. Li*¹, *Y. Wang*², *Y. Li*⁵. 1) School of Life Science, Liaoning Normal University, Dalian 116029, CHINA; 2) School of Life Science, Xiamen University, Xiamen 361005, CHINA; 3) Department of Medical Genetics, China Medical University, Shenyang 110001, CHINA; 4) Laboratory for Conservation and Utilization of Bio-resources, Yunnan University, Kunming 650091, CHINA; 5) Institute of Bioinformatics, Tsinghua University, Beijing 100084, CHINA.

Extensive interest has been expressed over the molecular mechanism and evolution of alternative splicing leading to human diseases. We have analyzed 2,903 single base substitutions from the coding regions of 118 alternatively spliced genes associated with human diseases retrieved from the Swiss-Prot, Human Gene Mutation Database and Human Gene Nomenclature database. Our results show that the proportions of substitutions are A/G or G/A, 28.14%; C/T or T/C, 31.97%; G/T or T/G, 13.65%; C/G or G/C, 12.47%; A/C or C/A, 7.44 %; and A/T or T/A, 6.34%, and those of the first, second and third bases of codons are 49.26%, 42.16% and 8.58%, respectively. There is an overall preponderance of transitions, i.e., A/G and C/T substitutions, over transversions (60.11% vs. 39.89%). The hierarchy of nucleotides undergoing substitution at the first, second and third bases of codons are C>G>A>T, G>C>T>A, and C>G>T>A, respectively. A rather high GC content in the coding regions was noticed. With mean substitution ratios being at 10.47%, 84.38%, 5.15%, respectively, for the high (65~81.06%), medium (40~65%), and low GC ranges (16.67~40%), the influence of GC content on substitution rates seems to be quite obvious. Substitution rates seem to be influenced mostly by the nature of substituted bases, existence of CpG di-nucleotides, and nearest flanking nucleotides. Substitution rate in middle exons (1 per 101bp) is significantly lower than those in 5'- and 3'- adjacent exons (81bp and 82 bp, respectively). Furthermore, there is a strong negative correlation between exon length and the rate of substitutions ($r=-0.1192$, $P<0.0001$).

Program Nr: 1135 from the 2004 ASHG Annual Meeting

AMPGEN - Attribution of missing persons by genotyping: User-friendly software for DNA forensics and pedigree-based genetic databases. *W. Niu, P. Gopalakrishnan, G. Zhang, R. Chakraborty.* Center for Genome Information, University of Cincinnati, Cincinnati, OH.

DNA-based human identification problems relate to forensics as well as validation of pedigree-based genetic databases. These problems are generally of three categories: Transfer Evidence (i.e., DNA profile of a question sample is from a single source, and it matches the profile of a known subject); DNA Mixture (i.e., the evidence DNA profile is a mixture, and statistical supports for different scenarios of mixture origin are needed); and Kinship Analysis (i.e., the evidence profile is to be assigned to a missing family member, based on DNA profile of one or more relatives of the family). Statistical genetic algorithms for addressing these problems are well established, but the computational methods may be complex and varied, depending on the assumptions made, and databases used. AMPGEN is a user-friendly platform to carry out such computations, based on user-specified sets of assumptions, population databases, and degree of conservativeness. The modules of this software require minimal data entry (to avoid transcriptional errors), and minimal genetic expertise to formulate the problem, but they provide comprehensive analyses based on alternative methods that are rationalized by population genetic theory. Linked with validated worldwide databases, the robustness of computations can be checked against unknown population origin of the question sample. AMPGEN also produces a report of the computations, explained in easy to understand language, and is accompanied with hypertext help files providing theoretical backgrounds of the computations and concepts, along with their literature citation. The modules can be integrated into any laboratory information management system (LIMS) to check accuracy of pedigree relationships, presence of contamination due to mixture, and presence of duplicates or related individuals in large genotype databases. Currently structured for use with the CODIS STR loci, AMPGEN can easily accommodate any panel of genomic polymorphic markers. (Research supported by a grant from the Department of Development, State of Ohio).

Recent breakthroughs in the identification and evaluation of single nucleotide polymorphisms in the human genome have given researchers the opportunity to carry out large-scale scans for signals of natural selection in the genome. With the data now available, we introduce the robust software package Finch that incorporates multiple tests for selection including our own Long-Range Haplotype (LRH) Test. Finch can handle whole genome datasets such as an entire release of the International Human Haplotype Map, allowing scientists to scan the genome in a single sitting or analyze and create images of their region of interest. We first show the efficacy of the program using previously known genes to be under selection including HBB, G6PD, CCR5, and LCT. We then show its use in analyzing a large-scale multi-population dataset, 160 genes in 3 populations. Finally we present examples drawn from the analysis of the public HapMap data, potentially identifying new regions under selection.

Program Nr: 1137 from the 2004 ASHG Annual Meeting

Evolutionary rates of essential and non-essential genes for fertility. *D.G. Torgerson, B.R. Whitty, R.S. Singh.*
Department of Biology, McMaster University, Hamilton, ON, Canada.

Sex and reproduction related genes have been shown to evolve rapidly across a variety of taxa, particularly for genes involved in male reproduction. However the exact mechanisms for rapid evolution may be complex and heterogeneous, as an essential reproductive function may be as evolutionarily important as viability. We calculated nucleotide sequence divergence in over 900 orthologous human and mouse sequences that were implicated to be important in either fertility or viability using mouse knockout mutation phenotypes. We compared the evolutionary rates of 1) genes affecting male or female fertility, 2) genes affecting one or both genders, 3) genes that are more or less essential for fertility, and 4) genes affecting fertility or viability. Our data suggest that in some cases genes essential for fertility are as evolutionarily conserved as those essential for viability, and we hypothesize that the rapid evolution of sex and reproduction related genes is facilitated through an increased specialization of reproductive function.

Effects of Natural Selection on Inter-population Divergence at Polymorphic Sites in Human Protein-Coding Loci.

M. Yeager^{1,2}, *B.R. Packer*^{1,2}, *R. Welch*^{1,2}, *A.W. Bergen*², *S.J. Chanock*^{1,3}, *A.L. Hughes*⁴. 1) Core Genotyping Facility, DCEG/NCI/NIH, Gaithersburg, MD; 2) Intramural Research Support Program, SAIC-Frederick, NCI-FCRDC, Frederick MD 21702; 3) Section on Genomic Variation, Pediatric Oncology Branch, National Cancer Institute, National Institutes of Health, Gaithersburg MD 20892-4605; 4) Department of Biological Sciences, University of South Carolina, Columbia SC 29208.

2784 single nucleotide polymorphisms (SNPs) in 396 protein-coding genes were analyzed with respect to gene diversity within samples of individuals representing the three major historic human populations (African, European, and Asian) and with respect to inter-population genetic distance. Reduced levels of both intra-population gene diversity and inter-population genetic distance were seen in the case of both SNPs in the 5' UTR and nonsynonymous SNPs causing radical changes to protein structure. Reduction of gene diversity at SNP loci in these categories was evidence of purifying selection acting at these sites, which in turn causes a reduction in inter-population divergence. By contrast, a small number of SNP loci in these categories revealed unusually high genetic distances between the two most diverged populations (African and Asian), suggesting that the latter loci may have historically been subject to divergent selection pressures. Interestingly, these cases include immune system genes, hormones and hormone receptors, and metabolic enzymes, which might plausibly have been subject to different selective pressures in different environments over the course of human evolution.

The C677T polymorphism in the Methylenetetrahydrofolate Reductase Gene in Rheumatoid Arthritis Mexican Patients. *J.P. Mena¹, I.P. Davalos^{1,2}, J.I. Gamez³, L. Gonzalez³, F. Munoz-Valle¹, M. Vazquez del Mercado¹, G. Martinez¹, L. Sandoval², L.E. Figuera^{1,2}, M. Salazar-Paramo^{1,3}.* 1) Centro Universitario de Ciencias de la Salud, Departamento de Fisiologia, Universidad de Guadalajara; 2) Division de Genetica, CIBO, IMSS; 3) Unidad de Investigacion Medica en Epidemiologia Clinica, HE, CMNO. Guadalajara, Jalisco, Mexico.

The C677T polymorphism in the 5,10-Methylenetetrahydrofolate Reductase (MTHFR) gene, is responsible of the thermolabile form of the enzyme, reduced availability of 5-methyltetrahydrofolate (circulating form of folate) and mild hyperhomocysteinaemia. Moderate hyperhomocysteinaemia related to folate deficiency has been described in patients with cardiovascular risk and also in patients with autoimmune diseases including Rheumatoid Arthritis (RA), suggesting that immune activation could be involved in the development of hyperhomocysteinaemia (Schroecksnadel 2003).

Objective: To determine the frequency of MTHFRC677T in patients with RA. Methods: Group RA consisted in 60 RA mestizo Mexican patients diagnosed according to the American College of Rheumatology 1987 (ARA) and Group M consisted in 140 normal mestizo Mexican individuals. Both groups were typed for the MTHFRC677T by PCR/RFLP Hinf I method. Results. Genotype frequencies GF % (n) in Group RA group were: CC 27% (16) CT 60% (36), TT 13% (8). and GF in Group M were CC 31% (44) CT 52% (72), 17% (24). Allele Frequencies AF % (n) were in Group RA C 57% (68) T 43% (52) AF in Group M C 57% (160), T 43% (120). Results: Interpopulation comparisons were similar (Chi square, 1.27, p 0.36) Conclusions: The were similar MTHFRC677T AF between the two groups.

Evolutionarily dynamic G-protein-coupled receptor regulates the development of human cerebral cortex. X.

Piao^{1, 2}, *R. Collura*³, *A.S. Bailey*³, *D. Reich*⁴, *M. Ruvolo*³, *C.A. Walsh*². 1) Division of Newborn Medicine, Children's Hospital, Boston, MA; 2) HHMI, Dept. of Neurology, BIDMC, Harvard Medical School; 3) Dept. of Anthropology, Harvard University; 4) Dept. of Genetics, Harvard Medical School.

The mammalian cerebral cortex is characterized by complex patterns of anatomical and functional areas that differ markedly between species, but the molecular basis for this functional subdivision is largely unknown. We studied an inherited condition in which specific regions of the cortex are preferentially disrupted. Bilateral frontoparietal polymicrogyria (BFPP), a recessively inherited genetic disorder of human brain, shows severely abnormal architecture in the frontal lobes, suggesting that the BFPP gene is essential for normal development of the human frontal lobes. We have previously identified GPR56 as a causative gene for BFPP. In mouse, Gpr56 expression is found in the embryonic and adult brain specifically in areas consistent with early neurogenesis. The pattern of Gpr56 expression and the anatomy of BFPP imply that GPR56 most likely regulates the normal development of the human frontal lobes. The frontal lobes of the human brain are the most highly developed part relative to other animals and it has long been thought that the evolution of the frontal lobes parallels the development of human communication and civilization. Therefore GPR56, a gene regulates the frontal cortical development, is a candidate gene for involvement in the development of the human brain. Sequence analysis of GPR56 reveals substantial evolutionary differences between mammals and nonmammals in that the N-terminal domain that defines GPR56 is unique to animals with a cerebral cortex. In addition, evolutionary analysis of GPR56 revealed a pattern of molecular evolutionary constraint in the clade containing humans and chimpanzees that is different from that in other primates ($P < 0.05$) and may be due to directional selection. Thus, GPR56 is not only essential during human cerebral cortical development and patterning, but may have been important in the evolution of the cerebral cortex beginning in the human-chimpanzee common ancestor.

Maternal lineages and Alzheimer disease risk within the Old Order Amish. *J. van der Walt¹, S. Slifer¹, P.C. Gaskell¹, W.K. Scott¹, E.R. Martin¹, A. Crunk², D. Fuzzell², M. Creason¹, L. McFarland², K. Welsh-Bohmer³, S.R. Johnson³, C.E. Jackson⁴, C.C. Kroner¹, J.L. Haines², M.A. Pericak-Vance¹.* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN; 3) Department of Psychiatry and Behavioural Sciences, Duke University Medical Center, Durham, NC; 4) Scott & White, Temple TX.

The Old Order Amish, founded by a small number of Swiss immigrants, exist in culturally isolated communities across rural North America. The consequences of genetic isolation and inbreeding within this group are evident in increased frequencies of many monogenic diseases and several complex disorders. Conversely, the prevalence of Alzheimer disease (AD), the most common form of dementia, is lower within the Amish than in the general American population. Since mitochondrial dysfunction has been proposed as an underlying cause of AD and a specific haplogroup was found to affect AD susceptibility in Caucasians, we investigated whether inherited mitochondrial haplogroups affect risk of developing AD dementia in central Ohio and northern Indiana/southern Michigan Amish kin-groups. 95 independent matrilineages were observed across 9 large pedigrees and classified into 7 major European haplogroups. Haplogroup T is the most frequent maternal line represented overall in the Amish (35.4%) while observed in only 10.6% of outbred American and European populations. Furthermore, the frequencies of haplogroups J and K are lower (1.0%) than in the outbred data set (9.4-11.2%). Affected case matrilineages and unaffected control lines were chosen from pedigrees to test if specific haplogroups or SNPs confer risk of AD. We did not observe frequency differences between AD cases compared to controls overall or when stratified by sex. Therefore, we suggest that the genetic effect responsible for AD dementia in the affected Amish pedigrees is unlikely to be of mitochondrial origin and may be caused by nuclear genetic factors.

Reconstructing the genealogy of a BRCA1 founder mutation. *F. Marroni*¹, *G. Cipollini*², *F. Bonatti*², *P. Radice*³, *E. D'Andrea*⁴, *A. Contegiacomo*⁵, *J.E. Bailey-Wilson*⁶, *G. Bevilacqua*², *M.A. Caligo*², *S. Presciuttini*¹. 1) Center of Statistical Genetics, Univ. of Pisa, Italy; 2) Dept. of Oncology, Univ. of Pisa, Italy; 3) National Tumor Institute, Milan, Italy; 4) Dept. of Oncology and Surgery, Univ. of Padua, Italy; 5) U.O. Medical Oncology, II Univ. of Naples, Italy; 6) IDR, NHGRI, Baltimore, MD, USA.

The BRCA1*1499insA mutation was initially detected in three unrelated families from Tuscany, a region from central Italy, and was then reported in other Italian regions. Haplotype analysis was previously carried out with 4 closely linked markers in nine families, and the presence of a common compatible haplotype was determined. We have now extended the collection of independent pedigrees with this mutation to 14 families (7 from Tuscany, 6 from Northern Italy, and 1 from Southern Italy). We estimated the time to the most recent common ancestor (MRCA) of all mutation carriers using the length of the haplotype shared by pairs of individuals. DNA samples were obtained from 50 subjects (28 mutation carriers). Thirty-seven STR markers (DeCode map) were typed, spanning about 24 cM around the BRCA1 gene. Haplotypes were determined using Merlin 0.9 and GeneHunter 2.1. The length in cM of the haplotype shared by all possible pairs of mutation carriers provided a triangular matrix of haplotype sharing. We obtained the time to the MRCA of any two individuals, given the length of the shared haplotype and the recombination fractions between adjacent markers, by computer simulations. This allowed us to convert the matrix of haplotype sharing into a distance matrix, in which each element corresponded to the most likely number of meioses separating any two individuals (twice the number of generations since their MRCA). The genealogical tree of the affected haplotypes was then obtained by submitting this distance matrix to the program KITSCH of the package PHYLIP. The final estimated time to the MRCA of all families was 30.4 generations. Its standard error was obtained by bootstrapping. Assuming a generation time of 25 years, the common ancestor lived 75994 years ago.

Association among homocysteine gene polymorphisms (C677T, A1298C in MTHFR gene and 844ins86 in CBS gene) with atherosclerotic cardiovascular disease in Mexican patients. Z.G. Ruiz-Portillo¹, L. Gonzalez-Herrera¹, V. Suarez-Solis², H. Laviada-Molina², A. Gonzalez-delAngel³. 1) Genetics, C.I.R. Dr. Hideyo Noguchi, Merida, Yucatan, Mexico; 2) Faculty of Medicine, Autonomous University of Yucatan; 3) Department of research in Human Genetics. National Institute of Pediatrics.

Atherosclerotic coronary artery disease is the most common cause of Cardiovascular Diseases (CVD), which is the first cause of mortality in Mexico. Elevated homocysteine levels have been associated with increased risk for CVD. Molecular defects in genes encoding enzymes involved in homocysteine metabolism may account for hyperhomocysteinemia and CVD in some populations. Homozygous individuals for the allele C677T-MTHFR have a significantly higher risk for CVD, particularly in the setting of low folate status. The frequency of the allele C677T is one of the highest in our population. Therefore, in this study, we analyzed the role of these three polymorphisms and their interactions in association with CVD in Mexican patients. 52 subjects with atherosclerotic CVD, demonstrated by coronariography were the case group and 31 health subjects without coronary lesion also confirmed by cardiac catheterism, were included as the control group. Polymorphisms were determined by PCR-RFLPs. Allelic, genotypic and Haplotypic frequencies were compared between cases and controls using the statistical software EpiInfo 2000. Results showed a statistically significant difference for the C677T allele ($p=0.0014$, OR= 2.23, IC= 1.11-4.88) for the Homozygous TT genotype. ($p=0.005$) and the TT/AA haplotype ($p=0.0018$), therefore suggesting a positive association between this polymorphism and CVD. For the polymorphisms A1298C-MTHFR and 844Ins68-CBS, a statistically significant difference was not found between cases and controls ($p>0.05$). Our data suggests that the C677T polymorphism in MTHFR gene and the homozygosity for this allele are associated to CVD in our population, confirming that C677T allele and the TT genotype are risk factors for CVD.

Extensive and breed specific linkage disequilibrium in *Canis familiaris*. *E.A. Ostrander¹, N.B. Sutter¹, M.A. Eberle¹, H.G. Parker¹, B. Pullar¹, E.F. Kirkness², L. Kruglyak¹.* 1) Human Biology Division, Fred Hutchinson Cancer Research Center, Seattle, WA; 2) The Institute for Genomic Research, Rockville, MD.

The 156 breeds of registered dogs in the U.S. offer a unique opportunity to map genes important in disease susceptibility, morphology, and behavior. Linkage disequilibrium (LD) is of current interest for its application in whole genome association mapping, since the extent of LD determines the feasibility of such mapping. We have measured LD at five loci, none of which is under obvious selective pressure, in the Akita, Bernese Mountain Dog, Golden Retriever, Labrador Retriever, and Pekingese breeds in order to evaluate the utility of association mapping in dogs. Approximately 20 unrelated dogs were genotyped in each breed at each of five loci on canine chromosomes 1, 2, 3, 34, and 37. At each locus SNPs and indels were discovered and typed by resequencing STSs spaced one, two, three, and six Mb apart. Distances were based on alignment between the human genome and TIGR's 1.5x shotgun Poodle sequence. Strikingly, LD in canines is much more extensive than in humans. The distances at which median D' falls to 0.5 vary from 500-800 Kb in the Golden Retriever and Labrador Retriever to 2 Mb in the Bernese Mountain Dog and Pekingese, and 3.7 Mb in the Akita. This compares with just 30 Kb in a human CEPH population. LD in dog breeds is 20-100 times more extensive than in human populations. These findings correlate with dog breed history. The Golden Retriever and Labrador Retriever are the most popular U.S. breeds, and their populations have never experienced bottlenecks, unlike the other breeds, all of which underwent tight population bottlenecks this century. With extensive LD in dogs, a correspondingly smaller number of markers will be required for association mapping studies as compared with humans.

Empirical evaluation of inferred population structure from Y-chromosomal haplotypes. *J.E. Ekins¹, J.B. Ekins¹, L. Layton¹, N. Myres¹, L.A.D. Hutchison¹, K. Hadley¹, U.A. Perego¹, J.L. Peterson¹, M.L. Lunt¹, S.S. Masek¹, A.A. Nelson¹, M.E. Nelson¹, K.L. Pennington¹, A. Sims¹, T. Tolley¹, A. Welch¹, S.R. Woodward¹.* ¹ Sorenson Molecular Genealogy Foundation, Salt Lake City, UT; ² Department of Micro and Molecular Biology, Brigham Young University, Provo, UT.

Human population dynamics is an area of active research, primarily addressing movement through the Pleistocene era. Investigations addressing modern histories have been more limited, but are valuable in multiple areas: disease linkage and association studies, constructing reference populations for forensic questions, and reconstructing personal histories. Herein we characterize a diverse set of 1895 samples from various world populations genotyped at 24 NRY STR loci, with documented paternal genealogies extending to an average of 7 generations (max. 15). Using the *structure* algorithm we describe a method to hierarchically decompose a population into increasingly homogenous groupings. Cluster membership is affirmed by pairwise analysis of inter-cluster vs. intra-cluster MRCA times, as well as molecular diversity measures. This population structure, inferred from the genotypes of living individuals, is compared to historical genealogical records where loose geographic correlations and paternal lineage designations are observed. The final clusters are indicative of relatively recent paternal lineages, with a median depth of ~40 generations within a cluster. The presented high-resolution statistical analysis makes it practical to use individual NRY haplotype data to distinguish between closely related individuals, in order to investigate relatively recent population histories.

Interpreting missense variants in Oculocutaneous Albinism Genes Tyrosinase and P Gene: an evolutionary approach. *M.S. Greenblatt¹, S. Duraisamy¹, C. McBride¹, J.P. Bond¹, W.S. Oetting².* 1) Univ of Vermont; 2) Univ of Minnesota.

Oculocutaneous Albinism (OCA) is characterized by lack of skin and eye pigment, UV sensitivity, predisposition to skin cancer, and developmental eye defects. OCA is caused by mutations in several genes, most commonly the tyrosinase (OCA1) and P genes (OCA2). Tyrosinase is the key enzyme catalyzing melanin pigment synthesis from tyrosine; the P gene encodes a transport protein. Understanding their intragenic conservation patterns can help to predict functionally critical amino acids (AA), where variants are likely to cause OCA. To assess quantitatively the predictive value of AA conservation we have: 1) made sequence alignments and phylogenetic trees of the tyrosinase and P genes, 2) computationally studied their intragenic AA conservation patterns, and 3) tested how well the patterns predict OCA-associated and non-disease associated variants, using the Albinism database (<http://albinismdb.med.umn.edu>).

RESULTS: Evolutionary variation in the existing database of sequences is sufficient to determine statistically significant conservation of codons for tyrosinase but not for P gene. The SIFT program correctly predicted 82 % of the OCA1 associated tyrosinase variants and both of the non-OCA-associated polymorphisms, and 94% of the OCA2-associated P gene variants. However, 4 of 6 P gene polymorphisms were incorrectly predicted to be deleterious based on conservation in the three known P gene sequences (human, pig, mouse). To achieve 82% sensitivity for predicting OCA1-associated tyrosinase variants, cutoff scores for AA conservation would classify 50% of codons as conserved, with resulting 50% specificity, 100% Pos Predictive Value (PPV), and only 9% Neg Predictive Value (NPV). For predicting OCA2-associated P gene variants, cutoff scores to achieve 85% sensitivity would classify 73% of codons as conserved, with resulting 50% specificity, 91% PPV, and 38% NPV.

CONCLUSIONS: 1) Adequate databases of sequences, mutations, and polymorphisms are needed to confirm the validity of predictions based on evolutionary AA conservation. 2) >80% prediction of deleterious mutations is possible. 3) More P Gene sequences are needed to validate evolutionary predictions.

A simulation study comparing three methods for individual admixture estimation. *V.L. Martinez-Marignac¹, M.R. Vaughn¹, I. Halder², M.D. Shriver², E.J. Parra¹.* 1) Department of Anthropology , University of Toronto, Mississauga, Ontario, Canada; 2) Department of Anthropology, Pennsylvania State University, University Park, USA.

Population-based association studies are a promising approach for mapping genes involved in complex traits and diseases. However, these studies are prone to false positive results due to population structure. One potential source of population structure is admixture stratification (e.g. variation of individual ancestry between individuals in an admixed sample). Admixture stratification can have a profound effect in association studies in admixed populations, potentially leading to significant results for a substantial number of genetic markers that are not functionally related to the complex trait being studied. The problems outlined above can be eliminated by controlling for individual ancestry in the statistical analysis. A number of software programs are available that implement different strategies to estimate individual ancestry in admixed populations. However, there has not been a systematic evaluation of the relative merits of these programs. In this study, we simulated different admixture scenarios and evaluated three widely used programs to estimate individual ancestry: STRUCTURE, ADMIXMAP and a maximum likelihood method (ML, Chakraborty 1986). We created, by simulation, admixed samples with different ancestral contributions and different levels of admixture stratification. The programs STRUCTURE, ADMIXMAP and ML were run on the simulated population data to determine the ability of each program to correctly identify individual admixture and population stratification under the alternative admixture scenarios. We explored the effect of factors such as the number of parental populations, the number of informative markers, the availability of parental frequency data (only tested for STRUCTURE and ADMIXMAP) and the effect of misspecification of parental frequencies (only tested for ADMIXMAP).

Association Studies between the Angiotensin I-Converting Enzyme (ACE) gene Polymorphisms and Essential Hypertension in Koreans. *D.J. Shin¹, J. Kim¹, Y. Bae¹, E. Kim¹, J. Kim¹, H. Park², C. Park², S. Kim³, J. Lee³, Y. Jang², S.J.K. Yoon¹.* 1) Research Institute of Molecular Genetics, Catholic Research Institutes, Seoul, Republic of Korea; 2) Cardiovascular Genome Center, Yonsei University Medical Center, Seoul; 3) DNA Link, Inc, Seoul.

The gene encoding angiotensin I-converting enzyme (ACE) is one of the most important candidate genes in studies of the genetic susceptibility to blood pressure (BP) regulation and essential hypertension (EH). Although there are many reports demonstrating the association of ACE gene polymorphisms with EH in different ethnic populations, the results are still controversial. The aim of this study is to evaluate whether ACE variants are associated with an increased risk of EH in a sample of 916 unrelated Korean subjects, comprised of 458 sex- and age-matched normotensive controls and 408 hypertensive cases with clinically diagnosed hypertension. We examined six polymorphisms (A2400T, C2547T, ACE I/D, G14480C, A14519G and A22982G) in the ACE gene. We found that 2400AA and 2547TT homozygotes independently conferred an increased risk to high BP in hypertensive females only ($p=0.004$ and 0.013 , respectively). When the subjects were divided into two groups by onset age, the frequencies of 2400AA, 2547TT, II and 14519AA genotypes were significantly associated with BP in the females aged 55 years ($p=0.001$, 0.005 , 0.026 and 0.026 , respectively). Conversely, in the older female subjects aged 55 years and in males, neither systolic nor diastolic BP was not statistically significant among the genotypes. In the haplotype-based analyses, combining all six ACE variants, we found that only one set of haplotype (ATICAA) was positively associated with hypertension (OR 1.244; 95% CI 1.008-1.535; $p=0.042$) in the younger subjects. Additionally, the ACE gene haplotype structure of the hypertensives was more heterogeneous than that of the normotensives. Our results demonstrated that ACE gene haplotype was associated with EH and might interact positively with 2400A and 2547T alleles of ACE gene in younger Korean females aged 55 years. Therefore, further study in this field will have a close clinical relevance to EH and cardiovascular disease..

Establishment of Taiwan Han Chinese Cell and Gene bank: Comparing SNP profiles in MHC region with Caucasians. *W.H. Pan¹, C.S.J. Fann¹, J.Y. Wu¹, S.I. Hung¹, Y.T. Hung², Y.J. Chen¹, C.L. Hsu¹, C.J. Liao¹, Y.T. Chen¹.*
1) Inst of Biomed Sci, Academia Sinica, Taipei; 2) Dept of Political Sci, National Taiwan U, Taipei, Taiwan.

The purpose is several folds: (1) to preserve Taiwanese genetic materials, (2) to document their genetic variation, and (3) to serve as controls for disease gene mapping/association studies. 98 % of our population are composed of Chinese migrated from Fukien and Guandong provinces of China with the remaining 2 % of aborigines. We adopted a stratified, 3-staged, probability clustering sampling scheme. 329 non-aboriginal townships or city districts as primary sampling units (PSU) were grouped into 6 strata. Two to 8 PSUs were drawn in each stratum, proportional to its size. Then, 6 to 24 villages or city blocks were selected within each PSU. Within each village, included were 25 to 42 people aged 20 and older whose parents and grandparents were Han Chinese. This scheme was designed such that the proportion of samples in each stratum represents the distribution of the entire population and there were 278 subjects in each of the 6 age groups (20-, 30-, 40-, 50-, 60-, 70-) in men and in women, respectively. Plasma/DNA/lymphocytes were banked; blood chemistry, blood pressure, peak flow, and anthropometric parameters were measured; and questionnaire on ethnicity, disease history, life styles, and short portable mental status was administered. EBV-transformed lymphoblastoid cell lines were established. We completed the study in 3439 people. 94 individuals were randomly selected for SNP genotyping using MALTI-TOF mass spectrometry in the major histocompatibility complex (MHC) region (6p21.3). In 191 SNPs for which allele frequencies from 136 founders of CEPH families are available for comparison, 121 were significantly different ($p < 0.05$). Among these, 24 SNPs of CEPH families were not polymorphic in our population. For the remaining 70, allele frequencies were not statistically different. We conclude that SNP profiles in the MHC region differ considerably between Taiwan Han Chinese and CEPH families. This cell and gene bank is a powerful resource for studying genetic variation and disease association.

ALFRED The ALlele FREquency Database an update. *H. Rajeevan¹, K.-H. Cheung^{1,2}, S. Stein¹, H. Deng¹, J.R. Kidd¹, A.J. Pakstis¹, D. Chudnov², P.L. Miller², K.K. Kidd¹.* 1) Genetics, Yale U. Sch. Medicine, New Haven, CT 06520-8005 USA; 2) Medical Informatics, Yale U. Sch. Medicine, New Haven, CT.

ALFRED (<http://alfred.med.yale.edu>) is an actively curated database designed to make allele frequency data on anthropologically defined human population samples readily available to the scientific community. All data in ALFRED is considered to be in the public domain and available for use in research and teaching. All polymorphisms and most populations in ALFRED are linked to various external resources. The evolution of ALFRED has moved mainly in three directions: (1) a new GIS-based map interface to display population data on a map, (2) implementation of a new interactive data retrieval tool and synonyms/alternate names for ALFRED primary names, and (3) expansion of the database by increasing the quantity, quality, and accessibility of data in ALFRED.

The prototype SVG-based map interface will be replaced by a mature and stable product--GIS based map interface and analysis tools. This map interface will dynamically display all ALFRED populations and enable a user to make selections from the map based on geographic locations and then follow the links for population information or allele frequency tables. The new interactive data retrieval tool allows users to perform 2 types of searches: (1) seek entries in ALFRED, (2) seek frequency tables using gene and population names which will retrieve an updatable matrix of polymorphism x population indicating the presence or absence of frequency tables for each combination. ALFRED is updated daily and it currently has information on 987 polymorphic sites typed on at least one population sample and 358 populations typed for at least one polymorphism for a total of 21,010 frequency tables (one population typed for one site). Helpful search options and web viewing enhancements are also available from the web interface. For example, the list of publications underlying the data can now be searched by the name of any author and the allele frequency data linked to that particular publication can be quickly retrieved. ALFRED is supported by a grant from U.S. NSF BCS0096588.

Characterization of SNPs in human promoter sequences using dbQSNP, an SSCP-based SNP-

finding/quantification system. *T. Tahira*¹, *Y. Kukita*¹, *K. Higasa*¹, *Y. Suzuki*², *S. Sugano*², *K. Hayashi*¹. 1) Res Ctr Genetic Info, Med Inst Bioreg, Kyushu Univ, Fukuoka, Japan; 2) Dept Med Genome Sci, Grad School Frontier Sci, Univ Tokyo, Tokyo, Japan.

SNPs in promoter regions may potentially modify gene expression level and yield phenotypic diversity of individuals, i. e. disease susceptibility. We characterized SNPs in 1.2 kb genomic regions proximal to transcription start sites (TSS) at a large-scale using dbQSNP, a laboratory information management system that assisted SNP finding/allele frequency estimation by concerted analysis of SSCP and sequencing. SNPs found in this system were highly reliable, since most of SNPs were validated by two independent methods. We have screened SNPs in 8 Japanese individuals and collected 4969 SNPs in putative promoter regions of 3851 genes. Allele frequencies of 3134 SNPs were determined by quantifying SSCP peaks of two pools (Japanese and Caucasian) after compensating for unequal peak heights in heterozygotes, and 2138 of them were assigned as frequent SNPs (SNPs of minor allele frequency >10% in Japanese). To examine the efficiencies of our SNP-discovery pipeline, we Blast-searched the genomic regions targeted by us against external SNP databases. Approximately 34% of our SNPs (18% of our frequent SNPs) in these regions were new (not in dbSNP, build 121). Only one eighth of our SNPs was registered in JSNP. We compared our allele frequency values with those in JSNP using SNPs common in the two databases. The two values were in excellent correlation ($R^2 = 0.85$) although the subjects were independently collected in two distant areas in Japan, indicating Japanese as well mixed population. On the other hand, allele frequencies were strikingly different between Japanese and Caucasian ($R^2 = 0.40$). Some of the SNPs revealed high F_{st} values (>0.5), possibly due to differential selection between the two populations. All the above data were made accessible through dbQSNP Public.

Polymorphism in both promoters of Hepatocyte Nuclear Factor 4-alpha are associated with Type 2 Diabetes in the Amish. *C.M. Damcott¹, N. Hoppman¹, S.H. Ott¹, L.J. Reinhart¹, J. Wang¹, J.R. O'Connell¹, B.D. Mitchell¹, A.R. Shuldiner^{1,2}.* 1) Division of Endocrinology, Diabetes, and Nutrition, University of Maryland School of Medicine, Baltimore, MD; 2) Geriatric Research and Education Clinical Center (GRECC), Veterans Administration Medical Center, Baltimore, MD.

Hepatocyte nuclear factor 4-alpha (HNF4A) is a transcription factor that regulates expression of genes involved in glucose metabolism and insulin action. HNF4A is located on chromosome 20q13 in a region of overlapping linkage to type 2 diabetes (T2DM) in several Caucasian and Asian populations. Recently, two groups independently identified SNPs in an alternate upstream promoter (P2) of HNF4A that were associated with T2DM and explained a large portion of the reported linkage in their Ashkenazi Jewish and Finnish populations. We genotyped haplotype-tagging SNPs (htSNPs) across the two promoter regions and the coding region of HNF4A in individuals with T2DM (n = 137), impaired glucose tolerance (IGT) (n = 139), and normal glucose tolerance (NGT) (n = 342) from the Amish Family Diabetes Study (AFDS) to test for association with T2DM and related traits. We observed a significant association between the rs2425640 SNP in the P1 promoter region and T2DM (OR = 1.60; p = 0.03) and a borderline association between the rs1884614 SNP, an htSNP representing the haplotype block that includes the P2 promoter, and both T2DM (OR = 1.40; p = 0.09) and the combined T2DM/IGT trait (OR = 1.35; p = 0.07). We subsequently genotyped rs1884614 and rs2425640 in an expanded set of 821 nondiabetic AFDS subjects and found association between rs1884614 and glucose area under the curve during an oral glucose tolerance test (additive model: p = 0.022; dominant model: p = 0.010). The results of this study provide evidence that variants in both the P1 and P2 promoters of HNF4A increase risk for typical T2DM.

Linkage disequilibrium in the region of the putative diabetes gene, calpain-10 (*CAPN10*). *L. del Bosque Plata*¹, *M.G. Hayes*², *N.J. Cox*^{2,3}, *G.I. Bell*^{1,2,3}. 1) Biochemistry & Molecular Biology, Univ Chicago, Chicago, IL; 2) Human Genetics, Univ Chicago, Chicago, IL; 3) Medicine, Univ Chicago, Chicago, IL.

Patterns of linkage disequilibrium (LD) depend on a number of factors including population size and structure, founder effects and admixture, as well as gene-specific factors such as selection and rates of mutation and recombination. Recent studies have shown considerable heterogeneity in LD between regions and among populations suggesting it is important to characterize these underlying patterns in order to effectively use LD for fine-scale mapping of disease genes. We present here LD maps for several populations at calpain-10 (*CAPN10*) a gene associated with altered risk of type 2 diabetes mellitus. We analyzed 42 SNPs spanning a 483,498 bp region in 510 normal individuals of different ancestry: African American 50; European 62; Chinese (Southern Han) 49; Japanese 28; Mexican (mestizo) 52; and Amerindian 269 (Nahua 41, Otomie 57, Totonaca 43, Mazatecan 74, Huastecan 28 and Zapotecan 26). We used the measures D , r^2 , Collins and Mortons LD Units, and the population genetic parameter for recombination ρ (ρ), to assess LD differences between populations. One thousand bootstrap samples were collected to obtain the variance in estimates of D and the Wilcoxon signed-ranks test was used to test for significant differences in between populations. We found that *CAPN10* is located within a block of LD conserved across all populations although the level of LD varied between the populations. Across the entire region, we found lower levels of LD in African-Americans than in European and Asian populations. The Mexican group had more extensive LD than Europeans. The Amerindians had the most extensive LD with LD varying among the populations, both in extent and pattern, consistent with the complex and different patterns of demographic history in the different groups. We also found differences in population recombination rate ρ , among the different groups that we studied implying major differences in population history in this region.

Mitochondrial DNA variability in Koreans and Mongolians. *A.V. Lunkina*¹, *M.V. Derenko*¹, *T. Grzybowski*², *B.A. Malyarchuk*¹, *I.A. Zakharov*³, *D. Miscicka-Sliwka*², *D.T. Tsedev*⁴, *K.S. Park*⁵, *Y.M. Cho*⁵, *H.K. Lee*⁵, *Ch.H. Chu*⁶. 1) Genetics Department, Institute of Biological Problems of the North, Magadan, Russian Federation; 2) The Ludwik Rydygier Medical University in Bydgoszcz, Bydgoszcz, Poland; 3) Vavilov Institute of General Genetics, Moscow, Russia; 4) Institute of Biological Sciences, Mongolian Academy of Sciences, Ulaanbaatar, Mongolia; 5) Seoul National University, College of Medicine, Seoul, Korea; 6) Department of History, Kangwon National University, Chunchon, Korea.

Based on comprehensive mtDNA (HVR1/HVR2 sequencing combined with RFLP typing of informative coding region polymorphisms) analysis the gene pools of Koreans (N=164) and Mongolians (N=48) were characterized in details. It was shown that their gene pools are represented by a common set of East Eurasian mtDNA haplogroups (M7c, M8a, C, D4, G1a, G2, A, B4, B5, F1a, F1b, N9a). In addition to aforementioned haplogroups, haplogroups M7a, M7b, M9a, G3, F1c, D5, and Y were identified in Koreans, and haplogroups M10 and Z in Mongolians. Caucasoid-specific component represented by West Eurasian mtDNA haplogroups K, U4 and N1a was found only in Mongolians with a frequency of 10.4 per cent. The phylogenetic and statistical analyses results based on mtDNA variability data in South Siberian, Central and East Asian populations demonstrate the considerable degree of inter-population differentiation which is determined both by geographical and linguistical factors. Analysis of pairwise F_{ST} -distances has demonstrate the considerable genetic similarity between Koreans and Northern Han populations, which are, in turn, clearly differentiated from Southern Han populations. Mongolians occupy the intermediate position between South Siberian and Central/East Asian groups. This study was partly supported by Russian Foundation for Basic Research (grant N. 04-04-48746).

Genetic variation in "reproductive switch" and aging in *Drosophila*. *N. Abedi, M. Beikpoor, A. Zamiri, M. Zeinali, S.M. Hosseini-Mazinani, J. Koochmeshgi.* Research Institute for Life, Tehran, Iran.

Exploring evolutionary pressures underlying the relationship between reproductive parameters (e.g.: age at maturity) and aging is one of the key themes in aging research. We propose that "reproductive switch" is at the heart of this relationship. In a basic model, we divide the life history of an organism into two phases: pre-reproductive and reproductive. In the pre-reproductive phase, life is geared towards optimal health and in the reproductive phase towards optimal reproduction, though some aspects of organism's life in this phase may be detrimental to health in the long-term. This concept is consistent with the notion of antagonistic pleiotropy. The later an organism throws the "reproductive switch" and enters the reproductive phase, the longer it lives. We propose that there is an inherent genetic variation in the timing of reproductive switch. In some individuals in the population, this switch is thrown sooner, i.e. with less food intake and in some individuals later, i.e. with more food intake. This variation allows the population as a whole to adapt to varying levels of food availability. Based on this concept, we try to understand *Drosophila* breeding experiments that aim at life extension. We propose that overcrowding at the larval stage is the main factor in these experiments, bringing out the inherent variation in the timing of the genetic switch: Under overcrowded conditions, those larvae needing less food to throw the switch enter the reproductive phase of adult fly sooner but those needing more food take longer and consequently live longer. While under normal culture conditions of abundant food, all larvae reach the reproductive phase of adult fly more or less at the same time. Currently, we are focusing on a series of experiments based on this concept and investigating the possible effects of overcrowding on age at death, pattern of reproduction, and body size in individuals of populations of *Drosophila*.

Evidence of Homoplasmy in Insulin Degrading Enzyme (IDE) and the Implications for Studies of Association.

J.S.K. Kauwe¹, T. Maxwell¹, P. Novotny², S. Smemo², A. Goate², A. Grupe³. 1) Department of Biology, Washington University, St. Louis, MO; 2) Department of Psychiatry, Washington University School of Medicine, St. Louis, MO, USA; 3) Celera Diagnostics, Alameda, CA, USA.

We used 19 SNPs in 265 controls and 300 cases perform cladistic analyses of phenotypic association. Haplotypes were estimated using the software PHASE. A set of 95% plausible haplotype trees was estimated using statistical parsimony in TCS. The tree was inspected for recombination and recombinant haplotypes were removed. Haplotype categories were defined by a nesting algorithm. Association between Alzheimers disease and haplotypes were investigated using a series of nested contingency analyses. From the PHASE results we inferred the existence of 54 haplotypes in our sample population. Two statistically significant recombination events were detected in the tree ($p=0.05$ and 0.01). The tree also shows evidence of homoplasmy in most of these SNPs. No significant permutational chi-square values were detected in the nested contingency analyses. The results of the cladistic analyses of phenotypic association are consistent with the single SNP analyses of this population. However, the evidence of homoplasmy has some implications regarding the non-replication between samples, which is often observed between studies investigating this region. Sites showing homoplasmy are not ideal as single-site markers of association because identity by state does not reflect identity by descent. Under such conditions patterns of linkage disequilibrium can be complex, possibly resulting in increased rates of type II error. Thus, the use of homoplasious sites as single-site markers of association can confound traditional association studies and may contribute to our inability to replicate results between sample populations.

Characterization of melanocortin 1 receptor variants in Asians and Oceanians. *K. Nakayama*¹, *A. Soemantri*², *F. Jin*³, *S. Harihara*¹, *T. Ishida*¹. 1) Department of Biological Sciences, The University of Tokyo, Tokyo, Japan; 2) Diponegoro University, Semarang, The Republic of Indonesia; 3) The Chinese Academy of Sciences, Beijing, The Peoples Republic of China.

Melanocortin 1 receptor (MC1R), a Gs protein coupled receptor, plays a pivotal role in regulation of eumelanin and pheomelanin synthesis in melanocytes. The MC1R gene (*MC1R*) is known to be polymorphic among Europeans where several nonsynonymous variants of the *MC1R* have been associated with fair skin color and red hair. Such nonsynonymous variants show dramatic decrease in intracellular cAMP production following -melanocyte stimulating hormone (MSH) treatment. We previously identified nine nonsynonymous variants, Arg67Gln, Val92Met, Ile120Thr, Phe147, Arg151Cys, Thr157Ile, Pro159Thr, Arg163Gln and Ala166Gly, of the *MC1R* in 30 Asian and Oceanian populations; however, functional consequences of these variants are still unknown. To characterize the potential of intracellular cAMP production in these nine nonsynonymous variants, we measured activity of MC1R by using transient expression in COS-7 cells and enzymoimmunological assay. Among these nine MC1R variants, Phe147, Arg151Cys, Ile157Thr and Pro159Thr variants, which were identified among high latitude East Asians, showed dramatic decrease in cAMP production. These four variants were located in the second intracellular loop of MC1R that is important to G protein coupling; therefore, the decrease in cAMP production is expected to be caused by disruption of G protein coupling rather than insufficient -MSH binding. It is thus conceivable that the rare presence of individuals with blond hair and fair skin color in high latitude East Asians. Arg67Gln, Val92Met, Ile120Thr, Arg163Gln and Ala166Gly variant slightly lowered cAMP production compared with wild type MC1R, however, there were no substantial effects on dose-dependent response to -MSH stimulation. The present results support participation of nonsynonymous variants on the *MC1R* in variation in pigmentation phenotypes of Asians.

Recent Primate and ongoing human evolution of the CMT1A-REPs. *T. Ohyama*¹, *M. Khajavi*¹, *M. Hurles*², *J.R. Lupski*¹. 1) Dept. of Mol. & Human Genetics, Baylor College of Medicine, Houston, TX; 2) The Wellcome Trust Sanger Institute, Cambridge, UK.

Structural features of the human genome can result in a genome architecture leading to susceptibility for DNA rearrangements associated with genomic disorders such as Charcot-Marie-Tooth disease type 1A (CMT1A) and hereditary neuropathy with liability to pressure palsies (HNPP). This genome architecture consisting of region specific low copy repeats (LCR) provides homologous sequence substrates for nonallelic homologous recombination (NAHR) that result in DNA rearrangements. Previous studies indicate that LCRs evolved through segmental duplications during primate speciation and likely still undergo evolutionary changes potentially making the human genome more susceptible to genomic rearrangements. Here, we report the results of screening 96 DNAs from 48 world populations for CMT1A-REP LCRs using the HGDP-CEPH Human Genome Diversity Panel (www.cephb.fr/HGDP-CEPH-Panel/). In all analyzed populations we identified two CMT1A-REPs, but in the samples from Central Africa, we observed the presence of different sized bands. In order to examine the evolution of CMT1A-REPs, we identified and sequenced nonhuman primate BAC clones which contain the entire proximal CMT1A-REP in chimpanzee and distal CMT1A-REP in chimpanzee and gorilla, respectively. We concluded that CMT1A-REPs are dynamically evolving and the pattern and rate of nucleotide substitution potentially play a critical role in the continuous genome evolution.

Genetic Structure of Indian Populations. *N. Rosenberg*¹, *C. Gonzalez*², *L. Nino-Rosales*⁴, *V. Ninis*⁴, *P. Das*⁴, *L. Molinari*³, *G. Zapata*³, *J. Weber*⁵, *J. Belmont*³, *P. Patel*^{2,3}. 1) Dept Molec Comp Biol, Univ Southern California, Los Angeles, CA; 2) Institute for Genetic Medicine, Univ Southern California, Los Angeles, CA; 3) Dept Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 4) Dept Neurology, Baylor College of Medicine, Houston, TX; 5) Marshfield Clinic Research Foundation, Marshfield, WI.

There is a growing recognition of the importance of assessing genetic variation amongst various human populations, not only for understanding the origins and evolution of humans, but also because of its relevance to the genetic dissection of complex disease, and response to environmental agents, such as drugs. Despite the large diversity of peoples within India, populations from India have been largely underutilized in studies of genetic variation. We have begun a study of the structure of populations whose mother tongue is one of 15 major Indian languages by conducting a genome scan (Marshfield Panel 13) in 24 unrelated individuals from each group. Within one group that speaks Gujarati, we are analyzing 24 unrelated individuals from each of six villages in Gujarat State that practice endogamy to determine if such groups represent genetic isolates. Using these data, in conjunction with worldwide data on the same markers (Rosenberg et al., *Science* 298:2381-2385, 2002), we will determine the pattern of population structure and admixture within India, and we will analyze the relationships of groups from India to those from other parts of the world. The analysis will identify markers of particular informativeness for ancestry inference within India, and will be more broadly applicable to genetic mapping in individuals of Indian ancestry.

Mitochondrial polymorphism in prehistoric and present-day Andean populations of Chile: Signatures of chronological evolution and population size changes. *F. Rothhammer*¹, *S.A. Barton*², *R. Chakraborty*³. 1) Human Genetics Program, Faculty of Medicine, University of Chile, Santiago, Santiago 7, Chile; 2) Human Genetic Center, Univ. Texas School of Public Health, Houston, TX; 3) Center for Genome Information, Dept. Environmental Health, Univ. Cincinnati, Cincinnati, OH.

To investigate whether or not the prehistoric populations of Chile represent the ancestors of the present-day native populations of Chile, this research used the mitochondrial haplogroup and control region sequence data recently published from these populations under the framework of analysis of longitudinal population-based data. Data analyzed consists of haplotype information from 61 prehistoric mtDNA samples (of age ranging from 3,900 to 500 yrs old), and 172 contemporary individuals. The results indicate that the temporal changes of mtDNA haplogroup diversity and sequence mismatch distributions between samples of contemporary and prehistoric populations are consistent with the hypothesis of chronological evolution. This observation is also confirmed by phylogenetic reconstruction of control region sequence evolution of 30 prehistoric samples, and 43 contemporary samples. During the period of 3,900 years of evolution, the haplogroup A showed evidence of declining frequencies over time, with conjoint increase of the frequency of haplogroup B. Analysis of data under the framework of temporal evolution suggests considerable changes of effective population size over time (i.e., reduction of effective size by at least one-third, over the last 500 years of evolution), with evolutionary rates of divergence in the mtDNA genome remaining virtually unchanged over time. Low frequency of haplogroup B in prehistoric populations of Chile has also relevance for natural history of disease occurrences in this part of this region, particularly for diseases that are influenced by mitochondrial mutations. (Data analysis of this research is supported by NIH grant GM 41399 to RC).

A robust test of selective neutrality of SNPs in different pathways of environmentally relevant genes. X. Sheng, R. Chakraborty. Ctr Genome Information, Univ Cincinnati, Cincinnati, OH.

Resequencing efforts of the NIEHS-sponsored environmental genome project (EGP) have generated a public domain database of single nucleotide polymorphism (SNP) sites residing on a large number of environmentally relevant genes of different pathways (<http://egp.gs.washington.edu>). Genotypes on these SNP sites have been scored on individuals of different anthropological origin, making this database subject to population substructure effects. Consequently, to examine whether or not these SNP sites are subject to forces of natural selection, analytic methods have to be robust against the impact of population substructure effects. Under the assumption that the SNP sites follow the infinite site model of mutations, the contribution to relative heterozygosity, plotted against the gene frequencies of alleles, provide such a robust test. Extracting polymorphism data on a total of 10,152 SNPs on 92 genes belonging to 7 pathways (apoptosis; cell cycle; base excision repair, BER; nucleotide excision repair, NER; transcription coupled repair, TCR; double strand break repair, DSB; and mismatch repair, MMR) from the EGP database, we conducted tests of selective neutrality of these SNPs. Our results indicate that SNPs on three pathways have mild signatures of natural selection (deleterious selection effects seen for 2,601 SNPs on 26 genes of the BER pathway, and for 1,030 SNPs of 4 genes of the MMR pathway, and overdominant selection effect for 1,397 SNPs on 12 genes of the DSB pathway). These results are not always consistent with alternative tests already performed on this dataset, and in part this discordance is due to the effect of underlying population substructure present in the database. Considering that our test procedure (based on relative heterozygosity contributed by alleles of different gene frequency classes) is invariant under population substructure, we conclude that this robust test provides indications of existence of both overdominant and deleterious mutations in maintaining polymorphisms at SNP sites residing on functional genes of several pathways. (Research supported by the NIH grant GM 41399 to RC).

Accelerated evolution of the PACAP precursor gene during human origin. *B. Su*^{1,2}, *YQ. Wang*¹, *YP. Qian*², *S. Yang*¹, *H. Shi*¹, *CH. Liao*¹, *HK. Zheng*³, *J. Wang*³, *A. Lin*⁴, *L. Cavalli-Sforza*⁴, *P. Underhill*⁴, *R. Chakraborty*², *L. Jin*^{2,5}.

Pituitary adenylate cyclase-activating polypeptide (PACAP) is a neuropeptide abundantly expressed in the central nervous system, and involved in regulating neurogenesis and neuronal signal transduction. The amino acid sequence of PACAP is extremely conserved across vertebrate species, indicating a strong functional constraint during the course of evolution. However, through comparative sequencing, we demonstrated that the PACAP precursor gene underwent an accelerated evolution in the human lineage since the divergence from chimpanzees, and the amino acid substitution rate in humans is at least seven times faster than in other mammal species resulting from strong Darwinian positive selection. Eleven human-specific amino acid changes were identified in the PACAP precursors which are conserved from murine to African apes. Protein structural analysis suggested that a putative novel neuropeptide might have originated during human evolution and functioned in the human brain. Our data suggested that the PACAP precursor gene underwent adaptive changes during human origin and may contribute to the formation of human cognition.

Genetic evidence supports demic diffusion of Han culture. *B. Wen¹, H. Li¹, D. Lu¹, X. Song¹, F. Zhang¹, Y. He¹, F. Li¹, Y. Gao¹, X. Mao¹, L. Zhang¹, J. Qian¹, J. Tan¹, J. Jin¹, W. Huang², R. Deka³, B. Su^{1,3,4}, R. Chakraborty³, L. Jin^{1,3}.*

1) Institute of Genetics, Fudan University, Shanghai, Shanghai, China; 2) Chinese National Human Genome Center, Shanghai, China; 3) Center for Genome Information, Department of Environmental Health, University of Cincinnati, Cincinnati, OH; 4) Key Laboratory of Cellular and Molecular Evolution, Kunming Institute of Zoology, the Chinese Academy of Sciences, Kunming, Yunnan, China.

The spread of culture and language in human populations is explained by two alternative models: the demic diffusion model (DDM) which involves massive movement of people, and the culture diffusion model (CDM) that refers to the occurrence of mainly cultural impact between populations with limited genetic exchanges. The mechanism of the peopling of Europe has long been debated on whether the diffuse of agriculture and language from Near East was concomitant with substantial movement of farmers. The Han people which share the same culture and language exceeds 1.16 billion (2000 census), and is by far the largest ethnic group in the world. To understand the expansion process of Han culture is thus of great interests to researchers in many fields. Here we show, by systematically analyzing Y chromosome and mitochondrial DNA (mtDNA) variations in the extant Han populations, the pattern of the southward expansion of Han culture is consistent with DDM, and more interestingly, males played a larger role in this expansion.

Selective trends in 22 bitter-taste receptor genes. *S. Wooding*¹, *U.-k. Kim*², *L.B. Jorde*¹, *D. Drayna*². 1) Dept. of Human Genetics, Univ. of Utah, Salt Lake City, UT; 2) NIDCD, NIH, Rockville, MD.

Bitter-taste perception in humans is mediated by a small family of G-protein coupled receptors that reside on the surface of taste buds, where they are exposed to potential ligands as they pass over the tongue. Anecdotal evidence has long suggested that bitter-taste perception played an important role in the course of human evolution by allowing humans to detect and avoid the many bitter toxins produced by plants as a means of defense against herbivores. Patterns of variation in one bitter-taste receptor gene, T2R38, are consistent with the view that balancing natural selection has fostered high levels of diversity. To determine whether other bitter taste receptor genes have been under similar selective pressures, we resequenced the complete coding regions of 21 bitter taste receptor genes in 60 humans from Africa (n = 31), Asia (n = 10), Europe (n = 9), and North America (n = 10). Tajima's D test for selective neutrality revealed that when tested individually, no D value departed significantly from theoretical expectation; however, the mean observed D value (= -0.36) was significantly greater than theoretical expectation under the assumption of population growth ($p < 0.01$) and was also significantly greater than the mean in a sample of more than 1600 other genes ($p < 0.01$). Similarly, while no individual FST value was significantly greater than expected, the mean observed FST was significantly greater than a simulated expectation ($p < 0.01$) and was also significantly greater than the mean in a sample of more than 25,000 SNPs. These findings suggest that human populations are, on average, more different with respect to bitter-taste receptor genes than they are with respect to other regions of the genome, a pattern best explained by the effects of recent local adaptation.

Rapid evolution of two Pexin-domain-containing proteins in Primates; implications for Human disease. *G.J. Wyckoff, A. Bulavtseva, J.E. Paschall, M. Yang.* Div Molec Biol & Biochemistry, Univ Missouri, Kansas City, Kansas City, MO.

We undertook to examine the evolution of matrix metalloproteinase genes within primates. Hemopexin (HPX) and matrix metalloproteinase 12 (MMP12) are both members of the metalloproteinase family of proteins, which bind free metal ions (e.g., copper or iron) in the body. Mutation or dysfunction in matrix metalloproteinase genes may be important causal factors in human disease, as they protect against oxidative stress. Absence of MMP12 in model organisms leads to greater rates of emphysema, whereas HPX is a potential biomarker for Alzheimers Disease and may be causally involved with the disease state. In examining 16,000 human-mouse gene orthologs and more than 200,000 protein motifs, we determined that both HPX and MMP12 contain hemopexin-like repeat domains that are rapidly evolving and have Ka/Ks rates above 1.0: a hallmark of positive, Darwinian selection. The N-terminal Pexin-domain in HPX has a Ka/Ks ratio of 1.1 between humans and mice, compared with a gene-wide average of 0.4. The C-terminal Pexin-domain of MMP12, in contrast, has a Ka/Ks of 0.81, versus a gene-wide average of 0.5 for the mouse-human ortholog comparison. Analysis of fixed differences in this region shows that rare amino acid changes are abundant. Although there are many members of the metalloproteinase gene family, only HPX and MMP12 showed convincing evidence of Darwinian selection. Our further examination of human polymorphism in these genes suggests that Darwinian pressure has been active during the evolution of these genes in primates. Since HPX and MMP12 are demonstrably under selection, possibly due to their functional roles, we suggest that this evolutionary analysis may help to augment future research into diseases associated with oxidative stress.

Adaptive evolution of MrgX2, a human G protein coupled receptor involved in nociception. *S. Yang¹, Y. Liu¹, A. Lin³, L. Cavalli-Sforza³, B. Su^{1,2}.* 1) Kunming Institute of Zoology, the Chinese Academy of Science, Kunming, Yunnan, China; 2) Center for Genome Information, Department of Environmental Health, University of Cincinnati, Cincinnati, OH; 3) Department of Genetics, Stanford University, Stanford, CA.

MrgX2 is a G-protein coupled receptor which is specifically expressed in the sensory neurons of the peripheral nervous system and involved in nociception. We sequenced the coding region of the MrgX2 gene in world-wide human populations and seven representative nonhuman primate species. Our results indicated that MrgX2 evolved rapidly in primates, especially in the lineage leading to humans. We observed four fixed amino acid substitutions in humans that were caused by strong Darwinian positive selection, implying that MrgX2 has undergone adaptive changes during human evolution. By reconstructing the secondary structure of the human MrgX2, we demonstrated that three of the four human-specific amino acid substitutions are located in the extra-cellular domains, and may alter the interaction between MrgX2 and its ligand, consequently, contributing to the adaptive change of human nervous system during human origin.

Evolution of abcr proteins in vertebrates. *A.N. Yatsenko, W. Wiszniewski, M. Jamrich, J.R. Lupski.* Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

The *ABCR* (*ABCA4*) gene encodes a retinal-specific ATP-Binding Cassette transporter. Mutations of *ABCA4* are responsible for several macular degenerations. The protein appears to function as a flippase of all-*trans*-retinaldehyde (*atRAL*) and/or its derivatives across the membrane of outer segment (OS) disks, and is a potentially important element in recycling visual cycle metabolites. However, our understanding of the role of ABCR in the visual cycle is limited due to the lack of a direct functional assay. An evolutionary analysis of ABCR may aid in the identification of conserved elements, the preservation of which implies functional importance. To date, only human, murine, and bovine *ABCR* genes have been described. We have identified *abcr* genes from African (*X. laevis*) and Western (*S. tropicalis*) clawed frogs. Using sequences of the frog *abcrs*, annotated *T. rubripes* *abcr*, and mammalian ABCR proteins, we performed a comparative analysis and describe the evolutionary relationships between the vertebrate *abcrs*. We note that in addition to the transmembrane and ATP-binding domains, several segments are conserved in both intradiscal loop (IL) domains. Nonconserved segments were found in the IL and cytoplasmic linker (CL) domains. Our collective data support the current model that two distinct *abcr* progenitors (half-transporters) combined to form a full *abcr* progenitor in ancestral chordates. We speculate that evolutionary alterations may increase the retinoid metabolite recycling capacity of ABCR, and potentially improve dark adaptation.

Ethiopia: between Sub-Saharan Africa and Western Eurasia. *V. Yotova*¹, *A. Lovell*¹, *C. Moreau*¹, *S. Bourgeois*¹, *F-X. Xiao*¹, *D. Gehl*¹, *J. Bertranpetit*², *E. Schurr*³, *D. Labuda*^{1,4}. 1) Centre de Recherche, Hopital Sainte-Justine, Universite de Montreal, Montreal, Quebec, Canada; 2) Unitat de Biologia Evolutiva, Universitat Pompeu Fabra, Barcelona, Catalonia, Spain; 3) Centre for the Study of Host Resistance, McGill University, Montreal, Quebec, Canada; 4) Departement de Pediatrie, Universite de Montreal, Montreal, Quebec, Canada.

Situated at the gateway of the southern out-of-Africa route, Ethiopia has become central to population genetic studies investigating the out of Africa expansion of modern humans, as shown by Y chromosome and mtDNA studies. To gain a complementary perspective to the contribution of the maternal or paternal lineages, we have analyzed a sample of 72 chromosomes from Semitic speaking Amhara, Cushitic speaking Oromo and Ethiopian Jews with the X-linked 8kb *dys44* haplotype at Xp21, and compared these results with 826 chromosomes from Middle Eastern, African, Asian and European populations. We report that the distribution of alleles of a variable T_n repeat, and the spread of haplotypes containing Africa specific alleles, provides evidence of a genetic continuity from Sub-Saharan Africa to the Near East, and furthermore suggests that a bottleneck occurred in Ethiopia. Ethiopian genetic heterogeneity, most likely resulting from periods of admixture, can clearly be seen in principal component analysis of haplotype frequencies. The two largest ethnic groups of Ethiopia, the Amhara and Oromo, were not found to be statistically distinct, based on an exact test of haplotype frequencies, presumably due to widespread gene flow within and across the region. The Ethiopian Jews also appear as an admixed population, possibly of Jewish origin, though the current data does not allow confident conclusions to be drawn regarding their ancestry. However, evidence of a closer relationship between Ethiopian and Yemenite Jews is provided, likely a result of indirect gene flow between the two and/or neighboring populations.

Signature of a selective sweep at the human CYP3A locus. *K.R. Ahmadi¹, S. Tate¹, M.E. Weale¹, Z.Y. Xue², N. Soranzo¹, D.P. Yarnall², J.D. Briley², T.D. Spector³, N.K. Spurr², D.K. Burns², A.D. Roses², A.M. Saunders², D.B. Goldstein¹.* 1) Biology (Galton Labs), University College London, London, UK; 2) Genetics Research, GlaxoSmithKline, Research Triangle Park, North Carolina; 3) Twin Research & Genetic Epidemiology Unit, St Thomas Hospital, London, UK.

The members of the CYP3A subfamily are the most abundantly expressed cytochrome P450 enzymes in the liver and are responsible for the metabolism of around half of all prescribed drugs. Until now there have not been a systematic study into the role of selection in shaping the genetic diversity at this locus. Our aim was to study the pattern of variation at the CYP3A locus in the CEPH and the Japanese. We genotyped a total of 67 SNPs throughout the CYP3A cluster (1 SNP / 3.5 kb). In support of previous reports our results showed that in the CEPH no SNPs were found to have a frequency higher than 7% in almost 150 kb of this cluster. We also found a similar consistent pattern in the Japanese although in this population all but 3 of the variants had a minor allele frequency between 25 and 30% ($F_{st} \sim 0.2$). The pattern of LD in the two populations was remarkably similar with the cluster falling almost entirely into a single block of LD with the same 2 haplotypes making up 95% of the total haplotype diversity. We used the data from the HapMap to show that at least in the CEPH this remarkable lack of diversity over such a long stretch of the human genome is rare. We speculate that the most likely target for this selection is the CYP3A5*3 splice variant which is responsible for a significant reduction in functional CYP3A5 protein and has been previously associated with systolic BP (sBP) in African Americans. To look at the pattern of geographic variation for this allele, we genotyped the *3 allele in populations from Southern Italy, China, India, Ethiopia, Cameroon, the Pacific, and a total of 877 Caucasian female individuals from the adult twin registry in the UK with sBP and diastolic BP (dBP) measurements. Our results show a remarkable degree of differentiation for the ancestral allele with a global F_{st} value close to 0.3. We fail however to show a significant association between the *3 allele and sBP and dBP in Caucasians.

Positive selection in MAOA gene is human exclusive: determination of the putative amino acid change selected in the human lineage. *A.M. Andres^{1,4}, M. Soldevila¹, A. Navarro¹, K.K. Kidd², B. Oliva³, J. Bertranpetit¹*. 1) Unitat de Biologia Evolutiva, Facultat de Ciències de la Salut i de la Vida, Universitat Pompeu Fabra (UPF), Barcelona, Spain; 2) Department of Genetics, Yale University School of Medicine, New Haven, USA; 3) Laboratori de Bioinformàtica Estructural (GRIB), Universitat Pompeu Fabra, Barcelona, Spain; 4) Current address: Molecular Biology and Genetics, Cornell University, Ithaca, NY, USA.

Monoamine oxidase A (MAOA) is the X-linked gene responsible for deamination and subsequent degradation of several neurotransmitters and other amines. Among other activities, the gene has been shown to play a role in locomotion, circadian rhythm and pain sensitivity, and to have a critical influence on behavior and cognition. Previous studies reported a non-neutral evolution of the gene, due to positive selection in the human lineage. To determine whether this selection was human-exclusive or shared with other species, we performed a population genetic analysis of the pattern of nucleotide variation in non-human species, including bonobo, chimpanzee, gorilla, and orangutan. Footprints of positive selection were absent in all but the human lineage, suggesting that positive selection has been recent and unique to humans. To determine which human-unique genetic changes could have been responsible for the differential evolution, the whole coding region of the gene was compared between human, chimpanzee and gorilla. Only one human exclusive non-conservative change is present in the gene: Glu151Lys. This human substitution affects protein dimerization according to a 3D structural model that predicts a non-negligible functional shift. It is the only candidate position at present to have been selected to fixation in humans during an episode of positive selection. Divergence analysis among species showed that, even under positive selection in the human lineage, the MAOA gene did not experience accelerated evolution in any of the analyzed lineages.

Segmental duplications define regions of chromosome and gene evolution in mammal genomes. *L. Armengol¹, J. Cheung², T. Marquès-Bonet³, A. Navarro³, S.W. Scherer², X. Estivill¹.* 1) Center for Genomic Regulation, Barcelona, CATALUNYA; 2) Department of Genetics and Genomics, Hospital for Sick Children, Toronto, Canada; 3) Pompeu Fabra University, Barcelona, CATALUNYA.

Segmental duplications (SDs) are known to have a role in gene evolution. Both generating new copies of genes that can accumulate mutations without being constrained by evolution and by generating totally new genes by fusion of different transcripts. A role in chromosomal evolution has also been suggested since they have been found to be enriched in human/mouse synteny breakpoints. We decided to confirm this implication of SDs in synteny breakpoints and we used two evolutionary close organisms whose genomic sequences are available: rat and mouse. Latest alignments between mouse and rat genome sequences were obtained from the UCSC. Over 1.5 million anchors were chained into 1953 syntenic clusters longer than 250 kb (Manhattan distance). Those were further grouped into higher order structures and resulted in a total of 102 synteny blocks. These synteny blocks defined 82 and 81 regions of break of synteny (BOS) respectively in the mouse and rat genomes. GC content, repeat composition, gene content, and presence of SDs was assessed in the whole no-block regions and in a region of +/-25 kb around the boundaries of the breaks of synteny. No significant differences in GC content or in repeat composition were observed. Gene content analysis revealed that breakpoint regions are gene rich regions, while no differences are observed if we compare no-block and syntenic regions. SDs were present in the majority of synteny break regions both in the mouse and in the rat genomes. When compared to a random distribution of breakpoints along the chromosomes, the association was very significant. Rates of evolution (Ka/Ks ratio) were also calculated, and were found to be higher for genes in no-block regions than for the rest of genes in the genome. This difference was even higher when taking into account genes located on SDs. The confirmation of the presence of SDs in regions of BOS in species from a different evolutionary lineage reinforces the view of a role of SDs as hotspots for chromosomal evolution.

Y-chromosomal SNP-STRs variation in Russian populations of Eastern Europe. *M.V. Derenko¹, B.A.*

Malyarchuk¹, M. Wozniak², T. Grzybowski², J. Czarny², D. Miscicka-Sliwka². 1) Institute of Biological Problems of the North, Magadan, Russia; 2) The Ludwik Rydygier Medical University in Bydgoszcz, Forensic Medicine Institute, Bydgoszcz, Poland.

We analyzed 12 Y-chromosomal SNP markers (RPS4Y, SRY-8299, M89, 12f2, M9, M20, 92R7, SRY-10831, DYS199, Tat, LLY22g, YAP at DYS287) and 10 microsatellite markers (DYS19, DYS385, DYS389, DYS390, DYS391, DYS392, DYS393, DYS437, DYS438, DYS439) in 338 males from 8 Russian populations of Eastern Europe. SNP analysis demonstrates that Russian gene pool is very close to central-eastern European populations. In AMOVA analysis using SNP markers, 5 per cent of the Y-chromosome variation was found between Russian populations. The MDS analysis based on Y haplogroup FST values revealed that the strongest division was between some northern Russian populations (Pskov and Pomor Russians) together with all Uralic- and Baltic-speaking populations and the remaining Russian populations clustered together with Slavonic-speaking groups (such as Poles, Ukrainians, Belorussians). Similarity of northern Russians with Uralic- and Baltic-speaking populations of Eastern Europe may be explained by increased frequency of haplogroup N3 (more than 35 per cent) found in these populations. Y-STR analysis within haplogroup N3 allowed determining a ratio of Uralic and Baltic variants of haplogroup N3 distinguished by a difference at DYS19 (Zerjal et al. 2001). Our study shows that high frequency of haplogroup N3 in Pskov population is caused by the presence of Baltic-specific STR-haplotypes (64 per cent of N3-chromosomes), whereas, in average, 80 per cent of N3 haplotypes found in the majority of Russian populations from central and southern regions of European Russia are characterized by Uralic-specific STRs. This work was supported by the Russian Fund for Basic Research (03-04-48162) and the Polish State Committee for Scientific Research (3P04C 04823, 2002-2005).

Haplotype diversity and sequence divergence in segmental duplications. *M.E. Hurles¹, S.J. Lindsay¹, S.E. Hunt¹, M. Khajavi², J. Lupski².* 1) Wellcome Trust Sanger Institute, Cambridge, United Kingdom; 2) Dept. of Molecular and Human Genetics, Baylor College of Medicine, Texas, USA.

The human genome appears enriched for segmental duplications compared to other mammalian and non-mammalian genomes. Many of these segmental duplications are sufficiently similar that they can be recognised as substrates for homologous recombination during meiosis. The resulting Non-Allelic Homologous Recombination (NAHR) events can generate disease-causing rearrangements and gene conversion mutations as well as structural polymorphisms. The complexity of studying high copy number sequences has caused the medical and evolutionary consequences of NAHR to be under-ascertained. This is especially true for studies of complex diseases and of the evolution of duplicated genes. Sequence variation among individuals is key to understanding both of these issues. It has been noted that single nucleotide polymorphisms (SNPs) in dbSNP are enriched within segmental duplications, although there is debate as to whether this apparent increase in sequence diversity is real or artefactual. We have developed a novel method for experimentally determining haplotypes within segmental duplications called Anchored Shotgun Haplotyping. We have applied this method to generating datasets of haplotypic variation in and around known hotspots of NAHR activity within several segmental duplications. We have characterised the sequence variation within humans as well as sequence divergence between humans and other hominoid species. These data are complemented with analyses of SNPs derived from flow-sorted chromosomes that map to inter-chromosomal segmental duplications. We find sequence variation to be significantly elevated within humans and between hominoids within specific portions of some segmental duplications. Simulations suggest that these data are best explained by localised gene conversion between segmental duplications. The complex haplotypic structures that are formed may confound association-based searches for genes underlying complex disease, but potentially facilitate the identification of rearrangement hotspots from comparative genome sequences.

The evolutionary conservation of four satellite III DNA subfamilies among primates. *M. Jarmuz*¹, *R.*

*Bandyopadhyay*², *C.D. Glotzbach*^{1,3}, *K.A. Bailey*^{1,3}, *A.L. Rosa*^{1,3}, *L.G. Shaffer*^{1,3}. 1) Health Research and Education Center, Washington State University, Spokane; 2) Department of Human and Molecular Genetics, Baylor College of Medicine, Houston, TX; 3) Sacred Heart Medical Center, Spokane, WA.

Satellite DNA likely plays an important role in eukaryote chromosome structure and karyotypic evolution through the facilitation of exchange events. In the present study, we analyzed satellite III DNA (satIII DNA) from two subfamilies characterized by their sequence composition: the GGAAT monomer sequence is predominant in the first group, whereas in the second a roughly equal representation of GGAAT and GGAGT motifs are found. Both groups are present in the short arms of the acrocentric chromosomes and in chromosomes 9 and Y in human and share high homology. In our study, we determined the distribution of four subfamilies of satIII DNA from group 1 (pTRS-63, pW-1) and two from group 2 (pR-4, pTRS-47) in 25 primate cell lines by FISH, Southern hybridization and PCR with primers specific to each subfamily. We also determined the presence or absence of the subfamilies in four human reference cell lines and a panel of monochromosomal hybrids of the acrocentric chromosomes. Using FISH with each subfamily as a probe we determined the chromosomal distribution and co-localization of satIII DNA with the rRNA genes in each species. These satIII subfamilies were not detected in squirrel monkey, african green monkey, baboon, or rhesus monkey but were found in orangutan, indicating that these subfamilies appeared suddenly in this species. The orangutan contains the largest number of satIII-bearing chromosomes (n~19), with a reduction in gorilla, chimpanzee and human to only 2-12 chromosomes, depending on the subfamily. These subfamilies co-localize with rDNA genes in all of the acrocentric chromosomes in orangutan, whereas in gorilla co-localization is present for only one chromosome pair or is absent depending on the subfamily. Chimpanzee and human share the most similar patterns with co-localization on one to five pairs of acrocentric chromosomes depending on the subfamily. These results show striking interspecies variability among primates and support the appearance of satIII DNA ~10 MYA in primates.

PTC-tasting and negative evidence for balancing selection. *K.K. Kidd¹, A.C. Davidson¹, A.J. Pakstis¹, W.C. Speed¹, L. Bartoshuk², V. Duffy^{2,3}, J.R. Kidd¹.* 1) Dept Genetics, Yale U. Sch. Medicine, New Haven, CT; 2) Dept Surgery, Yale U. Sch. of Medicine, New Haven, CT; 3) School of Allied Health Sciences, U. of Connecticut, Storrs, CT.

Recent studies identify the *TAS2R38* taste receptor gene on 7q as the primary influence on the classical PTC taste threshold polymorphism. One study concluded that human population frequencies support R.A.Fishers hypothesis that balancing selection maintains this polymorphism. We report a much larger and extensive global sampling (over 2000 individuals, 40 populations) than previous studies for 3 coding region SNPs and 3 flanking SNPs as well as sequence data for multiple individuals from each of several other species of apes. Five of 8 possible haplotypes for the coding SNPs occur in our samples with two very common haplotypes worldwide corresponding to the classical taster and non-taster phenotypes. A third common haplotype occurs in African populations (5%-44%) and two low frequency haplotypes are found in various African and European samples. The average frequency of the taster haplotype differs substantially across the populations of the major geographical regions about 0.45 in Africa, 0.5 in S.W.Asia, 0.4 in Europe, 0.6 in East Asia, and 0.8 in the Americas. High levels of LD characterize the coding region spanning ~1KB. Sequence results in 5 ape species indicate the presence of different, non-conserved polymorphisms for this gene. Non-taster, null alleles occur in chimpanzee and orangutan that differ from each other and from human non-taster alleles. While the pattern of 2 high frequency alleles outside of Africa is consistent with balancing selection, the frequencies vary significantly among populations. We conclude that weak purifying selection and random genetic drift may best explain the global distribution. Published studies have also implicated differences in taste perception with dietary choices that have important health outcomes. Our ability to characterize the *TAS2R38* receptor at the molecular level now make possible studies to disentangle the multiple factors affecting taste of bitter substances. Supported in part by NIH grants GM57672 and AA09379 (KKK) and NSF SBR-9632509 (JRK).

Evolutionary insights into drug metabolism: Evidence for positive selection in Drug Metabolism and Drug transporter genes. *H.A. Madsen¹, C.A. Sprankle², A.M. Saunders², N.K. Spurr², D.K. Burns², M.J. Stanhope¹, B.T. Koshy².* 1) Bioinformtic Sciences, Glaxo Smith Kline, Collegeville, PA-19426; 2) Genetics Research, Five Moore Drive, Research Triangle Park, NC-27709.

Most genes reported to be under diversifying selection involve host pathogen responses. There has also been evidence of diversifying selection on genes involved in olfaction, as well as on the tumor suppressor gene, BRCA1. We utilized a comparative evolutionary approach to understand genetic selection pressure involved in the phenotypic differences in drug metabolism between humans and species that are used for pharmacokinetic and toxicological evaluation of drugs such as rodents and non-human primates. We examined the sulfotransferases (SULT1A), a key enzyme family which plays an important role in the metabolism and bioactivation of many endogenous compounds and xenobiotics, as well as the ABCB1 drug transporter which has been implicated in the phamacokinetics of many drugs. The PAML (phylogenetic analysis using maximum likelihood) package was used to search for evidence of positive (diversifying) selection. The omega ratio (dN/dS ratio), a commonly used criterion for detecting adaptive evolution, quantifies the rate of non-synonymous to synonymous substitution; an omega>1 indicates that natural selection is favoring non-synonymous codon changes over synonymous codon changes. A comparison of SULT1A and ABCB1 mRNAs from ten mammalian species revealed several sites that had an ratio greater than 1. One of these sites, codon 89 in SULT1A, varies among human isozymes and affects substrate specificity. Our findings are intriguing and indicate that differential selective pressures operating on drug metabolizing enzymes and transporters may have important implications for drug discovery.

The CAG-repeat polymorphism of the DNA polymerase gamma gene in North Eurasian human populations. *B.A. Malyarchuk¹, M. Papuga², T. Grzybowski², M. Wozniak², M.V. Derenko¹, J. Czarny², I.A. Zakharov³, D. Miscicka-Sliwka².* 1) Institute of Biological Problems of the North, Magadan, Russia; 2) The Ludwik Rydygier Medical University in Bydgoszcz, Forensic Medicine Institute, Bydgoszcz, Poland; 3) Vavilov Institute of General Genetics, Moscow, Russia.

To estimate the level of variability of the nuclear gene for the catalytic subunit of mitochondrial DNA polymerase gamma (POLG), polymorphism of the CAG microsatellite repeat was studied in 1155 healthy individuals representing 18 populations of North Eurasia. These samples were grouped into three geographic areas: Europe, Southwest Asia and Siberia/East Asia. We have observed that 10-repeat allele of POLG gene is the most frequent in all populations studied, being found at frequency of 96, 93 and 88 per cent in Siberian/East Asian, Southwest Asian and European populations, respectively. The frequency of 11-repeat allele ranges from 9 per cent in Europe to 5.7 per cent in Southwest Asia and to 3.3 per cent in Siberia/East Asia. The remaining alleles ranging from 6 to 13 repeats were found at very low frequencies, with a maximum number of private alleles in Europe (6-8-repeats). The heterozygosity ranges from 22 per cent in Europe and 13.6 per cent in Southwest Asia to its lowest value of 7.4 per cent in Siberia/East Asia. Out of 13 observed POLG genotypes, only four of them are in common among human populations studied, but seven and two different genotypes were found as private ones, in European and Siberian/East Asian populations, respectively. Differences among regional groups account for 2 per cent of the total variation. Finally, the present study provides evidence for a clinal distribution of POLG gene heterozygosity in North Eurasian populations. This pattern could be related to the demographic history of human populations (including human migrations and genetic drift), meanwhile the effect of balancing selection (at least, in European populations) should also account for the observed differences. This work was supported by the Ludwik Rydygier Medical University in Bydgoszcz (grant BW 61/04) and by the grant from the Far-East Branch of the Russian Academy of Sciences (04-3-A-06-039).

Program Nr: 1178 from the 2004 ASHG Annual Meeting

Treescan: A method using haplotype networks to direct genotype/phenotype association studies. *T.J. Maxwell, A.R. Templeton, MICORTEx*. Department of Biology, Washington University in STL, St. Louis, MO.

Tree-scanning walks across a haplotype network using each side of an evolutionary branch to define a two-allele system. The first step is to build a phylogenetic network and test for recombination. The resulting nonrecombinant network is used to define a set of *a priori* contrasts by splitting each branch to divide the haplotypes into two groups of alleles. Phenotypic permutations across the resulting genotypes defined by the two alleles are used to find the significance of each contrast (different statistics for discrete or continuous data) with a multiple tests correction that retains the correlation structure. If a significant contrast is found, a conditional permutation procedure is used to cut a second branch while keeping the first branch cut to split the haplotypes into a three allele system. Tree-scanning preserves statistical power by pooling haplotypes while minimizing the number of tests with an evolutionarily relevant *a priori* criterion. It provides an interpretive framework that can recognize and correct for homoplasy, identify multiple independent effects within a region, potentially localize physical regions with rare recombinants, and can be extended to multilocus epistasis studies. Examples are demonstrated with a large data set of human cholesterol related phenotypes and ApoE genotypes.

Detecting signatures of natural selection in skin pigmentation candidate genes using locus specific pairwise F_{ST} .

*H. Norton*¹, *J. Akey*², *M. Shriver*¹. 1) Department of Anthropology, Pennsylvania State University, University Park, PA; 2) Fred Hutchinson Cancer Research Center, Seattle WA.

Pigmentation of the skin is an easily visible example of human phenotypic variation. Natural selection may have shaped global variation in human skin pigmentation by acting on genes controlling the production and distribution of melanin, the primary pigment of the skin. Melanin acts as a natural sunscreen, suggesting that large amounts of melanin in the skin may be adaptive in environments where ultraviolet radiation is high and that lower levels of melanin may be adaptive in the higher latitudes where ultraviolet radiation is not as strong. Recent studies suggest that SNPs in some pigmentation candidate genes may have an effect on normal variation in human pigmentation. This work examines locus specific pairwise F_{ST} values ($lspF_{ST}$) for SNPs in 5-6 pigmentation candidate genes in pairwise comparisons of six geographically diverse human populations. These values are then compared to an empirical $lspF_{ST}$ distribution based on 11,078 autosomal SNPs typed in the same or similar population samples. High $lspF_{ST}$ values may be suggestive of population differentiation due to the effects of natural selection, although these high values may also have been caused by genetic drift. Pigmentation candidate SNPs with high $lspF_{ST}$ values between populations known to differ in skin pigmentation suggest that the SNP may have a functional effect on pigmentation. High $lspF_{ST}$ values between populations with similar pigmentation phenotypes may suggest convergent evolution. Two such SNPs showing high $lspF_{ST}$ values between European and East Asian populations were identified in a preliminary population screen. Where possible, levels of LD surrounding putative selected SNPs will be examined to help determine if high $lspF_{ST}$ levels are due to drift or to natural selection.

Patterns of nucleotide sequence diversity among humans and great apes at the Arginine Vasopressin Type II Receptor Gene (*AVPR2*). *L.A. Pfeifer*¹, *B.C. Verrelli*², *S.A. Tishkoff*¹. 1) Department of Biology, University of Maryland, College Park, MD; 2) Center for Evolutionary Functional Genomics, School of Life Sciences, Arizona State University, Tempe, AZ.

The primary action of the peptide hormone arginine vasopressin (AVP) is antidiuresis. Binding of AVP to the type II AVP receptor (*AVPR2*) in the kidney allows for reabsorption of body water and electrolytes. Mutations in the *AVPR2* gene encoding this G-protein coupled receptor, located at Xq28, cause the disease X-linked nephrogenic diabetes insipidus (NDI). While a number of studies have identified *AVPR2* mutations in individuals with NDI, nucleotide sequence variation at this gene has not been previously investigated in a random sample of individuals from ethnically diverse populations. Here, we present the analysis of 2,500 bp of *AVPR2* and its proximal promoter region from over 150 humans originating from indigenous populations of: Eastern, Western, and Southern Africa, the Middle East, Europe, Asia, Australo-Melanesia and the Americas. We also assessed *AVPR2* in a sampling of great ape species. Thus far we have identified 19 single nucleotide polymorphisms (SNPs) in humans, including nine novel SNPs not previously reported. Five of these SNPs result in amino acid (aa) replacements, which may have functional implications. Notably, two of the aa changing SNPs found in this study were previously reported as disease-causing mutations in individuals with NDI. We also observe 68 fixed differences between the human and great ape lineages; nine of these are aa fixed differences. Because *AVPR2* plays a critical role in osmoregulation, we have tested for evidence of selection acting at this locus across human populations originating from ecologically and geographically diverse regions. This study provides estimates of *AVPR2* nucleotide and haplotype diversity that may be useful for disease association studies, for reconstructing the history of *AVPR2* protein evolution since the split of humans from their most recent common ancestors, and for studying the genetic basis of adaptation in humans.

Program Nr: 1181 from the 2004 ASHG Annual Meeting

Evidence of Balancing Selection at the Promoter Region of *HLA-G*. Z. Tan, K. Vigh, C. Ober. Department of Human Genetics, The University of Chicago, Chicago, IL 60637.

The primary site of expression of *HLA-G* is at the fetal-maternal interface. Because of its immunosuppressive properties and limited polymorphism in the coding region, *HLA-G* is thought to contribute to maternal tolerance of the fetus. Recently we reported 18 SNPs in the 1350 bp upstream of exon 1, which includes all the known regulatory elements, an unusual haplotype structure, and an association with miscarriage in the Hutterites (Ober C, et al. *AJHG* 72:1425). To further study this region, we used haplotype-specific PCR and sequenced the promoter in 44 African Americans (AA), 44 Caucasians (CA) and an orang. We identified 24 SNPs, comprising 10 unique haplotypes (9 in AAs; 8 in CAs) that fell into 2 divergent clades. Tajimas D was 2.56 in the AAs ($P=0.005$) and 2.20 in the CAs ($P=0.02$); nucleotide diversity was high ($=0.006$ in both). These features are consistent with the presence of an old balanced polymorphism. To further test this hypothesis, we sequenced in the orang and AAs 1.3 kb downstream of the promoter region, between which there was little LD. We performed an HKA test, which revealed greater than expected diversity in the human promoter region ($P<0.05$). These combined data are consistent with the hypothesis that the *HLA-G* promoter region has been subject to balancing selection, perhaps due to the opposing needs to protect the fetus from rejection and maintain immune competence at the maternal-fetal interface. Supported by HD21244 and HL72414.

Functional analysis of protein-altering variants of membrane transporters in human populations. *T.J. Urban¹, M.K. Leabman¹, R. Sebro², N. Risch², K.M. Giacomini¹*. 1) Biopharmaceutical Sciences, UCSF, San Francisco, CA; 2) Department of Genetics, Stanford University School of Medicine, Stanford, CA.

Although considerable progress has been made toward characterizing the nature and degree of human DNA sequence variation, there remains a general deficiency in information on human phenotypic variation at the single-gene level. We systematically analyzed the function of all protein altering variants of nine membrane transporters in heterologous expression systems. Coding region variants were identified by screening a large sample (n = 247 to 276) of DNA from ethnically diverse subjects. In total, we functionally analyzed 79 protein altering variants, including 75 non-synonymous variants, two insertions, one deletion, and one nonsense mutation. Ten percent of all tested protein-altering polymorphisms (i.e., variants found at allele frequencies greater than 1% in at least one major ethnic group) were non-functional or had significantly reduced function, defined as <50% of activity compared with the reference sequence. Of the 79 variants studied, 16 (18%) had significantly decreased function. Decreased function variants had a significantly different allele frequency distribution (i.e., a skew toward lower population allele frequencies for decreased function variants) (p=0.01, log rank test) and were more likely to alter evolutionarily conserved amino acid residues (p=0.00913, logistic regression) than variants that retained function. Among variants that retained function, evolutionary conservation was also a significant predictor of the degree of change in function (p=0.04955, log rank test). Collectively, these data indicate that variants that have grossly impaired function are present at lower allele frequencies than those that do not, and that function in cellular assays is the best predictor of human fitness. The data suggest that variants that alter evolutionarily conserved residues but retain function in cellular assays may yet influence occult functions or quantitative degrees of function that are important in human fitness.

Signature of natural selection revealed at HLA region with microsatellites: Further Data. *H. Xu*¹, *R. Deka*², *M. Kimmel*³, *Y.X. Fu*⁴, *R. Chakraborty*². 1) Dept Epidemiology, Univ Texas MD Anderson CA Ctr, Houston, TX; 2) Center for Genome Information, Department of Environmental Health, University of Cincinnati, Cincinnati, OH; 3) Department of Statistics, Rice University, Houston, TX; 4) Human Genetics Center, School of Public Health, University of Texas, Houston, TX.

Natural selection is one of the major factors in the evolution of all organisms. Detecting the signature of natural selection has been the central theme in evolutionary genetics. With the availability of microsatellite data, it is of interest to study how natural selection can be detected with microsatellites. Currently used tests of natural selection presume that mutations at the loci follow the infinite allele/site models, in the sense that at each site at most only one mutation event is recorded, and each mutation leads to an allele not seen before in the population. Microsatellite loci do not obey these mutation models, since the new alleles at such loci can be created either by contraction or expansion of tandem repeat sizes of core motifs. We developed a new test of neutrality taking account of a generalized model of forward-backward stepwise mutations. As confounding factors of natural selection, the effects population expansion and population substructure on the test were also studied. Applying the new test to the microsatellite loci from human HLA region revealed the signature of natural selection.

Mutation rate and variation patterns among 16 SARS coronavirus genomic sequences. Z. Zhao^{1,2}, Y.-X. Fu³. 1) Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University, Richmond, VA; 2) Center for the Study of Biological Complexity, Virginia Commonwealth University, Richmond, VA; 3) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX.

The outbreak of severe acute respiratory syndrome (SARS) caused a severe global epidemic in 2003 and linked to hundreds death and thousands in hospitals. The virus causing SARS was identified as a novel coronavirus (SARS-CoV) and multiple genomic sequences were revealed since mid-April, 2003. Understanding the evolutionary mechanism of SARS-CoV, including mutation rate and pattern of variations, is fundamental for battling against the deadly pathogen. We analyzed 16 complete genomic sequences with available clinical histories during the SARS outbreak. After careful examination of multiple-sequence alignment, 114 single nucleotide variations were identified. The properties of amino acid changes in the different genomic regions were analyzed and compared. The reconstructed phylogeny indicated two subgroups, one isolated in mainland China and the other included those connecting to index patient A. We applied three strategies to infer the mutation rate in SARS-CoV genome by using the 11 genomic sequences for which the divergent time can be inferred. The mutation rate was estimated to be $0.80 - 2.38 \times 10^{-3}$ nucleotide substitution per site per year which is in the same order of magnitude of other RNA viruses. The estimates of mutation rates led to the inference that the SARS-CoV could have been with humans in the spring of 2002 without causing a severe epidemic. The synonymous and nonsynonymous substitution rates were estimated to be $1.67 - 4.67 \times 10^{-3}$ and $1.16 - 3.30 \times 10^{-3}$ per site per year, respectively. The genome-wide Ka/Ks ratio indicated little selective pressure, but a few genes might have been subjected to very recent natural selection.

Maternal Thrombotic Risk Factors For Small Gestational Age. *F.B. Atac¹, N. Ozbek², H. Verdi¹, S. Cetintas², E. Ozyurek², F.I. Sahin¹, B. Gurakan², A. Haberal³.* 1) Medical Biology and Genetics, Baskent University Faculty Of Medicine , Ankara-Turkey; 2) Pediatrics, Baskent University Faculty Of Medicine, Ankara-Turkey; 3) Obstetrics and Gynecology, Baskent University Faculty Of Medicine, Anaka-Turkey.

Altered maternal homeostasis as a result of point mutation or single nucleotide polymorphism in coagulation factors has been reported as a new and frequent risk factor in Small for Gestational Age (SGA), in addition to several fetal and placental factors. Therefore, we assessed whether maternal thrombophilic risk factors such as, Factor V Leiden (FVL), Prothrombin G20210A (Prt G20210A) and methylene tetrahydrofolate reductase (MTHFR) C677T mutations are associated with SGA in Turkish population. 57 maternal blood samples from mothers having babies with SGA formed the study group of this study. Control group was consisted of 67 maternal blood samples withdrawn from women without any obstetric complication. Every patient included in this study was informed about the DNA analysis consequence of the withdrawn blood sample and was requested to sign the written informed consent form. Genomic DNA was prepared from leukocyte pellets by sodium dodecyl sulphate (SDS) lysis, ammonium acetate extraction and ethanol precipitation. Restriction fragment size analysis was performed by visualising digested PCR products for FVL, Prt G20210A, MTHFR C677T mutations, and separated by electrophoresis in an ethidium bromide stained 12% polyacrylamide gel. Based on the preliminary findings obtained from the present work (Table 1), we concluded that MTHFR C677T mutation may be suggested as a risk factor for the SGA outcome in our population and screening could help the assesment of patients.

Gene mutation	Study Group (n=57)	Control Group (n=67)
FVL (WT)	100% (n=57)	98.50% (n=66)
FVL (Heterozygote)	-	1.50% (n=1)
Prt G20210A (WT)	100% (n=57)	97.00% (n=65)
Prt G20210A (Heterozygote)	-	3.00% (n=2)
MTHFR C677T (WT)	57.89% (n=33)	68.65% (n=46)
MTHFR C677T (Heterozygote)	40.35% (n=23)	29.85% (n=20)
MTHFR C677T (Homozygote mutant)	1.75% (n=1)	1.50 (n=1)

Genetic diversity in the coding regions of three members of the glutathione peroxidase family. *C. Leger¹, M. Simoneau¹, M.-C. Theberge¹, H. Vasquez¹, J.-F. Lefebvre¹, E. Levy^{1,3}, D. Sinnott^{1, 2}, D. Labuda^{1,2}.* 1) Hopital Sainte-Justine, Universite de Montreal, Montreal, Quebec, Canada; 2) Departement de Pediatrie, Hopital Sainte-Justine, Universite de Montreal, Montreal, Quebec, Canada; 3) Departement de Nutrition, Hopital Sainte-Justine, Universite de Montreal, Montreal, Quebec, Canada.

Reactive oxygen species (ROS), while having recognized functions, may also cause damage to the cell. Three members of the glutathione peroxidases family, GPX1 (or cGPX), GPX2 (GPX-GI) and GPX3 (plasma GPX), appear at the first line of defense against ROS. Thus, polymorphisms in the corresponding genes, may represent genetic susceptibility factors. In this study, we characterized variations within the coding sequence of GPX1, 2 and 3 in a worldwide panel of 180 DNA samples by dHPLC analysis, sequencing and subsequent genotyping of variants. These genes differ substantially in their variability in human populations. Five SNPs (nucleotide diversity $h=0.07\%$) and a tri-nucleotide repeat (oligoalanine tract) were found in GPX1; 18 SNPs ($h=0.12\%$) in GPX3; and only 3 singleton SNPs ($h=0.002\%$) in GPX2. All substitutions appeared neutral, with the exception of a P to L substitution located at a phylogenetically variable C-end terminus GPX1. Among 7 GPX1 haplotypes, further diversified by tri-nucleotide repeat, three accounted for 98% of all 294 chromosomes tested; in GPX3 five haplotypes out of 19 observed represented 85% of the sample. Virtual absence of diversity in GPX2 was neither correlated with its evolutionary conservation, since its divergence from the chimpanzee ($\sim 1\%$) was comparable to that of GPX3, nor with a lower regional recombination rate (1.6 cM/Mb). Interestingly, in GPX3 Asians were statistically different from other population group essentially due to partition of major haplotypes, H15 in Asia and H12 elsewhere. Of note, there is a positive correlation between the rate of hepatocarcinoma and the population frequency of GPX3 haplotypes harboring opposite SNP1071 alleles (i.e. H12 and H15) suggesting its possible association with this disease. Supported by Valorisation Recherche Quebec.

CYP3A4 gene polymorphism in renal transplant recipients and the association with cyclosporine clearance. *D.O. McDaniel, S. Harrison, W.H. Barber, L.S. McDaniel.* Dept Surgery/Neurology, Univ Mississippi Medical Ctr, Jackson, MS.

CYP3A4 plays an important role in the metabolism of immunosuppressive drugs, including cyclosporine. Most organ transplant recipients in addition to immunosuppressive drugs also take medications for other conditions. The administration of multiple drugs might have an adverse effect in drug distribution following long-term drug treatment. Because of variability in the drug uptake and clearance, this might have a great impact on the outcome of allograft survival. We have demonstrated interindividual variation in CYP3A4 expression in different individuals. Such variation is hypothesized to be due to polymorphism within the promoter region of the gene causing difference in the level of expression. The aim was to determine the allelic frequency of the CYP3A4 variants in African-American kidney recipients, and to examine a possible association with cyclosporine elimination in the transplant setting. Blood samples from 77 patients and 67 matched controls were studied by single nucleotide polymorphism (SNP) and PCR. CYP3A4 G genotype was present in 82.5% of renal transplant patient population. The GG homozygous allele was 4-fold higher in patients than in controls. The frequency of G was significantly higher in the Mississippi population (82.5%) as compared with African-American population (53%) reported elsewhere. There was a trend towards higher cyclosporine clearance index and AA genotype, indicating that the effect of CYP3A4 might be more evident in a homozygous GG genotype. Such information might allow improved strategies for immunosuppressive drugs such as cyclosporine and tacrolimus that are commonly used to prevent allograft rejection.

Fine linkage disequilibrium mapping using the coalescent with recombination. *F. Larribe*¹, *K. Morgan*². 1) Human Genetics, McGill University, Montreal, Quebec, Canada; 2) Human Genetics and Medicine, McGill University, Montreal, Quebec, Canada.

We present new developments on a multilocus fine mapping linkage disequilibrium methodology using the ancestral recombination graph (ARG) to model the history of related haplotypes. A trait influencing mutation (TIM) is assumed to have occurred in one haplotype of the population some time in the past. This mutation is assumed to be unique (non recurrent) and to have a high penetrance. Based on a sample of cases and controls from this population, the method evaluates the likelihood of the position of the TIM along the sequence, leading to a maximum likelihood estimator. The history of the population, based on both cases and controls, is modelled by the coalescent process with recombination, which is probably a better model than other previously used models like star genealogies or trees. The evaluation of the likelihood is done with the importance sampling method of Griffiths and Tavar which we have adapted to this context. The method can be used with SNPs or micro-satellite markers and can take into account variable population size. This computationally intensive Monte Carlo method should be generalizable to others contexts, as it is directly based on the coalescent process. We present results of simulations and results on a real data set. It is well known that inference in the ARG is difficult, and we show that despite some variability in the likelihood profiles, the method works well and is promising. We discuss some problems, and finally present some future research directions.

Genetic Diversity in Two Urban Populations on the Southern Coast of Ghana. *J. Benn Torres*¹, *A.C. Stone*². 1) Dept Anthropology, Univ New Mexico, Albuquerque, NM; 2) Dept Anthropology, Arizona State Univ, Tempe, AZ.

Understanding genetic diversity in West Africa is of importance because it provides insight into African population history and overall human diversity, as well as into the history of the African Diaspora. Studies regarding genetic diversity in West African populations are comprehensive but generally reference continental population history, disease, or species origin and do not usually consider urban diversity. In this analysis mtDNA hypervariable region I (HVI) and four Y chromosome markers are examined in 152 unrelated individuals representing nine different ethnicities from two metropolitan areas, Cape Coast and Accra, in Ghana, West Africa. This investigation highlights genetic diversity and examines the relationship between tribal affiliation and genetic markers. In addition, comparisons concerning diversity relationships are made between these data and those published from other African and African- derived populations. The DNA samples in this study were collected via cheek cell swabs, extracted using a standard phenol-choloroform method, and amplified by PCR. Electrophoresis, sequencing, or Taqman, were used to determine the genotype for each locus. The heterozygosity and frequencies for each of these markers were calculated and compared with previously published data. Preliminary analysis at several of the loci indicated, firstly, that more analysis is need to ascertain the relationship between genetic haplotypes and tribal affiliation, and second, that overall, the genetic diversity observed in these urban samples are higher than in other non-urban West African populations.

Study of Phylogenetic relations of two North Indian Populations based on Mitochondrial & Y Chromosomal DNA Polymorphisms. *A.J.S. Bhanwer¹, K. Thangaraj², S. Sharma³, R. Singh¹, L. Singh².* 1) Department of Human Genetics, GND University, Amritsar; 2) Centre for Cellular & Molecular Biology, Hyderabad; 3) National Centre for Applied Human Genetics, JNU, New Delhi.

The human nature to explore has led us for the quest of unravelling the mystery of our origins. The Out of Africa theory of human origin and migration and its supporting concepts suggest India as one of the most interesting global regions in human evolution. Some of the most ancient waves of human migration appear to have passed through India & North India is considered as the Melting pot of the Indian populations & has an important role in peopling of India. Due to their property of uni-parental inheritance mtDNA and Ychromosomal markers are most effective molecular genetic tools for these evolutionary and phylogenetic studies. The current study traces phylogenetic relationship of two North Indian populations Kashmiri Pandits & Ramgarhia Sikhs with other Indian and world populations using these markers. The Y-biallelic markers based haplogrouping for both these populations show a great genetic affinity as the major haplogroups found are F(0.230 & 0.36),O(0.11 & 0.18),K(0.11 & 0.18),R(0.29 & 0.28) and Q(0.26 & 0.0) in Kashmiri Pandits and Ramgarhia Sikhs respectively and show almost equal haplogroup distribution pattern. The absence of haplogroup Q in Ramgarhia Sikh population indicates an ancient population admixture and recent population specification which may occur due to recent population and caste specific socio-culture differentiation. 9bp polymorphism is absent. Both show close affinity to Vanuatu (Melanesian), a rare Polynesian population by neighbour joining method based on F_{st} distance values of mtDNA HVR I data from two population groups and other world population. The mismatch pair distribution analysis based on HVR I sequence data show a population expansion in both the population groups but a more ancient expansion in Kashmiri Pandits than Ramgarhia Sikh population. Analysis of 4 mtDNA bi-allelic markers in Ramgarhia Sikhs showed the presence of mtDNA haplogroups M and R in high frequency along with haplogroup U to some extent indicating a conserved maternal inheritance.

Presence of deep-rooted YAP lineages in some population groups of Jammu and Kashmir. *A.K. Bhat^{1,2}, S. Sharma¹, A. Saha¹, M. Dhar², R. Bamezai¹.* 1) NCAHG, SLS, Jawaharlal Nehru University, New Delhi, Delhi, India. ; 2) Department of Biotechnology, University of Jammu, J&K, India.

There is a complete non-availability of the genetic analysis to reflect upon genetic relatedness of different population groups of the state of Jammu and Kashmir in India. Ancient documentations such as Nilmatpuran and Ragtarangni do throw some light on early peopling of the region but it is inconsistent with excavation done at Burzihama in Kashmir. Since, Y Chromosome and mitochondrial genome analysis have proved of help in tracing the origin of a population, this study was carried out on 168 samples [133 male, 35 female] from three major population groups, representing Kashmiri Pandits [KPs], Kashmiri Muslims [KMs] and Ladakhis. KPs are believed to be the true representatives of Aryans whereas, the majority of KMs are believed to be the descendants of converted Hindus and the Ladakhis are considered close to Tibetians. The Y chromosomal markers: 12 biallelic and 4 Y-STRs and the two mitochondrial variable regions, HVRI and HVRII, were analysed. A deep-rooted African YAP+ lineage at a frequency of 2.5% in KMs, hinted towards some sort of antiquity in the peopling of Kashmir. The Tibetan lineage of YAP+ chromosomes [9.5%] was found in the Ladakhi population. The other clades (YCC) were: clade C, 3.8% in KPs, 2.6% in KMs; clade J, 4% in KPs, 13% in KMs and 4.6% in Ladakhis and clade R1a, 15.3% in KPs, 18% in KMs. The Y-STR data reflected that the studied populations are close to rest of the Indian populations. A molecular variance of 72.68% and 67.02% was observed at HVRII and HVRI loci respectively among population within groups. The presence of almost similar clades in both KPs and KMs suggested a common ancestry for both populations. The presence of Tibetan lineage in Ladakhi population probably reflected the geographical and cultural proximity of the two populations. Whether this lineage migrated from Ladakh to Tibet or vice-versa needs to be explored. The presence of an African YAP+ lineage though in less frequency was a unique finding which in future studies will be helpful in tracing the human migration from Africa into Asia through Kashmir.

Polymorphisms in Genes of Glutathione Metabolism: Promoter Regions. C. Labbe¹, C. Moreau¹, V. Yotova¹, D. Gehl¹, J.F. Lefebvre¹, P. Beaulieu¹, S. Langlois¹, M.C. Théberge¹, H. Bélanger¹, C. Zotti², D. Sinnott¹, D. Labuda¹, *Regulatory Genetics Consortium*. 1) Hemato-Oncology Center, Sainte-Justine Hospital, Montreal, QC, Canada; 2) McGill University and Genome Quebec Innovation Centre, Montreal QC Canada.

Regulatory polymorphisms that modify genetic expression may have an impact on the susceptibility to diseases and/or on the differential response to treatment. Enzymes of glutathione metabolism are of special interest because of their involvement in detoxification of the cell and its protection against reactive oxygen species. To learn about genetic diversity in their bona fide promoter regions of the corresponding genes, we characterised variability of 2 kb segments upstream of the transcription start site. Polymorphisms were ascertained in a world sample of 40 individuals and studied further in an extended sample of five continental populations (n = 80) and 8 subpopulations (n=142). Three genes have been studied so far: nucleotide diversity of 0.08% was found in GSTT1 and GSS (with 6 and 9 segregating sites, and 6 and 11 haplotypes, respectively), and of 0.21% for GSTP1 (13 sites and 16 haplotypes). The most frequent haplotype of GSTT1 (44%) is a deletion of the entire gene. The remaining haplotypes diversity at 0.55 is lower than in GSS (0.71) or GSTP1 (0.71). While GSTT1 and GSS haplotypes can be explained entirely through mutations, the GSTP1 haplotype network indicates recombination episodes. PC analyses based on haplotype frequency in continental populations demonstrate striking differences between Africa and the rest of the world for each one of these genes. Although no deviation from neutrality was detected by Tajimas and Fus tests in neither of the segments analysed, an elevated FST of 0.288 in the case of GSTT1 suggests that selection had an impact on the evolution of this gene. The work on other GS-transferases (GSTM1, GSTM3, GSTM4) is in progress. Supported by Genome Quebec/Canada.

Population genetic of *bona fides* regulatory regions. D. Labuda¹, C. Moreau¹, S. Langlois¹, D. Gehl¹, P. Beaulieu¹, J.F. Lefebvre¹, H. Vasquez¹, C. Labbé¹, M.C. Theberge¹, H. Bélanger¹, C. Zotti², D. Sinnott¹, Genome Quebec Regulatory Genetics Consortium. 1) Res Ctr, St-Justine Hosp, Univ Montreal, Montreal, PQ, Canada; 2) Genome Quebec Innovation Ctr, McGill University, Montreal, PQ, Canada.

Diversity of human DNA is currently under intense scrutiny, leading us to better understanding of human origins, evolution, demographic history and population structure, essential to genetic epidemiological quest of complex diseases. In fifteen candidate genes, the promoter regions, arbitrarily defined as 2 kb segments directly upstream of the transcription start site, were screened by dHPLC in 40 individuals of African, Middle-Eastern, European, East Asiatic and Amerindian descent. The polymorphisms were characterized by sequencing and subsequently genotyped in an extended panel of 80 individuals representing the same population groups. We found between 3 and 18 (average of 10) segregating sites in the 2 kb regulatory region. Nucleotide diversity estimates of 0.03 to 0.19 %, from both allele frequencies (average 0.08%) and the number of segregating sites (0.1%) fit well the genomic average. Haplotype worldwide diversity was 0.65 (0.27 to 0.84) and their numbers from 4 to 21 (average 10) correlated with the count of segregating sites, as if recombination played little role in diversifying these haplotypes. Yet, in one third of these segments, recombinations (gene conversions) could have been documented suggesting that some of these putative regulatory segments recombine more often than the genomic average and could thus reside in the recombination hot spots. The partitioning of haplotype diversity varies substantially among continental groups suggesting the possibility of diversifying and/or balancing selection acting on these genomic segments. Besides advancing our knowledge of the promoter regions, knowing these characteristics will find application in planning the association studies and in using the candidate gene approach in particular. Supported by Genome Quebec/Canada and by Valorisation Research Quebec.

Haplogroup U5a: the signature of an Upper Palaeolithic migration from West to East Eurasia? *K.P. Mooder¹, T.G. Schurr², F.J. Bamforth¹*. 1) Human Identification Laboratory for Archaeology, Department of Laboratory Medicine and Pathology, University of Alberta, Edmonton, Alberta, Canada; 2) Department of Anthropology, University of Pennsylvania, Philadelphia, PA.

The prehistory of Siberia is still relatively uncharacterised, including the population origins of those who initially inhabited the region. One intriguing facet of Siberian prehistory was the Upper Palaeolithic occupation of the Lake Baikal region at sites known as Mal'ta and Buret'. Archaeological excavations revealed these groups to share a remarkably similar material culture with those living contemporaneously in eastern Europe; however, insufficient numbers of human remains were discovered at these sites to make inferences about their population affinities. We provide potential support for a West Eurasian contribution to the gene pool of prehistoric Siberia with the mtDNA analysis of two Neolithic Lake Baikal cemetery populations. Dating from 6125 to 2020 B.C., these two groups not only possess a wide variety of East Eurasian mtDNA haplogroups but also harbour HVI polymorphisms characteristic of the West-Eurasian haplogroup U5a at frequencies of 5 to 10%. A survey of prehistoric mtDNA datasets reinforces the presence of U5a in the matrilineal structure of East-Eurasia and North America prior to European contact. Given these observed archaeological and biological affinities, it will be worthy to explore whether the dispersal of U5a and other West Eurasian haplogroups in prehistoric and modern East Eurasian populations provides insight into how the matrilineal population structure of this region has evolved.

Mitochondrial DNA polymorphisms in four ethnic groups from Mongolia. *B. Munkhbat*^{1, 2}, *H. Hayashi*¹, *K. Tounai*¹, *T. Katoh*¹, *G. Oyungere*², *N. Munkhtuvshin*², *H. Inoko*¹. 1) Dept Molecular Life Science, Tokai University School of Medicine, Isehara, Kanagawa, Japan; 2) Central Scientific Research Laboratory, National Institute of Medicine, Ulaanbaatar, Mongolia.

An analysis of mitochondrial DNA (mtDNA) polymorphism has been an essential tool for human diversity and molecular evolution studies allowing the insights of maternal lineage contributions. Here we will demonstrate the results of our comprehensive mitochondrial DNA analysis in Mongolians with the purpose to reveal matrilineal genetic affinity among contemporary Mongolians. The extended population samples including 475 unrelated individuals representing four indigenous populations, Khalkh, Uriankhai, Zakhchin and Khoton-Mongolians, are analyzed in present study. In brief, more than 50 haplotype-associated polymorphic sites comprising sequence variations in HVS-I, HVS-II and the coding region are investigated by direct sequencing, RFLP, and newly designed TaqMan probe assays in order to identify composite genetic structure of Mongolian ethnic groups from the view of mtDNA haplogroups. Moreover, highly complex genetic characteristics of four Mongolian ethnic groups will be discussed on the basis of extensive analysis of combined data from Y-chromosomal, X-chromosomal and mtDNA diversity studies in overall. In addition, the comparative analysis with the data available from neighboring populations from Central and Eastern Asia would be considered.

Frequency of mtDNA Haplogroups in five Mexican indigenous populations. *R. Peñaloza¹, IB. Alvarez¹, L. Buentello², I. Mendoza³, G. Gonzalez-Valencia³, J. Torres³, F. Salamanca¹.* 1) Unit of Human Genetics, IMSS, Mexico City; 2) IIA, UNAM; 3) Unit of Infectious Diseases, IMSS, Mexico City.

Abstract: Mitochondrial DNA (mtDNA) haplogroups from five indigenous Mexican groups not related, were analysed previous consent informed. We extracted DNA from leukocytes of peripheral blood by conventional methods and amplified five regions of mtDNA by PCR and finally used restriction enzyme as described previously (Moraga et al., 2000). We found the four American haplogroups with different frequencies. The results show that Nahuas from Milpa Alta presented the highest frequency of D haplogroup, probably because a special race mixture or high endogamy. The haplogroup A was frequent in Nahuas from Guerrero, Otomis from Hidalgo, Purepechas from Michoacan and Tzeltales from Chiapas. These results are in agreement with other authors.

The 9-bp deletion in the region V of mitochondrial DNA in several population of Zulia State-Venezuela. *L. Pineda, M. Portillo, L. Borjas, M. Sanchez, W. Zabala, E. Fernandez.* Medical Genetic Unit, University of Zulia, Maracaibo, Venezuela.

Zulia state, at the western of Venezuela, is considered a product of european and african admixture with the local amerindians, however, these are marked differences in this mixture according to the population studied. In this research, as a part of a great proyect to study genetic diversity of Zulia State, we report the preliminary results about the amerindian femenine contribution in several population of this state. Therefore, it was analyzed by PCR, the presence of deletion of one of the two copies of 9 bp in the V region of the mitochondrial DNA, that defines the amerindian haplogroup B in a sample of 266 individual coming from three populations of Zulia: Maracaibo, capital of the state, San Jose de Heras, a negroid group and Wayuu, representing the Arawak amerindian linguistic group. The deletion was present in all of the populations: 15%, 5% and 47%, respectively. The low frequency of this haplogroup in Maracaibo and San Jose de Heras suggests the presence of others amerindian haplogroups or a low amerindian contribution with an important contribution of others ethnic groups in these populations. The frequency observed in Wayuu group may be reflecting the presence of haplogroups derived of intermarriage processes with others local amerindians and mixed groups with different mitochondrial DNA. These results are agreed with the historical and demographic reports about the Zulia and demostrated that the deletion of 9 bp was useful to track through the time, the amerindian femenine contribution to the contemporary populations of the Zulia State.

Haplotype Diversity of the Y-chromosome in Six Mexican Populations. *H. Rangel-Villalobos*¹, *L.A. Riberos*¹, *L. Sandoval*², *L.E. Figuera*². 1) Molecular Genetics Laboratory, Universidad de Guadalajara, Ocotlan, Jal., Mexico; 2) Centro de Investigacion Biomedica de Occidente (CIBO-IMSS), Guadalajara, Jal., Mexico.

The non-pseudoautosomal region of the Y-chromosome constitutes a genetic record easily interpretable to obtain valuable anthropological information about the history of worldwide populations. Two bi-allelic loci (YAP and DYS199) and five STRs (DYS19, 389a, 390, 391 and 393) of the non-pseudoautosomal region of the Y-chromosome were analyzed in males from the largest and most widely distributed population in Mexico (Mestizos) and from three Mexican Amerindian tribes: Huichols, Purepechas and Tarahumaras. The allelic distribution of all seven loci was established and it was pairwise compared between populations. For YAP locus, any significant difference ($p > 0.05$) was observed among all four populations. The Amerindian-specific allele DYS199-T was more frequent in Mexican tribes than in Mestizos, establishing the minimum Amerindian component in the Mestizo sample as 18.6%. Tarahumaras were peculiar by its diminished frequency for DYS199-T respecting to Purepechas and Huichols. Mexican Mestizos were different ($p < 0.05$) to Huichols, Purepechas and Tarahumaras in five, four and two STRs, respectively. Eighty-eight different haplotypes were observed among the 156 haplotypes obtained. They were grouped in three haplogroups according to the markers YAP (+/-) and DYS199 (C/T):-/C, -/T and +/C. The greater haplotype diversity (D) was observed in Mestizos (98.6 %) and the lower in Huichols (87.17 %). The haplotype variation of the Y-chromosome in Mexican populations was analyzed by AMOVA. The inter-population and intra-population variations were significant ($p < 0.0001$) and constituted the 78.5% and 21.5%, respectively. We discuss our findings with previous results about the same populations using autosomal markers (Hum. Biol. 2000, 72: 983-995).

Serial segmental duplications during primate evolution result in complex human genome architecture. P.

Stankiewicz¹, C.J. Shaw¹, M. Withers¹, K. Inoue¹, J.R. Lupski^{1,2,3}. 1) Dept Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Pediatrics, Baylor College of Medicine; 3) Texas Children Hospital, Houston, TX.

The human genome is particularly rich in low-copy repeats (LCRs) or segmental duplications (5-10%), and this characteristic distinguishes us from lower mammals such as rodents. How and why the complex human genome architecture consisting of multiple LCRs has evolved, remains an open question. Using molecular and computational analyses of human and progenitor primate genomic regions, we analyzed the structure and evolution of LCRs that resulted in complex architectural features of the human genome in proximal 17p. We found that multiple LCRs of different origins are situated adjacent to one another, whereas each LCR evolved at different time points > 25 to 3-7 million years ago, during primate speciation. Evolutionary studies in primates indicated abundant communication between the LCRs by gene conversion. The DNA transposable element MER1-Charlie3 and retroviral ERVL elements were identified at the breakpoint of the t(4;19) chromosome translocation in *Gorilla gorilla*, suggesting a potential role for transpositions in evolution of the primate genome. Thus, a series of consecutive segmental duplication events during primate evolution resulted in complex genome architecture in proximal 17p. Some of the more recent events led to the creation of novel genes that in human are expressed primarily in the brain. Our observations support the contention that serial segmental duplication events orchestrated primate speciation both by the generation of novel fusion/fission genes as well as by genomic inversion associated with decreased recombination rates further facilitating gene divergence.

Haplotype structure and recombination in *CAPN10*, a diabetes candidate gene. *V.J. Clark¹, J. Vander Molen¹, M. Hammond¹, A. Stone², A. Di Rienzo¹.* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Anthropology, Arizona State University, Tempe, AZ.

It has been proposed that *CAPN10* variation contributes to the risk of type 2 diabetes. The entire *CAPN10* gene was previously re-sequenced in four population samples (Italians, the Hausa of Cameroon, Han Chinese, and Mazatecos from Mexico) in our laboratory. This study revealed a 4 kb region with an excess of polymorphism levels relative to divergence and relative to genome-wide levels of variation. To elucidate the relevance of this unusual genomic region to type 2 diabetes susceptibility, several aspects of nucleotide variation [patterns of polymorphism, haplotype structure, and linkage disequilibrium (LD)] were assessed by re-sequencing an additional set of Mexican-American type 2 diabetes cases and controls. Network analysis of the case-control and population sequence data reveals distinct patterns of haplotype structure between the Hausa (native Africans) and the non-African population samples. Further analysis of SNP haplotypes indicates 5 haplotype clusters common among non-Africans. With this analysis we were able to refine previously identified type 2 diabetes risk haplotypes composed of other SNPs in *CAPN10* (*i. e.* UCSNP-43, -19, and -63) in multiple populations and Mexican-American cases and controls. To complement the haplotype analyses, we are exploring the contribution of increased local rates recombination (a recombination hotspot) to the accumulation of polymorphism in this region. Sliding-window analysis of recombination (summarized by the H_{01} estimator of 4Nr) across the *CAPN10* gene indicates lower levels of LD coinciding with the peak of polymorphism; this pattern is most distinct in the Hausa. Analyses of sequences from 15 Western chimpanzees show, unlike in human populations, no local increase of either polymorphism levels or rate of recombination. Therefore, it appears that changes in mutation and recombination rates have occurred after the split of the human and chimpanzee lineages. We anticipate that this multi-faceted approach to explore patterns of variation in *CAPN10* will inform the design of future type 2 diabetes case/control association analyses.

Methods for improving haplotype reconstruction with microsatellite loci. *J.B. Ekins¹, L.A.D. Hutchison^{1,2}, J.E. Ekins¹, N.M. Myres¹, K. Hadley¹, L. Layton¹, M.L. Lunt¹, S.S. Masek¹, A.A. Nelson¹, M.E. Nelson¹, K.L. Pennington¹, U.A. Perego¹, J.L. Peterson¹, A. Sims¹, T. Tolley¹, A. Welch¹, S.R. Woodward^{1,3}.* 1) Sorenson Molecular Genealogy Foundation, Salt Lake City, UT; 2) Department of Computer Science, Brigham Young University, Provo, UT; 3) Department of Micro and Molecular Biology, Brigham Young University, Provo, UT.

Derivation of haplotype information from unphased genotypic data is vital to many genetic and genealogical questions, including the reconstruction of population history. Microsatellite loci exhibit higher mutation rates than biallelic loci and thereby become good candidates for asking questions about recent population history. These rates contribute to higher levels of identical-by-state allele values and offer a reasonable explanation for the lower absolute success rates obtained for STR datasets by haplotype reconstruction algorithms like PHASE v.2.0.2 (when compared to SNP datasets). This difficulty is exacerbated by the low average density of STR loci in the genome (as compared with available SNP loci) which, generally speaking, increases the noise of recombination events between pairs of loci. Selection parameters such as measures of disequilibrium have been successfully used to improve success rates when applied to SNP datasets. Herein, selection parameters (e.g. LD) and informational parameters (e.g. the extent of population admixture) are shown to improve haplotyping success rates in datasets containing linked STR loci. In addition to the use of simulated datasets (such as phase known diplotypes produced by combining haploid data), phase reconstruction trials using large, real STR datasets of phase-known diploid individuals are performed for the first time-- answering the need to establish success rates within real datasets composed of microsatellite loci. We also present a new haplotype reconstruction algorithm that iteratively infers population haplotype prevalences and haplotype phase probabilities for each sample. Our algorithm provides for the novel use of prior knowledge about individual-level admixture, and operates $\sim 6 \times 10^3$ times faster than PHASE, while achieving comparable levels of accuracy on equivalent datasets.

Variations in C3, C3a receptor and C5 genes affect susceptibility to bronchial asthma. *F. Kamada¹, K. Hasegawa², M. Tamari², M. Shimizu^{2, 3}, N. Takahashi², X.Q. Mao³, S. Doi⁴, H. Fujiwara⁴, A. Miyatake⁵, K. Fujita⁶, Y. Aoki¹, S. Kure¹, Y. Matsubara¹, T. Shirakawa^{2, 3}, Y. Suzuki¹.* 1) Department of Medical Genetics, Tohoku University School of Medicine, Sendai, Japan; 2) Laboratory for Genetics of Allergic Diseases, SNP Research Center, The Institute of Physical and Chemical Research (RIKEN), Yokohama, Japan; 3) Department of Health Promotion and Human Behavior, Kyoto University School of Public Health, Kyoto, Japan; 4) Osaka Prefectural Habikino Hospital, Osaka, Japan; 5) Miyatake Asthma Clinic, Osaka, Japan; 6) College of Nursing, University of Shiga, Shiga, Japan.

Bronchial asthma (BA) is a common chronic inflammatory disease characterized by hyperresponsive airways, mucus over-production, eosinophil activation and the production of IgE. The complement system plays an immunoregulatory role at the interface of innate and acquired immunity. Recent studies have provided evidence that C3, C3a receptor and C5 are linked to airway hyperresponsiveness. To determine whether genetic variations in the genes of the complement system affect susceptibility to BA, we screened single nucleotide polymorphisms (SNPs) in the C3, C5, C3a receptor (C3AR1), and C5a receptor (C5R1) genes and performed association studies in the Japanese population. The results of the single-SNP case-control study suggested an association between 4896C/T in the C3 gene with atopic childhood BA ($P=0.0078$) and adult BA ($P=0.010$). When patients were stratified according to high total IgE levels, 4896C/T was more closely associated with childhood and adult BA ($P=0.0057$ and $P=0.00057$, respectively). Furthermore, a patient-only association study suggested that severity of childhood BA was associated with 1526G/A of the C3AR1 gene ($P=0.0057$). We identified a high-risk haplotype of the C3 gene for childhood ($P=0.0021$) and adult BA ($P=0.0058$) and a low-risk haplotype for adult BA ($P=0.00011$). We also identified a haplotype of the C5 gene that was protective against childhood ($P=0.0000014$) and adult ($P=0.00063$) BA. These results suggest that the C3 and C5 pathways of the complement system play important roles in the pathogenesis of BA and that polymorphisms of these genes affect susceptibility to BA.

Portuguese and non-Portuguese origins of Machado-Joseph disease (MJD): a worldwide haplotype study. S.

Martins^{1,2}, *C. Gaspar*³, *I. Silveira*², *F. Calafell*⁴, *G. Rouleau*³, *P. Coutinho*⁵, *A. Amorim*^{1,6}, *J. Sequeiros*^{2,7}. 1) IPATIMUP, Portugal; 2) UnIGENE, IBMC, Porto, Portugal; 3) Centre for Research in Neuroscience, McGill Univ, Montreal General Hosp, Montreal, Canada; 4) Unitat de Biologia Evolutiva, Fac Ciències de la Salut i de la Vida, Univ Pompeu Fabra, Barcelona, Spain; 5) Serv Neurologia, Hosp S Sebastião, St^a M^a Feira, Portugal; 6) Fac Ciências, Univ Porto, Portugal; 7) ICBAS, Univ Porto, Portugal.

The name Machado-Joseph disease for a type of spinocerebellar ataxia resulted from the description of the disorder among the first families of Portuguese-Azorean origin. At present, this is the most common autosomal dominant ataxia in the world, affecting many different ethnic populations. Following a worldwide study, where two SNP-based haplotypes were found in families of Azorean extraction, we recently reported their uneven distribution in mainland Portugal. The ACA haplotype, specific to the Flores island, and shared by the vast majority of non-Portuguese families, is present in all patients from northeastern Portugal; on the other hand, the GGC haplotype, found in S. Miguel island and only in 7 non-Portuguese families, is mainly in the center and Tagus valley, accounting for 72.6% of the families.

We now studied 150 families from different origins with six intragenic SNPs. Additionally, and taking into account their higher mutation rate, four microsatellites, spanning less than 260 kb from the (CAG)_n, were assessed to unravel more about the recent history of these populations and, consequently, about the origins and possible routes of the mutations. Results from 89 Portuguese and 61 non-Portuguese families suggested either a very ancient origin of the TTACAC haplotype, or different mutational events spread worldwide. Nevertheless, the low microsatellite diversity of this MJD haplotype in Portugal suggests its recent introduction in our population. On the contrary, the GTGGCA lineage may be of Portuguese origin since it shows the highest molecular diversity among the patients harbouring this haplotype.

Program Nr: 1204 from the 2004 ASHG Annual Meeting

Database characterization of Y-chromosomal 39-locus haplotypes. *N.V. Myres¹, J.E. Ekins¹, K. Hadley¹, U.A. Perego¹, J.B. Ekins¹, L.A.D. Hutchison¹, L. Layton¹, M.L. Lunt¹, S.S. Masek¹, A.A. Nelson¹, M.E. Nelson¹, K.L. Pennington¹, J.L. Peterson¹, A. Sims¹, T. Tolley¹, A. Welch¹, S.R. Woodward^{1,2}.* 1) Sorenson Molec Genealogy Fndn, Salt Lake City, UT; 2) Dept. Microbiology, Brigham Young University, Provo, UT.

Forensic analysis based on Y-chromosomal STR loci relies on haplotype frequency estimates for assessing the significance of matching haplotypes. Current frequency estimates, accepted by the forensics community, are based on the minimal 9-locus and extended 11-locus haplotypes. To augment current estimates, the present study reports frequencies for the minimal and extended haplotypes for a dataset of 7,976 male samples collected in the United States, Canada, Europe, Oceania, South America, and Asia . These haplotypes are further extended to a total of 39 loci, for which frequencies are also reported. Additionally, up to 15 generations of paternal-line genealogy was collected for each male to provide a historical interpretation for observed haplotype stratification among populations, as measured by pairwise RST-statistics.

Allele at the *MRP1* gene locus shows evidence of positive selection in the Caucasian population. Z.H. Wang¹, K. Tang², E.J. Lee³, S.S. Chong^{4,5}, C.G. Lee^{2,6}. 1) Bioengineering Div, National Univ. of Singapore (NUS), Singapore; 2) Biochemistry Dept, NUS, Singapore; 3) Pharmacology Dept, NUS, Singapore; 4) Pediatrics, O&G Depts, NUS, Singapore; 5) Dept of Pediatrics, O&G, Inst Genetic Med JHU SOM, USA; 6) Medical Sciences Div, National Cancer Center, Singapore.

The multidrug resistance-associated protein 1, MRP1 (ABCC1) is a 190 kDa founding member of the C subfamily of the ATP binding cassette (ABC) superfamily of transport proteins. Like the multidrug transporter, MDR1, MRP1 effluxes similar spectrum of drugs and are commonly expressed in a large number of drug resistant malignancies. Hence, similar to the MDR1 transporter, single nucleotide polymorphisms (SNPs) within the *MRP1* gene may account for differences in drug response or disease susceptibility between different individuals. To facilitate association studies of this gene locus with complex diseases and drug response, we examined the haplotype and linkage disequilibrium (LD) profiles across the *MRP1* gene among the Chinese, Malay, Indian, Caucasian and African American populations. Thirteen SNPs spanning 186.4 kb of the *MRP1* locus were genotyped in 91-96 individuals from each ethnic population. Unlike the *MDR1* gene, the *MRP1* gene locus exhibited greater haplotype diversity and weaker LD. Nonetheless, despite its weak LD, a high frequency haplotype showed extended haplotype homozygosity across 135 kb in the Caucasian population. Notably, using coalescent simulations, statistically significant ($P < 0.05$) evidence of positive selection was observed for an allele contained in the high frequency haplotype in the Caucasian but not other populations under 4 different population models (constant size, expansion, bottleneck and structure) and 3 recombination rate assumptions (2.6, 1.3 and 0.65). Interestingly, alleles at the *MDR1* gene locus also demonstrated evidence of positive selection but in the Chinese and not the Caucasian population (Tang, et al 2004, Human Molecular Genetics 13:783-797). Taken together, these results suggest that different evolutionary pressures on different populations may result in the selection of different genes with similar functions in the different population.

Program Nr: 1206 from the 2004 ASHG Annual Meeting

A population genetic study of APOE and CYP2D6. *H. Payami, L. Moses, D. Yearout, M. Zhu, J. Montimurro, R. Keefe.* Wadsworth Ctr, NY Department Health, Albany, NY.

Association studies hold the greatest promise for dissecting genetics of complex disorders. Proper matching of cases and controls is thought to be essential, but in reality impractical. Most studies use the same controls for different patient populations, operating with the assumption that allele frequencies do not vary by age or sex. We question if unrecognized variations in control frequencies may be a reason why association studies are often irreproducible. The aim of this study was to assess genotype and allele frequencies of APOE and CYP2D6, two widely studied candidate genes, as a function of age and sex, and to test for deviations from Hardy Weinberg equilibrium (HW). We genotyped 1748 Caucasian individuals; binned data in 4 age groups: newborns (n=573), 20-49 yrs (n=279), 50-79 yrs (n=340), and 80+ yrs (n=556); and used Chi square for analysis. CYP2D6 frequencies deviated significantly from HW (p=.0001): *4 heterozygous was reduced, while both homozygous were increased. The same pattern (suggestive of heterozygous disadvantage) was seen in newborns (p=.03), which was an unbiased series of consecutive births, 20-49 yr group (p=.02), 80+ yr group (p=.003); in men (p=.005) and in women (p=.009). CYP2D6 frequencies did not vary significantly by age or sex. APOE findings were the opposite: all age groups were in HW, but there was significant genotype (p=.03) and allele frequency (p=.002) variation by age. This age effect was significant in women (p=.007) but not in men; and was driven primarily by the drop in e4 frequency in 80+ age group. In summary, CYP2D6 frequencies do not vary by age or sex, hence case-control matching for these variables is not critical. Departure from HW suggests the possibility of selective inferiority for the CYP2D6 mutant/wt heterozygous genotype. Sex and age matching is critical for APOE and can lead to spurious disease associations if ignored. We recommend that population genetic studies be performed routinely on candidate genes, before embarking on disease association studies. (Supported by NIH grants AG08017, NS36960, U24AG21886; and Oregon Newborn Screening).

Frequency of MTHFR C677T, MTHFR A1298C, Factor V Leiden G1691A and Prothrombin G2010A mutations in Systemic Lupus Erythematosus and normal mestizo Mexican populations. *M. Salazar-Paramo^{1,3}, I.P.*

Davalos^{2,3}, L. Gonzalez-Lopez⁴, L. Sandoval², L.E. Figuera^{2,3}, I.C. Valera^{1,3}, J.I. Gamez-Nava^{1,3}. 1) Unidad de Investigacion en Epidemiologia Clinica, IMSS; 2) Division de Genetica, CIBO, IMSS; 3) Departamento de Fisiologia, CUCS, Universidad de Guadalajara; 4) Departamento de Reumatologia, HGZ 110. Guadalajara, Jalisco, Mexico.

Systemic Lupus Erythematosus (SLE) is the prototype of autoimmune diseases. The prevalence of arterial and venous thrombotic events in SLE is high. Thrombophilia is an abnormal phenomenon related with increased formation of embolisms. Thrombophilic risk factors acquired and genetic (MTHFR C677T, MTHFR A1298C, FV G1691A and prothrombin G2010A mutations) represent a hypercoagulability risk. Objective: To determine the allelic (AF) and genotypic frequencies (GF) of MTHFR C677T, MTHFR A1298C, FV G1691A and prothrombin G2010A mutations in SLE and compared to a control group. Methods: The populations consisted of two groups: 1) Group SLE: mestizo Mexican patients with SLE (ACR1982) and 2) Group N: normal mestizo Mexican individuals. Groups were typed for the thrombophilic mutations by the PCR/RFLP method. Hardy-Weinberg Equilibrium was tested by chi square. Results: Group SLE, MTHFR C677T AF % (n): C 48(58), T 52(62), MTHFR A1298C: A 63(75), C 37(45). When analyzed combination of 1298AC/677CT genotypes in SLE group only 13% were 1298AA/677CC. FV G1691A: G 100(120), A 0(0), prothrombin G2010A: G 98(104), A 2(2). Group N, MTHFR C677T AF % (n): C 60(47), T 40(31), MTHFR A1298C: A 72(62), C 28(24), FV G1691A: G 98(84), A 2(2), prothrombin G2010A: G 96(92), A 4(4). Conclusions: AF differences between SLE and N group had not statistical significance. With respect to MTHFR C677T/A1298C, 87 % of the SLE had almost one mutated allele.

Reconciling estimates of linkage disequilibrium in the human genome. *Y. Chretien*^{1,2}, *I. Pe'er*^{2,3}, *P. de Bakker*^{1,2}, *M. Daly*^{2,3}, *D. Altshuler*^{1,2,4}. 1) Department of Molecular Biology and Diabetes Unit, Massachusetts General Hospital, Boston, MA; 2) Broad Institute of Harvard and MIT, Cambridge, MA; 3) Whitehead Institute of Biomedical Research, Cambridge, MA; 4) Department of Genetics and Medicine, Harvard Medical School, Boston, MA.

Patterns of LD in human populations determine the power of indirect association methods. Many large-scale surveys of LD have been performed, but the results of different studies have yielded inconsistent pictures of LD and the number of SNPs needed for LD mapping. We aimed to reconcile these previous reports by examining how descriptions of LD vary depending on attributes of the sampling scheme: SNP ascertainment, minor allele frequency spectrum, marker density, size of region examined, and the sample size in which allelic associations are defined.

We compared multiple characteristics of the data (pairwise measures of LD, haplotype blocks) across five large-scale, publicly available datasets: the HapMap ENCODE project [see abstract by Gabriel et. al.]; a series of genes resequenced by SeattleSNPs; a region of chromosome 20 studied by the Sanger Center; the Gabriel et al dataset published in 2002, and the genome-wide SNP data (>600,000 markers) from the HapMap project. To control for the effect of population origin, this report considers only datasets collected using the same European population (CEPH).

The five datasets appear quite dissimilar when taken at face value. These differences can largely be reconciled, however, based on the sampling schemes used by investigators. For example, the use of dbSNP and direct resequencing are largely similar as long as the frequency spectrum of SNPs identified is considered. These results provide a robust, consistent picture of LD across the human genome, and underscore the importance of understanding the biases inherent in the available approaches: characterizing modest sized regions and numbers of chromosomes by resequencing (as in SeattleSNPs) or sampling subsets of SNPs from the public SNP map (as in the HapMap data), and the different LD properties of SNPs in different allele frequency classes.

Evaluation of the Role of the Transition to Transversion Ratio on the Estimate of the Linkage Disequilibrium Coefficient. *J. Krushkal*¹, *E.F. Ryder*², *M. Pungliya*³. 1) Department of Preventive Medicine and Center of Genomics and Bioinformatics, University of Tennessee-Memphis, Memphis, TN; 2) Department of Biology and Biotechnology, Worcester Polytechnic Institute, Worcester, MA; 3) Genaissance Pharmaceuticals, Inc., New Haven, CT.

Genetic association studies attempt to identify genetic variants that show nonrandom associations with disease traits. A true, or non-spurious association of an allele at a polymorphic marker locus with disease is assumed to be caused by the linkage disequilibrium of the marker allele with a disease allele.

Because two biologically different types of nucleotide substitution, transitions and transversions, often occur at different rates, many previous studies have shown that for estimation of evolutionary distances among divergent sequences from different species it is important to properly evaluate the pattern of nucleotide substitution, i.e., the contribution of different types of nucleotide changes. In this work, we studied the effect of the differences between transitions and transversions on the association among alleles from sites of closely related sequences from the same species. We investigated the role of the transition/transversion ratio on the estimated value of linkage disequilibrium coefficient, D , between a pair of single nucleotide polymorphism (SNP) loci. We investigated the SNP frequency distribution and estimated the transition/transversion ratio among human SNPs using public SNP databases. A range of transition/transversion ratios and different recombination rates were then used to simulate sequence evolution in human populations. For every set of parameters studied, the mean estimated values of the linkage disequilibrium coefficient were independent of the transition/transversion ratio.

Program Nr: 1210 from the 2004 ASHG Annual Meeting

Patterns of genetic diversity, haplotype structure, and linkage disequilibrium at interleukin-4 (*IL-4*) and interleukin-13 (*IL-13*) in human populations. A. Ranciaro, E. Tarazona-Santos, S.A. Tishkoff. Biology, University of Maryland, College Park, MD.

IL-4 and *IL-13* are cytokines mapped to 5q31 involved in Th2 immune response against parasites such as *Plasmodium Falciparum* and helminthes. Because infectious disease has likely resulted in selective pressure during human evolutionary history, *IL-4* and *IL-13* are candidate genes to be targets of natural selection. They also play a role in susceptibility to common complex diseases of the immune system such as asthma and allergies. We have examined nucleotide variation in a 2.5 kb region of *IL-4* (including the promoter containing a SNP (-589 CT) associated with resistance to malarial infection and other infectious diseases) and 3.9 kb of *IL-13* (including the entire coding and promoter regions) in 280 individuals (*IL-4*) and 132 individuals (*IL-13*) from West Africa, East Africa, Asia, Europe and South America. We observed different patterns of nucleotide diversity, haplotype structure and linkage disequilibrium in African and non-African populations, and we identify a set of htSNPs from each geographic region that will be useful for functional genetic association studies of complex disease. We observe an excess of high frequency derived alleles in Europeans and East Africans at *IL-13* and high frequencies of two divergent haplotype clades at *IL-4* (each associated with different alleles at SNP -589). We use several statistical tests to distinguish the effects of natural selection and demographic history on patterns of genetic diversity at these loci. The results of this study will have important implications for identification of SNPs and haplotypes useful for gene-mapping studies of complex diseases, as well as for studies of genetic susceptibility to infectious diseases influenced by Th2 immune response, and the genetic basis of adaptation during human evolution. Funded by BWF and Packard Career awards, and NSF grant BCS-0196183 to ST.

Association of the NRAMP1 gene polymorphisms and susceptibility to tuberculosis in Mestizo population of Mexico. *L. Sandoval*¹, *M.C. Ruvalcaba Garcia*¹, *A. Corona Nakamura*², *G. Amaya Tapia*⁴, *L.E. Becerra Solano*^{1,3}, *L. Martin del Campo Plascencia*⁵, *M.C. Moran Moguel*^{1,3}, *T.P.K. Reddy*¹, *I.P. Davalos Rodriguez*^{1,3}, *L.E. Figuera*^{1,3}, *F. Rivas*³, *J.M. Cantu*³. 1) Divisiones de Genetica y Medicina Molecular, CIBO-IMSS, Guadalajara, Mexico; 2) Infectologia, HE, CMNO, IMSS, Guadalajara, Mexico; 3) Doctorado en Genetica Humana, Universidad de Guadalajara, Mexico; 4) Infectologia, Hospital General de Occidente, SSA, Guadalajara, Mexico; 5) LLARRE, IMSS, Guadalajara, Mexico.

Tuberculosis (TB) is a major cause of human mortality by infectious agents. It has been well established that the host genetic background is an important modulator of TB susceptibility. Several genes linked to TB susceptibility have recently been identified. These include NRAMP1, VDR, IFN-gR, HLA haplotypes, IL-10, IL-12 and their receptors. Genetic polymorphisms of NRAMP1 affect innate host resistance probably through the defective production and function of Nramp1, and the NRAMP1 gene has been associated with TB susceptibility in several ethnic groups. The aim of the present study was to determine whether NRAMP1 polymorphisms are associated with TB susceptibility in a Mestizo population of Northwest Mexico. A total of 56 pulmonary TB (PTB) patients, 27 extrapulmonary TB patients (ETB), and 73 healthy control subjects (C) were studied. Four NRAMP1 polymorphisms: a single nucleotide change in intron 4 (469 + 14G/C, INT4), a non-conservative single-base substitution at codon 543 (D543N), a TGTG deletion in the 3 untranslated region (1729 + 55del4, 3UTR) and a microsatellite GT repeat at 5 to exon 1 ([GT]n), were typed by PCR-RFLP. Genotype distribution in all three groups showed no deviation from Hardy-Weinberg equilibrium. Inter-group comparison yielded no significant difference for allele and genotype distributions at regions INT4, D543N, (GT)n. Only allele 3UTR del were found increased in the PTB group (16.1%) when compared to group C (6.8%, $X^2 = 5.57$; $p = 0.02$). These results support an association between NRAMP1 3UTR polymorphism and PTB.

Different patterns of Linkage Disequilibrium (LD) among Corsica sub-populations. *G. Sole*¹, *V. Latini*¹, *L. Varesi*², *M. Memmi*², *G. Vona*³, *A. Cao*¹, *M.S. Ristaldi*¹. 1) INN-CNR, Selargius (CA), CA, Italy; 2) University of Corte, France; 3) University of Cagliari, Italy.

Genetic isolates with a history of a small founder population, long-lasting isolation and population bottlenecks represent exceptional resources in the identification of genes involved in the pathogenesis of multifactorial diseases. In these populations the disease allele reveals Linkage Disequilibrium (LD) with markers over significant genetic intervals, therefore facilitating disease locus identification. This study has been designed to examine the amount and decay of LD with distance in some sub-populations of Corsica: Corte, Niolo, Bozio, (located in the mountainous north-center of the island) and Ajaccio (located in the south west of the island in a stretch of coast area). Furthermore LD has been analyzed in the general population of Corsica in order to assess the average LD extension in the island. We have analyzed the LD extension on the Xq13.3 genomic region that has been widely used as a measure of general LD in a given population and to compare the levels of LD between populations. We have found an extreme variability of amount of LD among the different populations. Bozio and Niolo show an high degree of LD while Corte, Ajaccio and the general population of Corsica show low degree of LD. The same variability characterizes the pattern of disequilibrium: distance can explain from less than 2% up to 50% of the total LD variation in relation with the different populations. These results are likely due to a different genetic structure in these isolates (even if geographically neighbouring). Number of founders, expansion rate, amount of immigration are factors that could affect the observed micro differentiation and LD extension. Our results stress the importance of choosing the proper sub-populations to carry out studies aimed to the identification of genes involved in complex diseases, because differences in demographic history of the isolated populations demand different strategies.

Allele frequencies of seven short tandem repeat loci in the northern Iranian population. A. Ghamari¹, B. Moghimi², S.S. Hosseini³, H. Najmabadi³. 1) Genetics research center, Social welfare Univ., Tehran, Tehran, Iran; 2) Medical department, university of Tehran; 3) Kariminejad Najmabad Pat. Genetics Center.

The short tandem repeat (STR) loci are highly polymorphic markers, which are of major importance in the field of linkage studies, gene mapping and DNA fingerprinting. To be useful in these areas, any marker must display a significant degree of polymorphism. We studied the informativity of seven of these markers in the northern Iranian population. DNA was extracted from blood samples of 50 normal unrelated individuals. Seven different loci namely, TPOX, HUMTH01, F13B, D16S539, D13S317, D8S1179, and D5S818 were amplified by PCR for each DNA sample. Polyacrylamide gel electrophoresis of PCR products and home-made allelic ladders was carried out, followed by allele frequency and heterozygosity rate determination for each marker. The heterozygosity of markers were calculated as follows: D16S539: 0.812, D13S317: 0.7876, D8S1179: 0.7992, D5S818: 0.761, HUMTH01: 0.7842, F13B: 0.7614, and TPOX: 0.6634. These data offer D16S539 as the most informative marker in the northern Iranian population, followed by D8S1179, D13S317, HUMTH01, F13B, D5S818, and TPOX, respectively. The heterozygosity of about 0.7 for all of markers guarantees using them in linkage studies, gene mapping and DNA fingerprinting.

A single nucleotide polymorphism at the perilipin gene associated with reduced body fat in the Newfoundland population. *G. Sun, C. French, S. Cooke, G. Martin, A. Ma, A. Kennedy, H. Zhang.* Genetics, Memorial Uni. of Newfoundland, St. John's, Newfoundland, Canada.

Perilipin is a hormone-regulated phosphoprotein that coats the surface of lipid droplets in adipocytes and plays an important role in the regulation of human adipocyte lipolysis. The present study was designed to investigate whether a single nucleotide polymorphism (SNP) in the perilipin gene associates with body composition in a large population. Six hundreds and twelve subjects (105 men and 507 women aged 19 to 60) were recruited from the genetically homogeneous population of the Canadian province of Newfoundland and Labrador (NL). Subjects were healthy and at least a third generation resident of NL. Percent body fat (%FAT), percent trunk fat (%FAT-T), lean body mass (LBM) and fat mass (FAT) were measured using dual-energy X-ray absorptiometry. Genomic DNA was extracted from whole blood. An adenine to guanine substitute (A/G) SNP located in the 3rd intron of the perilipin gene was genotyped using TaqMan technology (Assay-On-Demand SNP genotyping kit). A chi square analysis was performed to determine Hardy-Weinberg equilibrium. Association analysis was performed using SPSS software. The frequency of the minor G allele was significantly higher in subjects whose %FAT-T <28% than those whose %FAT-T > 38% (0.32 vs. 0.25; $p < 0.05$ by chi square test). Moreover, %FAT-T was compared among GG, AG and AA genotype groups. GG homozygous subjects showed the least (33.0%), followed by AG heterozygous (36.3%) and AA homozygous subjects with the highest %FAT-T (36.6%) ($p < 0.05$ by ANOVA adjusted for age and gender, and corrected by Bonferroni). Our study showed that the minor G allele associates with significantly less %FAT-T. The same trend was observed for %FAT but was not statistically significant. This is the first study to show that a polymorphism in the perilipin gene is associated with the variation of central obesity at the population level.

Program Nr: 1215 from the 2004 ASHG Annual Meeting

High-throughput resequencing of mitochondrial DNA from major human haplogroups using base-specific cleavage and MALDI TOF mass spectrometry analysis. *M. Ehrich¹, M. Nelson², J. Turner¹, M. Langdown², D. van den Boom¹.* 1) Dept Molecular Biology, SEQUENOM Inc., San Diego, CA; 2) Dept Biostatistics, Sequenom Inc., San Diego, Ca.

Many studies have attempted to link variations in the mitochondrial genome to various diseases with an excess of maternal inheritance. However, to date, few common variations with measurable effects have been identified. One possible reason for the lack of success may be the absence of common variations responsible for the mitochondrial component of disease susceptibility. If rare variations are responsible for the mitochondrial contribution to disease risk, this could only be identified and verified by complete sequence assessment. Here we present a novel application using base-specific cleavage and MALDI TOF mass spectrometry analysis that enables high-throughput mitochondrial resequencing. We established a set of 20 PCR amplicons to analyze the complete mitochondrial genome of 186 individuals in a case-control study. Each group contained 88 individuals from the common European H/V haplogroup and one individual from each of the other common haplogroups (J, U, T, A, I). We found a total of 281 SNPs in all samples. Currently, 120 of the identified SNPs are not listed in the Mitomap database. Within the H/V haplogroup, the vast majority of genetic variations are rare, occurring only in one or two subjects. It is noteworthy that two scientists carried out the sequencing effort in a single day.

Program Nr: 1216 from the 2004 ASHG Annual Meeting

Mitochondrial DNA Data Analysis Using Applied Biosystems SeqScape Software v2.1.1. *A. Pradhan, Q. Doan, J. Sorenson, R. Fang, C. Forbes, S. Vijaychander, R. Nutter, S. Nidtha, P. Baybayan.* Applied Biosystems, Foster City, CA.
