Modifier genes play an important role in the pathogenesis of heart failure (HF). The use of animal models of HF is one approach to identifying modifier genes whose role in human HF can be studied. Using this approach, we previously identified Collagen Type XXIV, alpha 1 (*COL24A1*) as a candidate gene for *Hrtfm2* (Heart failure modifier 2) in the Calsequestrin transgenic mouse model of HF. In order to confirm its role as a modifier of human HF, we identified 11 missense SNPs in *COL24A1* by sequencing the gene in 16 human HF patients. Preliminary analysis identified a suggestive association between one SNP, A61V, and ejection fraction (EF) in a small subset of human HF patients (n=243). We now report a significant association between *COL24A1* and EF in a second, larger human population. Subjects from the CATHGEN sample of the Duke database for coronary artery disease were selected according to EF and their CAD index (CADi), a validated angiographical measure of the extent of coronary atherosclerosis that correlates with outcome. Our population consisted of 301 young cardiac patients (age < 55) and 168 older cardiac patients (age > 55) with reduced EF, and 204 elderly subjects (age > 60) with normal EF matched for the extent of CAD. The association of *COL24A1* with EF was tested using linear regression to examine the relationship between genotype and EF adjusting for covariates. By genotyping 5 *COL24A1* exon 3 missense SNPs in our entire population, we identified a significant association between EF and 3 *COL24A1* coding SNPs: V95M (p=0.0161), P151L (p=0.0218), and E340K (p=0.0137). An examination of mean EF by genotype revealed that each minor allele is associated with a decrease in EF in a gene dose dependent manner. We note that the allele frequencies of each variant are small. In conclusion, we identified *COL24A1* as a high target candidate gene for a modifier of HF using a mouse model of HF. We now demonstrate a significant association between 3 *COL24A1* SNPs and EF in a 968 patient population. These data support a role for *COL24A1* as a modifier gene of human HF.

Gender dependent association of thrombospondin-4 A387P polymorphism with myocardial infarction. *J. Cui*^{1,2}, *E. Randell*^{1, 2, 4}, *J. Renouf*⁴, *G. Sun*², *F-Y. Han*^{1, 2, 4}, *B. Younghusband*¹, *Y-G. Xie*^{1, 2, 3, 4}. 1) Dept. of Genetics; 2) Dept. of Lab Med; 3) Dept. of Pediatrics, Memorial University, St. John's, NL, Canada; 4) Program of Lab Med, Health Care Corporation of St. John's, NL, Canada.

Background - A recently identified novel missense variant of Thrombospondin-4 (TSP4), A389P (29926 GC) was shown to have a possible proatherogenic effect based on function studies. Only a few genetic association studies have been published and with contradictory results. We have been taking advantage of the genetically isolated population of Newfoundland to study the impact of a variety of gene variants on risk for myocardial infarction (MI). As part of this study we tested the hypothesis that the TSP-4 gene variant is a risk factor for MI. The Newfoundland population is a genetically isolated population, which allows us to avoid genetic admixture, a commonly faced challenge in association studies. **Methods and Results** We performed a case control study in 500 patients with MI and 500 normal control individuals from the Newfoundland population. Genotyping of TSP4, A389P (29926 GC) was conducted using real-time PCR. The gene frequency of TSP-4 A387P in the Newfoundland population was determined to be 23.1% which is similar to that reported using other Caucasian populations elsewhere. Slightly increased carrier frequency, allele frequency and frequency of homozygosity for the 387P allele were observed in patients with MI compared with controls (43.6% vs. 41.8%, 24.9% vs. 23.1% and 6.2% vs. 4.4% respectively), but the differences did not reach statistical significance. However, when the distribution of the TSP-4 A387P variant was further analyzed by sub-grouping patients and controls according to age and sex, an increased prevalence of the 387P allele was observed in female patients with MI compared with the sex matched controls (OR = 1.34, 0.93 to 1.94). Furthermore, homozygosity for the 387P allele was significantly associated with female patients compared with the female controls (OR = 2.96, 1.29 to 6.78, P=0.008). **Conclusions**- We conclude that the TSP-4 A387P polymorphism is associated with MI in females, especially when present in the homozygous state. This suggests a gene dosage effect.

APOE4 Allele is Associated with Poor Functional Outcome after Ischemic Stroke. *K. Furie^{1,4}, M. Sale², J. Stein^{3,4}, M. Ning^{1,4}, A. Muzikansky¹, R. Betensky⁵, S. Greenberg^{1,4}, B. Hyman^{1,4}, S. Rich², F. Hsu², P. Kelly^{1,6}.* 1) Massachusetts General Hospital, Boston MA; 2) Center for Human Genomics, Wake Forest Univ School of Medicine, Winston-Salem, NC; 3) Spaulding Rehabilitation Hospital, Boston MA; 4) Harvard Medical School, Boston MA; 5) Harvard School of Public Health, Boston MA; 6) Mater University Hospital, Dublin, Ireland.

Background: APOE4 allele, a susceptibility gene for Alzheimer's disease, is associated with a higher risk of recurrent stroke and poor functional outcome after other neurological insults. The relationship between APOE genotype and functional outcome after ischemic stroke is controversial. We hypothesized that the APOE4 allele would predict poor functional recovery following ischemic stroke. Methods: We enrolled consecutive ischemic stroke patients admitted to a single in-patient acute rehabilitation hospital. Stroke severity (NIHSS) and demographic data were obtained at baseline. Functional status (Functional Independence Measure [FIM] score) was determined at admission, discharge, and at 6-months. Standard RFLP methods using Hha I digest and high-resolution agarose electrophoresis of exon 4-derived PCR products were used for E2, E3 and E4 allele typing. Results: Of 252 patients enrolled, APOE genotypes were available on 214 subjects. The mean age was 66.7 years. 57% were male. The mean FIM was 6723.7 on admission, 9327.0 on discharge, and 10133.1 at 6 months. The mean change in FIM between admission and discharge was 25.517.2 and between admission and 6-month follow-up, 32.928.9. The genotype frequencies were E2/3 11.2%, E2/4 1.87%, E3/3 70.56%, E3/4 14.49%, E4/4 1.87%. In a multiple regression model, the APOE4 allele predicted FIM score at discharge, independent of age and baseline stroke severity ($p=0.0155$). Conclusion: In this sample, the APOE4 allele independently predicted functional outcome following ischemic stroke. This may be an important factor to consider in the design and interpretation of clinical trials in stroke recovery.

A multigenic approach for investigating the synergistic effects of Down syndrome congenital heart disease

candidate genes using the *Drosophila* heart. *T.R. Grossman*¹, *R.J. Wessells*², *G.M. Barlow*³, *R. Bodmer*², *J.R.*

*Korenberg*³, *E. Bier*¹. 1) Division of Biology, UCSD ,La Jolla, CA; 2) The Burnham Inst, La Jolla, CA; 3) Med Genet, Cedars-Sinai Med Center, UCLA, Los Angeles, CA.

Down syndrome (DS) is a major cause of congenital heart disease (CHD). Molecular studies have established a candidate region that includes D21S55 (21q22.13) through the telomere. Potential candidate genes for DS-CHD were prioritized based on their expression in the heart and on homology to genes involved in AV cushion morphogenesis. These genes are: SH3BGR, DSCAM, WRB, Collagen VI A1/A2, Collagen XVIII and HES1. It has been suggested that trisomic inheritance of these gene(s) is sufficient to cause subsets of DS-CHD. We chose to use the *Drosophila* heart as an in vivo system to study the effect of mis-expression of the candidate genes in the heart in an attempt to identify which gene(s) are responsible for the DS-CHD phenotype. *Drosophila* is the invertebrate genetic model system most closely related to humans and is emerging as a powerful tool for analyzing the function of human disease genes. Key determinants of cardiogenesis in the fly also play fundamental roles in early cardiac specification in vertebrates. Using the UAS-GAL4 system we mis-expressed the human candidate genes and their fly counterparts in the fly heart. The effect of mis-expression of the candidate genes on the formation and physiology of the heart is being studied using sensitive physiological assays. In addition, we are examining potential synergistic interactions between the different candidate genes by mis-expressing them in the heart in each possible permutation, an approach that would not be practical in the mouse model system. Our preliminary results show that mis-expression of DS-CHD candidate genes can result in significant heart defects such as decreased heart rate and increased rate of stress-induced heart failure. We also show that the same genes that exhibit a significant heart defect result in strong visible phenotypes when mis-expressed in the eye or in the wing. Taken together these results indicate that mammalian DS-CHD genes are active in the fly heart and may interfere with its normal function and physiology.

5-Lipoxygenase Promoter Polymorphism is Associated with Myocardial Infarction, Elevated C-reactive Protein, and Fasting Insulin Levels. *J. Hartiala*¹, *E. Ipp*², *C. Tymchuk*¹, *A. Lusis*³, *M. Mehrabian*³, *T. de Bruin*⁴, *H. Campos*⁵, *H. Allayee*¹. 1) Dept of Prev Medicine, Univ Southern Calif, Los Angeles, CA; 2) Dept. of Medicine, Harbor-UCLA Med Cntr, Los Angeles, CA; 3) Dept. of Medicine, UCLA, Los Angeles, CA; 4) CardioVasc Res Inst, Maastrich Univ. the Netherlands; 5) Dept. of Nutrition, Harvard School of Public Health.

Coronary artery disease (CAD) is the most common cause of death in Western societies and develops as a result of the complex interaction between genetic and environmental factors. In previous studies with mice, we provided evidence that 5-lipoxygenase (5-LO) deficiency resulted in a profound resistance to aortic lesion development. By examining the human 5-LO gene, we further demonstrated that shorter (i.e. 3 and 4) repeats of a promoter polymorphism were associated with carotid atherosclerosis, C-reactive protein (CRP) levels, and fasting plasma insulin in a randomly ascertained population. To confirm these initial observations, we have now genotyped the same polymorphism in two additional cohorts. In a group of 412 combined hyperlipidemic individuals, the frequency of the 4 allele was significantly higher in those who had suffered a myocardial infarction (MI) than those who had not (0.21 vs. 0.15; $P < .05$). Additionally, homozygosity for the 4 allele was associated with elevated fasting insulin ($P < .05$) in these individuals. In a second cohort consisting of MI patients ($n=1029$) and matched controls ($n=1096$), there was no significant difference in the frequency of the 4 allele, perhaps due to genetic heterogeneity and/or population differences. However, control individuals in this cohort who were homozygous for the 4 allele had significantly elevated levels of plasma CRP (3.9mg/L vs. 2.8mg/L; $P < .04$) and fasting insulin (21mEq/L vs. 15mEq/L; $P < .03$) compared to control individuals with other genotypes. These associations with CRP and insulin were not observed in the MI group, perhaps due to the physiological and inflammatory effects of suffering an MI. Taken together, these findings confirm our initial observations and provide support for the pleiotropic role of 5-LO in CAD and characteristics of the metabolic syndrome in humans.

Polymorphism in ornithine carbamoyltransferase (OTC) is associated with hypertension related phenotypes.

M.Z. Labuda¹, J. Uwabo¹, Y. Sun¹, D. Gaudet², F. Gossard¹, Z. Pausova¹, T. Kotchen³, A.W. Cowley³, J. Tremblay¹, P. Hamet¹. 1) Res Ctr, Hotel Dieu Hospital, Montreal, Quebec, Canada; 2) Complex Hospitalier de la Sagamie, Chicoutimi, Quebec, Canada; 3) Medical College of Wisconsin, Milwaukee, USA.

OTC is a nuclear gene encoding a mitochondrial enzyme. If deficient it causes an inborn error of urea cycle metabolism. Here we present an association study between OTC, hypertension (HT) and related phenotypes among subjects from French Canadian families. An ATT insertion/deletion in the intron 5 of OTC gene with the frequency of 31/69% was used. The sample consisted of 774 individuals from 115 families with HT and dyslipidemia. All blood pressure (BP) measurements were higher among gen1 males and females (1/1+1/2) comparing to gen2 carriers. The difference was strong among HT but not among normotensive (NT) with the highest differences for sleep (mmHg),: systolic, diastolic, mean arterial BP and for heart rate : 12.5, 6.9, 10.2 and 6.4 (p from 0.005 to 0.001), after correction for age, gender and years of HT. Only in males a difference in SBP was observed in response to standing (higher increase in males). While gen1 was similarly associated with BP increase in both genders, an opposite effect for some phenotypes was observed. Gen1 males had higher Na excretion by 29 mg/min, p=0.04 while females had lower by 32.8, p=0.001 and also females had lower Na concentration by 21.0 mg/dl p=0.003 in the urine, after correction for urine volume, age and body size. These differences were not accompanied by difference in aldosterone level, but gen1 males had lower renin change after water load (0.10 vs. 0.51ng Al/ml/hr, p=0.02). Also gen1 males had higher lvm (left ventricle mass) by 30.1g, p=0.05 while females had lower lvm: 39.1, p=0.03. In qualitative analysis a strong dimorphism was detected for late onset HT with odds ratio, OR=10.3 (p=0.01) for gen2 males and OR=3.4(p=0.03) for gen1 females. In conclusion: OTC gene is involved in hypertension and some related metabolic phenotypes in French Canadians with a strong gender dimorphism in sodium metabolism, heart hypertrophy and in predisposition to late onset HT.

Genetic Variations of ETS1 Gene Associated with Hypertension in Japanese. *H. Morisaki¹, I. Yamanaka¹, A. Takashima¹, Y. Kokubo², H. Tomoike³, T. Morisaki^{1,4}.* 1) Dept Bioscience, NCVC Research Inst, Suita, Osaka, Japan; 2) Dept Preventive Cardiology, NCVC, Suita, Osaka, Japan; 3) NCVC Hospital, Suita, Osaka, Japan; 4) Dept Molecular Pathophysiology, Osaka U Grad Sch Pharm Sci, Suita, Osaka, Japan.

ETS1 is an important transcription factor widely involved in many aspects of vascular development, remodeling, and atherosclerotic changes, which are important features of hypertensive pathophysiology. We selected 5 SNPs in the ETS1 gene locus as locus-representing markers and conducted a large-scale association study using consecutive Suita Study samples in Japan, comprised of 1014 women and 866 men, to evaluate the genetic effects of ETS1 on the hypertensive phenotype. Logistic regression analysis showed that 2 SNPs in the promoter region, (-1015)2G/3G and (-606)A/T, were significantly associated with the hypertensive phenotype in men and women, respectively. (-606)T-allele frequency was significantly higher than that of (-606)A-allele in hypertensive cases ($p=0.00004$), and (-606)T carriers were significantly associated with the hypertensive phenotype in females after adjusting for age, BMI, smoking, alcohol consumption, and history of hyperlipidemia or diabetes ($p=0.003$, OR 1.73). For females over 60 years old, the adjusted OR increased to 1.87. ANCOVA analysis using samples from non-medicated subjects also showed that SBP and DBP were significantly higher among (-606)T carriers than non-carriers. Further, male (-1015)3G carriers showed a significant association with the normotensive controls ($p=0.0149$, OR 0.60) and (-1015)3G alleles were significantly less frequent than (-1015)2G alleles in hypertensive cases, suggesting that these may have a protective effect on the hypertensive phenotype. Haplotype analysis revealed that the (-1015)2G/(-606)A haplotype was significantly less frequent in hypertensive females. Our results show that common genetic variations in promoters of the ETS1 gene are associated with the hypertensive phenotype in Japanese.

Genome-wide association study to identify genes related to myocardial infarction and their functional analyses.

K. Ozaki¹, K. Inoue², H. Sato³, A. Iida⁴, Y. Ohnishi¹, H. Sato³, K. Odashiro², M. Nobuyoshi², M. Hori³, Y. Nakamura^{4,5}, T. Tanaka¹. 1) Dept Cardiovascular Diseases, RIKEN, Tokyo, Japan; 2) Department of Cardiology, Kokura Memorial Hospital, Kitakyushu, Japan; 3) Department of Internal Medicine and Therapeutics, Osaka University Graduate School of Medicine, Suita, Japan; 4) Laboratory for Genotyping, SNP Research Center, The Institute of Physical and Chemical Research (RIKEN), Yokohama, Japan; 5) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, University of Tokyo, Tokyo, Japan.

Myocardial infarction, one of the leading causes of death in the world, is characterized by abrupt occlusion of coronary artery resulting in irreversible damage to cardiac muscle. A number of molecules have been reported to be possibly involved in its pathogenesis, including those that mediate inflammation. Lymphotoxin- (LTA) is one of the earliest cytokines produced in vascular inflammatory processes, and it has been recently shown that functional variations in LTA are associated with susceptibility to myocardial infarction by a large-scale genetic association study using single nucleotide polymorphism (SNP). Here we show that LTA binds to galectin-2, a member of galactose binding lectin family, whose function is not well characterized. Case-control association study revealed a SNP in *LGALS2* encoding galectin-2 was also associated with susceptibility to myocardial infarction. This genetic change was shown to affect transcriptional level of galectin-2, which led to altered secretion of LTA possibly by mediating its intracellular trafficking through binding to microtubules, thereby affecting the degree of inflammation. Both proteins were shown to be expressed in the smooth muscle cells (SMCs) and macrophages in the human atherosclerotic lesions. Our findings implicate the importance of LTA cascade in the pathogenesis of myocardial infarction.

ZASP and Melusin variants are Associated with Dilated Cardiomyopathy and Ventricular Dilation Secondary to Hypertension. V. Palumbo¹, A. Belgrano¹, A. Gatti¹, S. Crovella¹, A. Amoroso¹, M. Vatta^{2,1}. 1) Department of Reproductive and Developmental, University of Trieste, Trieste, Trieste, Italy; 2) Department of Pediatrics (Cardiology), Baylor College of Medicine, Houston, Texas, USA.

ZASP is a striated muscle protein essential for maintaining the structural integrity of the Z-line during biomechanical stress. Recently, ZASP mutations have been identified in dilated cardiomyopathy (DCM). Melusin is a striate muscle protein that interacts with the Integrin 1 cytoplasmic domain and localizes to the costameres. Melusin plays a crucial role in the hypertrophic response to mechanical overload. Melusin-null mice, if subjected to pressure overload develop cardiac remodeling and DCM. We investigated the role of ZASP and Melusin in DCM and ventricular dilation secondary to pressure overload due to primary hypertension. We screened 100 DCM and 100 probands with essential hypertension and secondary DCM for mutations in ZASP and Melusin. We identified the C302T missense mutations in ZASP (P101L residue change) in one DCM proband, and the G511A mutation in one patient with secondary DCM (A171T aminoacid substitution). In addition, two synonymous single nucleotide polymorphisms (SNP) were found in exonic and intronic sequences throughout the gene. Two novel Melusin variants were detected in secondary DCM: a synonymous SNP (C872T) that affects the consensus motif of an exonic splicing enhancer (ESE) and segregates with the cardiac phenotype in the proband's family, and a 7 bp intronic duplication in close proximity of exon 6 5'-splice site (IVS6+12_18dupTTTTGAG) in a sporadic case. All ZASP and Melusin variants were absent in 200 control chromosomes. Secondary structure prediction suggests abnormal protein in ZASP mutants, and altered splicing for Melusin variants. We hypothesize that ZASP variants affects the Z-line structural integrity during pressure overload and chronic mechanical stress. Melusin, unlike ZASP, does not appear to play a role in the sarcomeric structural organization; rather it seems to act as biochemical sensor during chronic cytoskeletal mechanical tension as it occurs in ventricular dilation secondary to hypertension.

Promoter Polymorphisms of Heme Oxygenase 1 and Their Influence on Cardiovascular Disease in African Americans. *J. Pohorence Ferguson, Y. Liu-Stratton, G.E. Cooke, P.F. Binkley.* Division of Cardiovascular Med, OSU Davis HLRI, Columbus, OH.

Heme oxygenase-1 (HO-1) is upregulated by stimuli that produce reactive oxygen species, and plays a protective role in cardiovascular diseases involving oxidative stress. A loss of HO-1 activity increases tissue susceptibility to oxidative damage and has been associated with the evolution of cardiovascular disease in animal models and human subjects. The transcriptional activity of HO-1 is reduced by a promoter microsatellite polymorphism, while a T(-413)A polymorphism in the promoter has been found to increase HO-1 transcriptional activity. Sequence analysis was performed on DNA extracted from a total of 377 subjects, 166 normal controls and 211 patients with cardiovascular disease, to examine the frequency of these polymorphisms. In the case of the microsatellite polymorphism, an allele was classified as L if the forward sequence (GT) repeat was 24 or the reverse sequence (AC) repeat was 27. The L allele was found to occur more frequently in African American subjects than Caucasian subjects, with 77% of African Americans having the L allele versus 55% of Caucasians ($p = 0.0002$). Examining the frequency of the T(-413)A polymorphism revealed that 98% of the subjects with an A at position 413 also had an L allele in the microsatellite polymorphism ($p = 0.0001$). When the population was divided by race, all African American subjects possessing an A at 413 also had the L allele ($p = 0.0004$). These findings are significant because they show that the African American population contains two seemingly contradictory polymorphisms in the promoter of the HO-1 enzyme. Further research is necessary to examine how the presence of both polymorphisms influences HO-1 transcription, and how this affects the development of cardiovascular disease in the African American population.

Genetic variation in COL6A1 in Down Syndrome individuals with congenital heart defects and their parents.

R.E. Pyatt¹, M. Gupte¹, M. Lee¹, C. Torfs², G. Capone³, K. Dooley⁴, S.B. Freeman¹, S.L. Sherman¹. 1) Dept Human Genetics, Emory Univ, Atlanta, GA; 2) Public Health Institute, Birth Defects Study, Emeryville CA; 3) Dept of Pediatrics, Johns Hopkins Medical Institutions, Baltimore, MD; 4) Sibley Heart Center, Dept of Pediatrics, Emory University, Atlanta, GA.

Approximately 40% of individuals with Down syndrome (DS) are born with a congenital heart defect (CHD) and atrioventricular septal defects (AVSD) are the most common of those. Collagen VI, a heterotrimeric protein, is expressed in fetal and adult heart. The Collagen 6A1 gene (COL6A1) is located within a region of chromosome 21 implicated in the causation of DS-associated CHD and alterations in COL6A1 function or expression could negatively affect heart septation. Using a case (DS with AVSD) /control (DS without CHD) approach, we examined the association of genetic variation in the COL6A1 gene with the development of AVSD in DS individuals. Three haplotype blocks (5' block spanning exons 1-5, middle block spanning exons 5-20, 3' block spanning exons 21-35) tagged by 5 SNPs were identified from Patil et al (Patil et al, 2001, Science 294:1719-1722). Genotype frequencies in these 5 SNPs were then examined in 52 DS individuals with AVSD, 73 DS individuals without CHD, and all respective parents. Analyses were done separately for Caucasians(C) and African-Americans (AA). Comparison of frequencies for the two SNPs capturing the 3' block revealed significant differences between cases and controls (C $p=0.008$, $p=0.008$ / AA $p=0.018$, $p=0.004$) and between the respective Caucasian parents (C $p=0.016$, $p=0.005$). Significant differences were also noted between cases and controls, and parents for the 5' block tagged SNP in AA and in the middle block tagged SNP in C. Additionally we genotyped 4 coding SNPs (1 in exon 19 and 3 in exon 35) and found no significant difference between any of the study groups. Re-sequencing of 50 individuals of either population has failed to identify SNPs with >10% frequency in the coding portion of the triple helical region of the gene. This study supports previous reports describing increased genetic variation in COL6A1 in DS individuals with CHD.

***GATA4* Mutations in Patients with Congenital Heart Disease.** A. Tomita-Mitchell¹, D. McElhinney², C. Maslen³, V. Garg⁴, D. Srivastava⁴, E. Goldmuntz¹. 1) The Children's Hospital of Philadelphia, Philadelphia, PA; 2) The Children's Hospital, Boston, MA; 3) OHSU, Portland, OR; 4) UT Southwestern, Dallas, TX.

A recent report has implicated mutations in the transcription factor *GATA4* as a cause of familial cardiac septal defects. Mutations in *NKX2.5*, a molecular partner of *GATA4*, have been identified in familial and sporadic non-syndromic congenital heart disease (CHD), including septal and conotruncal defects. We hypothesized that *GATA4* mutations would be found in additional subjects with septal or related conotruncal defects. Our CHD patient cohort included: Tetralogy of Fallot (TOF, 201), ventricular septal defects (VSD, 137), atrial septal defects (ASD, 124), D-transposition of the great arteries (76), double outlet right ventricle (45), truncus arteriosus (20), interrupted aortic arch (11), L-transposition of the great arteries (10), and other malformations (3). Conotruncal and VSD patients tested negative for 22q11 deletions. We evaluated the *GATA4* coding region and exon-intron boundaries for sequence variants in our cohort by Denaturing HPLC (n=503) or Conformation Sensitive Gel Electrophoresis (n=124). Samples showing peak or band shifts were reamplified from genomic DNA and sequenced.

Four non-synonymous mutations (G93A, Q316E, A411V, D425N) were identified in five patients (ASD, 2; VSD, 2; TOF, 1) and were not seen in a control population of 88 individuals by direct sequencing. All four affected amino acid residues are conserved across species and two of the mutations lead to changes in polarity. Nine synonymous mutations were also identified in fifteen patients and were not observed in the control population.

In summary, we identified four non-synonymous variants in five of 627 subjects. Our data suggest these four variants could be disease related but additional functional studies are required. It appears that disease-related *GATA4* mutations occur in a small fraction of CHD patients and that *GATA4* mutations may be etiologically important in conotruncal as well as septal malformations.

Systematic search for SNPs within candidate genes for essential hypertension in a high-risk Chinese population.

*Y. Zhao*¹, *Z. Sun*¹, *Y. Li*¹, *H. Liu*¹, *J. Lu*¹, *Y. Liang*¹, *C. Li*¹, *J. Shi*², *X. Ji*³, *J. Li-Ling*¹. 1) Department of Medical Genetics, China Medical University, Shenyang 110001, CHINA; 2) Department of Clinical Epidemiology, First Affiliated Hospital, China Medical University, Shenyang 110001, CHINA; 3) Laboratory for Conservation and Utilization of Bio-resources, Yunnan University, Kunming 650091, CHINA.

Essential hypertension has become a primary risk for premature death. Since 1999 we had started to investigate a relatively isolated population in Zhangwu, a rural county in northeast China, where an unusually high prevalence of the disease (40.0% in males and 32.0% in females, n=5208) was discovered. Following blood sampling a systematic study for single nucleotide polymorphisms (SNPs) in candidate genes including endothelial Na channel beta-subunit (beta-ENAC), G-protein beta3-subunit (GNB3), the beta-adrenoceptor gene (beta-AR) family, and With-no-lysine=K 4 (WNK4) was performed. So far we have excluded association between SNPs in the exon12 of beta-ENAC including T594M, which was studied extensively in Africans. As for GNB3, although our data did not support it a susceptible gene in the whole population, statistics did suggest that an 825C/T polymorphism may play an important role in the pathogenesis in females (n=133, control=257, P<0.05). For the beta-AR gene family, four SNPs have been studied (beta1-AR: Arg389Gly and Gly49Ser; beta2-AR: Arg16Gly; beta3-AR: Trp64Arg), among which the first two were strongly associated with the disease (n=144, control=174, P=0.0348 and P=0.0000, respectively). On expression analysis, cytoplasmic cAMP of homozygotes for Arg389 and Ser49 were significantly higher than those of homozygotes for Gly389 or Gly49. Screening for SNPs in WNK4, in particular Ala589Ser in exon8 has found a strong association between a T allele and onset of hypertension (n=259, control=235, P<0.05). As a missense mutation, the Ala589Ser polymorphism in exon8 may diminish the function of WNK4 kinase through substitution of a nonpolar residue alanine with a polar residue serine. Our further work will include analysis of more SNPs (and haplotype(s)) and study of structural and functional significance of particular genotypes.

Proteomics Analysis of L-6TG Cell Line Constitutively Expressed Pantothenate Kinase 4 (PANK4). *Y. Li¹, Q. Feng¹, M. Xiong², J. Zuo¹, Y. Meng¹, F. Fang¹*. 1) National Laboratory of Medical Molecular Biology, Institute of Basic Medical Sciences, Peking Union Medical College, Chinese Academy of Medical Sciences, 5# Dong Dan San Tiao, Beijing, P. R. China 100005; 2) Human Genetics Center, The University of Texas, Health Science Center at Houston, Houston TX 77030, USA.

A novel gene, pantothenate kinase 4 (PanK4), was cloned from the SD rat skeleton muscle stimulated by high concentration glucose. PanK4 had been identified to interact with the M2-type pyruvate kinase (Pkm2), which is a key enzyme in the glycolysis pathway. The result showed that PanK4 might involve in the blood glucose control. In order to find more factors that might be affected by PanK4, the proteomics analysis of myoblast cell line L-6TG constitutively expressed PanK4 protein was carried out. From the 2-D gel result, there are 100 hundreds protein spots existing in experimental groups but not in the control groups. By the MALDI-TOF-MS analysis to these spots, heat shock 70kD protein 8, 58 kD glucose regulated protein, Muscle specific enolase and Gamma-actin were identified. The result showed that PanK4 might involve in the Akt/PKB pathway, Jat/Stat pathway: IL-6 receptor family, glycolysis and cell skeleton activation. PanK4 might be a very important factor in regulating the insulin pathway, blood glucose control and some genes transcription.

ALK4: A Possible Role in Neoplasia in Ulcerative Colitis. *S. Mahid*¹, *M. Fox*¹, *D. Colliver*¹, *W. Zacharias*², *S. Galandiuk*¹. 1) Dept. of Surgery, Price Institute of Surgical Research, University of Louisville, Louisville, KY; 2) Brown Cancer Center, University of Louisville, KY.

Background: Inflammatory Bowel Diseases consist of a group of poorly understood disorders including Crohns disease (CD) and ulcerative colitis (UC). Both disorders are associated with an increased risk of colorectal cancer. While numerous IBD susceptibility loci have been characterized, none have been linked with neoplastic progression. Methods: Affymetrix U95 Av2 arrays were used. mRNA was obtained from benign UC, UC dysplasia and UC colon cancer in 3 individuals each who had all 3 tissue types. Transcripts that were present were fit using a repeated measure design across tissue types using SAS Proc Mixed (SAS, Inc.) Results: 699 transcripts were differentially expressed in UC dysplasia compared to benign UC; this was statistically different in 132. Gene profiles in development of dysplasia largely differed from those in progression from dysplasia to cancer. Prior case control studies in our population confirmed an association with IBD susceptibility locus 2 on chromosome 12q. Interestingly, this was the site of one of the statistically differentially expressed genes in dysplasia: ALK4 Least Squares Means, Overall Means: Benign 411, Dysplasia 862.9, Cancer 661.1. Conclusion: ALK4 a TGF- superfamily receptor and tumor suppressor gene is located on 12q3, within the IBD 2 locus. Paradoxically, it was over expressed in dysplasia as compared to benign UC. Upon activation with activin, ALK-4 receptor complexes and phosphorylates Smad 2, which in turn complexes with Smad 4 and may activate or repress the transcription of various genes. We believe that ALK-4 may play a role in neoplastic progression in UC despite its role as a tumor suppressor gene.

Small nucleolar RNAs HBII-52 at chromosome 15q11.2 display a high density of SNPs in autistic patients. M.

Ogorelkova¹, C. Cerrato¹, X. Estivill^{1,2}. 1) Gene and Disease Programme, Centre of Genomic Regulation, Barcelona, Catalonia, Spain; 2) Experimental and Health Sciences Department, Pompeu Fabra University, Barcelona Biomedical Research Park, Barcelona, Catalonia, Spain.

Chromosome 15q11-q13 has been suggested as a candidate region for autism, based on whole genome screens and linkage disequilibrium studies. In addition, cytogenetic abnormalities at the 15q11-q13 locus are relatively frequent in autistic patients. Several brain-specific, paternally imprinted small nucleolar RNAs (snoRNAs) genes with unknown function have been identified at chromosome 15q11.2. HBII-52 snoRNAs are of particular interest since they might be involved in post-transcriptional modifications of the serotonin 2C receptor mRNA. HBII-52 snoRNAs are located within segmental duplications and are present in multiple copies with an elevated sequence identity. Gene conversion and duplicon-mediated rearrangements might occur in this region and therefore could lead to clinical consequences. In Spanish autistic patients, we analysed by SSCP and sequencing of 25 of the 47 HBII-52 snoRNA genes (~6250 bp) searching for either SNPs or de novo gene conversion events. We have detected 20 SNPs and a microdeletion in 20 chromosomes analyzed. The study of the parental chromosomes has ruled out de novo gene conversion events. Given the small number of chromosomes analyzed, the observed SNP density (~3.36/1 kb) is strikingly high. Interestingly, three patients displayed minor alleles for multiple SNPs (>5) in the analyzed region. These SNPs might represent paralogous sequence variants and might be indicative for partial duplications of the HBII-52 region. The study of larger sample of autistic patients and control individuals should allow us to evaluate if accumulation of multiple SNP alleles or possible duplications of HBII-52 snoRNAs region is indeed relevant to autistic disorder.

I/D Polymorphism of angiotensin-Converting Enzyme (ACE) gene in a population with morbid obesity in Spain.
*M. Orera*¹, *C. Palma*³, *D. Saavedra*², *B. Moreno*². 1) Genetics Unit, H Gregorio Marañon. C/ Dr. Esquerdo N 46, 28007 Madrid, Spain; 2) Obesity Unit; 3) Biochemistry Dpt.

BACKGROUND:The renin-angiotensin system (RAS) plays a role in the pathogenesis of metabolic diseases. This system is expressed in human adipose tissue, where angiotensin II stimulates the production of prostacyclin, which affects adipogenesis and adipocyte metabolism. The human ACE gene contains a polymorphism consisting of the presence (I) or absence (D) of a 287-bp in intron 16 of the ACE gene. Genotype DD patients have higher plasma and tissue concentrations of ACE. We investigated the association of the I/D polymorphism of the ACE gene with the presence of morbid obesity in a sample of a population from Spain. **MATERIALS AND METHODS:**We performed a complete familial and personal history from 30 patients with morbid obesity (BMI > 35). We collected the following data: Birth weight, age of obesity onset (apparent causing effect) speed of obesity progression, actual weight and maximum weight. We also asked the patients about their nutritional habits (compulsive and anxious eating) previous dieting (type, duration, results), medication, co-morbidities and related treatments. The physical exam included size, weight, BMI, body fat distribution, and regular biochemical parameters. **RESULTS:**The ACE polymorphism was detected by polymerase chain reaction (PCR) amplification, following the Genomica kit protocol. The genotype DD was found in 80% of the morbid obesity population, the ID in 10% and the genotype II in 10% of patients, respectively. The allele frequencies was 85% for the D allele and 15% for I allele. The data corresponding to a control population of 108 volunteers were: DD 38%, ID 50 % and II 12%, with and allele frequency of 63% D and 37% I. The statistical analysis shows a significant difference ($p < 0.05$) between the frequency of the DD genotype in the morbidly obese patients and the control subjects. **CONCLUSIONS:** These results suggest that the genotype DD could be considered as a risk factor for morbid obesity in this sample population from Spain.

Gender Difference in the Genetics of ADHD. *L. Park*¹, *K. Nummy*², *M. Rappley*⁴, *J. Nigg*³, *K. Friderici*². 1) Genetics Program; 2) Microbiology and Molecular Genetics; 3) Department of Psychology; 4) Peds/Hum. Dev., Michigan State University, East Lansing, MI.

ADHD is a prevalent, costly, impairing, chronic psychiatric disorder originating in childhood and showing high heritability. Molecular genetic studies of it have generally overlooked potentially crucial gender differences in genetic susceptibility. Like many other psychiatric disorders, ADHD clearly differs by gender in prevalence, at least in childhood, and apparently also in symptom expression and clinical correlates. Two probable models could explain the greater incidence of ADHD in boys: the polygenic multiple threshold model and the constitutional variability model. The former posits that girls require more genetic risk factors than boys to be affected; the latter suggests that different causal factors affect girls and boys differently. Our association tests grouping girls and boys separately using eight polymorphisms on three candidate genes for ADHD strongly support the constitutional variability model in the gender differences observed in ADHD. The dopamine transporter (SLC6A3) and the α -2A-adrenergic receptor gene (ADRA2A) were related to ADHD significantly in girls, whereas the dopamine receptor D4 (DRD4) was related to ADHD significantly in boys. This result might be explained by gender differences in the dosage sensitivity of the catecholamine system identified previously, which is derived from gender different expressions of those genes and differential susceptibility of dopaminergic system in dopa-responsive dystonia. These candidate genes may reflect different causal factors between genders for ADHD. However, the possibility cannot be excluded that the similarity of basic family genetic background predisposes to ADHD leading to common etiology between genders. Our genetic data also support this by showing the association for two of the genes, ADRA2A and DRD4, are in the same direction for both genders. The genetic difference between genders in ADHD seems to be important yet questionable in the etiology of ADHD. Taken together our data demonstrate that genetic susceptibility to ADHD is regulated differently in girls and boys.

HLA B44 is associated with decreased severity of autoimmune lymphoproliferative syndrome in individuals with CD95 mutations. *M.M. Vacek¹, A.A. Schäffer², J. Davis¹, R.E. Fischer¹, J.K. Dale³, S.E. Straus³, J.M. Puck¹.* 1) Genetics and Molecular Biology Branch, NHGRI/NIH, Bethesda, MD; 2) Computational Biology Branch, NCBI/NIH, Bethesda, MD; 3) Laboratory of Clinical Infectious Disease, NIAID/NIH, Bethesda, MD.

Autoimmune lymphoproliferative syndrome (ALPS) is a disorder of lymphocyte apoptosis characterized by nonmalignant lymphadenopathy and splenomegaly, expansion of T cells lacking CD4 or CD8 surface markers and increased incidence of autoimmune diseases and lymphoma. Most patients with ALPS have dominant, heterozygous mutations in the tumor necrosis factor receptor superfamily member 6 gene (TNFRSF6), which encodes CD95, also known as Fas, a mediator of apoptosis signaling. The specific Fas mutation a person carries influences the severity of disease. Mutations causing disruption of the intracellular death domain of the CD95 molecule impair apoptosis the most and are associated with the highest penetrance of ALPS features and the greatest morbidity in mutation-bearing relatives of affected probands. However, wide variation in the incidence and severity of clinical and laboratory features of ALPS is seen among members of pedigrees who share the same mutation, implying that additional factors modify the ALPS phenotype. To evaluate HLA as a candidate modifier locus we typed HLA A, B, DQB1, and DRB1 alleles in 317 individuals from 63 unrelated families with defined TNFRSF6 mutations associated with ALPS. We also developed a quantitative severity score and performed statistical analysis with TRANSMIT and FBAT. Among healthy mutation-bearing individuals, transmission of HLA-B44 was significantly overrepresented (nominal $P < 0.009$) as compared to transmission in patients with severe clinical features of ALPS. The B44 allele may exert a protective role in ALPS.

Region Specific Toxicity of Mutant Huntingtin in Human Huntingtons Disease Brain is Directly Replicated in YAC128 Mouse Model. *J.M. Van Raamsdonk^{1,2}, Z. Murphy², M.R. Hayden^{1,2}.* 1) Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Centre for Molecular Medicine and Therapeutics, University of British Columbia, Vancouver, B.C., V5H 4H4, Canada.

Huntingtons disease (HD) is an age onset neurodegenerative disorder that primarily affects the striatum and cortex despite ubiquitous expression of the mutant huntingtin (htt) protein. The YAC128 mouse model of HD has been shown to recapitulate the behavioural abnormalities, cognitive deficits and neuropathology seen in human HD. Here we demonstrate region specific toxicity within the brain that corresponds to the regions affected in HD. At 12 months of age, YAC128 mice show decreased striatal volume (10.4 % decrease; WT = 12.1 0.1 mm³, N = 8; YAC128 = 10.8 0.2 mm³, N = 8; p < 0.001), decreased cortical volume (6.7% decrease; WT = 18.0 0.4 mm³, N = 8; YAC128 = 16.8 0.4 mm³, N = 8; p = 0.04) and decreased volume of the globus pallidus (10.8 % decrease; WT = 1.6 0.06 mm³, N = 8; YAC128 = 1.43 0.04 mm³, N = 8; p = 0.04). At this time point, the volume of the hippocampus (WT = 4.89 0.24 mm³, N = 8; YAC128 = 4.95 0.41 mm³, N = 8; p = 0.9) and the volume of the cerebellum (WT = 48.1 1.3 mm³, N = 5; YAC128 = 50.5 0.9 mm³, N = 5; p = 0.2) are unchanged suggesting that, as in humans, mutant htt has a preferential toxicity for the striatum, cortex and globus pallidus with less toxic manifestations in the hippocampus and cerebellum. We will also present data on the region specific expression levels of mutant and wild type htt protein within the brain and correlate htt expression to the observed pathology. Overall, the ability of YAC128 mice to accurately model human HD will allow us to gain insight into the region specific toxicity in human HD and supports the use of YAC128 mice in pre-clinical therapeutic trials for HD.

Microarray analysis of gene/transcript expression in Angelman syndrome: Deletion versus UPD. *D.C. Bittel¹, N. Kibiryeva¹, Z. Talebizadeh¹, D.J. Driscoll², M.G. Butler¹*. 1) Children's Mercy Hospitals and Clinics and University of Missouri-Kansas City School of Medicine, Kansas City, MO; 2) University of Florida, College of Medicine, Gainesville, FL.

Angelman syndrome (AS) is a neurodevelopmental disorder characterized by severe learning difficulties, ataxia, subtle dysmorphic facial features, and a happy disposition. AS and Prader-Willi syndrome (PWS) were the first examples of genomic imprinting in humans and result from genetic abnormalities of the chromosome 15q11-q13 region. AS results from functional defects in the *UBE3A* gene located within 15q11-q13. Defects in *UBE3A* can be caused by maternal deletion (65-75%), paternal uniparental disomy (UPD, 3-5%), imprinting defects (ID, 3-10%) or point mutations or small deletions within the *UBE3A* gene (5-10%). The remaining AS subjects have no identifiable molecular abnormality (10-14%). The genetic subtypes of AS have a number of phenotypic and behavioral differences. AS subjects with deletions tend to have the most severe phenotype. AS subjects with UPD or ID have a lower incidence of hypopigmentation, microcephaly, and seizures. To further our understanding of the complex nature of gene expression in the 15q11-q13 region and to identify candidate genes/transcripts which contribute to the variation in individuals with AS we have generated cDNA microarrays containing most of the genes/transcripts from the region. We compared gene expression from actively growing lymphoblastoid cell lines established from nine male subjects [6 with AS (3 with 15q deletion and 3 with uniparental paternal disomy 15 or UPD) and 3 controls]. Expression patterns were consistent with expectations for genes known to be biallelically expressed (e.g., *GAPD*, *FBN*), paternally expressed (e.g., *SNRPN*) or maternally expressed (e.g., *UBE3A*, *ATP10C*). Paternal or maternal allele expression bias was detected in several genes/transcripts in our study (e.g., *GABRA5*, *GABRB3*). Our results indicate subtle and unpredicted changes in gene expression which may explain phenotypic differences among genetic subtypes of AS. Furthermore, these results support our previously reported microarray gene expression studies in PWS.

Genes epistatic to *FMRI* involved in the autism behavioral phenotype. *S.T. Nowicki*^{1,2}, *L. Li*^{3,5}, *D.B. Milliken*¹, *J.P. Gregg*^{1,4}, *R.J. Hagerman*^{1,2}, *D.M. Rocke*⁵, *P.J. Hagerman*^{1,3}. 1) M.I.N.D. Institute, UCDMC, Sacramento, CA; 2) Div. of Developmental and Behavioral Pediatrics, Dept of Pediatrics, UCDMC, Sacramento, CA; 3) Dept of Biochemistry and Molecular Medicine, School of Medicine, UC Davis, Davis, CA; 4) Dept of Pathology, UCDMC, Sacramento, CA; 5) Dept of Applied Science, Div of Biostatistics, UC Davis, Davis, CA.

Fragile X syndrome (FXS) is a single-gene disorder with a strong association with autism (AUT). Approximately 33% of patients with FXS will have autism. Our hypothesis is that one or more genes, from a larger pool of autism susceptibility genes, are responsible for the autism phenotype associated with FXS. To test this hypothesis, we analyzed the gene expression profile of 27 patients divided in 2 groups (Group 1: 5 patients with FXS+AUT and 9 patients with FXS, Group 2: 5 patients with FXS+AUT and 8 patients with FXS). A cognitive assessment and ADOS-G were performed. Total RNA was isolated from whole blood. Samples were prepared and analyzed on the HG-U133A (Group 1) and the HG-U133Plus2.0 (Group 2) gene chips using standard protocols (Affymetrix). The data from each group was transformed and normalized as described by Geller et al. [(2003) *Bioinformatics* 19:1817]. A two-sample t-test was performed between the FXS+AUT and FXS samples for each group. There were 1,113 probes in common from both groups that were differentially expressed. The Ingenuity Pathway Analysis tool found 427 genes that were contained in 116 global networks that involved 926 total focus genes from the database. Several cellular mediators of neurotrophic factor signaling were differentially expressed including Cdc42, JNK, -catenin, JIP1/2/3, PP2A, MEK1/2, AKT, JAK1, JIP1, mTOR, PINCH1, and TSC1. Many of these intracellular signaling pathways are involved in axon outgrowth and guidance, and dendritic branching and arborization. The RT-PCR validation of these targets and the metabolic consequences will be discussed. These data support our hypothesis that differential gene expression in FXS patients with autism offers additional clues to identify epistatic genes that contribute to the development of autism.

Maternal genetic polymorphisms of folate pathway and risk of Down Syndrome in Campania, Italy. *I. Scala¹, M. Sellitto¹, B. Granese¹, S. Salomé¹, M. Cestari¹, A. Sammartino², A. Pepe¹, C. Nappi², G. Sebastio¹, P. Mastroiacovo³, G. Andria¹.* 1) Dept of Pediatrics, Federico II University, Naples, Italy; 2) Dept. of Gynecology and Obstetrics, Federico II University, Naples, Italy; 3) International Centre on Birth Defect, Rome, Italy.

Down syndrome (DS) is caused by trisomy of chromosome 21. The molecular mechanisms of non-disjunction are elusive. Genetic polymorphisms of folate pathway have been associated with DS in some studies, but not in others. We present a comprehensive study of polymorphisms of genes of the folate pathway in mothers as risk factors for DS in Campania, Italy. DNA from 84 DS mothers and from 233 controls from the same population was analysed for the following polymorphisms: methylenetetrahydrofolate reductase (MTHFR) C677T and A1298C, methionine synthase reductase (MTRR) A66G, cystathionine-beta-synthase (CBS) 844ins68, methionine synthase (MTR) A2756G and reduced-folate carrier 1(RFC1) A80G by specific restriction enzymes. MTHFR 677TT, CBS 844ins68, MTRR 66GG and MTR 2756GG genotypes were not associated with increased risk of DS. Conversely, the MTHFR 1298CC and the RFC1 80GG genotypes were more frequent in DS mothers vs controls with a 2.29-fold increased risk (OR 2.29; 95% CI 0.98-5.37) and a 2.22-fold increased risk (OR 2.22; 95% CI 0.96-5.12) of DS, respectively. MTHFR 677TT and 1298CC genotypes were associated with maternal age at delivery. By stratifying the DS mothers' population by the age at delivery, we found a statistically significant association between mothers younger than 30 years old and MTHFR TT genotype (<25 years: OR 11.25; 95% CI 1.66-87.6; 25-29 years: OR 5.4; 95% CI 1.05-30.44). The MTHFR 1298CC genotype was associated with maternal age at delivery \geq 30 years (OR 4.49; 95% CI 0.9-43.3). The role of folate/homocysteine metabolism in DS is under evaluation in several settings with discordant results, due to three main critical issues: wide difference of allelic frequencies in various populations, choice of controls, study sample size. Well designed collaborative multicenter study and a comprehensive polymorphisms evaluation could help to address the issue.

Identification of disease genes using gene network models inferred from gene expression profiles. *D. di Bernardo*¹, *T.S. Gardner*², *J.J. Collins*². 1) Computational biology, TIGEM, Naples, Naples, Italy; 2) Department of Bioengineering, Boston University, Boston, MA.

Genetic diseases result from a hierarchical chain of events initiated by the mutation of a single gene and resulting in the dysregulation of several genes (secondary responders). We propose a computational approach to identify disease genes from whole genome gene expression profiles. The approach analyzes the expression profile of a mutated cell using a gene-network model to distinguish the mutated gene, responsible for the disease, from genes that exhibit only secondary responses. This approach was successful in *Saccharomyces cerevisiae* and it can be scaled up to mammalian organisms. Our approach first constructs a computational model of regulatory interactions in the organism. The model is learned using a training data set of whole-genome expression profiles resulting from a variety of treatments (knockouts, chemical agents, etc.). Second, we apply the model of regulatory interactions to the expression profile obtained from a yeast strain with a mutation in one of its genes. The model analyzes the mutant profile to suppress expression changes of genes that are due to internal regulatory influences (secondary responders) and amplifies the expression changes of the mutated gene. The result is a list of genes ranked by their likelihood of being the mutated gene. We tested our algorithm on a data set consisting of 300 whole-genome yeast expression profiles. We tested the ability of the algorithm to identify 11 genes with mutated promoters in the data set. The algorithm correctly identified the gene in 10 out of the 11 cases (91% correct). In contrast, expression-change ranking identified the correct gene for only 4 of the 11 mutations. We examined whether the algorithm could identify mutations that affect only protein activity, but not mRNA expression level. We applied the algorithm to a yeast strain carrying a mutation yielding a truncated protein and successfully identified the mutated gene. Our approach could be applied to mammalian organisms. Expression profile obtained by treating cells with compound libraries may serve as suitable data set for analysis by the algorithm.

Association of the 744TC polymorphism in the P2RY12 gene with response to clopidogrel following coronary stent implantation. *U. Cavallari¹, E. Trabetti¹, M. Biscuola¹, D.J. Angiolillo², A. Fernandez-Ortiz³, E. Bernardo³, C. Ramirez³, M. Sabate³, P. Jimenez-Quevedo³, R. Moreno³, R. Hernandez-Antolin³, C. Banuelos³, J. Escaned³, F. Alfonso³, M.A. Costa², T.A. Bass², C. Macaya³, P.F. Pignatti¹.* 1) Dept. Mother-Child & Biol-Genetics, Univ Verona, Verona, Italy; 2) Cardiovascular Center - Shands Jacksonville - Univ Florida, USA; 3) Cardiovascular Institute - San Carlos Univ Hospital, Madrid, Spain.

Clopidogrel inhibits the purinergic receptor P2Y, G-protein coupled, 12 (P2RY12). Recently, polymorphisms of this receptor have been associated with platelet aggregation and have been suggested to modulate the broad interindividual clopidogrel response. The 744TC polymorphism of the P2RY12 gene was assessed in a total of 116 pts undergoing elective coronary stenting: 36 pts receiving a standard 300 mg loading dose (Group A) and 80 pts on long-term clopidogrel (75 mg/d) treatment (Group B). Platelet function, including platelet aggregation (PA) and platelet activation, was assessed. PA was assessed by light transmittance aggregometry in platelet-rich plasma stimulated with ADP (6 M). Platelet activation was assessed by P-selectin expression and activated GPIIb/IIIa (anti-Fibrinogen-FITC) using whole blood flow cytometry in ADP (2 M)-stimulated platelets. Platelet function was assessed at baseline (pts only on aspirin) and 4 and 24 hours following clopidogrel loading dose in Group A and when pts were on clopidogrel treatment for at least 1 month in group B. Patients were similar for baseline demographic and clinical characteristics. No differences were observed between groups for any of the assessed platelet function profiles according to genotype. In conclusion, the 744TC polymorphism of the P2RY12 gene did not appear to be associated with platelet response to clopidogrel in this group of patients.

Replication study of PDE4D and ALOX5AP gene variants in a Scottish Stroke population. *S. Gretarsdottir¹, A. Helgadóttir¹, D. St.Clair², A. Manolescu¹, J. Cheung², G. Thorleifsson¹, A. Pasdar², U. Thorsteinsdóttir¹, S.F. Grant¹, A. Kong¹, J.R. Gulcher¹, K. Stefansson¹, M.J. MacLeod².* 1) deCODE Genetics, Reykjavik, Iceland; 2) Aberdeen Royal Infirmary and University of Aberdeen Medical School, Aberdeen, UK.

Genetic variations in two genes have recently been associated to common forms of stroke in Iceland, the Phosphodiesterase 4D gene (PDE4D) and 5-Lipoxygenase activating protein (ALOX5AP) (Gretarsdottir et al.2003, NatGen 35:131-8; Helgadóttir et al.2004, NatGen 36:233-9).To further assess the contribution of the PDE4D and ALOX5AP variants to stroke a replication case-control study was carried out in a Scottish stroke population (n=574 patients and n=718 controls).The majority of the Scottish patients had ischemic stroke.The replication was carried out by genotyping the previously identified PDE4D (at-risk and protective haplotype) and ALOX5AP (HapA and HapB).Comparison of the estimated haplotype frequency of the Icelandic ALOX5AP at-risk haplotype (HapA) between Scottish stroke patients and controls showed that the patients had a significantly higher frequency than controls (allelic frequency 18.5% versus 14.3%, respectively, p=0.007).The ALOX5AP variant called HapB, a variant found to be associated with myocardial infarction in British individuals,did not show association to stroke in this Scottish cohort.The Icelandic PDE4D protective haplotype was also significantly replicated in the Scottish stroke cohort (allelic frequency in patients 16.8% versus 20.5%in controls,p-value=0.0078).The Icelandic at-risk haplotype (defined by microsatellite AC008818-1 allele 0 and SNP 45 allele G)was not shown to confer risk of stroke.However by exchanging the microsatellite allele from 0 to 4 a significant difference was observed between Scottish patients and controls (allelic frequency 22.1%versus 17.7%,p=0.006).Taken together,our results point to an important role for both the ALOX5AP and PDE4D genes in the pathogenesis of common forms of stroke, not only in Icelanders but also in a population outside Iceland.

Genetic and functional evidence for the role of USF1 transcription factor in hyperlipidemias. *J. Naukkarinen¹, M. Gentile¹, A. Soro-Paavonen², J. Saarela¹, P. Pajukanta³, M-R. Taskinen², L. Peltonen^{1,3}.* 1) Department of Molecular Medicine, National Public Health Institute, Finland and Department of Medical Genetics, University of Helsinki, Biomedicum, 00290 Helsinki, Finland; 2) Department of Medicine, Helsinki University Central Hospital, Helsinki, Finland; 3) Department of Human Genetics, David Geffen School of Medicine at UCLA, University of California, Los Angeles, California 90095-7088, USA.

Familial combined hyperlipidemia (FCHL) is the most common familial dyslipidemia in man. It is characterized by elevated levels of serum total cholesterol, triglycerides or both and is observed in about 20% of individuals with premature coronary heart disease.

We recently reported the discovery of a major gene behind FCHL on 1q23. Linkage and association was established to a transcription factor called USF1 representing an important regulator of numerous genes involved in lipid and glucose metabolism (Pajukanta et al. *Nature Genetics*, 2004). Component traits of FCHL overlap with the metabolic syndrome and type II diabetes suggesting that USF1 may contribute to the molecular background of these conditions as well. The linkage of the USF1 region on 1q23 to FCHL and type II diabetes has already been replicated in several populations and recently USF1 was found to be associated with glucose and lipid parameters in a European wide study sample (Putt et al. *Hum Mol Genet*. 2004)

Our analyses of expression profiles in fat biopsy samples from individuals with FCHL indicate differences in the expression level of the USF1 regulated genes conditional on the associated haplotype. The functional role of this DNA region was studied in vitro. A putative regulatory element identified in the associated haplotype was shown to enhance expression of a reporter gene and a 20bp DNA region was also shown to bind a factor from nuclear extract in a gel-shift experiment. Furthermore, a SNP within this 20bp segment seems to influence specificity of the binding, implying its functional importance in the dynamics of USF1 expression and hence in dyslipidemias.

Association between soluble guanylate cyclase (sGC) subunit gene, GUCY1A2, and hypertension in a black South African population. *M. Penny*¹, *S. Bentivegna*², *S. Lebejko*², *L. Wood*², *G. Wimpenny*³, *P. Colman*³. 1) Clinical Pharmacogenomics, Pfizer Global Research and Development (PGRD), Sandwich Laboratories, Kent, UK; 2) Discovery Pharmacogenomics, PGRD, Groton Laboratories, CT, USA; 3) Biostatistics and Reporting, PGRD, Sandwich Laboratories, Kent, UK.

The role of sGC in the NO-signalling pathway and the regulation of blood pressure together with the observation of altered sGC subunit expression in rat models suggest that they are good candidate genes for hypertension. A total of 24 (single nucleotide polymorphisms) SNPs in the four sGC subunit genes (6 each in GUCY1A3 and GUCY1B3, 5 in GUCY1A2 and 7 in GUCY1B3 gene were genotyped in 371 hypertensive and 360 control subjects of black South African origin.

A statistically significant association was observed between one SNP (A+6312G) present in intron 2 of the GUCY1A2 gene and hypertension. The estimated increased risk of hypertension in the total population, adjusting for the effects of age, gender and BMI ranged from 1.9 (1.38-2.61) for possession of one additional rare G allele to 3.6 (2-6.81) for two additional rare alleles ($p=0.001$). No other SNP tested in GUCY1A2 or any other sGC gene was associated with disease. This is the first study to identify a genetic association between an sGC subunit gene and hypertension in humans. It is unclear how the GUCY1A2 intron 2 SNP predisposes to hypertension, it may occur in a regulatory region of the gene or may influence splicing, alternatively the association may be due to linkage disequilibrium with SNPs in the promoter of the gene that have yet to be studied. A study to replicate these findings is currently underway in a second black population.

Polymorphisms in antioxidative defences. The Generale Study. A. Rautanen¹, G.A. Fowkes², U. Diczfalusy³, J. Kaikkonen⁴, J. Kere¹, A. Lee², J. Luedemann⁵, K. Nyysönen⁴, H.E. Poulsen⁶, P. Prati⁷, R. Salonen⁴. 1) Finnish Genome Center, and Department of Medical Genetics, University of Helsinki, Finland; 2) Wolfson Unit for Prevention of Peripheral Vascular diseases, and Cardiovascular Research Unit, University of Edinburgh, UK; 3) Department of Medical Laboratory Sciences and Technology, Huddinge University hospital, Huddinge, Sweden; 4) Research Institute of Public Health, University of Kuopio, Finland; 5) Institute of Epidemiology and Social Medicine, University of Greifswald, Germany; 6) Department of Clinical Pharmacology, Rigshospitalet, Copenhagen, Denmark; 7) Department of Neurology, Gervasutta Hospital, Udine, Italy; 8) Department of Hematology, San Bortolo Hospital, Vicenza, Italy; 9) Institute of Community Medicine, University of Tromsø, Norway.

The GENERALE is a European multi-centre prospective follow-up study on genetic and environmental risk factors for ageing-related atherosclerosis and cardiovascular events. A subset of IMT, AMI, and stroke cases and matched controls were chosen from five large European population cohorts. The primary hypothesis is that oxidative stress with certain genetic backgrounds enhances atherosclerosis. In the current sub-study we measured the association between candidate gene polymorphisms involved in antioxidative defenses (glutathione peroxidase (GPX1), glutathione S-transferases, haptoglobin, paraoxonases (PON), superoxide dismutase (SOD), myeloperoxidase) and antioxidant enzyme activities in addition to F2-isoprostanes. Polymorphisms in GPX1, PON1, and PON2 genes were significantly associated with the enzyme activities, unlike SOD2 polymorphism. F2-isoprostanes, biomarkers of lipid peroxidation, were correlated with several tested polymorphisms. Interaction of background variables (e.g. smoking) was taken into account in the multivariate model. The allele frequencies of candidate polymorphisms varied between different parts of Europe, the prevalence of GPX1-Pro197Leu (48% in Finland, 29% in Italy), and GSTP1-Ile104Val (25% in Finland, 36% in Germany) differing most among Europeans.

Association between TAFI genotype and risk of MI in white Caucasian male subjects selected from individuals enrolled in a cardiovascular clinical trial. *J. Richmond*¹, *P. Milos*¹, *A. Power*², *S. Bujac*³, *M. Penny*³. 1) Discovery Pharmacogenomics, Pfizer Global R&D, Groton, CT, USA; 2) Clinical Pharmacogenomics, Pfizer Global R&D, New London, CT, USA; 3) Clinical Pharmacogenomics, Pfizer Global R&D, Sandwich, Kent, UK.

Thrombin-activatable fibrinolysis inhibitor (TAFI) has a role in the regulation of fibrinolysis and has been implicated as a risk factor in cardiovascular disease (CVD). The TAFI gene is polymorphic and there is evidence that plasma TAFI antigen levels are genetically controlled. Published data on TAFI genotype and risk of CVD are conflicting. Data suggest that genetic variants that correlate with low levels of TAFI antigen are associated with a decreased risk of DVT and increased risk of MI.

Forty-eight healthy volunteers with TAFI antigen measurements were genotyped for 7 single nucleotide polymorphisms (SNPs) in the TAFI gene. Three groups of subjects were defined from a population of white Caucasians enrolled in the Atorvastatin Comparative Cholesterol Efficacy and Safety Study (ACCESS): 1- Subjects with an historical MI- (340 males, 135 females); 2- Subjects without an historical MI and with atherosclerosis (573 males, 598 females); 3- Subjects without a historical MI and no evidence of atherosclerosis (310 males, 397 females). Multivariate association between TAFI genotype and MI status was carried out as well as logistic regression with adjustment for any confounders. Two TAFI SNPs accounted for approximately 50% of the variability in TAFI antigen in healthy volunteers. A significant association between low TAFI antigen predicting genotype and increased risk of MI was observed in males in the ACCESS study. The estimated increased risk of MI ranged from 1.2 in men possessing one low TAFI antigen predicting allele up to 2.1 for two alleles. There was also evidence that the effect of TAFI genotype on risk of MI is not the same in males and females. Establishing the relationship between TAFI genotype, antigen level, and activity is the next step in understanding the association between TAFI and CVD.

Association study of the OLR1 gene with coronary artery disease and acute myocardial infarction. *E. Trabetti¹, M. Biscuola¹, U. Cavallari¹, G. Malerba¹, R. Galavotti¹, S. Friso², D. Girelli², N. Martinelli², O. Olivieri², F. Pizzolo², R. Corrocher², P.F. Pignatti¹.* 1) Dept.Mother-Child & Biol-Genetics, Univ Verona, Verona, Italy; 2) Dept. Clinical & Experimental Medicine, Univ. Verona, Verona, Italy.

Oxidised LDL receptor 1 (OLR1 or LOX 1) has been considered a good candidate gene for atherosclerosis and myocardial infarction since it is upregulated by various proatherogenic stimuli and induced in vitro by inflammatory cytokines. Seven polymorphisms have been identified in the OLR1 gene and associations between these SNPs and coronary artery disease (CAD) or acute myocardial infarction (AMI) have been reported in different populations. Aim of our study was to investigate an association of OLR1 gene polymorphisms with AMI and CAD in a North East Italian population sample. For this purpose, a total of 575 individuals subjected to coronarography were genotyped for the following three OLR1 gene SNPs: IVS4-73CT, IVS4-14AG and 501GC. Allele and genotype frequencies were determined in the following four groups of patients: 165 AMI, 156 non AMI, 294 CAD, 281 non CAD. The distribution of genotypes in each group was in Hardy-Weinberg equilibrium. We confirmed a complete L.D. between the two IVS4 SNPs. No statistically significant difference was observed in allele or genotype distribution in AMI or CAD patients compared to controls. In conclusion, the data here reported do not provide evidence for strong association of AMI or CAD with the OLR1 gene. Further studies on OLR1 and on OLR1/other gene polymorphisms interaction could probably lead to explain the genetic involvement in AMI and CAD in the Italian population.

Association of a SNP in MGEA5 encoding O-GlcNAcase with diabetes in Mexican Americans. *D. Lehman¹, D.-J. Fu², K. Hunt¹, R.J. Leach¹, R. Arya¹, H. Abboud¹, R. Duggirala³, T. Dyer³, H.H.H. Goring³, J. Blangero³, M.P. Stern¹.*
1) Dept of Medicine, Univ TX Health Sci Ctr, San Antonio TX; 2) Lilly Research Laboratories, Eli Lilly and Co, Indianapolis IN; 3) Dept of Genetics, Southwest Foundation for Biomedical Research, San Antonio TX.

Excess O-glycosylation of proteins by O-linked N-acetylglucosamine (O-GlcNAc) may be involved in the pathogenesis of type 2 diabetes. O-GlcNAcase, encoded by MGEA5 on 10q24.1-q24.3, reverses this modification by catalyzing the removal of O-GlcNAc. STZ, a beta cell toxin used to induce diabetes in rodents, acts by inhibiting O-GlcNAcase. We have previously reported linkage of type 2 diabetes and age at diabetes onset to an overlapping region on chromosome 10q in the San Antonio Family Diabetes Study (SAFADS). We, therefore, investigated MGEA5 as a positional candidate in this population of Mexican Americans. To identify variants, all exons and flanking intronic sequence, 5 and 3 UTRs, 1 kb upstream of exon 1, and all of introns 10 and 11 were resequenced in 22 diabetic and 22 non-diabetic subjects. We identified 24 SNPs of which 19 are novel (minor allele freq is 0.02 to 0.25). All SNPs were genotyped in 436 individuals from 27 families whose data were used in the original linkage report. Each SNP was tested for association with the traits diabetes and diabetes age-of-onset using a measured genotype approach, as implemented in SOLAR. Significant association of nonredundant SNP LLY-MGEA5-14 (mg14, minor allele freq is 0.04), located in intron 10, was observed with the traits diabetes age-of-onset ($p=0.001$) and diabetes ($p=0.012$). We investigated whether this variant was responsible for the original linkage signal by including it as a fixed effect in the linkage analysis, leading to a drop in LOD score from 3.77 to 2.84. These results suggest that this variant may partially account for diabetes risk in Mexican Americans. SNP mg14 is located within intron 10, which contains an alternate stop codon, so this variant could alter expression of MGEA5 isoforms, although functional studies will be necessary to confirm this. Alternatively the mg14 variant may be in LD with true functional variants in this region.

Single nucleotide polymorphisms in GRPR gene in male patients with autism. *L. Zhang¹, R.J. Schroe², Y. Jiang¹, C. Obie¹, D. Valle^{1,3}, R. Stevenson², T. Wang¹.* 1) Dept Human Genetics, JHMI, IGM, Baltimore, MD; 2) Greenwood Genetic Center, SC; 3) Howard Hughes Medical Institutions.

Autism is a neuropsychiatric disorder characterized by severe social and communication deficits with restricted or repetitive behaviors or interests. Genetic factors play important roles in the development of autism and males are four times more likely to be affected than females. To identify X-linked autism susceptibility genes, we studied X-linked gene expression in lymphoblast cell lines from males with autism using a combination of X chromosome cDNA microarray, quantitative real-time PCR, and Northern blot analysis. We found reduced expression of gastrin-releasing peptide receptor (GRPR) gene in several cell lines. In follow up sequence analysis of GRPR in 92 probands, we identified 13 SNPs: 5 synonymous cSNPs, 3 of which not previously reported; and 8 were found in introns or 5- and 3-UTRs. Interestingly, we identified a single G>A substitution in the 5-UTR in 9 of 92 (10%) probands and in 5 of 242 (2%) controls ($X^2=9.88$, $p<=0.01$). In all tested cell lines (n=4) carrying the G>A substitution steady state level of GRPR mRNA were reduced to less than 20% of normal. GRPR is a G-protein coupled receptor that is expressed in the limbic system, an area of the brain involves in emotion, affection and attention. Interestingly, a previously reported female with autism had an X;8 translocation with the breakpoint in intron-1 of GRPR (Ishikawa-Brush et al., 1997), and a recent study of Grpr knockout mouse revealed an enhanced amygdala-mediated long-term memory for fear. These observations suggest that further evaluation of the genetics and function of GRPR are warranted to understand its possible roles in autism.

Mutations in the Genes for MODY are not a Common Cause of Early-Onset Type 2 Diabetes in Minority

Populations. *H. Allayee*¹, *D. Parker*², *A. Stammreich*², *J. Canales*², *G. Scheel*², *A. Lusic*³, *E. Ipp*². 1) Dept Prev Med, Univ Southern Calif, Los Angeles, CA; 2) Dept of Med, Harbor-UCLA Med Cntr, Torrance, CA; 3) Dept of Med, UCLA, Los Angeles, CA.

In recent years, type 2 diabetes is increasingly diagnosed at younger ages, particularly in minority populations such as Mexican-Americans and African-Americans. Maturity onset diabetes of the young (MODY) is defined classically as a Mendelian dominant form of type 2-like diabetes developing before age 25 in a proband or at least one family member. To determine whether mutations in the genes for the most common causes of MODY could account for the early-onset type 2 diabetes observed in minority patients, we screened the coding regions and flanking intronic boundaries of the hepatocyte nuclear factor 1-alpha (HNF1a), HNF4a and glucokinase genes by heteroduplex analysis and direct sequencing. The study population (n=29) consisted of 17 Mexican-Americans and 9 African-Americans families that fulfilled the traditional diagnostic criteria for MODY. Apart from previously described common polymorphisms, no mutations were found in 28 of the probands. One African-American subject, who developed type 2 diabetes at the age of 25, was heterozygous for a Tyr322Cys substitution in exon 5 of HNF1a. The sibling and father of the proband developed diabetes at age 26 and 52, respectively, and were also heterozygous carriers of the variant. Physiological testing of these family members revealed a significant insulin secretion defect in response to a bolus glucose infusion. Using the PolyPhen program, which predicts the functional consequence of amino acid substitutions, a cysteine residue at position 322 would severely damage the function of HNF1a. Taken together, these results suggest that the Y322C substitution is most likely a previously undescribed disease-causing MODY mutation. Furthermore, the very low frequency of mutations in the common MODY genes in a population enriched for this disorder (i.e., fulfill the classical definition for MODY), suggests that diagnostic criteria for this early-onset form of diabetes should be carefully re-evaluated, particularly in those patients of minority descent.

Variation in *NCB5OR*: studies of relationships to type 2 diabetes, MODY, and gestational diabetes mellitus. G. Andersen¹, L. Wegner¹, C.S. Rose¹, J. Xie², H. Zhu², K. Larade², A. Johansen¹, J. Ek¹, J. Lauenborg³, T. Drivsholm⁴, K. Borch-Johnsen^{1,4}, P. Damm³, T. Hansen¹, H.F. Bunn², O. Pedersen^{1,5}. 1) Steno Diabetes Center, Gentofte, Denmark; 2) Brigham and Womens Hospital, Harvard Medical School, Boston, USA; 3) Obstetric Clinic, National University Hospital, Rigshospitalet, Copenhagen, Denmark; 4) Research Centre for Prevention and Health, Glostrup University Hospital, Glostrup, Denmark; 5) Faculty of Health Science, Aarhus University, Aarhus, Denmark.

Recent data show that homozygous *Ncb5or*^{-/-} knock-out mice present with an early-onset non-autoimmune diabetes phenotype. Furthermore, genome-wide scans have reported linkage to the chromosome 6q14.2 region close to the human *NCB5OR*. We therefore considered *NCB5OR* to be a biological and positional candidate gene and examined the coding region of *NCB5OR* in 120 type 2 diabetic patients and 63 patients with maturity-onset diabetes of the young (MODY) using denaturing high performance liquid chromatography (dHPLC). We identified a total of 22 novel nucleotide variants. Three variants (IVS5+7del(CT), Gln187Arg, and His223Arg) were genotyped in a case-control design comprising 1246 subjects (717 type 2 diabetic patients and 529 subjects with normal glucose tolerance). The Gln187Arg variant was also genotyped in 140 women with previous gestational diabetes mellitus (GDM). In addition, four rare variants were investigated for co-segregation with diabetes in multiplex MODY or early-onset type 2 diabetes families. The IVS5+7del(CT) variant was associated with common late-onset type 2 diabetes ($p = 0.03$); however, we failed to relate this variant to any diabetes-related quantitative traits among the 529 control subjects. There was no evidence for co-segregation of mutation genotype with disease affection status among families with MODY or early-onset type 2 diabetes. Thus, variation in the coding region of *NCB5OR* is not a major contributor in the pathogenesis of non-autoimmune diabetes.

Polymorphisms in the FOXP3 gene confer susceptibility to Type 1 Diabetes. *M. Bjoernvold¹, L.C. Stene², G. Joner³, K. Dahl-Joergensen³, K.S. Roenningen², B. Skinningsrud¹, D.E. Undlien¹.* 1) Medical Genetics, University of Oslo, Norway; 2) Norwegian Institute of Public Health; 3) Department of Pediatrics, Ulleval University Hospital.

Type 1 Diabetes (T1D) is a T-cell mediated autoimmune disease which leads to destruction of insulin producing beta-cells in the pancreas. It is a genetically complex disease. The FOXP3 gene located on chromosome Xp11.23 plays an important role in normal immune homeostasis. It encodes a DNA binding protein which is a transcription-repressor protein involved in regulatory T cell activity. It is expressed in CD4+CD25+ regulatory T-cells, and mutations in this gene is known to cause a rare, serious disease (IPEX, OMIM #304790) characterized by severe generalized autoimmunity. Two independent studies have analyzed common polymorphisms in FOXP3 in T1D with conflicting results. A Japanese study found that a polymorphism in the promoter region were associated with T1D while a study from Sardinia found no evidence for association. We have genotyped two microsatellite polymorphisms in intron zero and 5, respectively in 360 T1D children and their parents and analyzed for association with T1D using the transmission/disequilibrium test (TDT). The markers were in strong linkage disequilibrium. Our result did indicate an association between FOXP3 and T1D. The (TC)₂₆ allele of the dinucleotide repeat in intron 5 was transmitted 76.9% of times compared to the expected 50% ($p = 0.005$). Our results did also suggest an interaction between FOXP3 and HLA class II susceptibility alleles. Our results differ from those observed among Japanese. In the Japanese population an association with the microsatellite in intron zero was found. This could imply that there is an other hitherto unidentified polymorphism in the region that is primarily involved, and that the linkage disequilibrium pattern in Norway and Japan differ, leading to association with different markers in the two populations. We are now performing an independent case control study with about 500 cases and 1700 controls to see if we can replicate these results.

SNP fine mapping on chromosome 14q23-q24 for type 2 diabetes in Finns. *L.L. Bonnycastle¹, A.U. Jackson², P. Chines¹, N. Riebow¹, L.J. Scott², K.L. Mohlke¹, N. Narisu¹, W.L. Duren², H. Zhuang¹, M. Li², M.R. Erdos¹, T.T. Valle³, K. Silander³, J. Tuomilehto³, R.N. Bergman⁴, M. Boehnke², F.S. Collins¹.* 1) NHGRI, Bethesda, MD; 2) U. Michigan, Ann Arbor, MI; 3) Nat'l Public Health Inst., Helsinki, Finland; 4) U. Southern California, Los Angeles, CA.

The aim of the Finland-United States Investigation of NIDDM Genetics (FUSION) study is to identify genes that predispose to Type 2 Diabetes (T2D) and contribute to diabetes-related quantitative traits. A genome scan of 737 Finnish affected sibling pair families with microsatellite (STRP) fine-mapping to a density of 1.4 cM, yielded a maximum LOD score (MLS) of 2.26 at 55.5 cM on chromosome 14q23-q24. This MLS is the third largest in the 737 families. Ordered subset analysis of families with low resting pulse and low triglycerides generated LOD scores 4.97 ($p=.0049$) at 55.0 cM, and 4.96 ($p=.0061$) at 61.0 cM, respectively. A QTL for HDL-to-cholesterol ratio (MLS=1.88) among affected individuals was observed at 49.5 cM. When conditioning on families with negative linkage evidence on chromosome 6 at 77 cM, the T2D linkage peak increased to MLS=5.52. We are currently engaged in extensive fine mapping of a 23 cM (20 Mb) region, centered on the linkage peak and including our 1-LOD support interval. We selected a total of 1381 SNPs from HapMap SNPs (www.hapmap.org), selecting SNPs with $r^2 < 0.8$, non-synonymous dbSNP cSNPs, and additional dbSNPs to fill large gaps (>30kb) and gaps with low linkage disequilibrium between the HapMap SNPs. The resulting average SNP density is one per 13 kb. These SNPs are being genotyped using the Illumina platform on 806 probands from T2D families, 605 affected and unaffected siblings of these probands, and 657 normoglucose tolerant controls. Results to be reported will include 1) comparison of linkage results from SNPs and STRPs; 2) association analyses of SNPs and haplotypes with disease status and disease-related quantitative traits; and 3) an assessment of whether the association evidence can explain the linkage signals.

Follow-up of a Type 2 Diabetes Whole-Genome Linkage Study. *L.P. Briley¹, A.P. Philip², M.C. Karnoub², M.G. Ehm², P.L. St.Jean², R.G. Winkler³, G. Chandra^{4,5}, D.P. Yarnall¹, A.J. Nelsen², D.D. Kelly², J.H. Charnecki², K.W. Johansson², M.J. Wagner^{4,6}.* 1) Portfolio Genetics, GlaxoSmithKline, RTP, NC; 2) Genetic Data Sciences, GlaxoSmithKline, RTP, NC; 3) Bioinformatics, GlaxoSmithKline, RTP, NC; 4) Genetics Research, GlaxoSmithKline, RTP, NC; 5) United States Patent and Trademark Office, Washington, D.C. (present affiliation); 6) First Genetic Trust, Deerfield, IL. (present affiliation).

Type 2 diabetes is a disease with both genetic and environmental components that causes many long-term healthcare complications and costs billions of dollars annually. GlaxoSmithKline undertook a series of genetic studies to follow up the genome-wide type 2 diabetes linkage study reported in 2000. Fine-mapping of SNPs was performed in three of the linkage regions identified by the whole-genome scans. Association was seen in these regions for a number of SNPs using a variety of analysis methods. Recently, a large replication study in four additional populations was completed on 251 SNPs from associations in the fine-mapping studies, as well as candidate genes. For comparison, we also studied several SNPs in the known diabetes susceptibility gene PPAR-gamma. In the chromosome 1q linkage region (18 MB), two SNPs 24 KB apart showed association in multiple tests in at least three populations. In the chromosome 12q linkage region (14 MB), one SNP showed association in at least three populations in multiple tests. In the chromosome Xq linkage region (18 MB), five SNPs in five different locations throughout the region showed association in multiple populations with multiple tests. This work may lead to increased understanding of type 2 diabetes and to the identification of novel susceptibility genes and drug target pathways.

Examination of PPP1R3B as a candidate gene for the type 2 diabetes and MODY loci at 8p23. *J.S. Dunn¹, W.M. Mlynarski^{1,2}, M.G. Pezolesi¹, C. Powers¹, A.S. Krolewski^{1,2}, A. Doria^{1,2}.* 1) Genetics and Epidemiology, Joslin Diabetes Center, Boston, MA; 2) Department of Medicine, Harvard Medical School, Boston, MA.

The product of the *PPP1R3B* gene (G_{T}) is the regulatory subunit of a phosphatase involved in the modulation of glycogen synthesis in the liver and skeletal muscle. The *PPP1R3B* gene is located on chromosome 8p23 in a region that is linked with T2D and maturity-onset diabetes of the young (MODY) in the Joslin Study on the Genetics of Type 2 Diabetes (Pezolesi et al., 2004, Kim et al., 2004). We examined whether sequence variants at the *PPP1R3B* locus are responsible for the linkage with diabetes observed at this location. The two exons of this gene and 1.5 kb of the 5' flanking region were sequenced in the probands of 13 Joslin families (8 with type 2 diabetes, 5 with MODY) showing the strongest evidence of linkage at 8p23. We observed a total of 20 SNPs: two in the 5' flanking region, one in the intron (9 bp 5' of exon 2), and 17 in the 3' UTR. Four of these SNPs, representative of all others, were then genotyped in 79 type 2 and 21 MODY probands from the Joslin Study and in 91 unrelated controls. No statistically significant association with type 2 diabetes or MODY was observed. Results were similar when the analysis was restricted to families having the strongest evidence of linkage. Additionally, we examined the gene for the occurrence of splice variants. By means of RT-PCR, we identified an alternative transcript in which 8 bp are added at the 5' end of exon 2. Further study of this polymorphism revealed that expression of this larger transcript was contingent on the presence of the minor allele of an intronic SNP creating a new splice acceptor site. However, no association of type 2 diabetes or MODY was observed for this variant. In summary, variability in *PPP1R3B* does not appear to contribute to diabetes in our mostly Caucasian families. However, a role cannot be excluded in other populations such as Japanese, among whom linkage to diabetes is also observed at 8p23 and a non-synonymous mutation has been detected in the *PPP1R3B* gene.

Thrifty genotype effect on type 2 diabetes mellitus, in a sample in North West Colombia. *C. Duque¹, F. Uribe², G. Latorre², A. Villegas², L. Franco¹, N. Pineda^{1, 3}, G. Bedoya¹, A. Ruiz-Linares^{1, 3}.* 1) Laboratorio de Genética Molecular, Universidad de Antioquia. Medellín, Colombia; 2) Departamento de Medicina Interna, Facultad de Medicina, Universidad de Antioquia. Medellín, Colombia; 3) Galton Laboratory, Department of Biology, University College London, U.K.

One of the causes of type 2 diabetes mellitus (T2DM) could be obesity, since; it is strongly associated to insulin resistance, the main sign of T2DM. It has been postulated that the obesity susceptibility is caused by the interaction of mitochondrial (mtDNA) and nuclear variants, denominated Thrifty Genotype (TG), which have remained in Human migrant populations, as the Amerindian ones. In order to evaluate this interaction, we assessed the Amerindian TG effect on T2DM susceptibility in the population of Antioquia (Colombia) considered as a tri-ethnic admixture. We compared between cases and controls haplogroups and haplotypes frequencies in mtDNA as well as, the values of ancestry indexes obtained by seven nuclear markers. Seventy five percent of the mitochondrial haplogroups were of Amerindian origin and no differences in their frequencies were found. The values of haplotype variability estimators were significantly high in controls than in cases ($0.0004 < P_s < 0.006$). Differences were detected between the two groups in linkage disequilibrium and pairwise difference distributions. Four nucleotidic substitutions were found associated to the controls and one to the cases. The haplotypic variability in nuclear loci ($p = 0.009$) as well as the European admixture grade ($p = 0.016$) were higher in controls than in the cases. This is in concordance with the average values of Amerindian and African ancestry indexes that were higher in the cases (AAI $p = 0.0004$ and AfAI $p < 0.0001$ respectively). We found a direct relation between high values of AAI and the frequencies of Amerindian haplogroups and haplotypes. In this study we found for the first time, an evidence about of effect of TG determined by the interaction between high values of AAI, AfAI and mtDNA polymorphisms, on T2DM susceptibility in the population of Antioquia, also such effect would be modulated by the genetic variability in nuclear and mitochondrial genomes.

Large-scale genetic epidemiological and functional studies of the Thr130Ile and Val255Met polymorphisms in the Hepatocyte Nuclear Factor-4alpha gene in relation to type 2 diabetes. *J. Ek¹, C.S. Rose¹, D.P. Jensen¹, C.*

Glümer^{1,2}, K. Borch-Johnsen^{1,2,3}, T. Jørgensen², O. Pedersen^{1,3}, T. Hansen¹. 1) Steno Diabetes Center, Gentofte, Denmark; 2) Research Centre for Prevention and Health, Glostrup University Hospital, Glostrup, Denmark; 3) Faculty of Health Science, Aarhus University, Aarhus, Denmark.

HNF4A encodes an orphan nuclear receptor that plays crucial roles in regulating hepatic gluconeogenesis and beta-cell function. *HNF4A* is located on chromosome 20q13 in a region which in several studies has shown consistent linkage with type 2 diabetes mellitus (T2D), and recently, several common polymorphisms near the gene were shown to associate with T2D. Furthermore, rare mutations in the gene cause MODY1. The aim of the present study was to examine two rare missense polymorphisms in *HNF4A*, Thr130Ile and Val255Met, for altered function of HNF4A and for association with T2D. We have examined these polymorphisms by; 1) *in vitro* in transactivation studies using a *HNF4A* insert in an pcDNA3 vector and an *HNF1A* promoter driven dual *Renilla* and Firefly Luciferase reporter plasmid, and 2) by genotyping the variants in 1409 T2D patients and in 4726 glucose tolerant Danish white subjects. Both the Thr130Ile (76%, $p=0.04$) and the Val255Met (73%, $p=0.02$) variants showed significant decrease in transactivation level compared with wildtype. Further, the Thr130Ile variant had a significant increased allele frequency among T2D patients (4.2% (95% CI: 3.4-4.9)) compared to glucose tolerant subjects (3.4% (3.1-3.9)) (OR=1.26, $p=0.04$). The rare Val255Met polymorphism had a similar frequency among type 2 diabetic patients (0.1% (0-0.2)) and in glucose tolerant subjects (0.1% (0-0.2)). In conclusion, the Thr130Ile and the Val255Met polymorphisms decrease the transactivation activity of *HNF4A* and the Thr130Ile polymorphism increases risk of diabetes in the Danish Caucasian population.

Association of the Estrogen Receptor 1 gene with Type 2 Diabetes in African American and Caucasian American populations. *C.J. Gallagher^{1,4}, C.D. Langefeld², J.C. Mychaleckyj^{3,4}, J.N. Hirschhorn⁵, B. Henderson⁶, C.J. Gordon⁴, B.I. Freedman³, S.S. Rich², D.W. Bowden^{1,3,4}, M.M. Sale^{3,4}.* 1) Dept Biochemistry, Wake Forest Univ Sch Medicine, Winston-Salem, NC; 2) Dept Public Health Sciences, Wake Forest Univ Sch Medicine, Winston-Salem, NC; 3) Dept Internal Medicine, Wake Forest Univ Sch Medicine, Winston-Salem, NC; 4) Dept Human Genomics, Wake Forest Univ Sch Medicine, Winston-Salem, NC; 5) Departments of Genetics and Pediatrics, Harvard Medical School and Program in Medical and Population Genetics, Broad Institute, MIT/Harvard, Boston, MA; 6) Department of Preventive Medicine, Keck School of Medicine, University of Southern California, Los Angeles, CA.

We have completed a genome-wide scan for type 2 diabetes mellitus (T2DM) in 638 African American (AA) affected sibling pairs and found evidence for linkage (LOD=2.26) at 6q24-q27. The estrogen receptor alpha gene, ESR1, is in the linkage region. Mice and humans lacking a functional copy of ESR1 exhibit impaired glucose tolerance and obesity. We genotyped 53 SNPs that tag common haplotypes over 322 kb of the ESR1 gene in 380 AA T2DM cases and 276 AA controls. We performed tests of association on single SNPs and haplotypes reconstructed using a standard EM-algorithm. Two SNPs (10.9 kb separation) in intron 2 were associated with T2DM ($P=0.000037$ and 0.0131); common haplotypes within a haplotype block spanning intron 1 - intron 2 were also associated (global $P=0.00004$, likelihood-based permutation test). Additional SNPs were genotyped across 41 kb of intron 1-intron 2. 17 SNPs form 3 contiguous haplotype blocks in AA, and common haplotypes within each block were associated with T2DM (global $P<0.0001$). These 17 SNPs were also genotyped in 300 European American (EA) T2DM cases and 310 EA controls. There were two significantly associated single SNPs ($P=0.0150$ and $P=0.0192$) and an associated 4-SNP haplotype ($P=0.033$) in the EA population. We present the first report of a T2DM gene positionally identified in an AA population. While these results need to be replicated in additional populations, they suggest that common variants in the intron 1 - intron 2 region of ESR1 contribute to T2DM susceptibility.

Metanalysis of the Insulin Promoter Factor-1 (Ipf-1) D76N Missense Mutation in an European Type 2 Diabetes Mellitus (T2D) Population. *J.F. Habener^{1,2,3}, E. Milord⁴, C. Gragnoli^{1,2,5}*. 1) Mol Endocrinology, MGH, Boston, MA; 2) HMS, Boston, MA; 3) HHMI, Boston, MA; 4) Millennium Ph, Inc, Cambridge, MA; 5) Bios Health Center, Rome, Italy.

Ipf-1 is the MODY4 gene, transcription factor regulator of pancreas development and of expression of beta-cell specific genes. A common missense mutation is Ipf-1 D76N, which has been shown to increase risk for T2D, to inhibit insulin promoter activity, and to decrease glucose-stimulated insulin-secretion in healthy subjects. As Ipf-1 D76N seems to be mostly a variation of European origin, we calculated the risk for T2D in D76N carriers by performing a metanalysis of Ipf-1 published data in all European populations including our Italian T2D cohort, which consists of 90 late-onset and 40 early-onset T2D subjects and 50 controls (Gragnoli C, 1998 and 2003). We retrieved all data on D76N in different population (French/UK/Danish-Italian/Swedish) including subjects with late-onset T2D, early-onset T2D and MODY and tested D76N for HWE and for association with T2D by Relrisk using the total cases, and subsets with late-onset or early-onset T2D (including MODY). The same tests were performed separately in the Italian cohort, and separately in the late-onset (early-onset is negative). D76N frequency in Italian late-onset T2D cohort is 0.01 and in total early-onset and late-onset Italian T2D cohort is 0.007. D76N frequency in 247 European early-onset T2D patients is 0.012, in 887 European late-onset T2D patients is 0.015, in 1134 total European T2D patients is 0.014, and in 1048 European controls is 0.007. D76N is in complete HWE in Italian, European and control groups. The RR for D76N in Italian late-onset T2D is 1.69 (OR=0.15-19.13, P=0.45), in Italian early- and late-onset T2D is 1.17 (OR=0.10-13.19, P=0.53), in European early-onset T2D cohort is 1.60 (OR=0.42-6.07, P=0.48), in European late-onset T2D cohort is 2.08 (OR=0.87-4.99, P=0.09) and in European early- and late-onset T2D cohort is 1.98 (OD=0.85-4.60, P=0.10). D76N does not achieve statistical significance in the association with T2D in the European cohort tested, however there is a trend towards association mainly with late-onset T2D.

Haplotype construction of the FRDA gene and evaluation of its role in Type 2 Diabetes. *J. Holmkvist¹, P. Almgren¹, H. Parikh¹, M. Zucchelli², J. Kere², L. Groop¹, C.M. Lindgren².* 1) Dept. of Endocrinology, Malmo University Hospital, S-205 02 Malmo, Sweden; 2) Dept. of Biosciences at Novum, Clinical Research Center, Huddinge University Hospital, 141 86 Stockholm, Sweden.

Friedreichs ataxia (FRDA) is a common neurodegenerative disease and studies have shown that FRDA is caused by an expansion of an intronic (GAA)_n repeat in the X25 gene on chromosome 9q13. Almost 20% of Friedreichs ataxia patients develop type 2 diabetes (T2D), and an additional 10% develop milder disturbances of glucose tolerance. Several groups have investigated the role of the X25 repeat in T2D. Others and we have detected linkage in T2D families to chromosome 9p13-q21. First, we investigated the trinucleotide repeat allele distribution in a sample of 220 transmission disequilibrium trios with IFG (n=50), IGT (n=72) and T2D (n=98) from the Botnia study. However, we failed to detect any association or transmission distortion to disturbed glucose tolerance. We performed a meta analysis to evaluate whether our data was consistent with previous findings and found significant evidence against association between the X25 intermediate trinucleotide repeat alleles and disturbed glucose tolerance (OR=1.04, 95%CI [0.86-1.26], p=0.7). This suggests that the repeat itself does not influence the development of type 2 diabetes. To test whether there was excess transmission of any of the present variants and/or haplotypes we examined linkage disequilibrium and haplotype structure over the X25 gene using 18 single nucleotide polymorphisms covering 67 kb. One SNP, rs2498429, 8 kb downstream the X25 gene was nominally associated with T2D in the trios (p=0.02) and (p=0.08) in a follow-up case control study (n=529/329). The combined analysis of the case-control and trio data supports the initial association (OR=1.66 95%CI [1.13-2.44], p<0.01). In addition, haplotype transmission disequilibrium tests (TDT4) showed an over transmission of haplotypes containing the rare variant of rs2498429. In conclusion, our data do not support a role for the Friedreichs ataxia gene in the pathogenesis of T2D, but points to the possibility that genetic variation downstream the X25 gene on chromosome 9 could increase risk for T2D.

Polymorphisms of Candidate Genes for Type 2 Diabetes in Asian Indian Males from central Trinidad. *HA. Keenan*^{1,2}, *CH. Bunker*², *MM. Barmada*², *RE. Ferrell*², *NI. Petro*², *A. Doria*¹, *DE. Kelley*². 1) Dept Genetics & Epidemiology, Joslin Diabetes Ctr, Boston, MA; 2) University of Pittsburgh, Pittsburgh, PA.

Diabetes is a complex disease with an established genetic component. We previously documented a type 2 DM prevalence rate of 34% among physically active Asian Indian males, aged 19-65 years, living in central Trinidad. A positive family history was reported by 81%. We examined the frequency of candidate gene polymorphisms in apM1 at position 276, GLUT-4 at codon 383, IRS-1 at codon 972, the pro12ala variation of PPAR-2, and the non-synonymous mutation of SPINK1 gene at codon 117. Among 274 Asian Indian males studied, the T allele of the apM1 gene was less prevalent in those with type 2 DM (18.2% v. 24.6% (p=0.09) than those without the disease, although this was not significant. However, when age adjusted, the genotype TT was significantly protective against type 2 DM in reference to GG, OR:0.15 (95% CI:0.03- 0.73). There was a trend of lower fasting plasma glucose levels among those who were homozygous for the T allele (101.9 mg/dL compared with 120.7 mg/dL (GG) and 123.2 mg/dL (GT), p= 0.29). Adiponectin levels in a subset (n=48) of individuals matched for BMI and age were not significantly associated with the apM1 genotype (GG 7.8 +/-6.2 ng/mL, GT 8.2 +/- 3.5 ng/mL, TT 7.7 +/-3.2 ng/mL, p=0.9). A borderline protective association of type 2 DM and the glycine to arginine mutation of codon 972 of IRS-1 was found (p=0.07). BMI was lower among those carrying the mutation (24.9 kg/m² v. 26.4 kg/m², p=0.06). Other than BMI, there were no significant differences in measures of fasting plasma glucose, insulin, HDL, LDLc, triglycerides, or total cholesterol between the genotypes of IRS-1. No associations were found between type 2 DM and polymorphisms at the other three loci. However, we document a higher proportion of homozygotes for the variant allele of the PPAR- 2 gene than in the Caucasian population (~3%). This preliminary study of polymorphisms in a population of Asian Indians complements the sparse data previously available regarding the genetic epidemiology of type 2 DM in this ethnic group and demonstrates an association of SNP 276 of apM1 with type 2 DM in Asian Indians.

Interleukin-18 promoter polymorphisms are not associated with type 1 diabetes in a UK population. R.J.L.

Martin¹, A.P. Maxwell², D. Carson³, A. Bingham³, D.A. Savage¹, C.C. Patterson⁴. 1) Department of Medical Genetics, The Queen's University of Belfast, Belfast, Northern Ireland; 2) Regional Nephrology Unit, Belfast City Hospital, Belfast, Northern Ireland; 3) Department of Child Health, The Queen's University Belfast, Belfast, Northern Ireland; 4) Department of Epidemiology, The Queen's University of Belfast, Belfast, Northern Ireland.

Interleukin-18 is a proinflammatory cytokine whose levels are increased in the subclinical stage of type 1 diabetes. Two single nucleotide polymorphisms at positions -607(C>A) and -137(G>A) of the IL-18 promoter have been reported to cause differences in transcription factor binding. The H4TF-1 nuclear factor binding site is altered at position -137, while a potential cAMP-responsive element-binding protein binding site is disrupted at position -607. Previous studies in Polish and Japanese populations have found an association between IL-18 promoter polymorphisms and type 1 diabetes. Association between IL-18 -607C/-137G and CTLA-4GG at nucleotide position 49 in exon 1 has also suggested a possible gene-gene interaction.

We performed case-control and family based association studies by pyrosequencing to assess if the IL-18 promoter polymorphisms were associated with the development of early onset type 1 diabetes in the Northern Ireland population. In addition we examined the relationship between IL-18 and CTLA-4 genotypes.

Chi-squared analysis of genotype and allele frequencies for the IL-18 polymorphisms in cases (n=129) compared to controls (n=426) found no significant difference ($p>0.05$). Assessment of allele transmission distortion in the 283 trios (proband and both parents) found no association between IL-18 polymorphisms and the development of type 1 diabetes. Comparison of IL-18 and CTLA-4 genotypes using logistic regression test for interaction did not exhibit association.

In conclusion, IL-18 promoter polymorphisms are not associated with type 1 diabetes in the Northern Ireland population and no interaction between IL-18 and CTLA-4 genes was found.

Association Studies of Kir6.2 E23K and PPAR P12A in an Italian T2D Cohort. *E. Milord*¹, *J.F. Habener*^{2,3,4}, *C. Gragnoli*^{2,3,5}. 1) Millennium Ph, Inc, Cambridge, MA; 2) Mol Endocrinology, MGH, Boston, MA; 3) HMS, Boston, MA; 4) HHMI, Boston, MA; 5) Bios Health Center, Rome, Italy.

The ATP-sensitive K⁺ channel subunit Kir6.2 is critical in glucose-mediated insulin secretion as a link between glucose metabolism and electrical cell activity. Large association studies and meta-analyses of Kir6.2 E23K have reported association with type 2 diabetes (T2D). The peroxisome proliferator-activated receptor (PPAR) is a member of the nuclear hormone receptor superfamily and is important for adipocyte differentiation and insulin sensitivity. Large meta-analyses have reported decreased risk for PPAR P12A for T2D development. Our aim was to test Kir6.2 E23K and PPAR P12A for association with T2D in an Italian cohort (205 patients, 105 controls from Rome). We amplified genomic DNA of all subjects by PCR with primers for E23K and for P12A. PCR products were controlled for amplification quality by 2% agarose electrophoresis gel, purified by Qiagen kit (Qiagen, Valencia, CA) and sequenced on both strands with fluorescein-labelled markers (3700 ABI PRISM). We tested for HWE cases and control genotypes by HWE software and for association with T2D alleles and genotypes by Relrisk. Genotypes were in HWE. Association results are: at E23K site, genotype KK (cases=0.17, controls=0.11) has RR=1.53 (OR=0.75-3.10, P=0.23), EK (cases=0.43, controls=0.41) has RR=1.09 (OR=0.67-1.77, P=0.72), EE (cases=0.39, controls=0.46) has RR=0.74 (OR=0.46-1.20, P=0.22), allele K has RR=1.31 (OR=0.92-1.88, P=0.13), E has RR=0.76 (OR=0.53-1.09, P=0.13); at P12A site, genotype AA (cases=0.004, controls=0.000) has RR=1.55 (OR=0.14-17.26, P=0.47), AP (cases=0.12, controls=0.12) has RR=0.98 (OR=0.48-2.01, P=0.96), PP (cases=0.87, controls=0.87) has RR=0.97 (OR=0.48-1.98, P=0.93), allele A has RR=1.07 (OR=0.54-2.12, P=0.84), P has RR=0.94 (OR=0.47-1.85, P=0.84). This is the first report of E23K and P12A study in Italians. Our study does not reach statistical significance, however extrapolation of our data suggests that Kir6.2 K23 allele and PPAR A12A genotype confer risk to T2D in Italians (13% due to chance, n.s., respectively). Our study enriches the public genotypes pool for further meta-analyses.

IRS 1 Gene Polymorphism in Turkish Type 2 Diabetes Mellitus Patients. *F.E. Orkunoglu¹, H. Mergen², E.S. Bolu³, M. Ozata⁴.* 1) Dept Medical Genetics, Gulhane Sch Medicine, Ankara,Turkey; 2) Dept Biology, Faculty of Science, Hacettepe University, Ankara,Turkey; 3) Dept Endocrinology and Metabolism, Gulhane Sch of Medicine,Ankara, Turkey; 4) Dept Endocrinology and Metabolism,GATA Haydarpaşa Training Hospital,Acibadem-Istanbul, Turkey.

Insulin receptor substrate-1 (IRS-1) is an endogenous substrate for the insulin receptor tyrosine kinase, which plays an important role in insulin signaling. Mutations in the IRS-1 gene are associated in some populations with Type 2 diabetes. To determine whether variation in the IRS-1 gene contributes to genetic susceptibility to Type 2 diabetes, the coding region of IRS-1 gene was analyzed for variation in 70 T2DM subject and 116 control patients using PCR-RFLP and DNA sequencing method. Three single base changes found (Gly972Arg, Ala512Pro, Ser892Gly). There was no significant association found any of these variants with diabetes except for Gly971Arg. This mutation were relatively more common in with 10/70 diabetic patients and 15/116 non-diabetic controls being heterozygous and 1/70 being and 0/116 non-diabetic controls being homozygous for this variant. As a conclusion, Ala512Pro, Ser892Gly, mutations are rare and Met613Val, Ser1043Tyr and Cys1095Tyr mutations are not found. Gly971Arg is more common in our population but may not be a major determiner to genetic susceptibility to Type 2 diabetes.

The T92A SNP in the Deiodinase 2 (DIO2) gene is associated with a reduced risk of type 2 diabetes: evidence for interaction with the PPAR2 gene. *I. Torrente¹, M. Fiorito¹, S. De Cosmo⁴, V. Guida^{1,2}, A. Colosimo^{1,6}, S. Prudente^{1,4}, E. Flex^{1,2}, R. Menghini⁵, M. Federici⁵, V. Trischitta^{1,3,4}, B. Dallapiccola^{1,2}.* 1) IRCCS-CSS Mendel, Rome, Italy; 2) Dept Exp and Pathol La Sapienza Univ Rome Italy; 3) Dept Clinic Sciences La Sapienza Univ Rome Italy; 4) Unit Endocrinology IRCCS-CSS Institute S.G. Rotondo Italy; 5) Dept Internal Med Tor Vergata Univ Rome Italy; 6) Dept Biomed Sciences Univ Chieti Italy.

The genetic background of Type 2 diabetes (T2D) is mostly unknown. Insulin resistance (IR) plays a major role in the pathogenesis of T2D. DIO2 converts thyroid pro-hormone T4 to the active T3 hormone and may play a role in modulating IR. A missense SNP (T92A) of DIO2 has been associated with IR in Caucasians. We genotyped the T92A SNP in 495 T2D and 598 Caucasian controls from Italy. The X92A genotype (i.e. T92A and A92A) was less frequent ($p=0.02$) among T2D (53.1%) than controls (63.7%): OR=0.6 (95% CI=0.4-0.9). The modulation of T2D risk is believed to be polygenic due to multiple gene-gene interactions. Several reports indicate that the P12A missense SNP in the PPAR2 transcription factor plays a role in T2D, with X12A genotype carriers (i.e. P12A and A12A) being at reduced risk. The risk of T2D of DIO2 X92A carriers was significantly reduced in the PPAR2 X12A (OR=0.25 95% CI=0.07-0.8, $p=0.025$) but not in the PPAR2 P12P (OR=0.7 95% CI=0.5-1.2, $p=0.2$) (p for interaction=0.05) group. To investigate the biological significance of this statistical interaction, we performed an EMSA using a radiolabeled oligonucleotide containing a putative binding site for PPAR2 identified in the DIO2 promoter region and in vitro translated PPAR2 with its RXR<ag> partner which is essential for transcriptional activity. A clear shift in the oligonucleotide mobility was observed, thus indicating that the PPAR2/RXR<ag> heterodimer specifically binds to the DIO2 promoter. These data demonstrate the association of the X92A genotype with a reduced risk of T2D in an Italian population. This effect is mediated by interaction with the PPAR2 gene which may be a consequence of specific binding of the PPAR2/RXR<ag> heterodimer to a putative site identified in the DIO2 promoter region.

Association analysis of the functional 1858CT polymorphism within the *PTPN22* gene in several autoimmune diseases. *M.K. Viken¹, S.A. Amundsen¹, A. Smerdel¹, K.M. Boberg², I.M. Gilboe³, V. Lilleby³, T. Kvien³, O. Forre³, L.M. Sollid¹, E. Thorsby¹, B.A. Lie¹.* 1) Institute of immunology, Rikshospitalet University Hospital, Oslo, Norway; 2) Medical Department, Rikshospitalet University Hospital, Oslo, Norway; 3) Department of Rheumatology, Rikshospitalet University Hospital, Oslo, Norway.

The gene *PTPN22* encodes a lymphoid Protein Tyrosine Phosphatase, which plays a role in suppression of T-cell activation. *PTPN22* is localized on chromosome 1p13, a region that shows linkage to rheumatoid arthritis (RA) and weakly to systemic lupus erythematosus (SLE). Recent studies have shown that a single nucleotide polymorphism (SNP) in *PTPN22* is associated with both RA and type 1 diabetes (T1D). The SNP (rs2476601, 1858CT) changes an amino acid and thereby disrupts the binding site for the negative regulatory kinase Csk. Due to the observed association with the two autoimmune diseases T1D and RA displaying different phenotypes, we wanted to investigate if this 1858CT SNP could be associated with autoimmune diseases in general. To test this hypothesis, we genotyped (by TaqMan assay, Applied Biosystems) several autoimmune diseases using case-control materials from the Norwegian population. The data sets consist of patients with primary sclerosing cholangitis (PSC; n=238), juvenile rheumatoid arthritis (JRA; n=319), SLE (n=162), celiac disease (CD; n=313) and controls (n=555). Given the minor allele frequency of 0.116 and the odds ratio of 1.79 previously reported in T1D, our study has the following power: 0.85 for PSC, 0.9 for JRA, 0.75 for SLE and 0.9 for CD. In SLE and PSC we did not observe any signs of association, while we found an association for carriers of the risk allele versus non-carriers in both JRA (OR=1.35; p=0.04) and CD (OR=1.34; p=0.04). We are currently testing the SNP in a Norwegian RA material (n=~600) in an effort to confirm the association already found in RA, thus placing our results in a broader perspective. In conclusion, the *PTPN22* 1858CT SNP may be a risk factor for several autoimmune diseases.

Significant association between PTPN22 gene polymorphism and type 1 diabetes in Newfoundland. *K.S. Wang¹, M. Liu¹, B. Bharaj¹, M. Lu¹, H.T. Chen¹, J.A. Curtis³, L.A. Newhook³, A.D. Paterson^{1,2}.* 1) Program in Genetics and Genomic Biology, The Hospital for Sick Children, Toronto; 2) Dept. of Public Health Sciences and Psychiatry, Univ. of Toronto; 3) Pediatrics, Memorial Univ. of Newfoundland, Canada.

PTPN22 encodes the lymphoid protein tyrosine phosphatase (LYP), a suppressor of T-cell activation that maps to 1p13. A SNP (rs2476601) in the PTPN22 gene has been reported to be associated with type 1 diabetes (T1D) using case-control studies in both North American and Italian samples (Bottini et al. 2004). We used the family based association test (FBAT) for an association study between the same SNP and T1D using DNA from 625 persons with T1D and 1532 relatives without diabetes from 834 nuclear families recruited from Newfoundland (NF) where there are documented founder effects and a high incidence of T1D. The TDTPHASE program was used to compare maternal and paternal transmissions as well as gender specific transmissions in probands because the risk of T1D may differ between males and females and some T1D susceptibility loci may be subject to genomic imprinting (i.e. the parental origin of a susceptibility allele affects penetrance). The minor allele frequency in probands was 0.17 and the locus was in Hardy-Weinberg equilibrium. FBAT showed that the minor allele was transmitted more often than expected to affected offspring ($Z=3.003$, $P=0.0027$). TDTPHASE indicated that the minor allele revealed significant transmission disequilibrium from parents to affected offspring ($P=0.00093$) but not to unaffected offspring ($P=0.43$). Interestingly, there was a significant difference between transmission of the minor allele to male and female affected offspring ($P=0.023$). In addition, the paternal allele showed significant transmission to affected male offspring ($P=0.00098$) compared to affected female offspring ($P=0.90$), while the same maternal allele was not associated in families with affected male or female offspring. In summary, our results confirm the previous report of a significant association between PTPN22 gene polymorphism and T1D, especially we find evidence for gender differences and parental original effects.

Tyrosine phosphatase polymorphism C1858T associates with type 1 diabetes but not with diabetic nephropathy.

M. Wessman^{1,2}, *S. Fröjdö*¹, *L. Sjöling*¹, *M. Parkkonen*¹, *R. Sallinen*¹, *J.A. Turunen*³, *V.-P. Mäkinen*^{1,4}, *K. Pettersson-Fernholm*¹, *C. Forsblom*¹, *J. Fagerudd*¹, *L. Peltonen*³, *P.-H. Groop*¹, on behalf of the FinnDiane Study Group. 1) Folkhälsan Institute of Genetics, Folkhälsan Research Center, Helsinki, Finland; 2) Biomedicum Helsinki, University of Helsinki, Finland; 3) Dept. of Medical Genetics, University of Helsinki and Dept. of Molecular Medicine, National Public Health Institute, Helsinki, Finland; 4) Lab. of Computational Engineering, Helsinki University of Technology, Finland.

Type 1 diabetes (T1D) is a significant medical problem worldwide with the highest incidence rate of 45/100,000 per year in Finland. T1D arises from an autoimmune destruction of the pancreatic β -cells leading to a complete dependence on exogenous insulin. About 30% of T1D individuals develop diabetic nephropathy, a condition characterized by increase in the arterial blood pressure, continuous albuminuria, and relentless decline in renal function. The functional SNP C1858T of the protein tyrosine phosphatase, nonreceptor-type 22 gene (*PTPN22*) encoding the lymphoid-specific intracellular phosphatase (LYP) was recently associated with T1D in North American and Sardinian populations. LYP is among the most powerful inhibitors of T-cell activation and thus a candidate for autoimmune diseases. Our aims were to study the role of this SNP in T1D and diabetic nephropathy in clinically well-defined Finnish T1D patients (n=1277). The T-allele was more frequent in T1D patients than in healthy subjects (n=184; p=0.000014). However, no association with diabetic nephropathy was detected. The allele frequencies in various sub-populations were almost identical, as well as the odds ratios for the T-allele carriers. A weak association observed between the T-allele and thyroxin treatment, an indicator for hypothyreosis, might imply the role of the C1858T variant in other autoimmune diseases. In conclusion, our results support the original finding showing that the functional variant C1858T resulting in an Arg620Trp substitution is associated with T1D. This variant might have a real impact on the pathogenesis of T1D since the association has now been detected in three different populations.

Screening of SNPs previously reported to be associated with type 2 diabetes in a Finnish population. *C.J. Willer¹, L.L. Bonnycastle², E. Smith², A.U. Jackson¹, A.D. Skol¹, K.L. Mohlke^{2,3}, L.J. Scott¹, N. Narisu², P.S. Chines², M.R. Erdos², R.N. Bergman⁴, J. Tuomilehto⁵, F.S. Collins², M. Boehnke¹.* 1) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 2) Genome Technology Branch, National Human Genome Research Institute, Bethesda, MD; 3) Department of Genetics, University of North Carolina, Chapel Hill, NC; 4) Department of Physiology and Biophysics, Keck School of Medicine, University of Southern California, Los Angeles, CA; 5) Diabetes and Genetic Epidemiology Unit, Department of Epidemiology and Health Promotion, and Department of Biochemistry, National Public Health Institute, Helsinki, Finland and Department of Public Health, University of Helsinki, Helsinki, Finland.

The Finland-United States Investigation of NIDDM Genetics (FUSION) study aims to identify genetic variants that influence susceptibility to type 2 diabetes and heritable variability in diabetes-related quantitative traits. We are undertaking an association study of a large number of candidate genes to complement other gene localization strategies we have employed in regions of linkage. The latter was successful in the identification of an association with the HNF4-alpha P2 promoter region ($p = .01$, OR = 1.34, CI = 1.07 - 1.66), which we have previously published. We performed a comprehensive literature search to survey previously reported associations between type 2 diabetes status and single nucleotide polymorphisms (SNPs). We found reports of significant associations with 106 SNP markers in 55 unique genes. Of the 106 SNPs identified, we have to date analyzed 19 SNPs for association in 795 cases and 426 controls. We identified one positive association with PPAR-gamma ($p = .001$, OR = 0.65, CI = 0.52 - 0.82) which we have reported previously. Four of the remaining SNPs were excluded because of difficulty mapping their position. Currently we are genotyping the remaining 83 SNPs in 790 cases and 650 controls using high-throughput genotyping by bead array (Illumina) or by MALDI-TOF (Sequenom). We will present analyses of association in 102 SNPs to assess replication of previously published associations with type 2 diabetes mellitus.

SHH, SIX3, and TGIF in holoprosencephaly- mutations, phenotype and image. How different they are? L.

Ribeiro¹, K. El-Jaick², M. Muenke², A. Richieri-Costa¹. 1) Hosp Rehab Craniof Anomalies, Univ Sao Paulo, Sao Paulo, Brazil; 2) National Human Genome Research Institute, Bethesda, MD.

Holoprosencephaly (HPE) is the most common developmental field defect resulting from a failure of midline division of the forebrain, it is etiologically heterogeneous, pathogenetically complex, and phenotypically variable. Abnormal forebrain cleavage results in three particular types of HPE: lobar, semilobar, and alobar, however, ethmocephaly, cebocephaly, premaxillary agenesis, absence of olfactory bulbs and tracts, structural anomalies of the corpus callosum, bilateral cleft lip/palate, single central incisor and hypotelorism compose a wide mosaic with each one of these findings nesting per se a holoprosencephalic phenotype. Different genes are implicated in the pathogenesis of HPE; these include SHH, ZIC2, SIX3, and TGIF, most of the cases are isolated and phenotypical manifestations are variable in each one. A distinctive phenotype was reported in patients with GLI2 mutations whose primary features include defective anterior pituitary formation and pan-hypopituitarism, with or without overt forebrain cleavage abnormalities, midfacial hypoplasia, isolated hypotelorism, solitary median maxillary central incisor, cleft lip/palate, and mid-face hypoplasia, leading to the so-called HPE-like phenotype, however, up to now there is no standard definition of this phenotype. We have ascertained a sample of 50 isolated HPE patients, 27 with typical HPE phenotype and 23 with the HPE-like phenotype. Mutational analysis and neuroimage evaluation was performed in all patients. SHH mutations were detected in 4 patients with HPE-like with normal MRI and in 1 patient with semilobar HPE. From the patients with SIX3 mutations 5 presented alobar HPE and 1 semilobar. The patient with TGIF mutation presented HPE-like phenotype, structural anomalies of the corpus callosum and increased size of IIIrd and IVth ventricles. Our data suggest that mutations involving the SIX3 gene are more deleterious in relation to the developing central nervous system than the genes involving the SHH signaling cascade since it is essential for the development of the anterior neural plate and eye in humans.

Mutations in steroid 5-alpha reductase type 2 and the severity of hypospadias. *J. Manson, M. Carr.* Dept Human Genetics and Pediatric Urology, Children's Hosp Philadelphia, Philadelphia, PA.

The purpose of this project is to evaluate gene-environment interactions in the risk for hypospadias. Our hypothesis is that allelic variants in genes controlling androgen action and metabolism (steroid 5-alpha reductase type 2 [SRD5A2] and the androgen receptor [AR]) will be highly associated with the risk for and severity of hypospadias. Parental exposure to environmental agents during pregnancy may further increase the risk for hypospadias in fetuses with a susceptible genotype, resulting in a gene-environment interaction. This is the first study in a large, outbred population to investigate gene-environment interactions on the risk of this birth defect. Families of case infants less than one year of age presenting for diagnosis/surgical repair of hypospadias in a Pediatric Urology clinic are recruited into the study. Families of affected control infants with renal anomalies are recruited from the same population. Parents are administered questionnaires to obtain information on reproductive and obstetrical history and exposures to drugs and environmental agents. Buccal swabs are collected from the mother, father and infant and DNA extracted for evaluation of candidate genes. Results to date on approximately 350 families indicate that there are no differences between groups for maternal or paternal occupational exposures, while case mothers reported significantly more exposures to paints and stains and case fathers to pesticides at home than their respective controls. The most common genotype finding in the study population was a V89L missense mutation in exon 1 of the SRD5A2 gene. There was a highly significant association between severity of hypospadias and the frequency of this mutation. There were no differences between case and control groups for CAG and GGC repeat lengths on the androgen receptor. The V89L mutation in the SRD5A2 gene is known to decrease activity of the enzyme by approximately 30%. To date, there is no significant gene-environment interaction between this mutation and environmental exposures.

MAOA gene polymorphisms in obsessive-compulsive disorder: Analysis of gender differences. *J.M. Geronimo, P.D. Arnold, M. Lanktree, M.A. Richter, J.L. Kennedy.* Neurogenetics, Centre for Addiction and Mental Health, Toronto, Ontario, Canada.

Obsessive-Compulsive Disorder, OCD, is a common and severe psychiatric illness that affects 1-3% of the population; it is characterized by recurrent, unwanted thoughts and/or repetitive behaviors. Some studies have reported that onset of the disorder is earlier for males (6-15 years versus 20-29 for females), and that OCD males and females are characterized by different symptoms. Thus, the clinical and biological heterogeneity of OCD suggest that the etiology of OCD may have a sex-linked component. One candidate gene on the X chromosome that is of particular interest for OCD is the gene for monoamine oxidase A (MAOA), since this MAO isozyme plays an important role in the degradation of the neurotransmitters norepinephrine, epinephrine, dopamine, and serotonin. In the current study, the MAO-A polymorphisms investigated were a 23-base-pair variable number of tandem repeats (VNTR) and a restriction fragment length polymorphism (RFLP) resulting from a single-base-pair substitution at MAO-A Exon8 (G297T).

These polymorphisms were analyzed in 68 OCD families including trios and families with at least one sib pair, of which 32 probands were male and 36 were female. Analysis using the Family Base Association Test (FBAT) showed preferential transmission of the four repeat VNTR allele in males ($z=2.14$, $p=0.03$) and no statistically significant association for females. However, in our total sample no statistically significant genotypic or allelic associations were detected for the VNTR (allele 4: $z=1.24$, $p=0.22$ and allele 3: $z=-1.01$, $p=0.31$) and Exon8 polymorphisms ($z=0.35$, $p=0.737$). Results were not corrected for multiple comparisons. These preliminary results suggest a sex-specific association of the MAOA VNTR, consistent with earlier studies of MAOA variants in OCD. Further investigation in larger samples is warranted.

Analysis of maternal smoking and sixteen detoxification genes in the in the etiology of orofacial clefts. *M. Shi*¹, *C. Christensen*², *C. Weinberg*³, *A. Lozada*⁴, *P. Romitti*⁵, *J.C. Murray*^{1,4,5}. 1) Dept Biological Sci, Univ Iowa, Iowa City, IA; 2) Center for the Prevention of Congenital Malformations, Institute of Public Health, Univ Southern Denmark, 5000 Odense C, Denmark; 3) Biostatistical Branch, National Institute of Environmental Health Sciences; 4) Dept Pediatrics, Univ Iowa, Iowa City, IA; 5) Dept Epidemiology, Univ Iowa, Iowa City, IA.

We extended our previous work on the investigation of potential interaction effects between maternal cigarette smoking and variants in smoking detoxification genes and risk of orofacial clefts. DNA samples from families with cleft cases as well as unaffected control families came from two population-based studies, one in Denmark and one in Iowa (US). A total of 3008 Danish and 2494 Iowa DNA samples were used in the study, out of which 1257 were case samples (including 823 complete case/parent triad sets). Genotyping was carried out on 25 single nucleotide polymorphisms in 16 genes involved in phase I and phase II detoxification pathways. Effects of maternal and fetal genotypes as well as the interaction between these genotypes and maternal smoking were tested. Statistical tests were also carried out to examine the interaction between the genes involved in the detoxification pathway as well as genes important for palatal embryonic development, such as *MSX1*, *TGFA* and *IRF6*. Logistic regression and log-linear modeling were applied in the analysis. Preliminary analysis showed statistically significant interaction effects between maternal smoking and the *EPHX1* T113Y polymorphism in Iowa samples and was suggestive of possible interaction effects between smoking and two of the *GST* genes, *GSTT1* and *GSTP1*. The analysis is now being extended to a recently acquired collection of 285 pentads consisting of the case, both parents and the maternal grandparents allowing for more specific characterization of maternal effects. This study will help us in understanding the possible roles played by gene-environment interaction as well as gene-gene interaction in the etiology of orofacial clefts.

Mutant ataxin-7 induced neurodegeneration in SCA7 transgenic mice. *L.A. Duvick, M.D. Kaytor, R.G. Ehlenfeldt, M.S. Berlinger, H.B. Clark, H.T. Orr.* Lab Medicine and Pathology, Institute of Human Genetics, Univ of Minnesota, Minneapolis, MN.

Spinocerebellar ataxia type 7 (SCA7) is an autosomal dominant neurodegenerative disorder caused by an expansion of a polyglutamine repeat within the *SCA7* encoded protein, ataxin-7. To gain insight into the molecular basis of Purkinje cell degeneration observed in this disease, the Purkinje cell specific promoter (*Pcp-2*) was used to over-express *SCA7* with 110 CAG repeats. Previous models of *Pcp-2 SCA7* transgenic mice failed to exhibit a phenotype and pathology until late in age. This was most likely due to low levels of ataxin-7 expression due to position integration effects of the transgene. To circumvent this, the transgene was inserted between insulator sequences from the chicken *-globin* gene. Insulators are regulatory elements that have been shown to protect gene expression from both positive and negative effects of chromatin at the insertion of a transgene. Four founder animals were identified that gave rise to lines that expressed ataxin-7 protein uniformly in the nucleus of Purkinje cells in the cerebellum. Staining of ataxin-7 in the cerebellum of transgenic mice showed regional differences in protein accumulation and pathology. At early time points (6 wks), ataxin-7 was diffusely nuclear but gradually accumulated into single large nuclear inclusions (NIs) in an anterior to posterior manner. Purkinje cell neurons that form large NIs seemed to be spared while cells that retained a diffuse staining pattern showed signs of neurodegeneration. This was quantified by measurement of the molecular layer, and number of cytoplasmic vacuoles in Purkinje cells in different regions of the cerebellum. Moreover these animals had a behavioral deficit by rotorod assessment at 12 weeks of age. This animal model of SCA7 further supports the idea that the formation of NIs is neuroprotective in polyglutamine disease.

Modulation of ataxin-1 phosphorylation. *M.D. Kaytor*¹, *C.E. Byam*¹, *S.D. Stevens*¹, *H.Y. Zoghbi*², *H.T. Orr*¹. 1) Dept Lab Medicine and Pathology, Institute of Human Genetics, Univ of Minnesota, Minneapolis, MN; 2) Howard Hughes Medical Institute, Dept Molecular and Human Genetics, Baylor College of Medicine, Houston TX.

Spinocerebellar ataxia type 1 (SCA1) is an autosomal dominant neurodegenerative disorder caused by the expansion of a glutamine repeat within the *SCA1*-encoded protein ataxin-1. We have previously shown that serine 776 (S776) of both wild type and mutant ataxin-1 is phosphorylated *in vivo* and *in vitro*. Moreover, S776 of ataxin-1 was shown to play a critical role in SCA1 pathogenesis. Preventing phosphorylation of this residue by replacing it with alanine resulted in a mutant protein found in the nucleus that was not pathogenic. To further investigate the biological function of phospho-S776 ataxin-1 we have developed a cell-culture based assay to screen for modulators of S776 phosphorylation. In this assay, ataxin-1 expression is monitored by EGFP fluorescence in cell lines stably expressing an EGFP-ataxin-1 fusion protein. The previously developed and characterized phospho-S776 ataxin-1 specific antibody (PN1168) is then used to assess ataxin-1 S776 phosphorylation. We are currently screening a library of 84 known kinase and phosphatase inhibitors. An initial screen of this library at a concentration of 25M identified 17 compounds capable of either increasing or decreasing the relative level of phospho-S776 ataxin-1 by at least 35%. Preliminary analysis of these hits places many of the inhibited kinases in a common pathway leading to ataxin-1 S776 phosphorylation. We are currently verifying the specificity and efficacy of these results by re-screening the library at a lower concentration of inhibitor. We have also begun to screen a library of 2000 drugs and natural products to identify additional modulators of ataxin-1 S776 phosphorylation. Screening for compounds that alter the phosphorylation of ataxin-1 will identify new molecular tools to aid in elucidating the mechanism of SCA1 pathogenesis. Moreover, identified compounds will provide potential leads toward the development of a therapeutic treatment for SCA1.

Genetic background modifies early disease events in the striatum of Huntingtons disease knock-in mice. A. Lloret, E. Janice, A. Teed, M. Hakky, M.E. MacDonald, V.C. Wheeler. Molecular Neurogenetics, Mass. General Hospital, Charlestown, MA. .

Huntingtons disease (HD) is a dominant neurodegenerative disorder caused by the expansion of a polymorphic CAG repeat that elongates a glutamine tract in huntingtin (Htt). Mutant Htt triggers the demise of vulnerable medium spiny neurons in the striatum and the onset of motor symptoms. Although the underlying process that determines disease onset is strongly CAG length-dependent, modifying factors have been implicated by variability in onset age not accounted for by CAG size. Studies of the *HD* mutation in *Hdh* knock-in mice have shown that long CAG repeats that lengthen the glutamine tract in murine huntingtin initiate a striatal-specific disease process. We have characterized a number of early striatal phenotypes in *Hdh*^{Q111} knock-in mice on an outbred CD1 background, as well as the striatal-specific time-dependent somatic expansion of the *Hdh*^{Q111} CAG repeat. To identify genetic modifiers of early disease phenotypes in *Hdh*^{Q111} knock-in mice we have generated congenic lines by repeated backcrossing of the *Hdh*^{Q111} allele onto three inbred genetic backgrounds, C57BL/6, 129Sv and FVB. We have investigated an early phenotype, the nuclear accumulation of mutant huntingtin, as well as the somatic instability of the CAG repeat in the striatum of these three lines. Quantitation of nuclear mutant huntingtin accumulation at 6 months of age revealed statistically significant differences between all three lines; C57BL/6 mice had the highest, 129Sv the lowest, and FVB an intermediate level. Nuclear mutant huntingtin levels on the C57BL/6 and 129Sv backgrounds were non-overlapping. Analyses of somatic instability in the three congenic lines indicate reduced levels of somatic expansion in 129Sv mice compared to the C57BL/6 and FVB strains. These data imply the presence of gene(s) that modify an early striatal phenotype and somatic expansion of the *HD* CAG repeat in *Hdh*^{Q111} knock-in mice. We are currently carrying out genetic crosses between the strains to determine the heritability of the genetic modifier(s).

Investigating a possible relation between candidate genes involving retinoid function and psychosis. *N.A. Akarsu¹, B. Akin¹, H. Okur¹, S. Ozer², T. Tuncali³, A. Gogus², A.B. Goodman⁴, A. Ulusahin².* 1) Gene Mapping Lab, Dept Pediatrics and; 2) Dept Psychiatry, Hacettepe Univ, Ankara, Turkey; 3) Dept Med Genet, Ankara Univ, Ankara, Turkey; 4) Massachussets Mental Health Center, Harvard Medical School, Boston MA.

Recent studies supported the continuum model of psychosis suggesting that transmission of psychosis is not specific to bipolar disorder or schizophrenia (SCH). We previously presented an inbred Turkish family with the continuum model (*Prog. Neuro-Psychopharmacology and Biol. Psychiatry* 2004;28: 255). Of 40 members examined, 18 had psychosis. The coexistence of rickets-alopecia syndrome (OMIM 277440) and psychosis in the same pedigree led us to investigate presumed relationship between vitamin D deficiency and psychosis. Linkage analysis excluded VDR locus on chromosome 12q13. We subsequently tested the additional hypothesis that retinoid dysregulation may be important in the etiology of SCH (*PNAS*; 1998;95;7240). A total of 57 DNA markers flanking or within the following loci were studied: RARA at 17q; RARB and PPARG at 3p; RARG at 12q; RXRA at 9q; DTNBP1, RXRB and PPARD at 6p; CRABP2 and RXRG at 1q22; DISC1 at 1q42; NURR1 at 2q; entire chromosome 22 containing PRODH, COMT, GRK3, APOL (4,2,1), and PPARA genes; LPL, NRG1, PPP3CC at 8p; DRD3, RBP1/RBP2 at 3q and DRD2, 5HT3 at 11q. Results from initial screening panel with a total of 12 affected cases were included in this study. A model-based approach was selected to perform linkage analysis. The individuals with a psychosis phenotype (SCH, schizoaffective disorder, bipolar and unipolar affective disorder with psychotic features) were regarded as affected. The parameters used in both simulation (SLINK) and linkage analysis were: The penetrance for gene carriers: 0.40 and for nongene carriers: 0.003, mutant allele frequency of 0.01 which reflects population prevalence 0.02 with 0.27 phenocopy rate. Positive lod scores were only obtained in RXRA, DTNBP1 and RXRG regions assuming autosomal dominant inheritance. Allele loss was observed in some family members in the DNA markers D6S1959 and D1S1679 (from DTNBP1 and RXRG locus respectively). Supported by NARSAD; Akarsu-2003II.

Analysis of the 9p22.3-22.1 region in Italian families with allergic asthma. *A. Beghini, G. Malerba, C. Bombieri, P.F. Pignatti.* Department of Mother and Child, Biology and Genetics, University of Verona, Verona, Italy.

We previously reported a genome scan for asthma in 123 Italian families. The following 4 phenotypes were studied: clinical asthma, total serum elevated IgE (IgE), skin prick test positivity to common aeroallergens (SPT) and bronchial hyperresponsiveness to methacholine (BHR). Markers on chromosome 9p22.3-22.1 (D9S285 and D9S157) showed suggestive linkage for IgE and SPT. The 19 families that presented null or positive linkage for SPT or IgE were selected for an association study by the transmission disequilibrium test (TDT). Five SNPs (single nucleotide polymorphisms) flanking the D9S285 and D9S157 markers were chosen. The SNPs have been selected from data base dbSNP (<http://www.ncbi.nlm.nih.gov>), Ensembl (<http://www.ensembl.org>) and SNPper (<http://snpper.chip.org>). Two SNPs, 751804 T/C and 2275256 G/A, were polymorphic in 20 unrelated subjects. The genetic analysis technique used was ddNTP Primer Extension or Minisequencing. The individuals of the 19 families were genotyped for the 2 SNPs with the SNaPshot Multiplex Kit (Applied Biosystems). The reaction products are analyzed on ABI PRISM 310 DNA sequencer (Applied Biosystems) and with the Genescan software. The observed frequency of the minor allele was 14% and 35% for SNP 751804 and SNP 2275256, respectively. TDT did not show any significant association for either SNP. Multilocus analysis showed a preferential transmission of haplotype TA for asthma ($p = 0.007$), IgE ($p = 0.0036$), SPT ($p = 0.0046$) and BHR ($p = 0.03$). These data suggest that a still unknown genetic factor might be located in the region. Other SNPs in the region have been selected for a finer localisation.

A comprehensive linkage analysis of putative bipolar affective disorder loci. *H. Xu*^{1,2}, *R. Cheng*², *J. Liu*², *J. Endicott*³, *J.E. Loth*³, *T.C. Gilliam*^{1,2}, *M. Baron*³. 1) Department of Genetics and Development, Columbia Univ, New York, NY; 2) Columbia Genome Ctr, Columbia Univ, New York, NY; 3) Department of Psychiatry, Columbia University, New York, NY.

Bipolar affective disorder (BP), also known as manic-depression, is a severe and common psychiatric disorder with complex etiology. Family, twin and adoption studies have implied a significant genetic component underlying the disease. However, the susceptibility genetic factors remain elusive. In a previous genome-wide scan of 343 microsatellite markers (average distance ~10 cM) in 40 multiplex pedigrees (373 genotyped individuals), we reported several potential loci for BP (J. Liu et al., 2003). In the present follow-up study, we have sought to narrow down the putative BP-linked regions for susceptibility gene identification. To this end, we saturated the 11 regions implicated in the genome-wide scan with 87 densely mapped microsatellite markers (average distance ≤ 2 cM) flanking the original linkage peaks. The sample genotyped included the original, extended pedigrees and an additional 16 multiplex families (a total of 862 individuals in 56 pedigrees). This is one of the largest and well-characterized samples reported to date. The 11 regions included in this study are 2p13-16, 3q27-28, 4q31, 8q13, 9q31, 10q21, 10q24, 17q11-12 (two-point parametric LOD scores ≥ 1.9), and 7q34, 13q32 and 14q21 (multipoint ASP LOD scores > 2). Linkage findings in some of these regions were also suggested by independent studies from other groups. Linkage analysis of the densely mapped genomic regions is underway, and the findings will be reported at the time of the presentation. For the genomic regions with verified linkage to BP in this comprehensive mapping, high-density SNPs across the linked regions will be genotyped for further elucidation of susceptibility genetic factors.

Chromosome 5q candidate genes in celiac disease: no evidence for the involvement of IL4, IL5, IL9, IL13, IL17B and NR3C1. *A.W. Ryan^{1,3}, J.M. Thornton^{1,3}, K. Brophy^{1,3}, J.S. Daly^{1,3}, C. O Morain¹, R.M. McLoughlin¹, N.P. Kennedy¹, M. Abuzakouk², F.M. Stevens⁴, C. Feighery², D. Kelleher^{1,3}, R. McManus^{1,3}.* 1) Clinical Medicine, Trinity College, Dublin, Ireland; 2) Dept. of Immunology, Trinity College, Dublin, Ireland; 3) Dublin Molecular Medicine Centre, Dublin, Ireland; 4) Department of Medicine, National University of Ireland, Galway.

Celiac disease (CD) is a complex autoimmune disorder of the small intestine, brought about by the ingestion of dietary gluten and related proteins in susceptible individuals. Genetic predisposition to CD is determined primarily by alleles at the HLA-DQB locus, while other MHC linked genes (6p21) and CTLA4 (2q33) have also been implicated. In addition, extensive family studies have provided strong evidence for a susceptibility locus on chromosome 5q. However, the position of maximum marker association to CD on 5q has varied considerably among family studies, and the causative gene has not yet been identified. We have assayed genetic variation at 13 single nucleotide polymorphism (SNP) loci from IL4, IL5, IL9, IL13, IL17B and NR3C1, all of which are present on chromosome 5q and have potential or demonstrated involvement in autoimmune and/or inflammatory disease, in a sample of 409 CD cases and 355 controls. SNPs were chosen on the basis of functional relevance, prior disease association and, where possible, prior knowledge of haplotype variation in European populations (haplotype tagging). The frequencies of the most common haplotypes in cases and controls respectively were: IL4/IL13, 0.665 vs. 0.691; IL5, 0.660 vs. 0.668; IL9, 0.406 vs. 0.437; IL17B, 0.492 vs. 0.483; NR3C1, 0.639 vs. 0.624. The frequencies of these (and the rarer) haplotypes were, therefore, similar in cases and controls. These results, which incorporate almost ten thousand genotypes from ethnically uniform population samples, provide good evidence that these loci are not associated with CD in this sample population. In addition, no evidence for the involvement of candidate genes IL12B and IBD5 has been provided by earlier studies. Further candidate gene regions for the elusive chromosome 5q CD susceptibility locus are currently under investigation.

Molecular genetic study of Apolipoprotein L gene family at 22q11-13 as candidates for schizophrenia. M.-C.

*Cheng*¹, *W.-H. Chien*², *H.-M. Liao*¹, *C.-H. Chen*^{1,3}. 1) Department of Psychiatry, Tzu-Chi Univ, Hualien, 970 Taiwan; 2) Institute of Aboriginal Health, Tzu-Chi Univ, Hualien, 970 Taiwan; 3) Institute of Human Genetics, Tzu-Chi Univ, Hualien, 970 Taiwan.

Background: Several genome-wide linkage and molecular genetic studies suggested that chromosome 22q11-13 is one of the susceptible loci for schizophrenia. Microarray analysis of postmortem brain of patients with schizophrenia revealed up-regulation of Apolipoprotein L (APOL) family gene expressions in the prefrontal cortex of schizophrenia. Since the APOL family genes are located at chromosome 22q11-13, we proposed that APOL gene family might be candidate genes for schizophrenia. Methods: To test this hypothesis, we systematically searched the APOL family genes for mutations at protein-coding sequences and promoter region using Denaturing High Performance Liquid Chromatography (DHPLC) and autosequencing. Results: We identified four, two, eight, twenty one, and four mutations in APOL1, 2, 3, 4, 5 genes, respectively. Several of these mutations result in missense mutations including E150K at exon 7 of APOL1; I245V at exon 6 of APOL2; S39R and V232M at exon 3 and exon 7 of APOL3, respectively; M156V, R220H, A316Q, and S323L at exon 8 of APOL4; M272T and M323T at exon 3 of APOL5. In addition, a GT to GG substitution was identified at conserved donor splicing site of intron 3 of the APOL4. Discussion: These mutations might affect the function of APOL family genes and cause pathology of schizophrenia. Currently, we are conducting a case-control study to test the association of these mutations with schizophrenia.

Localization of an Alcohol Dependence gene to the 5q GABAA cluster. *M. Radel¹, R. Vallejo¹, N. Iwata², R. Aragon¹, J.C. Long¹, M. Virkkunen³, D. Goldman¹.* 1) Laboratory of Neurogenetics, NIAAA, NIH, Rockville, MD; 2) Department of Psychiatry, Fujita Health University School of Medicine, Toyoake, Japan; 3) Department of Psychiatry, University of Helsinki, Finland.

Background: Behavioral and pharmacogenetic evidence links gamma-amino butyric acid type A (GABAA) receptors and chromosomal regions containing GABAA receptor genes to ethanol-related responses. The GABAA cluster on chromosome 5q is of particular interest in the genetics of Alcohol Dependence (AD) because of the gamma-2 subunit requirement for ethanol modulatory action on GABAA receptors, and due to previous linkage findings in mice and humans implicating both GABRA6 and GABRG2, and reported associations of GABRA6, GABRB2 and GABRG2 alleles with AD. Methods: Two large psychiatrically interviewed samples, a Southwestern Native-American (SWNA) sample (total n = 433) and a Finnish sample (total n = 511) with alcohol-dependent subjects and unaffected individuals were genotyped blind to diagnosis for six single nucleotide polymorphisms at the 5q GABAA gene cluster. Sib-pair linkage and case-control association analyses were performed in addition to linkage disequilibrium mapping to investigate the role of these genes in susceptibility to AD. Results and conclusions: Sib-pair linkage of GABRG2 to AD was observed in Finns ($P = 0.008$). Association of the GABRB2 1412T allele with AD was detected in both Finns ($P = 0.01$), and in the SWNA tribe ($P = 0.008$), and the GABRA6 1519T allele was associated with AD in both Finns ($P = 0.01$) and the SWNA tribe ($P = 0.03$). Linkage disequilibrium mapping with haplotypes yielded evidence for an AD predisposition locus in the region of the GABAA 5q gene cluster in both populations. For Finns the most highly significant findings were at GABRA6 (empirical $P = 0.007$) and the region spanning from the GABRA6 1519T>C polymorphism to the GABRG2 IVS8 +99C>A polymorphism (empirical $P = 0.05$). For the SWNA tribe the most highly significant signals were also at GABRA6 (empirical $P = 0.04$) and the region spanning from the GABRA6 1519T>C polymorphism to the GABRG2 IVS8 +99C>A polymorphism (empirical $P = 0.05$). In both populations, haplotype localization implicates GABRA6 and GABRG2.

Effects of gene interactions on male fertility. *W. Engel¹, B. Drabent², A. Meinhardt³, I. Adham¹, I. Schwandt¹, S. Wolf¹, U. Sancken¹, K. Kleene⁴, K.C. Nayernia¹.* 1) Inst Humangenetik, Univ Gottingen, Gottingen, Germany; 2) Department of Biochemistry, University of Gttingen, 37073 Gttingen, Germany; 3) Department of Anatomy and Cell Biology, University of Giessen, 35378 Giessen, Germany; 4) Department of Biology, University of Massachusetts, Boston, Massachusetts.

About 15% of couples have reduced fertility and in approximately one-half of all cases the reason is male infertility, usually of genetic origin. It is obvious that the molecular basis of male (in)fertility is not a linear order of genetic events but the interaction of complex genetic networks. Triple knockout mice were used to investigate the interactions of five genes that are expressed in meiotic and haploid spermatogenic cells in mice, transition protein 2 (Tnp2), proacrosin (Acr), histone H1.1 (H1.1), histone H1t (H1t) and sperm mitochondria-associated cysteine-rich protein (Smcp). TNP2 functions in the replacement of histones and the initial condensation of the spermatid nucleus. The linker histone subtypes H1.1 and H1t are expressed at high levels in meiotic and early haploid cells. ACR, a protease that is stored as a proenzyme in the acrosome, is activated during the acrosome reaction and functions in binding of sperm to the zona pellucida. SMCP is a structural protein in the outer membranes of sperm mitochondria that functions in motility. Previous work demonstrates that homozygous knockout mice lacking each of these proteins individually exhibit no defect in fertility on mixed genetic backgrounds. In contrast, the present study demonstrates that five triple knockout lines, *Acr/H1.1/Smcp*, *Acr/Tnp2/Smcp*, *Tnp2/H1.1/Smcp*, *Acr/H1t/Smcp*, *Tnp2/H1t/Smcp* exhibit drastic reductions in fertility on mixed genetic backgrounds. Analysis of fertility parameters reveal that the decreased fertility is due to line-dependent defects in sperm motility in vitro correlated with reduced migration in the female reproductive tract, and decreased fertilization due to defects in adhesion of sperm to the zona pellucida, the membrane surrounding the egg. These findings demonstrate that male fertility involves synergistic interactions of genes that function in sperm motility and sperm-egg adhesion during fertilization.

Childhood-Onset Mood Disorder: Haplotype Analysis of Tryptophan Hydroxylase 1 and 2 Polymorphisms and Suicide Attempts. *J. Strauss*¹, *N. Bulgin*¹, *N. King*¹, *C. George*², *S. Shaikh*¹, *M. Kovacs*², *J.L. Kennedy*¹. 1) Neurogenetics Section, CAMH, Toronto, ON, Canada; 2) Western Psychiatric Institute and Clinic, University of Pittsburgh Medical Center, Pittsburgh, PA.

As part of a study of risk factors for childhood-onset mood disorder (COMD), we examined tryptophan hydroxylase markers for association with suicidal behaviour, a common feature of depressive illness. Observations that tryptophan hydroxylase 2 (TPH2) is expressed in murine brain, while tryptophan hydroxylase 1 (TPH1) is not (Walther et al. *Science* (2003)299:76) have been made. Evidence points to the same differential expression in humans (Zill et al. *Eur Neuropsychopharmacol* (2004)14:284). TPH1 variants have been associated with suicidal behaviour and completed suicide in multiple studies. We investigated the -6526G>A and A218C polymorphisms of TPH1 and the hCV245410, rs1487280 and rs1872824 variants of TPH2 for association with suicide attempts in a sample of 176 subjects with onset of major depressive disorder or dysthymic disorder prior to the age of 14 (97 with attempts, 79 without). Allelic chi-square results indicated no association of the three TPH2 markers in COMD probands with at least one lifetime suicide attempt ($0.70 < p < 0.96$). At the TPH1 locus, the -6526G>A polymorphism was not associated with lifetime history of suicide attempt ($p=0.80$), though the A218C variant exhibited a trend towards association ($\text{chisq}=3.03$, $\text{d.f.}=1$, $p=0.082$). PHASE v2.0 (Stephens et al. 2001) was used to examine haplotypes. Haplotype analysis demonstrated no significant differences between cases and controls for the four TPH1 haplotypes ($p=0.91$) or for the eight TPH2 haplotypes ($p=0.76$). To summarize, we found no association between TPH2 alleles and COMD subjects with suicide attempts. Instead, we remarked a trend for the TPH1 A218C marker to be associated with suicide attempts in this sample. No significant haplotype associations were seen. Our results are part of an emerging understanding of TPH and suicidal behaviour, and are interesting given the TPH isoforms' differing tissue expression.

Analysis of polymorphisms Bsm I, Apa I and Taq I in the Vitamina D Receptor gene (VDR) in patient with Osteoporosis in Venezuela. *L. Borjas-Fajardo, M. Zambrano, L. Pineda, E. Fernandez, P. Montiel, W. Zabala, MG. Portillo, MA. Sanchez, A. Morales, JA. Chacín, W. Delgado.* Unidad de Genetica Medica, Univ del Zulia, Maracaibo, Zulia, Venezuela.

The osteoporosis (OP) is a systemic and heterogeneous skeletal disease characterized by a low density of bony mass. Numerous studies have demonstrated that the genetic factors could represent 80-90% of the variability in the bone mineral density. One of the genes more studied in this field it is the receiving gene of the vitamin D (RVD). In this investigation it was carried out the analysis of the polymorphisms Bsm I, Apa I and Taq I of the gene RVD in a sample of 171 women, 76 normal women (group), 24 with osteopenia and 71 with osteoporosis. The DNA was extracted by means of the use of the derived combined technique of the method fenol-sevag and inorganic, it stops later on to amplify the exclusive sequences of the end 3` of the gene RVD applying the reaction in Chain of the polymerase (PCR). The association among the genotypes of the gene receptor of the vitamin D and the normal established categories and osteoporosis, they were statistically significant, being the population in genetic equilibrium for the three polymorphism. The genotype BB was presented in the groups control and with osteopenia in percentages of 20.83% and 21.05%, while in the group with osteoporosis occupied 56.33%. In the same way, the genotype AA was presented in the group with osteopenia in 8.33%, followed by the group control 28.95%, and the group with osteoporosis with 50.70%. The genotype tt was in the groups control and with osteopenia in percentages of 0- 10.53%, and in the group with osteoporosis in 25.35%. The haplotype BBAA_{tt} turned out to be a factor of risk for the osteoporosis, with a relative risk estimated by Ott of 4.4; while the haplotype Bbaa_{TT} showed to be a protection factor. These discoveries allow establishing association in our population of these genotypes of the RVD gene with the osteoporosis, just as it has been reported in other countries.

Analysis of the Alcohol Dehydrogenase (ADH3) and the Serine Protease Inhibitor, Kazal type 1 (SPINK1) Genes in Alcohol-Related Pancreatitis. *K.G. Monaghan, M.A. Kilar.* Medical Genetics, Henry Ford Hospital, Detroit, MI.

Background and Objectives: Alcohol dehydrogenase (ADH3) polymorphisms and serine protease inhibitor, Kazal type 1 (SPINK1) mutations, particularly N34S, have been examined in pancreatitis patients, although no study has analyzed both genes in the same patient. Previous studies suggested a possible association between ADH3 or SPINK1 and alcohol induced pancreatitis. We hypothesize that ADH3 polymorphisms and SPINK1 mutations are associated with alcohol-induced pancreatitis. **Experimental Approaches:** Three groups were analyzed in this study: Patients with alcohol-induced pancreatitis (N = 45), non-alcohol associated pancreatitis with a positive family history of pancreatitis (N = 8) and non-alcohol associated pancreatitis with a negative family history of pancreatitis (N = 51). The ADH3 *1 and *2 polymorphisms were analyzed by restriction fragment length polymorphism (RFLP) analysis. SPINK1 exon 3 was analyzed by direct DNA sequencing. **Results:** The ADH3 *1 and *2 allele frequencies between Caucasian and African American patients and normal controls did not differ. SPINK1 mutations were only identified among patients with non-familial, non-alcohol induced pancreatitis. Six of fifty-one patients (11.8%) had at least one SPINK1 mutation, including N34S, P55S, IVS3+2TC, and a novel mutation, V46D. One individual was compound heterozygous for N34S and IVS3+2TC. **Conclusions:** ADH3 is not likely to be involved in alcohol-induced pancreatitis in Caucasians or African Americans. Our results are in agreement with previous findings, that SPINK1 mutations are associated with non-familial idiopathic pancreatitis. However, our results suggest that SPINK1 mutations are not likely involved in alcohol-induced pancreatitis among Caucasians or African Americans. SPINK1 mutation analysis may be beneficial in determining the etiology of the disease in patients affected with idiopathic pancreatitis. Further studies regarding the penetrance of SPINK1 mutations are needed prior offering testing to asymptomatic at-risk family members.

Multi-dimensional Clustering Analysis using pulsed/non-pulsed Neural Network algorithms to extract Gene SNP molecular epistasis from a multiplex genotype in Deep Vein Thrombosis Studies. *D. Ross¹, J. Perrett², A. Arellano¹, L. Bare¹, F. Rosendaal³, S. Petitti⁴, J. Sninsky¹.* 1) Celera Diagnostics, Alameda, CA; 2) DNN Industries, Chippenham, UK; 3) LUMC, Leiden, The Netherlands; 4) Kaiser Permanente DOR, Oakland CA.

Complex genetic diseases in humans are responsible for major clinical and diagnostic burden on society. Complex interactions of multiple genes may underlie complex disease, a concept known as epistasis. DVT was chosen as a test case because there are previously reported SNPs (Factor V Leiden (FVL) and FII G20210A) and environmental factors (e.g., contraceptives) that influence its occurrence. Widespread testing for FVL in DVT has been constrained for multiple reasons, including the low allele frequency and the moderate risk for the heterozygote. Two datasets totaling 1100 individuals (49% cases and 51% controls) with phenotype for DVT, age, contraceptive use and sex were genotyped with a multiplex assay of 25 different markers. Multi-dimensional clustering analysis (MCA), which integrates evolutionary programming, pulsed and non-pulsed neural networks in a true parallel processing architecture, was used to identify markers, and their association with the case population. Under MCA, all marker and phenotype combinations were evaluated simultaneously. A group of gene-marker-genotype combinations were significant, and extracted as a group. Among the gene/SNP interactions associated with clinical outcome are FVL, FII-G20210A, CBS-G919A and TFPI-C536T. The identified group of gene/SNP markers suggests molecular epistasis of genes involved in the coagulation pathway. The risks of FVL and FII-20210A were supported by simple association tests. ROC curves were used to determine the predictive value of the group of gene/SNP markers as a diagnostic. The SNP group is more powerful (AUC 0.70) than, for example, testing for FVL alone (AUC 0.63), or FVL plus FII G20210A alone (AUC 0.65). The MCA procedure has the advantages of evaluating all of the interactions simultaneously, construction of algorithmic model for predictive diagnostic value and the ability to detect interactions that are not always reveal by other statistical tests.

Frequency and nature of Angelman syndrome *UBE3A* mutations in Japan. S. Saitoh, K. Hosoki, K. Takano, A. Sudo. Dept Pediatrics, Hokkaido Univ Sch Medicine, Sapporo, Japan.

About 10% of Angelman syndrome (AS) cases are caused by a mutation of *UBE3A*. The *UBE3A* gene shows tissue-specific imprinting with only the maternally derived allele expressed in certain areas of the brain. More than 50 mutations of *UBE3A* have been described in AS, all that are either maternally inherited or have arisen *de novo*. We have investigated 5 patients from 3 families and 30 sporadic patients with AS phenotypes in Japan for whom the *SNURF-SNRPN* DNA methylation test revealed a normal methylation pattern, ruling out a large deletion, uniparental disomy or imprinting defects. PCR amplification of genomic DNA and direct sequencing of all coding exons and flanking sequences was performed. We identified potential mutations in all 5 patients of 3 families (100%), and for 6 of 30 sporadic patients (20%). These included IVS14-2AG, 668delA and 1632_1633CGGA (S349X) in familial patients, and 3089_3094del6, IVS15-3_3030del9, 1842CG (P419R) and 3093_3096del4 in 6 sporadic patients. The 3093_3096del4 mutation was found in 3 independent patients and indicates a mutation hot spot in Japanese, while the other mutations were only identified in single patients. Two mothers of familial cases were carriers for the mutations, while another did not have the mutation and was most likely to have germline mosaicism. We could investigate only two mothers of sporadic patients and neither were carriers, suggesting that the mutations arose *de novo*. In conclusion, *UBE3A* mutations are commonly identified in familial patients but in only 20% of sporadic patients. This mutation detection rate is consistent with previous studies, indicating that *UBE3A* mutations are not the major cause of AS in sporadic patients with normal DNA methylation. A genotype-phenotype correlation was not conclusive in our series of patients. Nonetheless, clinical severity was relatively mild in these patients when compared to patients with a 5 Mb deletion. The identification of germline mosaicism for *UBE3A* mutations in our series of patients and the low frequency of *UBE3A* mutations in AS further highlights the significance and difficulty of genetic counseling in patients with AS.

Variation in the CYP2C9 and SCN1A genes influences clinical use of the anti-epileptic drug phenytoin. *S. Tate, C. Depondt, S. Sisodiya, S. Schorge, S. Shorvon, J. Sander, N. Wood, D. Goldstein.* Dept Biol, Univ Col London, London, United Kingdom.

Phenytoin is an effective and inexpensive anti-epileptic drug (AED) less widely used in Europe now, partly because of concerns about adverse reactions (ADRs). As with many AEDs, a broad range of phenytoin doses are used, with the final "maintenance" dose normally determined by trial and error. Starting doses are variable and may be reduced on presentation of one or more adverse reactions or increased if seizures are not controlled. Phenytoin also has a narrow therapeutic index, and nonlinear kinetics mean that small increases can result in disproportionate increases in serum levels. Empirical calibration of dose therefore may entail significant clinical harm in terms of delayed efficacy or adverse reactions. For these reasons phenytoin is an excellent candidate for pharmacogenetic diagnostics. If gene variants could be identified that predict appropriate starting doses or that identify individuals more likely to suffer ADRs, phenytoin could be used more effectively and with fewer side effects. There are also well-defined candidate genes that could harbour variants that influence drug response. Phenytoin targets voltage-gated sodium channels in the brain, encoded by the SCN family of genes (including the SCN1A, implicated in Mendelian forms of epilepsy). It is a substrate of P-glycoprotein, an efflux pump expressed at the brain blood barrier encoded by ABCB1, and the major drug metabolising enzyme is CYP2C9. We therefore assessed how variation in the CYP2C9, SCN1A, and ABCB1 genes influences the maximum dose (in most cases equivalent to the maintenance dose) of phenytoin in 270 patients treated with phenytoin. We report here that polymorphisms in both the CYP2C9 and SCN1A genes show highly significant associations with maximum dose. This retrospective study implies that genetically defined subgroups of patients require, on average, maintenance doses ranging from 250 to 376 mg of phenytoin per day, and sets the stage for a prospective evaluation of how pharmacogenetic diagnostics can be used to improve the use of phenytoin.

Association of novel insertion in NPHS2 (Podocin) gene with End-Stage Renal Disease (ESRD) in African Americans. *J.A. Engeler Dusel*^{1,2}, *K.P. Burdon*³, *P.J. Hicks*³, *B.I. Freedman*^{1,2}, *D.W. Bowden*^{2,3}. 1) Nephrology; 2) Internal Medicine; 3) Biochemistry, Wake Forest Univ School of Med, Winston-Salem, NC.

Podocin, encoded by NPHS2 and mapped to 1q25-31, is an integral membrane protein exclusively expressed in glomerular podocytes. Mutations in NPHS2 have been shown to cause autosomal recessive nephrotic syndrome and have been associated with proteinuria in several populations. We identified moderate evidence for linkage to ESRD on chromosome 1q25.1 in the region of NPHS2 (LOD 1.62) in a genome-wide scan in 296 African American (AA) siblings concordant for non-diabetic (non-DM) ESRD making this gene a positional candidate. We sequenced all coding regions and 2kb of promoter sequence of NPHS2 in 96 unrelated AA non-DM ESRD cases and 96 healthy AA population-based controls. Non-DM ESRD subjects (predominantly hypertension-associated ESRD) had a meanSD age at ESRD onset of 45.814.9 years and mean body mass index of 26.38.2 kg/m². Fifty three polymorphisms were identified with minor allele frequencies ranging from 1% to 44%, including 4 insertion/deletions. Twenty four polymorphisms were located in the promoter region, 10 were exonic, 13 intronic and 6 in the 3UTR. None were previously described as disease causing mutations. Four were novel non-synonymous SNPs (P20L, A44E, A61V and A242V). A242V showed borderline association with a frequency of 0.032 in cases and 0.074 in controls (p-value=0.06). This SNP and three relatively common synonymous coding SNPs (T1023C, C1275G and A1479G) were genotyped in an additional 192 cases and 96 controls, however, none were significantly associated. An A insertion polymorphism in intron 3, 9 bp downstream of exon 3 and close to the splice site was detected in 6 cases and no controls in the original sequencing. Statistical analysis demonstrated single SNP association to ESRD (p-value=0.014; Fishers exact test). This variant is undergoing further evaluation in the larger sample. In conclusion, although coding variants do not appear to contribute significantly to ESRD in the general population, the intron 3 insertion may be associated with non-DM ESRD in African Americans and NPHS2 may contribute to the development of this disease.

A novel approach for genetic predisposition to diabetic nephropathy. *A.J. McKnight, K.A. Pettigrew, D.A. Savage, A.P. Maxwell.* Nephrology Research Group, Queen's University of Belfast, Northern Ireland.

Diabetic nephropathy is the leading cause of end stage renal failure in the western world. There is substantial epidemiological evidence supporting genetic predisposition, but the exact model of inheritance is unknown. A number of conflicting association results have been reported, reflecting several factors including the limited examination of candidate genes, variation in selection criteria, and relatively small sample sizes.

We recently completed the first genome-wide, association screen using pools of genomic DNA derived from accurately phenotyped individuals. Caucasian type 1 diabetic patients with (case) and without (controls) nephropathy were recruited from Ireland. We employed 6000 microsatellite markers indirectly distributed throughout the genome, resulting in a final map resolution of 0.7 cM (~590 kb). All putatively associated regions from our initial screen were confirmed in repeat pools and the top 50 markers individually genotyped to confirm the association.

Independently, we developed a unique candidate gene directory for diabetic nephropathy. This resource contains current information on >1000 genes reportedly involved in the pathophysiology of diabetic nephropathy. The data was extracted from a variety of sources and collated into a centralised, readily accessible, web-based repository with all information presented for query and download in several formats. There are currently 1068 genes in the database [June 2004].

By combining these two approaches (positional and functional) we have identified several genomic regions and prioritised candidate genes that may be associated with diabetic nephropathy. Candidate genes are screened for variants using WAVE (dHPLC) technology. Variants are confirmed by direct capillary sequencing and genotyped using TaqMan, Invader or Pyrosequencing technologies in our All Ireland case (n=300) control (n=363) collection. Initial analysis of several candidate genes has revealed association with nephropathy for a potentially functional promoter variant *VEGF*-460C>T ($p<0.001$).

Genome-wide association study of idiopathic Parkinson's disease using 27,000 microsatellite markers. W.

Satake^{1,2}, Y. Hirota¹, Y. Momose³, I. Mizuta¹, G. Tamiya⁴, T. Ikuta⁴, S. Makino⁴, S. Sakoda², M. Yamamoto⁵, N. Hattori⁶, M. Murata⁷, H. Inoko⁴, T. Toda¹. 1) Div. Functional Genomics, Osaka Univ. Grad. Sch. Med., Osaka; 2) Dept. Neurol., Osaka Univ. Grad. Sch. Med., Osaka; 3) Dept. CBI, Grad. Sch. Med., Univ. Tokyo, Tokyo; 4) Dept. Mol. Life Sci. II, Tokai Univ. Sch. Med., Kanagawa; 5) Dept. Neurol., Kagawa Pref. Central Hosp., Kagawa; 6) Dept. Neurol., Juntendo Univ. Sch. Med., Tokyo; 7) Dept. Neurol., NCNP, Tokyo, Japan.

Parkinson's disease (PD), one of the most common human neurodegenerative diseases, is a complex disorder with multiple genetic and environmental factors influencing disease risk. Although several causal genes for Mendelian inherited PD (alpha-synuclein, parkin, UCH-L1, DJ-1, NR4A2, and PINK1) have recently been identified, genetic factors that influence idiopathic PD as strongly as APOE-E4 influences Alzheimer disease have not yet been identified. To identify susceptibility genes for idiopathic PD, we performed a genome-wide association study using approximately 27,000 microsatellite markers arranged at intervals of approximately 100kb throughout the genome. For the initial screening, we performed the association study with pooled DNA from 124 patients with PD and 124 normal controls. We analyzed the PCR products with the GeneScanTM software, and compared the pattern of the PCR products of pooled DNA from patients with PD and controls by the PickPeak software. We have finished analyzing the approximately 27,000 markers distributed throughout all the chromosomes and found associations ($p < 0.05$) in approximately 8% of the markers. We are currently performing systematic and comprehensive second and third screenings on all of these candidate markers using other sets of pooled DNA to exclude false positive associations, and expect that 10-20 markers will show significant associations throughout all three screenings. We will subsequently confirm these significant associations using individual samples. Genes in linkage disequilibrium with these markers may be associated with the pathogenesis of PD.

Quantitative perturbations of p53 (Real-time PCR) in Endometriosis: Differences between American and Icelandic Cases. *JL. Simpson*^{1,2}, *J.T. Gylfason*³, *R.T. Geirsson*^{3,4}, *D. Dang*¹, *K. Benediktsdottir*⁴, *V. Petursdottir*⁴, *A. Poindexter*¹, *J. Buster*¹, *S. Carson*¹, *F.Z. Bischoff*¹. 1) Depts OB/GYN; 2) and Hum/Mol Genet. Baylor Col of Med, Houston TX; 3) Faculty of Medicine, Univ Iceland; 4) Depts OB/GYN and Pathology, Landspítali Univ Hospital, Iceland.

Endometriosis is a non-neoplastic disorder, but shares similarities with malignancy (i.e. local invasion and metastasis). An attractive model for the underlying genetic cause in endometriosis is the multi-step mutation pathway. Using FISH techniques, we have shown that perturbations of chromosome 17 and the p53 locus occur frequently in severe/late stage endometriosis. Although reliable, FISH enumeration of signals is subject to observer skill and bias. We now report the use of quantitative real-time PCR to assess aberrations involving p53 copy number in eutopic endometrial and endometriotic tissue specimens. In addition, we compare American and Icelandic cases. **METHODS:** For American cases, fresh tissue specimens (n=21) and peripheral blood samples were obtained from women with advanced stage disease. Controls consisted of peripheral blood from 28 unaffected women undergoing tubal ligation. For Icelandic cases, paraffin embedded endometriotic and matched eutopic endometrial tissue (n=19) were obtained from women with advanced stage disease. DNA from tissue specimens was extracted and real-time quantitative PCR performed to quantify copies of the p53 gene compared to the ubiquitous GAPDH control locus. **RESULTS:** An expected normalized mean of 1.003 was observed for the p53 locus among control cases. Among samples collected in the USA, significant p53 gain (n=13) or loss (n=4) was observed in all but 4 of 21 cases compared to GAPDH. Surprisingly, we failed to observe either gain or loss of p53 in Icelandic patients (n=19). **CONCLUSIONS:** Our results support the role of non-random somatic alterations involving the p53 locus in the pathogenesis of most cases of late/severe stage endometriosis. Differences between Icelandic and American subjects could have implications for generalizability of population based genome wide approaches.

Large-scale case control study for bronchial asthma. *M. Tamari¹, T. Hirota¹, A. Matsuda¹, M. Akahoshi¹, K. Obara¹, N. Takahashi¹, M. Shimizu¹, S. Doi³, A. Miyatake⁴, K. Fujita⁵, T. Enomoto⁶, H. Saito⁷, Y. Suzuki⁸, Y. Nakamura⁹, T. Shirakawa^{1,2}.* 1) Lab for Genetics of Allergy, RIKEN SNP Research Ctr, Yokohama, Kanagawa, Japan; 2) Dept. of Health Promotion and Human Behavior, Kyoto University, Kyoto, Japan; 3) Osaka Prefectural Medical Center for Respiratory and Allergic Diseases, Osaka, Japan; 4) Miyatake Asthma Clinic, Osaka, Japan; 5) School of Human Nursing, The University of Shiga Prefecture, Shiga, Japan; 6) Japanese Red Cross Society, Wakayama Medical Center, Wakayama, Japan; 7) National Research Institute for Child Health & Development, Tokyo, Japan; 8) Department of Medical Genetics, Tohoku University School of Medicine, Sendai, Japan; 9) The Institute of Medical Science, The University of Tokyo, Tokyo, Japan.

Bronchial asthma is a complex disorder caused by combination of genetic and environmental factors. SNPs (Single nucleotide polymorphisms) are the most common form and are thought to be useful markers to identify genes susceptible human common disease. Systematic analysis to search an association between SNPs genotype and disease phenotype is expected to disclose a gene(s) related to complex diseases. To clarify the genetic factor implicated in the etiology of bronchial asthma, we have conducted genome-wide association studies with 86,100 randomly selected gene-based SNPs using the high-throughput multiplex PCR-Invader assay method. After first screening with 86,100 SNPs (94 asthmatic patients vs. 658 control samples), we have focused on 2026 SNPs revealed positive association ($p < 0.01$). Next, we have conducted association study in the second sample (470 childhood asthma, 470 adult asthma and 658 controls). Finally, 17 SNPs were significantly associated with asthma susceptibility ($p < 0.001$). A SNP#A was significantly associated with asthmatics ($p = 0.0000074$). The gene containing SNP#A express in bronchus, testis and lung tissues and lies on chromosome 3p21, a locus linked to asthma susceptibility. Using real-time quantitative RT-PCR, transient transfection reporter gene assays, EMSA, mRNA stability assays and immuno-histochemistry, functional analyses of genes containing these SNPs are on going.

Sequence Variants of the *DRD4* Gene in Autism; Further Evidence that Rare *DRD4* 7R Haplotypes are ADHD Specific. *D.L. Grady*¹, *A. Harxhi*², *M. Smith*², *P. Flodman*², *M.A. Spence*², *J.M. Swanson*², *R. Moyzis*^{1,2}. 1) Dept Biological Chemistry, Univ California Col Medicine, Irvine, CA; 2) Department of Pediatrics, University of California, Irvine, Medical Center, Orange, California, 92868, USA.

A high prevalence of rare dopamine receptor D4 (*DRD4*) alleles in children diagnosed with attention-deficit hyperactivity disorder (ADHD) has been reported (Grady DL, Chi H-C, Ding Y-C, Smith M, Wang E, Schuck S, et al. 2003, *Molecular Psychiatry* 8:536-545). In this prior study, extensive haplotype data of the *DRD4* locus was used to suggest that population stratification was not the explanation for the high prevalence of rare alleles. However, the population sample used as a control was obtained from diverse geographic locations, and hence specific local haplotype variants could have contributed to these observations. In order to test this possibility, DNA resequencing/haplotyping was conducted on 136 *DRD4* alleles obtained from autism probands, collected from the same geographic population as the prior ADHD probands (Orange County, CA). A number of studies have suggested that the susceptibility genes underlying these two disorders might partially overlap. Rare *DRD4* variants were not uncovered in this autism sample beyond that expected by chance. These results suggest strongly that the high prevalence of rare *DRD4* alleles in ADHD probands is due to ascertainment of the sample by diagnosis of ADHD.

Analysis of genetic variation and expression of the dysbindin1 gene in schizophrenia. *D.B. Wildenauer^{1,2}, S.G. Schwab^{2,3}, S. Mondabon⁴, M. Knapp⁵, M. Albus⁶, M. Borrmann-Hassenbach⁶, W. Maier⁴, A. Schmidt⁷, M. Hoehe⁸, B. Timmermann⁸, R. Reinhard⁸.* 1) CCRN, Claremont, WA, Australia; 2) School of Psychiatry, University of Western Australia, Perth, Australia; 3) WAIMR, Perth, Australia; 4) Dept of Psychiatry, University of Bonn, Germany; 5) Dept of Medical Statistics, University of Bonn, Germany; 6) Mental State Hospital, Haar, Germany; 7) ZI, Mannheim, Germany; 8) MPI Molecular Genetics, Berlin-Dahlem, Germany.

We reported recently association of single nucleotide polymorphisms within the dysbindin1 gene with schizophrenia in two independent family samples (Schwab et al, 2003, *Am J Hum Genet* 72:185-190) one sample comprising 79 families with at least two affected siblings and both parents available for genotyping and the second sample comprising 128 trio families (affected offspring with parents). None of the reported markers are located in exons or are known to cause functional or structural changes in the gene products. Our goal was to find the susceptibility alleles involved in development of schizophrenia. DNA sequence analysis has been used to analyze the genomic region for further variants. 96 patients with schizophrenia from our family samples have been included in the analysis. 79 DNA variants have been identified by sequence analysis, 29 having a minor allele frequency of 0.10 in the analyzed sample. So far, no exonic variation has been detected in the investigated region. In addition, we performed expression analysis using real time technology for relative quantification of RNA levels. 62 RNA samples isolated from immortalized lymphoblast cell lines from the patients of our family samples as well as RNA samples isolated from post mortem brain of 10 schizophrenic patients and 10 controls were available. No differences in RNA levels of dysbindin1 have been identified in post mortem brain tissue. However, preliminary results indicate statistical significant differences in the expression levels of dysbindin1 in lymphoblasts of our patients, if genotype information was used as a co-variant in the statistical analysis. The failure to detect exonic variants as well as the differences in gene expression suggests involvement of variants affecting transcription rate.

Lack of Association and Linkage of the Serotonin-2A Receptor Gene to Autism Spectrum Disorders. A.

ANAGNOSTOPOULOU^{1,3}, *X. Liu*^{2,3}, *H. Laine*^{1,3}, *J.J.A. Holden*^{1,2,3}, *ASD-CARC*⁴. 1) Dept. Physiology, Queen's University, Kingston, Canada; 2) Dept. Psychiatry, Queen's University, Kingston, Canada; 3) The Autism Research Program, Ongwanada Resource Centre, Kingston, Ontario; 4) www.autismresearch.ca.

Hyperserotonemia is one of the most consistent biochemical findings in Autism Spectrum Disorders (ASDs). It has recently been reported that autistic individuals with hyperserotonemia have decreased serotonin 2A (5HT2A) receptor binding. Antagonists of the 5HT2A receptor have been shown to reduce some symptoms of autism. These findings suggest that, based on its function, the HTR2A gene is a good candidate gene for autism susceptibility. In addition, two recent genome scans showed evidence for linkage of autism susceptibility to chromosome 13q, the location of the HTR2A gene, providing evidence for it as a positional candidate locus. We genotyped a SNP in the promoter region HTR2A (1438A/G) in 190 multiplex families, with 388 affected individuals. Of these, 138 families were from AGRE. The comparison group consisted of DNAs from 116 placentae, 138 controls and 334 random anonymous newborn bloodspots obtained from the Ontario Ministry of Health Newborn Screening Program and previously used for PKU testing. Of the multiplex families, 119 had at least two affected males, 59 had at least one affected male and one affected female, and the remainder had only affected females. The Family-Based Association Test (FBAT) did not show any preferential transmission of specific alleles in any of the family groups. Case-control comparisons showed that the genotype and allele frequencies in affected individuals did not differ statistically from sex-matched controls. Genotype-phenotype associations using the ADI-R data showed that the mean ADI-R scores for the 3 domains of autism, age-of-onset, and age at first phrase did not differ in individuals with different HTR2A genotypes. These results do not support a major role for the HTR2A gene in susceptibility to ASD, confirming findings by Veenstra-VanderWeele et al (2002) (*Am J Med Genet* 114:277-283). Supported by research grants from CIHR and OMHF to JJAH.

***CNTF* gene polymorphisms are associated with muscle strength variation in older adults.** D.E. Arking¹, T. Li², J. Walston², D. Fallin³, B. Beamer², Q.L. Xue², L. Fried², A. Chakravarti¹. 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Johns Hopkins University Older Americans Independence Center, Baltimore, MD; 3) Department of Epidemiology, Johns Hopkins University Bloomberg School of Public Health.

Skeletal muscle strength declines with age, and plays an important role in the development of disability and frailty. The etiology of strength declines is multifactorial, including decreasing levels of activity, increased inflammation and disease burden, declines in nerve/muscle synapses, and genetic variation. Ciliary Neurotrophic Factor (*CNTF*) is expressed in motor neurons where it protects the cells from apoptosis. We hypothesized that variation in genes that influence skeletal muscle mass maintenance will contribute to differences in muscle strength and disability. We tested this in the Womens Health and Aging 1 and 2 Cohorts of community dwelling older women, by genotyping 359 women between age 70-79 at 8 single nucleotide polymorphisms (SNPs) in and around the *CNTF* gene. We performed linear regression analyses, adjusting for age, BMI, osteoarthritis, and race, and identified significant associations between homozygosity for rs1800169 A allele and lower grip strength (-4.152.80, p0.004), and an additive effect of the rs2510559 T allele on knee strength (-1.811.27, p0.005). The rs1800169 A allele has been previously shown to be a functional variant, resulting in a complete absence of *CNTF* protein in homozygous individuals. These findings suggest that *CNTF* gene variation may play an important role in the loss of muscle strength, which in turn influences disability and frailty in older adults. These findings also provide evidence of physiologic pathways that may warrant future intervention studies in frail older adults.

Polymorphisms in the *Phospholipase A2 Group 2D (PLA2G2D)* gene on chromosome 1 are associated with asthma in U.S. Hispanics. *M.J. Basehore¹, E.R. Bleecker¹, L.A. Lange¹, M.S. Harkins², E.J. Ampleford¹, W.C. Moore¹, D.A. Meyers¹, T.D. Howard¹.* 1) Wake Forest Univ Sch Med, Ctr for Human Genomics, Winston-Salem, NC; 2) University of New Mexico, Dept. of Medicine, Albuquerque, NM.

Asthma is a common respiratory disease caused by airways inflammation and bronchial hyperresponsiveness (BHR) that results in variable airway obstruction and clinical symptoms. BHR represents an increased bronchoconstrictor response found in asthma and is measured by the methacholine concentration that causes a 20% decline in lung function (PC_{20} FEV₁). Previously, we have shown evidence for linkage to 1p32-p34 for asthma (LOD=2.92; Xu et. al, 2001) in 40 Hispanic families, as part of the Collaborative Study for the Genetics of Asthma. Several candidate genes reside within this region of linkage, including three of the 10 human phospholipase A2 genes. These three genes, *PLA2G2A*, *PLA2G5*, and *PLA2G2D*, are located in tandem on the chromosome. Association with asthma or a related phenotype was evaluated across the three genes using publicly available polymorphisms. The individuals studied were African-Americans (168 asthmatics; 269 controls), U.S. Caucasians (233 asthmatics; 245 controls), and U.S. Hispanics (116 asthmatics; 130 controls) from a case-control asthma population. Genetic analysis revealed the association of a *PLA2G2D* coding SNP (S80G) with PC_{20} in the Hispanic asthmatics ($p=0.004$). Subsequently, ten additional SNPs in *PLA2G2D* were evaluated for association, and two were also found to be associated with PC_{20} in the Hispanic asthmatics ($0.002 \leq p \leq 0.036$). There was a strong haplotype effect in this population across the *PLA2G2D* locus, and association of haplotypes with both asthma ($p=0.003$) and PC_{20} ($0.0006 \leq p \leq 0.028$) was observed. These data suggest that either single SNPs or haplotypes within *PLA2G2D* may influence the susceptibility and severity of asthma as well as the severity of airway constriction.

Two-loci association of insulin secretion in obese children. *P. BOILEAU¹, S. LE FUR¹, D. FRADIN¹, J.M. BAZIOMO², C. LE STUNFF¹, P. BOUGNERES¹.* 1) Dpt of Pediatric Endocrinology & U561 INSERM, Hôpital Saint-Vincent de Paul, Paris, France; 2) Dpt of Pediatrics, Hôpital de Ouagadougou, Burkina Faso.

The KIR6.2 gene encodes subunits of the KATP channel which regulates insulin exocytosis from b cells. The highly polymorphic INS VNTR located in the insulin gene promoter is associated with changes in transcriptional activity of the insulin gene. E23K, a common variant of KIR6.2 in Caucasians, leads to decreased insulin release in vitro, but its effects on insulin secretion are less easy to demonstrate in vivo. In 570 obese children, E23K and INS VNTR alleles showed only marginal effects on insulin secretion when each of the loci was examined individually. But when the two loci were combined for analysis, we found that obese children with KIR6.2 EE / VNTR I/I genotypes secreted more insulin than all other genotype combinations. This difference was important in boys (insulinogenic index: 97.14 in E/E & I/I; 51.6 in KK & I/III or III/III, $p < 0.005$; 74.4 in other genotypes $P=0.015$). Two West African populations were found to lack the E23K variant and have different VNTR alleles: the genotypic effects observed in Caucasians were therefore absent. These observations indicate the importance of the joint analysis of candidate genes in association studies of complex traits and illustrate the heterogeneity of genetic factors in different human groups.

Agouti-related protein (AGRP) promoter variant is associated with leanness and decreased risk for diabetes in West Africans. *C. Bonilla¹, R.K. Panguluri¹, L. Taliaferro-Smith¹, G. Argyropoulos², G. Chen¹, A.A. Adeyemo¹, R.A. Kittles¹, C. Rotimi¹, AADM study group.* 1) National Human Genome Center at Howard University, Washington, DC; 2) Pennington Biomedical Research Center, Baton Rouge, LA.

The role of the central melanocortin system in the development of obesity has been extensively studied. Single nucleotide polymorphisms (SNPs) within several candidate genes have been associated with food intake and obesity-related phenotypes however few of these associations have been replicated. SNPs in the Agouti-related protein (AGRP) gene coding (Ala67Thr, 199G/A) and promoter (-38C/T) regions have been reported to be associated with body mass index (BMI), fat mass (FM), and percent body fat, in populations of European and African descent. Given that AGRP is a natural antagonist of melanocortin receptors 3 and 4, which inhibit food intake, variants such as the -38C/T that alter promoter activity and affinity for transcription factors are likely to influence body composition and energy balance. In this study, we evaluated the association between the functional AGRP -38C/T promoter SNP and weight-related traits, namely BMI, FM and fat free mass (FFM), as well as on diabetes status in a well characterized population of 538 West Africans from Ghana and Nigeria. We report that women carrying two copies of the variant T allele had significantly lower BMI (OR=0.47; 95% CI, 0.26-0.89). Also, men with at least one copy of the variant T allele were over two times less likely to be diabetic than other men (OR=0.45; 95% CI, 0.22-0.91). Our results replicate previous findings and strongly implicate the AGRP -38C/T SNP in the regulation of body weight in West Africans. Whether the association with Type 2 diabetes is a consequence of the energetic imbalance caused by an increase in food intake or is a result of the independent action of AGRP on insulin secretion needs further investigation.

Pharmacogenetic Differences in Response to Bronchodilators Between Puerto Rican and Mexican Asthmatics. *E. Burchard*^{1,2}, *S. Choudhry*^{1,2}, *N. Ung*^{1,2}, *P.C. Avila*¹, *E. Ziv*¹, *S. Nazario*³, *J. Casal*³, *A. Torres*³, *K. Salari*^{1,2}, *J.R. Rodriguez-Santana*⁴, *J. Salas*⁵, *M. Selman*⁵, *R. Chapela*⁵, *D. Sheppard*^{1,2}, *S.T. Weiss*⁶, *J.G. Ford*⁷, *H.A. Boushey*¹, *J.M. Drazen*⁶, *W. Rodriguez-Cintron*³, *E.K. Silverman*⁶, from the *Genetics of Asthma in Latino Americans (GALA) Study*. 1) University of California, San Francisco, SF, CA; 2) Lung Biology Center, San Francisco General Hospital, SF, CA; 3) San Juan VAMC, University of Puerto Rico School of Medicine, San Juan, PR; 4) Pediatric Pulmonary Program of San Juan, San Juan, PR; 5) Instituto Nacional de Enfermedades Respiratorias (INER), Mexico City, MX; 6) Brigham and Womens Hospital, Boston, MA; 7) The Harlem Lung Center, Harlem Hospital and Columbia University, New York, NY.

Background: In the U.S., Puerto Ricans and Mexicans have the highest and lowest asthma prevalence, morbidity and mortality, respectively. Whether ethnic-specific differences in the response to drug treatment contribute to differences in outcome is unclear. Albuterol is the most commonly prescribed asthma medication worldwide. Genetic variants at the beta2 adrenergic receptor (2AR) may modify asthma severity and albuterol responsiveness. **Methods:** We used both family-based and cross-sectional analysis to test for association between 2AR SNPs and asthma severity and bronchodilator response in 684 Puerto Rican and Mexican families. **Results:** Among Puerto Ricans, the Arg16 allele was associated with greater bronchodilator response using both cross-sectional and family-based tests ($p = 0.01-0.00001$). In addition, we found a strong interaction of baseline Forced Expiratory Volume or FEV1 with the Arg16Gly polymorphism in predicting bronchodilator response. Among Puerto Rican asthmatics with FEV1 < 80% of predicted, but not in those with FEV1 >80%, there was a very strong association between this genotype and bronchodilator response. In contrast, there were only marginal associations between b2AR genotypes and drug responsiveness among Mexican asthmatics and these associations differed from those found in Puerto Ricans. **Conclusions:** Ethnic-specific pharmacogenetic differences in response to bronchodilator exist between Puerto Rican and Mexican asthmatics.

C-Reactive Protein (CRP) Haplotypes are Associated With Cardiovascular Risk Factors but not Insulin

Resistance: the IRAS Family Study. *I. Chen^{1,2}, K.D. Taylor^{1,2}, X. Guo^{1,2}, J. Cui¹, M.F. Saad², L.E. Wagenknecht³, S.M. Haffner⁴, J.I. Rotter^{1,2}.* 1) Cedars-Sinai, Los Angeles, CA; 2) UCLA, Los Angeles, CA; 3) Wake Forest University School of Medicine, Winston-Salem, NC; 4) University of Texas Health Center, San Antonio, TX.

CRP levels, an inflammatory biomarker, have been associated with several components of the metabolic syndrome, as well as incident diabetes and cardiovascular disease (CVD). Associations have been reported between variation in the CRP gene and plasma CRP levels. We examined the primary metabolic manifestations of variation in the CRP gene in a family cohort of Hispanic Americans (820 studied in San Luis Valley, CO and San Antonio, TX), and of African Americans (336 studied in LA, CA) in the IRAS Family Study. CRP (g/ml) and insulin (IU/ml) levels were determined by ELISA; fasting glucose (FG) (mg/dl) and lipids (mg/dl) by enzymatic colorimetry; Insulin sensitivity (IS) by the minimal model analysis of the frequently sampled intravenous glucose tolerance (FSIGT) test. Using the TaqMan MGB assay, we genotyped 5 SNPs in the CRP gene (rs1800947, rs2808630, rs2808631, rs3093062, rs3093066). Haplotypes were reconstructed using Simwalk2 and associations were tested using the General Estimating Equations (GEE) methods. We observed 6 haplotypes (H) with frequency 2% in founders (H1-H6). H1 was associated with a decreased FG (93.2 vs 96.5, $p=.001$), H3 with decreased TG (78.1 vs 122.4, $p=.023$), increased HDL-C (47.0 vs 43.8, $p=.016$), decreased TG/HDL-C ratio (1.90 vs 3.39, $p=.016$), and H4 with elevated CRP level (4.52 vs 3.14, $p=.011$) and higher FG (96.1 vs 93.6), but no association with IS. In summary, CRP gene haplotypes are associated, independently from IS, with 3 distinct CVD risk factors: CRP, FG, TG and HDL-C concentrations; suggesting that the role of inflammatory processes in diabetes and CVD associated with CRP may well be distinct from the role of insulin resistance related mechanisms.

Environment Dependent Association Between CD14 Gene and IgE Levels in Mexican and Puerto Rican Asthmatics. S. Choudhry^{1,2}, P.C. Avila¹, N. Ung^{1,2}, S. Nazario³, J. Casal³, A. Torres³, E. Ziv¹, J.R. Rodriguez-Santana⁴, J.K. Fagan⁵, J. Salas⁶, M. Selman⁶, R. Chapela⁶, D. Sheppard^{1,2}, H.A. Boushey¹, S.T. Weiss⁷, J.G. Ford⁵, J.M. Drazen⁷, W. Rodriguez-Cintron³, E.K. Silverman⁷, E.G. Burchard^{1,2}, from the *Genetics of Asthma in Latino Americans (GALA) Study*. 1) University of California, San Francisco, SF, CA; 2) Lung Biology Center, San Francisco General Hospital, SF, CA; 3) San Juan VAMC, University of Puerto Rico School of Medicine, San Juan, PR; 4) Pediatric Pulmonary Program of San Juan, San Juan, PR; 5) The Harlem Lung Center, Harlem Hospital and Columbia University, New York, NY; 6) Instituto Nacional de Enfermedades Respiratorias (INER), Mexico City, MX; 7) Brigham and Womens Hospital, Boston, MA.

Background: A genetic variant in the CD14 gene promoter, C-159T, has been associated with IgE and asthma in some studies, but not in others. Inconsistent results may reflect differences in environmental exposures, genetic heterogeneity, random error, or population stratification in case-control and cross-sectional studies leading to spurious associations. Family-based analyses are typically robust against the effects of population stratification. **Methods:** Using both family-based and cross-sectional designs, we analyzed the relationship between the CD14 C-159T genotypes and asthma-related phenotypes in Puerto Rican (n=393) and Mexican (n=274) asthmatics. In addition, we analyzed gene-by-environment interactions. **Results:** We found a significant association between the CD14 C-159T genotypes and log IgE in the presence of environmental tobacco smoke (ETS) exposure among Mexican and Puerto Rican asthmatics using both family-based (p=0.009 & 0.04, respectively) and cross-sectional analyses (p=0.07 & 0.00008, respectively). There were no significant associations between CD14 and IgE when analyses were performed among subjects who denied ETS exposure or when data were stratified by age, gender, or allergies to animals. **Conclusions:** The CD14 C-159T genotypes interact with tobacco smoke to modify IgE levels in asthmatics. Our data are consistent with multiple factors influencing asthma-related phenotypes including genetic and environmental.

Heme oxygenase-1 gene is associated with the rate of decline of lung function in smokers. *J-Q. He¹, P.D. Paré¹, J.E. Connett², N.R. Anthonisen³, A.J. Sandford¹*. 1) James Hogg iCAPTURE Center, University of British Columbia, Vancouver, Canada; 2) School of Public Health, University of Minnesota; 3) Faculty of Medicine, University of Manitoba.

Heme oxygenase-1 (HO-1) confers protection against oxidants in the lung. A (GT)_n repeats in the 5'-flanking region shows length polymorphism, and longer (GT)_n repeats were associated with lower transcriptional activity and pulmonary emphysema in Japanese individuals. However, we did not find association with rate of decline of lung function in whites. The aim of this study is to explore association of single nucleotide polymorphisms (SNPs) in the *HO-1* with rate of decline of lung function in smokers in the Lung Health Study (LHS). Five tag-SNPs (149G/A, 2790A/T, 3303G/C, 9531G/A and 15382A/G) in *HO-1* were selected from SeattleSNPs by linkage disequilibrium (LD) selection, which can select minimum number of SNPs to resolve the most common haplotypes. We selected 582 non-Hispanic whites with the fastest (n=278, FEV₁% predicted = -153.7 2.6ml/year) and with the slowest (n=304, FEV₁% predicted = 14.9 2.6ml/year) decline of FEV₁% predicted from among smokers followed for 5 years in the LHS. The associations were analyzed by logistic regression to adjust for potential confounding factors. The 9531G/A SNP, which is located at intron 3 but in perfect linkage with a SNP (2007G/A) in the promoter, was associated with the rate of decline of lung function. The frequencies of homozygous AA were 25.5% and 17.9% in smokers with fast decline and no decline of lung function respectively (unadjusted OR = 1.6, 95%CI = 1.1-2.3, p = 0.028). After adjusting for confounding factors such as age, sex, center, cigarette smoking and baseline of lung function, the adjusted OR = 1.8, 95%CI = 1.2-2.8, p = 0.006). This association was modified by methacholine responsiveness. The 9531G/A SNP is in LD with (GT)_n repeats with D' = 0.77 for longer (GT)_n allele (repeats 33). There were no associations between the other four SNPs and haplotypes with the rate decline of lung function. Further study of functional implications of 9531G/A and its relationship with (GT)_n repeats are warranted. Supported by the LHS and the CIHR.

A multilocus investigation of the dopaminergic pathway in Autism Spectrum Disorders. *J.A. Hettinger^{1, 3}, X. Liu^{1, 2, 3}, D.H. La^{1, 3}, J.J.A. Holden^{1, 2, 3}, ASD-CARC⁴.* 1) Department of Physiology, Queen's University, Kingston, Ontario, Canada; 2) Department of Psychiatry, Queen's University, Kingston, Ontario, Canada; 3) Autism Research Program, Ongwanada Resource Centre, Kingston, Ontario; 4) www.autismresearch.ca.

The identification of culprit genes for Autism Spectrum Disorders (ASDs) has proven elusive with conflicting findings reported on many candidate genes, mainly because of extensive phenotypic and genetic heterogeneity and limitations to the detection of genes of lesser or moderate effect. To overcome this, in our study of the dopaminergic system in ASD we examined family-based transmission (FBAT) of markers from genes involved in the synthesis, function, and degradation of dopamine. Findings implicating the dopaminergic system in a subgroup of individuals with ASD include decreased dopaminergic activity in the prefrontal cortex of autistic individuals and decreased levels of dopamine -hydroxylase (DBH) activity in affected individuals. In addition, we previously reported a possible maternal effect in which mothers in families with two or more affected sons had a higher frequency of the low activity DBH allele. We have now examined 22 polymorphisms in the PAH, TH, AADC, DBH, PNMT, and DAT genes in 132 multiplex (MPX- two or more affected individuals) families from the Autism Genetics Resource Exchange. Haplotype-FBAT was performed examining transmission of haplotypes. While single marker and gene haplotype transmissions were not significant on their own, there was over-transmission ($P=0.00076$) of 5 markers in the AADC (4bp Ins/Del, 826), DBH (-1021) and DAT (352, VNTR) genes. These findings suggest that a multilocus approach may permit the elucidation of the underlying pathways involved in the etiologies of ASDs. Further investigation, incorporating additional genes from the dopaminergic system and more extensive marker coverage, in conjunction with alternative analyses including recursive partitioning and ordered-subset analysis, are being used to determine the role of the dopaminergic pathway in ASD. Supported by a research studentship from OMHF to JAH and research grants from CIHR and OMHF to JJAH.

The genetic study of age at natural menopause: a familial aggregation and genetic association study. *Y. Hsu¹, H. Terwedow¹, Y. Feng¹, Y. Zhang¹, X. Xu^{1,2}.* 1) Prog Population Genetics, Harvard Univ, Boston, MA; 2) Anhui Medical Univ. Institute of Medicine, Anhui, China.

The purpose of this study was to explore the familial aggregation of age at natural menopause and the association between genetic variation in cyclooxygenase 2 lipoxygenase (ALOX12) and the age at natural menopause in a Chinese population. We initiated a community-based cross-sectional study among residents in Anhui Province, China since 2001. A total of 3304 women between 25-65 years of age from 1843 families were recruited. A standardized questionnaire was used to collect Subject's menstrual status, reproductive history, disease history, life style and dietary style. Intra sib pairs correlation coefficients of age at natural menopause, age at first menstruation and the duration (years) of menstruation were calculated. Regression model was used to test the family aggregation. A missense SNP (rs434473: A -> G; Asn322Ser) in ALOX12 gene was genotyped in women with menopause. There was 1245 (37.68%) women reported menopause naturally. The average age of menopause is 46.6 years old. The correlation coefficient (after adjusted current age) of age at natural menopause, age at first menstruation and the duration (years) of menstruation among siblings were 0.19(p<0.0001), 0.14(p=0.018) and 0.16 (p=0.007), respectively. If one of the siblings is menopause, after adjusted possible confounders, the other sibling has a significantly higher chance of being menopause. The adjusted OR was 8.89(p<0.0001). The age of menopause in women with GG genotype and GA genotype of SNP in ALOX12 gene were significantly older than the menopausal age in women with AA genotype. The adjusted regression coefficient is 2.39(p=0.006) and 1.67(p=0.033), respectively. Age at natural menopause, age at first menstruation and the duration (years) of menstruation were significantly associated among siblings. Genetic variation in ALOX15 gene is associated with age of natural menopause. Our findings suggest that genetic influences may play an important role in age of natural menopause.

Preliminary exploration of the Serotonin HTR1B gene and perfectionism as a trait in Attention Deficit

Hyperactivity Disorder. *A. Ickowicz¹, Y. Feng², K. Wigg², J. Quist³, T. Pathare¹, J. Crosbie¹, W. Roberts¹, M. Malone¹, R. Schachar¹, R. Tannock¹, J. Kennedy³, C.L. Barr^{1,2}.* 1) The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Cell & Molecular Division, Toronto Western Research Institute, University Health Network, Toronto; 3) Neurogenetics Section, Centre for Addiction & Mental Health, Toronto.

Serotonin [5-hydroxytryptamine (5HT)] plays an essential role in cognition, locomotor activity and the regulation of sleep, pain, mood, and aggression. Serotonin elicits its effects through a large family of receptors (HTR1-7). Polymorphisms of the HTR1B gene have been implicated in a variety of psychiatric disorders including Obsessive Compulsive Disorder (OCD) and Attention Deficit Hyperactivity Disorder (ADHD). Recent reports indicate that in clinical samples approximately 10% of ADHD subjects may experience co-morbid Obsessive Compulsive Behaviours (OCB) and increased perfectionism. The objective of this study was to investigate the association of obsessive behaviours, perfectionism and the HTR1B gene in a sample of 186 families with an ADHD proband. Six single nucleotide polymorphisms (SNPs) of the HTR1B receptor gene were genotyped using standard methods. In our sample, the subset of probands with confirmed ADHD diagnosis and OCB comorbidity was too small to enable a categorical analysis. However using a quantitative approach we observed significant evidence for an association of the perfectionism trait, as measured by the sub-scale E of the Conners Teacher Rating Scale (CTRS) and Conners Parent Rating Scale (CPRS) with one of the haplotypes generated by HBAT analysis (p values 0.040 and 0.054 respectively). Single marker analysis of the perfectionism trait performed using the FBAT program was not significant. Although these results are preliminary and should be interpreted with caution, they point in the direction of an association of the HTR1B gene and perfectionism as a quantitative trait in families with ADHD.

The molecular basis for *MPZ* truncating mutations that defines severity of inherited peripheral neuropathies. M.

*Khajavi*¹, *T. Ohyama*¹, *K. Inoue*³, *G.J. Snipes*², *J.R. Lupski*¹. 1) Department of Molecular & Human Genetics; 2) Department of Pathology, Baylor College Medicine, Houston, TX; 3) Dept. of Mental Retardation and Birth Defect Research, National Center of Neurology and Psychiatry, Tokyo, Japan.

Mutations in the *MPZ* gene cause dominantly inherited peripheral neuropathies with varying severity from Charcot-Marie-Tooth (CMT) disease (relatively mild alleles) to Dejerine-Sottas Neuropathy (DSN)/congenital hypomyelinating neuropathy (CHN) (severe alleles). A subset of *MPZ* mutations includes nonsense and frameshift alterations that result in premature termination codons (PTCs). We previously demonstrated that PTCs in the internal exons trigger the nonsense mediated decay (NMD) pathway, leading to destabilization of mutant *MPZ* mRNA. These alterations are exclusively associated with the CMT phenotype. In contrast, most mutations associated with a more severe DSN/CHN phenotype result in PTCs within the terminal or penultimate exons, and thus are undetectable by NMD and are stably translated into mutant proteins with a potential dominant-negative activity. However, a subset of PTC mutations at the 3' end of *MPZ* escapes the NMD pathway, yet causes a mild CMT phenotype. To delineate the molecular basis for phenotypic expression of *MPZ* truncating mutations, we examined functional properties of *MPZ* proteins that escaped NMD. We found that the frameshift mutations that disrupt the transmembrane domain lead to an intracellular accumulation of mutant proteins, mainly within the endoplasmic reticulum. This is accompanied by the identification of a higher number of apoptotic cells. Our data support the view that late frameshift mutations with a conserved transmembrane domain have a minor toxic effect and thus function as loss-of-function alleles, whereas a subset of truncated *MPZ* proteins acts as dominant negative, interfering with trafficking of wild-type *MPZ* to the cell surface, leading to a more severe form of peripheral neuropathy. These findings suggest that, when PTCs escape NMD, functional properties of mutant proteins may define the resulting phenotype in *MPZ*-mutation-causing peripheral neuropathies.

A positive association between adrenoceptor 1a and BMI in schizophrenic patients with exposure to antipsychotics. *T. Lan*^{1, 2, 5, 6}, *H. Hsieh*^{1, 5}, *Y. Liu*³, *F. Chu*³, *H. Sun*², *K. Chang*^{2, 3}, *H. Chiu*^{4, 5}. 1) Inst Genetics, Natl Yang-Ming Univ, Taipei, Taiwan; 2) Dept Adult Psychiatry, Tao-Yuan Psychiatric Center, Tao-Yuan, Taiwan; 3) Tao-Yuan Hospital, Tao-Yuan, Taiwan; 4) Section Psychiatry, Natl Yang-Ming Univ, Taipei, Taiwan; 5) Yu-Li Hospital, Hualien, Taiwan; 6) Inst Genetics, Tzu-Chi Univ, Hualien, Taiwan.

Overweight and obesity have been identified as a severe epidemic among schizophrenic patients, especially compared to the general population (obesity: 5% vs. 17.4% in male, 7.9% vs. 27.9% in female in Taiwan). We recruited 213 schizophrenic patients treated with antipsychotics for more than 6 months with their consent form completed in this study. The body mass index (BMI) was continuously recorded per month for 6 months as the major outcome. We genotyped several candidate genes related to metabolism or obesity, including 5HT2A, ADRA1A, ADRA2A promotor, and ADRB3 for each participant. After adjusting for age, sex, and dosage effect of the target allele from 5HT2A, ADRA2A promotor, and ADRB3 genes, a statistically significant association under GEE distribution ($p=0.013$) between BMI and the genotypes of ADRA1A was found in these schizophrenic patients. The Hardy-Weinberg equilibrium of these candidate genes were tested to be held in our samples. There is also no significant difference of allele or genotype distribution between our samples and the general population in Taiwan. This suggests the schizophrenic patients with a specific genotype of ADRA1A gene might have a higher BMI (or obesity severity) than those with other genotypes of ADRA1A continuously after an exposure to antipsychotics therapy previously.

The recently identified type 2A juvenile haemochromatosis gene (*HJV*), a second candidate modifier of the C282Y homozygous phenotype. *G. Le Gac*^{1,2}, *V. Scotet*², *C. Ka*², *I. Gourlaouen*¹, *L. Bryckaert*¹, *C. Ferec*^{1,2}. 1) Etablissement Francais du Sang, Brest, France; 2) INSERM U 613, Brest, France.

The most common form of hereditary haemochromatosis is an adult-onset condition usually associated with the *HFE* C282Y/C282Y genotype. The phenotypic expression of this genotype is heterogeneous and depends on a complex interplay of genetic and non-genetic factors. The aim of the present study was to determine if mutations in the recently identified *HJV* gene were associated with more severe iron overload phenotypes in C282Y homozygous patients. From a cohort of 492 C282Y homozygous patients, DHPLC/sequencing of the whole *HJV* coding region detected 13 patients (9 males and 4 females) with an additional *HJV* missense mutation in the heterozygous state (S105L (n=2), E302K (n=3), N372D (n=2), R335Q (n=2) or the previously described L101P (n=3) and G320V (n=1)). At the time of diagnosis, iron indices were available for 9 patients and appeared to be more severe than those observed in C282Y homozygous patients of identical sex and similar age ranges. The mean serum ferritin concentration of the 6 males with an *HJV* mutation was significantly higher than that of C282Y homozygous males without an additional mutation (2350.3 [=1429.9] vs. 1227.2 [=1130.1] g/L; p=0.0233, Student *t* test). We have recently reported that mutations in the gene that encodes hepcidin (*HAMP*) could explain one part of the C282Y/C282Y-related phenotypic heterogeneity by accentuating the iron burden. Our new data reveals that mutations in the *HJV* gene could be associated with a similar effect. Taken together, these results emphasize that a search for modifier genes could enable us to more precisely distinguish those C282Y homozygous patients with a higher risk to develop a severe iron overload and, consequently, clinical complications.

Program Nr: 2239 from the 2004 ASHG Annual Meeting

Association of SNPs within the serotonin transporter gene with depressive disorder and associated functional parameters. *S. Lucae, E.B. Binder, M.A. Ising, M. Uhr, B. Puetz, D. Salyakina, B. Mueller-Myhsok, S. Horstmann, P.G. Unschuld, M. Asmus, M. Koedel, F. Holsboer.* Max Planck Institute of Psychiatry, Munich, Germany.

The serotonin transporter gene promotor polymorphism (5-HTTLPR) has been described to be associated with response to treatment with SSRIs in patients with affective disorders. In this study we analyzed 8 SNPs throughout the SLC6A4 gene in 370 patients suffering from depressive disorder. We investigated gender differences, case/control associations, associations with response to antidepressant treatment, associations with neuropsychological items, as well as with neuroendocrinological data. We found no case/control association in the overall sample. However, when male patients with recurrent unipolar disorder were analyzed separately, we found a significance in 4 SNPs ($p=0.01$). Furthermore, we found an association regarding divided attention at admission and discharge in five SNPs ($p=0.001$) independent of gender differences. We found no association with response independent of the class of antidepressant treatment. 96 patients were treated with SSRI, 93 with mirtazapine and 64 patients were treated with tricyclic antidepressants. We could not find any significant effects regarding neuroendocrinological data emerging from combined dexamethasone-CRH tests. We are currently on the way to investigate SNPs in the promotor region and are going to determine 5-HTTLPR genotypes.

The brain-expressed tryptophan hydroxylase gene (TPH2) as a candidate gene for autism. *P. Malenfant*^{1,3}, *L.K. Waintraub*^{1,3}, *N. Novosedlik*^{1,3}, *X. Liu*^{1,3}, *J.J.A. Holden*^{1,2,3}, *ASD-CARC*⁴. 1) Department of Physiology, Queens University, Kingston, Ontario, Canada; 2) Department of Psychiatry, Queens University, Kingston, Ontario, Canada; 3) Autism Research Program, Ongwanada Resource Centre, Kingston, Ontario, Canada; 4) www.autismresearch.ca.

Autism is a severe neurodevelopmental disorder characterized by communication and social impairments, as well as repetitive interests and behaviours. Alteration of serotonergic pathways has been proposed to be part of the aetiology of a subgroup of cases of autism spectrum disorders (ASDs), making TPH, a gene encoding for the rate-limiting enzyme in the synthesis of serotonin, a good candidate gene for autism. With the recent identification of a second TPH isoform, TPH2, which is expressed in the brain, initial studies that attempted to link neurological disorders to TPH1 have to be revisited. Five TPH2 SNPs were genotyped in 288 affected siblings from 139 multiplex families, as well as in a comparison group of 190 randomly chosen newborns. The latter anonymous samples were obtained from the Ministry of Health of Ontario as heel prick blood spots for PKU screening. We performed case-control and family-based association studies, and examined the relationship between genotypes and phenotypes based on findings from the ADI-R. We found an increased G allele frequency for marker rs1487279 in families with at least one affected female (male-female and female-female families; $P=0.030$). In these families, the GG genotype was associated with an earlier age of first phrase ($P=0.025$). No significant results were obtained for the remaining 4 SNPs (-473A:T, rs1487279, rs1386492, rs1386494). The results suggest that there may be an association between autism and the TPH2 gene in the families with at least one affected female, but additional markers and families need to be examined to confirm this association. Supported by studentships from Queen's University, The Scottish Rite Charitable Foundation of Canada and Autism Society Ontario to PM and research grants from CIHR and OMHF to JJAH.

Multilocus analysis for the identification of at risk genotype in cardiovascular disease. *G. Malerba¹, E. Trabetti¹, M. Sandri², L. Xumerle¹, U. Cavallari¹, R. Galavotti¹, M. Biscuola¹, C. Patuzzo¹, P.F. Pignatti¹.* 1) Mother-Child & Biol, Genetics, Univ Verona, Verona, Italy; 2) CIDE - University of Verona, Verona, Italy.

The new methods are able to rapidly genotype many individuals for a large list of gene polymorphisms. Thus the complexity of the data is ever growing and the researches need to implement statistical methods that can reduce the complexity and target the relevant information. We developed an exploratory procedure implementing a classification tree-based recursive partitioning that aims to discover multigene patterns associated to the variability of the phenotype. The suggested marker-marker combinations were tested by logistic regression. The procedure was applied to a previously reported dataset of 1039 individuals characterized for coronary artery disease. Each individual was genotyped for 63 polymorphisms of 35 candidate genes. The noteworthy marker-marker patterns are: APOC3 -641 AA / APOC3 1100 CC (OR-corrected: 3.92, CI: 1.54-9.95, p=0.0041), APOC3 -455 TT / APOC3 1100 CC (OR-corrected: 3.83, CI: 1.50-9.76] p=0.00488), APOC3 -641 AA / ANP2238 TC/TT (OR-corrected : 3.53, CI: 1.15-10.79, p=0.0271), APOC3 -455 TT / ANP 2238 TC/TT (OR-corrected : 3.43, CI: 1.13-10.66, p=0.0295), ELAM128 ser-ser, ser-arg / LIPH 480 TT(OR-corrected: 0.14, CI: 0.03-0.66, p= 0.013). The polymorphisms APOC3 -641C/A and APOC3 -455T/C are tightly linked and were discordant in 34 individuals. Therefore they might be viewed as a single genetic factor carrying a similar information. The results indicate that multiplex genotyping can detect susceptibility polymorphisms and may help in finding possible gene-gene interactions associated to disease. Further studies should be performed to investigate the robustness of the method. Our results emphasize the need to account for complex multilocus influences when multifactorial diseases are studied. Acknowledgement: we thank S. Cheng, B. Rhee and HA. Erlich (Roche Molecular Systems, Inc., Alameda, CA, USA) for stimulating suggestions and for providing genotyping strips and reagents.

***parkin* mutations in a kindred with 4-generations of early-onset neuro-psychiatric disorders.** J.S. Montimurro¹, L. Moses¹, S. Factor², G.D. Schellenberg³, J.G. Nutt⁴, H. Payami¹. 1) Wadsworth Ctr., NYS Dept. of Health, Albany, NY; 2) Albany Medical Center, Albany, NY; 3) University of Washington VA Puget Sound Health Care System, Seattle, WA; 4) Oregon Health & Science University, Portland, OR.

parkin mutations, the most common known cause of Parkinsons disease (PD), are presumed recessive. We report transmission of *parkin* mutations over 4 generations. The proband with PD has a duplication (dup) of exons 2 & 3 (E2-3) and triplication (trip) of E4. To determine phase and configuration of the mutations we analyzed 11 relatives. Dosage was determined using semi-quantitative PCR on an ABI Prism 7000 Sequence Detection System using standard protocol. Samples were run in triplicate with -globin as the endogenous reference. Each assay was repeated four times, results averaged, and dosage assigned using standard cut-offs. We found 5 different mutant genotypes in 9 members of the same family: dup E2-3, trip E4 (proband, brother); del E2-3 (sister, niece); trip E2-E4 (sister, father, nephew); dup E2-4 (paternal grandmother); trip E2, 10 copies of E3, 17 copies of E4 (niece). Paternity and Mendelian transmission were established by haplotype analysis with 5 markers within and surrounding *parkin*. Using microsatellite haplotypes as a guide, the best explanation is 2 mutant chromosomes: dup E2-4 originating from the father and del E2-3 inferred to originate from the mother. The individual with multiple copies of E3 and E4 suggests de novo expansion. Of 12 individuals analyzed, 2 have compound mutations diagnosed with PD; 7 are heterozygous, 4 with parkinsonism, 3 teens unaffected; and 3 with no mutation are unaffected. Seven family members have psychiatric disorders: dementia, anxiety, depression, panic disorder, schizoid personality, alcoholism, drug abuse; 6 have mutation(s), 2 with PD, 4 with parkinsonism. This study demonstrates challenges in *parkin*. genotyping, the danger in misinterpreting test results without family data, and the lack of clear genotype-phenotype correlation. Novel findings include a possible link between *parkin*. and psychiatric disorders, and the possibility of de novo expansion/deletion in *parkin*.

Genetically determined dopamine levels are associated with obesity. *A.C. Need¹, K.R. Ahmadi¹, T.D. Spector², D.B. Goldstein¹.* 1) Department of Biology, University College London, London,UK; 2) Twin Research & Genetic Epidemiology Unit, St Thomas Hospital,London,UK.

The Western world is currently experiencing a pandemic of obesity, with a concomitant increase in associated factors such as heart disease, diabetes, osteoarthritis, and forms of cancer. Although this is clearly driven by lifestyle factors, family and twin studies have shown that BMI has a strong genetic component.

Human and animal studies have shown that DA is involved in appetite regulation, and here we have implicated a role for inherited reduction in dopamine (DA) metabolism in risk of obesity. We investigated functional polymorphisms in four genes that are responsible for DA reuptake and metabolism: COMT, DAT-1, MAOA and MAOB, in order to investigate how heritable variation in DA levels influences the risk of obesity. The COMT and DAT1 polymorphisms showed no association with either weight or BMI as quantitative traits, or with obesity in a case/control design. We found, however, that both MAOA and MAOB showed an excess of the low-activity genotypes in obese individuals (MAOA: $z = 15.45$, $p = 0.004$; MAOB: $z = 8.05$, $p = 0.018$). Additionally, the MAOA genotype was significantly associated with both weight ($p = 0.0005$) and BMI ($p = 0.001$) in a multiple regression model. When considered together, the at risk genotype - low activity genotypes at both the MAOA and MAOB loci - shows a relative risk for obesity of 5.01.

These results establish a connection between MAO activity and obesity. The fact that both MAOA and MAOB were associated suggests that this is mediated through their effects on DA metabolism. However they do not specify how DA levels influence obesity. We are therefore now assessing the relationship between MAOA and B and eating behaviours in a cohort of 8000 individuals, in order to confirm that these polymorphisms indeed result in heritable changes in eating behaviour.

TNF- G-308A polymorphism in patients with systemic lupus erythematosus from the western region of Mexico.

R. Ortiz^{1,2}, L.M. Cortes^{1,2}, L.L. Valdez^{1,3}, C. Ramos-Remus⁴, N. Olivares⁵, F. Rivas¹. 1) Western Biomedical Research Center, Instituto Mexicano del Seguro Social, Guadalajara; 2) Graduate Studies Program in Immunology, Universidad de Guadalajara; 3) Graduate Studies Program in Human Genetics, Universidad de Guadalajara; 4) Servicio de Reumatología, Hospital de Especialidades, CMNO-IMSS; 5) Hospital General de Occidente, Secretaría de Salud Jalisco, Guadalajara, Jalisco, Mexico.

Systemic lupus erythematosus (SLE) is considered multifactorial in its etiology. It can be regarded as a process that involves one or more environmental factors which act in a genetically susceptible individual. Over-expression of TNF- might be a significant risk factor for the development of SLE. The SNP G-308A in the promoter region of TNF- gene is related with the production of TNF- protein. It is known that allele A (TNF2) involves an increased transcriptional activity. Furthermore, TNF-, has been shown to be associated with autoimmune disorders, including SLE. The main objective of this study was to investigate the association between the G-308A polymorphism and SLE. This SNP was typed by PCR-RFLP in 73 individuals with SLE from the north-western region of the country, diagnosed according to the ACR criteria as well as in a control (C) group. This group consisted of 174 healthy volunteers living in Guadalajara, Mexico. In group C, allele TNF2 frequency was 10.1%, and genotype distribution was in agreement with HWE ($p>0.05$). In the group SLE, frequency of allele TNF2 was 17.1% ($p=0.03$ against group C), and genotype proportions were not different ($p>0.05$) from those of group C. This study's results are consistent with the idea that allele TNF2 is associated with the development of SLE in north-western Mexicans via increased TNF- levels.

Program Nr: 2245 from the 2004 ASHG Annual Meeting

Mutation analysis of RELN as a candidate gene for schizophrenia. *J. Saldivar, J.S. Muci, J. Feng, P.H. Burkhart, J. Yan, S.S. Sommer.* Dept Clinical Molecular Gen, City of Hope, Duarte, CA.

Schizophrenia is a common psychiatric disorder that displays non-Mendelian genetic inheritance. The glycoprotein reelin is secreted by GABA-ergic neurons during neural development, and several lines of evidence implicate reelin in the pathogenesis of schizophrenia. To test the hypothesis that mutations in the large reelin gene (RELN) may predispose to schizophrenia, coding exons and associated splice junctions of the RELN gene were analyzed in 64 patients with schizophrenia and 80 controls using the DOVAM-S followed by direct sequencing. DOVAM-S is a robotically enhanced, multiplexed, and highly redundant form of SSCP that detects virtually all mutations within a scanned genomic segment. A total of 5.1 Mb of the RELN genomic sequence was scanned. Multiple missense mutations occurring at highly conserved amino acids were identified, as well as different silent and intronic sequence changes. A dramatically high frequency of variants was found in African-American individuals. There was a non-significant excess of structural variants in schizophrenia relative to controls, warranting study in a larger sample.

Phenotype-genotype studies: the clue for unraveling the genetics of psychiatric disorders? *T.G. Schulze^{1, 2, 3}, S. Ohlraun^{1, 2}, J. Schumacher⁴, L. Kassem³, T. Becker⁵, J. Hauser⁶, S. Wellek¹, S. Cichon⁷, F.A. Henn¹, F.J. McMahon³, W. Maier², P. Propping⁴, M.M. Nöthen⁷, M. Rietschel^{1,2}.* 1) CIMH, Mannheim; 2) Dept of Psychiatry, Univ Bonn; 3) MAPGenetics, NIMH, Bethesda, MD; 4) Inst Hum Genet, Univ of Bonn; 5) IMBIE, Univ Bonn; 6) Dept of Adult Psychiatry, Univ Poznan; 7) Dept Med Genet, Univ Antwerp.

We have previously reported association between the G72/G30 locus and both schizophrenia and bipolar disorder (BD) in large samples of German cases and controls. A specific 4-marker risk haplotype confers risk to both disorders. Given the presumed role of G72/G30 in the neurochemistry of psychosis and its localization in a region (13q34) linked to schizophrenia and BD, we hypothesized the BD finding to be mainly due to an association with psychotic features. We performed a case-control analysis in the subset of 173 patients with delusions and/or hallucinations. Odds ratios increased only marginally. We were therefore interested in whether confining case definition to specific psychotic content might be better at detecting a potential genotype-phenotype correlation between BD and G72/G30. Using a logistic regression analysis on 21 OPCRIT items for delusional or hallucinatory content, we found the item lifetime history of persecutory delusions to be the only significant ($p=0.0047$) explanatory variable for the G72/G30 risk genotype. We then tested for association between G72/G30 and BD in the subset of patients with a history of persecutory delusions ($n=90$). We observed significant changes in the odds ratios (maximum increase from 1.33 to 1.83; $p=0.0024$) for the G72/G30 markers/haplotypes, compared to the overall sample of 300 BD patients. The same risk haplotype was associated in an independent BD sample from Poland when case definition was restricted to cases with persecutory delusions, while there was no association in the overall sample. Our data suggest that BD with persecutory delusions constitutes a distinct subgroup of BD and support the idea of a genetic overlap between schizophrenia and BD. Further analysis is needed to elucidate whether persecutory delusions per se is important or rather some other trait that correlates with it.

Progression of atherosclerosis in coronary artery bypass grafts is associated with the HMG-CoA Reductase gene.

K.D. Taylor, X. Guo, J. Cui, P.K. Shah, J.I. Rotter. Cedars Sinai Medical Ctr, Los Angeles, CA.

3-hydroxy-3-methylglutaryl-Coenzyme A reductase (HMGCR) is the rate-limiting enzyme for cholesterol synthesis and the target of statin drug therapy to reduce plasma LDL-cholesterol. The national Post-Coronary Artery Bypass Graft (post-CABG) Trial demonstrated that an aggressive regimen to lower LDL-cholesterol using statin therapy reduced, but did not eliminate, the progression of atherosclerosis in grafts. The aim of this study was to test whether HMGCR polymorphisms were also associated with the progression of atherosclerosis in grafts (progression). DNA was collected and atherosclerosis in grafts was measured using angiography at baseline and 4-5 years later in 843 subjects from the Post-CABG trial. These subjects were also genotyped for 5 HMGCR polymorphisms (mean spacing 4.1kb) using TaqMan MGB technology. Associations were tested with logistic regression (SAS). Analysis with HaploView demonstrated that all 5 SNPs formed one haplotype block. Haplotype 4 (H4, frequency 5.8%) was associated with a higher percentage of subjects showing the progression of atherosclerosis in grafts (progression in 46% of H4/- subjects vs 36% all other genotypes, $p=0.017$) while H2 (frequency 29%) was associated with a lower percentage of subjects showing progression (progression in 25% of H2/H2 subjects vs 39% all other genotypes, $p=0.0023$). There was a significant effect of H4/- or H2/H2 on the number of grafts with progression per subject ($p=0.0038$ and $p=0.0048$, respectively, adjusted for age, sex, BMI). No interaction between HMGCR variation and aggressive or moderate statin therapy was observed, nor did this effect appear to be mediated by LDL-cholesterol level. These results suggest that variation in HMGCR may influence the progression of atherosclerosis post-CABG by pathways in addition to those involving the LDL-cholesterol lowering effect of statins.

Criteria for evaluating the validity and utility of endophenotypes in psychiatric genetics: Application to executive functions and childhood ADHD. *I.D. Waldman.* Psychology, Emory University, Atlanta, GA.

There is renewed interest in psychiatric genetics in endophenotypes, constructs posited to be more directly and strongly influenced by relevant genes than manifest disorder. Several researchers have proposed criteria for the selection of endophenotypes that might be useful in finding genes that underlie psychiatric disorders and their symptoms. These criteria include: 1. good psychometric properties, 2. relation to the disorder and its symptoms in the population, 3. expression regardless of whether the disorder is currently present, 4. expression at a higher rate in the unaffected relatives of probands than in randomly selected individuals from the population, 5. the endophenotype and disorder are associated within families (i.e., they co-segregate), 6. the endophenotype is heritable, 7. common genetic influences underlie the endophenotype and the disorder, 8. the endophenotype must show association and/or linkage with one (or more) of the candidate genes or genetic loci that underlie the disorder, 9. the effects of a gene on a disorder are expressed either in full or in part through the endophenotype (i.e., the endophenotype *mediates* the gene-disorder relation), and 10. the effects of a particular gene or locus on a disorder are stronger in disordered individuals who also show the endophenotype (i.e., the endophenotype *moderates* the gene-disorder relation). In this talk, I review some of the analyses that may be used to evaluate the validity and utility of putative endophenotype measures consistent with these proposed criteria. I illustrate the use of such analyses to evaluate putative endophenotypes with data on childhood ADHD and executive function measures from both a candidate gene study of clinically-referred children with ADHD and a study of non-referred twins. I demonstrate that while the putative endophenotype measures showed association with several candidate genes in the dopamine system, and met many of the criteria proposed for their validity and utility, they did not meet all of the criteria and might have been rejected for use as endophenotypes in molecular genetic studies on that basis.

Genetic Analysis of DYX1C1 in native English speaking cohort. *K. Womble¹, E. Dawson¹, D. Sawyer².* 1) Innovative Projects, BioVentures, Inc., Murfreesboro, TN; 2) Center for Dyslexic Studies Middle Tennessee State University, Murfreesboro, TN.

Developmental dyslexia is considered a complex trait affecting up to 15% of the population. In order to find candidate genes that may be involved in developmental dyslexia, numerous linkage studies have shown linkage among several chromosomes including 15q21, specifically the DYX1C1 gene. We studied the DYX1C1 gene by sequencing all exons and flanking intronic regions in a native English speaking cohort that was tested to be either dyslexic or non-dyslexic from the Middle Tennessee area and were unable to reproduce the association found in the Taipale et al. (2003) DYX1C1 study. We found 8 single nucleotide polymorphisms, four of which coincide with the previous findings and three which were novel. One novel SNP found was located at chromosome location 15:53447790 causing a non-synonymous amino acid change Ile 276 Val that lies within a tetratricopeptide repeat domain (TPR) of DYX1C1. No significant associations of the polymorphisms which we observed in DYX1C1 were found in the dyslexic cohort studied when considered individually or as haplotypes. Therefore, our results do not support evidence for variations of the candidate gene DYX1C1, on chromosome 15q21 to be associated with dyslexia in our cohort. We conclude that population genetic and language culture differences contribute to the complexity of discovering and validating candidate genes for dyslexia.

Analysis of the 2q33 region in celiac disease. *K. Brophy¹, A.W. Ryan¹, C. Feighery¹, C. O'Morain¹, N. Kennedy², R. McLoughlin¹, F. Stevens³, D. Kelleher¹, R. McManus¹.* 1) DMMC and Trinity College, Ireland; 2) Dept. Medicine, Trinity College, Ireland; 3) NUI, Galway, Ireland.

Chromosome region 2q33 contains the immune regulatory genes, Cytotoxic T-Lymphocyte Antigen 4 (CTLA4), Inducible Co-Stimulator (ICOS) and CD28, making this region an interesting candidate for investigation in autoimmune disease. CTLA4 has previously been implicated in several autoimmune diseases including celiac disease (CD). Our aim was to establish whether an association exists between this region and CD in the Irish population using a comprehensive analysis for genetic variation. 393 celiac disease patients and 345 ethnically matched healthy controls were typed for the five htSNPs in CTLA4, seven SNPs in ICOS and three SNPs in CD28. Haplotype-tagging SNPs were predominantly chosen. Haplotype frequencies were estimated using computational analysis and allele, genotype, carrier status and haplotype frequencies were compared between populations. The CTLA4658 SNP was the only polymorphism found to show significant association, after correction for multiple testing using the Bonferroni method, between populations when allele, genotype, or carrier status frequency were analysed (carrier status (Allele C), $p=0.0017$). CTLA4+49, which has previously been implicated in CD in other populations, was not significantly associated in this study ($p=0.1072$). The CT60 SNP was included in the variants tagged by the haplotype-tagging approach of the CTLA4 gene. Using this method, we found CT60 to be marginally associated with disease ($p=0.0190$) prior to correction. Linkage disequilibrium analysis identified a block of LD incorporating the CD28 and CTLA4 polymorphisms and this CD28/CTLA4 haplotype was significantly associated with CD (patients 24.4%; controls 31.1%; $p=0.0061$). Our results suggest that CTLA4658 or a genetic variant in LD with CTLA4658 may be associated with disease. Furthermore, the haplotype block which includes the CD28/CTLA4 genes shows significant association with disease which is stronger than when either gene is analysed individually. This suggests that a causal variant associated with this haplotype may be linked with CD in this population.

Genetic Variation Upstream of NPY2R is Associated with Obesity in Men. *C. Campbell*^{1,2}, *H. Lyon*¹, *S. Purcell*³, *M. Daly*³, *L. Groop*⁴, *D. Altshuler*^{2,3,5}, *K. Ardlie*⁶, *J. Hirschhorn*^{1,2,3}. 1) Divisions of Genetics and Endocrinology, Childrens Hospital, Boston, MA; 2) Department of Genetics, Harvard Medical School; 3) MIT Broad Institute; 4) Department of Endocrinology, University Hospital MAS, Lund University, Malmö, Sweden; 5) Department of Molecular Biology, Massachusetts General Hospital; 6) Genomics Collaborative, Inc., Cambridge, MA.

Obesity is a growing worldwide epidemic. Approximately 50% of the variation in body mass index (BMI), a measure of obesity, is due to genetic factors, but the genetic variants that influence obesity remain unknown. We have studied the genes encoding three related peptides (NPY, PYY, and PPY) as well as their receptors (NPY1R, NPY2R, and NPY5R) for association with obesity. These peptides regulate appetite and food intake, and some of the corresponding genes are in regions of linkage to obesity. We defined the patterns of common variation in these genes in a sample of 96 chromosomes from 12 multigenerational pedigrees of European origin (CEPH). We then selected haplotype-tagging SNPs (htSNPs) that capture most of the common variation, and genotyped these htSNPs in patient populations. We used two large case-control studies, a US Caucasian panel and a Polish panel, consisting of cases (1200 US, 700 Poland) from the 90th-97th percentile in BMI and controls (600 US, 330 Poland) from the 5th-12th percentile in BMI. No statistically significant results were found for NPY, PYY, PPY, NPY1R, or NPY5R in the combined panels. Interestingly, five SNPs 0.6-5.0 kb upstream of the NPY2R gene showed a nominally significant association with obesity in men in both samples (combined $p=0.001$, odds ratio=1.34, 95% confidence interval, 1.12-1.59) for the best SNP). These results were replicated (one-tailed $p=0.034$, odds ratio=1.20) in men from 240 Scandinavian parent-offspring trios. The combined p -value for all three European-derived panels is 3.1×10^{-4} (odds ratio=1.27 95% CI, 1.12-1.45). The SNPs were not significantly associated with obesity in women. These results suggest that common variation in the NPY2R gene influences the development of obesity in men; we are in the process of attempting to further replicate this result in additional samples.

Haplotype analysis of SNPs in the CNR1 gene and association with progression in Marijuana Use. M.A.

Ehringer¹, C. Hopfer², S. Purcell³, S. Young¹, R. Corley¹, M. Stallings¹, S.H. Rhee¹, A. Smolen¹, K. Krauter⁴, T. Crowley², J.K. Hewitt¹. 1) Inst Behavioral Genetics, Univ Colorado, Boulder, CO; 2) Dept of Psychiatry, Univ Colorado Health Sciences Center, Denver, CO; 3) Whitehead Institute, MIT, Cambridge, MA; 4) Molecular Cellular and Developmental Biology, Univ Colorado, Boulder, CO.

Background: A number of adoption, twin, and family studies have indicated that genetic factors contribute to marijuana use and dependence. However, the specific genes contributing to a persons risk of becoming dependent on cannabis remain unknown. The cannabis receptor (CNR1) in addition to being expressed in the brain, is the principal site of action of delta-9-tetrahydrocannabinol (THC), the principal psychoactive ingredient in marijuana. This project involved utilizing the genomics resources to examine SNPs in the human CNR1 gene. **Methods:** 558 subjects participating in existing studies of substance abuse were selected for a pilot association study, on the basis that they had tried marijuana prior to age 16 and were at least age 17 or older at the last assessment (thus, allowing at least one year between initiation and progression). Approximately half of these individuals exhibited at least one DSM-IV dependence symptom for cannabis. TaqMan Assays-on-Demand from Applied Biosystems were used to genotype four SNPs within the CNR1 gene in all subjects. Using GOLD, the D measure of linkage disequilibrium between pairs of SNPs was determined to vary between 0.10 and 0.99 (G. Abecasis; <http://www.sph.umich.edu/csg/abecasis/GOLD>). We also used WHAP (S. Purcell; <http://www.broad.mit.edu/personal/shaun/whap>), a SNP haplotype analysis package, to test individual SNPs and haplotypes for possible associations with the phenotype of at least one dependence symptom. **Results:** CNR1 haplotypes, but not individual SNPs, were associated with progression in cannabis use. **Conclusions:** Further work in this area should contribute to the understanding of the underlying genetic and biological mechanisms contributing to progression of marijuana use. This work has been supported by the NIH/NIDA P60 DA 11015-05, DA015522, and DA000357.

Allele-specific transcript quantification detected haplotypic variation in the levels of the SDF-1 transcripts. R.

Kimura^{1, 2}, *T. Nishioka*², *A. Soemantri*³, *T. Ishida*². 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 2) Unit of Human Biology and Genetics, Department of Biological Sciences, Graduate School of Science, The University of Tokyo, Tokyo, Japan; 3) Department of Pediatrics, Faculty of Medicine, Diponegoro University, Semarang, Indonesia.

The *SDF1*-G801A, a SNP in the 3' untranslated region of the *SDF1* gene, has been reported to be associated with susceptibility to diseases such as AIDS and type-I diabetes by epidemiological studies probably through the altered levels of SDF-1 production. However, experimental studies of the effect of the G801A have not supported its functional importance. To examine whether other polymorphisms have *cis*-acting effects on *SDF1* expression, we carried out a haplotype analysis of the *SDF1* gene and the allele-specific transcript quantification (ASTQ) using Epstein-Barr virus-transformed lymphoblastoid cell lines. After a screening of SNPs in the *SDF1* gene, we selected 10 haplotype-tagging SNPs and genotyped for them. The haplotype phase were estimated from the genotype data by the PHASE program. For the ASTQ, we utilized the G801A polymorphism as a tag to distinguish each of the allele-specific transcripts and examined their proportion in each cell lines with heterozygous genotype for this polymorphism. A haplotype-based analysis of the ASTQ revealed that G+6201A in the intron 2 and C-668G in the promoter region are independently associated with the altered levels of the transcripts. In addition, another polymorphism in the promoter region, C-1652T, was associated with the different levels of response to the dibutyl cyclic AMP treatment that enhances *SDF1* transcription. These results suggested that other polymorphisms than the G801A do have functional roles in SDF-1 production. Providing evidence for the haplotypic variation in the levels of the transcripts, this study contributes to improving interpretation of the previous disease-association studies and selection of SNP markers for future studies. We show that the ASQT based on haplotype information is a powerful means to detect the *cis*-acting effect of polymorphisms on gene expression.

Association of DISC1 and bipolar disorder. *K. MAEDA*^{1,3}, *J. Chang*¹, *R. Youn*¹, *R. Kawahara*³, *M. McInnis*¹, *A. Sawa*^{1,2}. 1) Psychiatry, Johns Hopkins University, Baltimore, MD; 2) Neuroscience, Johns Hopkins University, Baltimore, MD; 3) Psychiatry, Tottori University, Japan.

Disrupted in Schizophrenia-1 (DISC1) was identified at the breakpoint of a balanced translocation segregating with schizophrenia and mood disorder in a large Scottish family. Additional findings of association between DISC1 and schizophrenia have been reported, but not with mood disorder. We conducted a family-based association study of DISC1 and bipolar disorder in 57 bipolar pedigrees. We performed direct sequences with 10 samples from the patients with bipolar disorder (BP) and identified a novel (unreported) SNP. Twelve SNPs were genotyped at the DISC1 locus, including the novel SNP, using the Taqman assay. The computer program FBAT was used for family-based TDT and haplotype analysis. Association at individual SNP was observed at rs3737597 in 3'-UTR of DISC1 gene ($P < 0.05$). Haplotype analysis identified one haplotype (HP1) that was overtransmitted to the BP phenotype ($P = 0.01$) and a second haplotype that was undertransmitted (HP2). There was evidence of gender influence in the transmission distortion, with overtransmission of HP1 to affected females ($P = 0.004$). Expression levels of DISC1 in lymphoblasts were compared between affected subjects with HP1 and unaffected subjects with HP2. There was a significant decrease in DISC1 expression in affected HP1 group compared to cell lines derived from unaffected subjects with the HP2 ($P = 0.006$). This difference was more pronounced in females ($P = 0.001$). These results suggest an association between DISC1 and bipolar disorder, and a decreased level of expression of DISC1 in lymphoblastoid cell lines from affected female subjects with the risk haplotype.

DNA repair polymorphisms and survival from bladder cancer in men. *G. Matullo*^{1,2}, *S. Guarrera*¹, *S. Polidoro*¹, *S. Gamberini*^{1,2}, *C. Sacerdote*³, *F. Saletta*¹, *L. Davico*³, *L. Fiorini*³, *D. Fontana*⁴, *A. Piazza*², *P. Vineis*^{1,3,5}. 1) ISI Foundation, Torino, Italy; 2) Dept Genetics, Univ Torino, Italy; 3) CPO Piemonte, Univ Torino, Italy; 4) Cattedra di Urologia, Univ Torino, Italy; 5) Imperial College London, UK.

In industrialized countries bladder cancer is the fifth most common cancer in men. The removal or repair of DNA damage have a key role in protecting the genome from the insults of cancer-causing agents. Polymorphisms in DNA repair genes have been identified and extensively studied in relation to the modulation of cancer risk, but few studies have been conducted on the relationship between genetic polymorphisms and survival from cancer. In the context of a survival study on 364 incident cases of transitional-cell bladder cancer, we investigated the survival status in relation to 13 polymorphisms in seven DNA repair genes (XRCC1-28152A/G, XRCC1-26651A/G, XRCC1-26304T/C, XPD-23591G/A, XPD-35931A/C, XRCC2-31479G/A, XRCC3-18067C/T, XRCC3-17893A/G, XRCC3-4541C/T, ERCC4-30147A/G, ERCC4-30028C/T, PCNA-6084G/C, ERCC1-19007C/T). All cases are men aged 40-74 followed up for mortality for an average of 65 months (range 0.36-126.24, median 48m, SD 37.6): of them, 90 died and 274 were surviving at the end of follow-up. According to univariate analysis, none of the analyzed polymorphisms showed statistically significant results considering a proportional hazard model though, after adjustment for age, stage, and grade, ERCC1-CC genotype was significantly associated with a worse prognosis (CC vs TT, HR=3.8, 95% CI=1.1-13.3). Histological grade and clinical stage are significantly associated with survival both at univariate (grade $p=0.00011$; stage $p=0.000046$) and age corrected multivariate analysis (grade G1=ref; HR_{G2}=8.2, 95% CI 1.0-63.4; HR_{G3 or >G3}=13.8 95% CI 1.5-123.5; stage A=ref., HR_{PT1}=1.3, 95% CI 0.6-3.0; HR_{PT2}=1.0, 95% CI 0.2-3.2; HR_{>PT2}=6.2, 95% CI 1.7-23.2). No evidence of a worse prognosis according to XRCC3, XRCC1, XPD/ERCC1 and ERCC4 genes estimated haplotypes has been obtained, except for the rare XRCC1-TAA haplotype ($p=0.015$). Our results support a limited impact of DNA repair polymorphism on bladder cancer survival.

DRD3 gene polymorphisms: significant observations in Parkinson's disease in India. *S. L.Punia*¹, *G. Nainwal*², *V.M. Khare*², *M. Behari*³, *U.B. Muthane*⁴, *B.K. Thelma*⁵, *R.C. Juyal*². 1) University of Delhi South Campus, New Delhi, India; 2) National Institute of Immunology, New Delhi, India; 3) Department of Neurology, All India Institute of Medical Sciences, New Delhi, India; 4) Department of Neurology, NIMHANS, Bangalore, India.; 5) Department of Zoology, University of Delhi, Delhi, India.

The dopaminergic pathway genes have been implicated for the etiology of Idiopathic Parkinsons disease (IPD) and also as drug induced adverse effects. DRD3, a D2 like receptor is an important gene in dopaminergic pathway and one of major targets of L-dopa and dopamine agonists. We have investigated the possible role of multiple polymorphisms in DRD3 gene in the pathogenesis of PD using a case-control approach. Three SNPs, (one in the promoter, one exonic, and one intronic) in DRD3 gene were genotyped by PCR-RFLP method in a total of 515 IPD subjects diagnosed according to UK PD brain bank clinical diagnostic criteria and 374 age, sex, and ethnicity matched population based controls. There is no allelic and genotypic association of any of these three markers with PD. Haplotypes were constructed separately for cases and controls using program PHASE2.0.2 and tested for global haplotypic significance using program CLUMP. We observed highly significant ($\chi^2=154.45$, $df=7$, $p\lll 0.05$) global haplotypic association with PD, which remain significant even after Bonferroni Correction for multiple comparisons. Susceptibility conferred by individual haplotype(s) was assessed by computing p value and Odds Ratio (OR) at 95% confidence interval (95% CI) of one haplotype vs. the rest. We observed highly significant deviation in the distribution of some of the haplotypes between cases and controls. Thus DRD3 gene polymorphisms may be a major genetic determinant in the etiology of PD in Indian population. Our results also reiterate the importance of analyzing SNP haplotypes vs. individual SNPs in association studies.

Simulations to evaluate sample stratification results an example using *TNFA* and schizophrenia. V. Saviouk¹, E.W.C. Chow², A.S. Bassett², L.M. Brzustowicz^{1,3}. 1) Dept Genetics, Rutgers Univ, Piscataway, NJ; 2) Dept of Psychiatry, Univ of Toronto, and Clinical Genetics Research Program, Centre for Addiction and Mental Health, Toronto; 3) Dept of Psychiatry, Univ of Medicine and Dentistry of NJ, NJ Medical School, Newark.

Previously we showed the association of *TNFA* H1 (-308A, -238G) haplotype with schizophrenia (SZ) by the Trimhap test ($p=0.0052$). Upon stratification of the data set based on the *TNFA* H1 haplotype there were several loci in the genome that showed linkage to SZ that were not detected in the initial scan (Brzustowicz *et al* Science, 2000). We have now applied simulation methods to assess the significance of these results.

Simulate was used to generate 1,000 replicates of full autosomal scans. Parametric linkage analysis was performed on each of the replicates. The pedigrees were analyzed as a single group, then divided into two subsets, based on the presence ($n=16$) or absence ($n=6$) of the *TNFA* H1 haplotype in the real data. In each subset, the maximum LOD and HLOD scores were recorded for each marker and, if ≥ 3.0 , were compared to the maximum LOD/HLOD values at the same marker in the whole replicate. For each replicate, the maximum increase in LOD/HLOD observed for all scores ≥ 3.0 was recorded for each of the two subsets. These values were organized to empirically evaluate the increase in LOD/HLOD scores in the real data.

Several loci showed interesting increases in LOD scores. However, only a single new locus, D1S1609 on 1q44, demonstrated a significant increase ($p=0.025$) in LOD score from 0.15 to 3.01, analyzed with a broad SZ phenotype and a dominant mode of inheritance. This replicates a positive result of linkage of SZ spectrum disorders to this area (Ekelund *et al* Hum Mol Genet, 2001). H1 *TNFA* haplotype partitions our sample into two parts, one with linkage to 1q44 (H1-) and one with the previously reported linkage to 1q22 (H1+) that did not exhibit any evident changes in significance upon stratification. We showed that simulations are pivotal in evaluating the results when sample stratification is utilized.

Screening of genes related with arachidonic acid metabolism for the susceptibility of aspirin induced asthma. T.

Sekigawa^{1,2}, *N. Jinnai*¹, *M. Kakihara*¹, *T. Sakagami*^{1,2}, *T. Nakajima*¹, *K. Yosida*¹, *S. Goto*¹, *I. Inoue*¹. 1) Division of Genetic Diagnosis, The Institute of Medical Science, The University of Tokyo, Tokyo; 2) Division of Respiratory Medicine, Graduate School of Medical and Dental Sciences, Niigata University, Niigata, Japan.

In a subset of asthmatic patients, aspirin and several other non-steroidal anti-inflammatory drugs (NSAID) that inhibit cyclooxygenase (COX) enzymes induced severe asthmatic attack generally termed aspirin induced asthma (AIA). We investigated allelic association of 370 single nucleotide polymorphisms (SNPs) of 63 candidate genes, mostly from arachidonic acid metabolic cascade, to AIA. After two rounds of screening with 198 AIA patients, multiple SNPs in prostaglandin E2 receptor subtype 2 (EP2) gene were associated with AIA ($P < 0.05$). 77 SNPs were identified in EP2 gene, and we applied 17 SNPs based on linkage disequilibrium and allelic frequencies (minor allele frequency > 0.1) for further association study. SNPs in the promoter region of EP2 gene, uS5, uS5b, and uS7, were significantly associated with AIA ($P = 0.039-0.001$). Haplotype analysis was undertaken and a significant association with AIA was observed ($P = 0.001$). The most significantly associated SNP, uS5, locating in the regulatory region of EP2 was in a STATs-binding consensus sequence. However, the STAT1 binding was not observed in gel mobility shift assay with HeLa nuclear extract, instead, an unidentified protein was specifically bound to the variant sequence. *In vitro* reporter assay in HCT116 cells, the site containing the uS5 variant showed a reduced transcription activity. Taken together, the uS5 variant serves as target for a repressor protein of transcription. The functional variant of EP2 gene associated with the risk of AIA would decrease the transcription of EP2 resulting in the reduction of the PGE2 braking mechanism of inflammation and thus could be implicated in the molecular mechanism underlying AIA.

Haplotype Analysis Of Four HTR1B Polymorphisms In Obsessive-Compulsive Disorder. *T.L. Sicard¹, P.D. Arnold¹, J. Geronimo¹, G.L. Hanna², M. Pato³, M.A. Richter¹, J.L. Kennedy¹.* 1) Neurogenetics, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2) University of Michigan, Ann Arbor, Michigan, USA; 3) VA Medical Center, Washington, DC, USA.

Obsessive-Compulsive Disorder (OCD) occurs in 1-3% of the US population and is among the ten leading causes of disability worldwide. It is characterized by obsessions, which are recurring and persistent undesirable thoughts or images, and compulsions, which are necessities to perform excessive rituals or repetitive acts in order to reduce anxiety. Genetic factors are believed to play a major role in the etiology of OCD, and disturbances of the serotonergic pathways have been implicated in this disorder. In the past, researchers have focused mainly on a single nucleotide polymorphism or SNP (861G/C) in the 5-HT-1D-beta receptor (HTR1B) gene, the results have been inconsistent. The aim of the present study was to examine genetic association between OCD and multiple polymorphisms in HTR1B in 85 nuclear families from Toronto, Ann Arbor and Washington. Four SNPs in HTR1B were examined: the common 861G/C SNP, a promoter SNP (-161A/T) shown to affect transcriptional activity and two additional SNPs located at the 5' (rs1213371) and 3' (rs200292) untranslated regions of the gene. Results were obtained for analysis of the haplotypes using Transmit program, however, no statistically significant haplotype associations were identified. Our results suggests that the HTR1B gene does not confer susceptibility for OCD in our sample, however, genotyping of additional SNPs for HTR1B in a larger sample of OCD families may be required in order to exclude the involvement of this gene.

Allelic and Expression Analyses of the Human Lipin 1 Gene in Finnish Dyslipidemic Families. *E. Suviolahti¹, K. Reue², RM. Cantor², A. Soro-Paavonen³, MR. Taskinen³, P. Pajukanta², L. Peltonen¹.* 1) Dept Molecular Medicine, National Public Health Institute, Helsinki, Finland; 2) Dept Human Genetics, David Geffen School of Medicine at UCLA, University of California, Los Angeles, CA; 3) Department of Medicine, University of Helsinki, Finland.

Dysfunction of the lipin 1 (*Lpin1*) gene is the cause of lipodystrophy, hypertriglyceridemia and insulin resistance in the fld mouse. The role of lipin 1 (*LPIN1*) in humans is so far unknown. We investigated seven intragenic single nucleotide polymorphisms (SNPs) and four microsatellite markers of the human *LPIN1* gene in 1109 individuals (538 males, 571 females) from 92 Finnish dyslipidemic families ascertained for a proband with either low high-density lipoprotein cholesterol (HDL-C) or familial combined hyperlipidemia (FCHL). The SNPs and their haplotypes were analysed for association with the critical traits that are abnormal in the fld mouse such as fasting serum triglyceride (TG), glucose and insulin levels as well as body mass index (BMI) and postheparin plasma activities of lipoprotein lipase (LPL) and hepatic lipase (HL), using the family-based association test (FBAT). In addition, *LPIN1* mRNA expression levels were determined in fat tissue of 19 individuals from low HDL-C and FCHL families and analysed for correlation with BMI and serum TG, glucose and insulin levels. Our analyses of *LPIN1* gene variants in dyslipidemic families revealed suggestive evidence for association with serum glucose and insulin levels as well as with LPL activity ($P < 0.05$). Furthermore, in females the most significant association was detected for HL activity ($P < 0.005$). *LPIN1* gene expression levels in fat tissue correlated with plasma levels of serum glucose ($r^2 = 0.40$) and insulin ($r^2 = 0.32$). In line with the results obtained previously from the mouse *Lpin1* gene, these results suggest that the human counterpart, *LPIN1*, may also have a role in the regulation of the glucose and insulin metabolism. This study also emphasizes the importance of murine models in the understanding of genetically complex human traits.

Program Nr: 2261 from the 2004 ASHG Annual Meeting

Untranslated Region Haplotype in Dysbindin Gene. Analysis in Schizophrenia. *D.Z.A. Voineskos, V. De Luca, T. Shinkai, G. Wong, J. Trakalo, J.L. Kennedy.* Neurogenetics, Centre for Addiction and Mental Health, Toronto, Ontario, Canada.

Several studies have supported the existence of many susceptibility genes of small effect for schizophrenia. Genome-wide linkage scans performed in schizophrenia families have provided evidence for region 6p24-21 where variability may confer susceptibility to schizophrenia. Recent studies have implicated that the DTNBP1 gene (dysbindin) in this region is strongly associated with schizophrenia. In a family association study of 116 families, we investigated three markers located in the 3 untranslated regions of the DTNBP1 gene, by genotyping with Assay by Design (ABI Applied Biosystems, Foster City, USA): the BfaI polymorphism (SNP 909706: an AG transition), rs1047631 (an AG transition), and rs742106 (a CT transition). We hypothesize that these three markers are functionally related and are more likely to affect the DTNBP1 expression than other intronic haplotypes that have previously been studied. Haplotype analysis was done using TRANSMIT, but the global chi-squared value was not significant ($\chi^2 = 4.8074$, $df = 3$, $p = 0.186477$). The hypothesis for DTNBP1 in schizophrenia remains of high interest, and more markers need to be typed at this gene to provide more detailed haplotype information and thus a more detailed test of this candidate locus.

Association between LMX1B haplotypes and primary open-angle glaucoma in individuals of African descent. A.

Woodroffe¹, G.R. Abecasis¹, P.R. Lichter², C. Ntim-Amponsah³, S. Moroi², W. Bromley⁴, E. Obeng-Nyarkoh⁴, C.A. Downs², T. Kijeck², K. Scott², V.L. Jaramillo-Babb⁵, D. Vollrath⁵, J.E. Richards². 1) Dept of Biostatistics, Univ of Michigan, Ann Arbor, MI; 2) Dept of Ophthalmology, Univ of Michigan, Ann Arbor, MI; 3) Univ of Ghana Medical School, Accra, Ghana; 4) Center for Human Genetics, Bar Harbor, ME; 5) Dept of Genetics, Stanford Univ, Stanford, CA.

Glaucoma is a blinding neurodegenerative disease that disproportionately affects individuals of African descent. Mutations in the LMX1B transcription factor are responsible for Nail-Patella Syndrome, which includes glaucoma as a variable feature. Here, we investigate the role of polymorphisms in LMX1B in susceptibility to non-syndromic primary open angle glaucoma (POAG) in subjects of African and European descent. We sequenced the 1119 bp coding region, 3' UTR, and flanking intronic regions in 155 subjects with POAG and 101 matched controls. 147 subjects are of African descent, 99 are of European descent. We found 23 polymorphisms in the LMX1B gene, 16 with a minor allele frequency >1%. We also found differences in allele and haplotype frequencies between the two populations, and therefore analyzed them separately. Initial single SNP association tests identified four associated SNPs ($p < 0.05$) in samples of African descent, all four SNPs map to intron 3. To compare haplotype frequencies between cases and controls, we estimated haplotype frequencies using the expectation-maximization algorithm. We analyzed each population separately and estimated significance levels by permuting case and control labels for all subjects. In individuals of African descent, we find significant differences in haplotype frequencies between individuals with POAG and unaffected controls. For example, considering the 16 common SNPs, one haplotype with a frequency of 9.42% occurred only in cases but not in controls ($p = 0.009$). In addition, there are significant differences in the distribution of rare haplotypes (frequency <5%) between the case and control group. In summary, our data provide evidence for association between haplotypes in LMX1B and POAG in individuals of African ancestry.

Allelic variants of the -aminobutyric acid B receptor subunit 2 (GABABR2) gene are associated with nicotine dependence. *J. Beuten*¹, *J.Z. Ma*¹, *T.J. Payne*³, *R.T. Dupont*², *K.M. Crews*³, *M.D. Li*¹. 1) Dept Psychiatry, UTHSCSA, San Antonio, TX; 2) The University of Memphis; 3) The University of Mississippi Medical Center.

Tobacco use is a major worldwide health problem, being responsible for 20% of all premature deaths; nearly one-third of the global adult population smokes. Nicotine dependence (ND) is a complex trait with strong genetic and environmental influences, although the susceptibility genes remain largely unknown. We genotyped 12 single nucleotide polymorphisms (SNPs) in the GABAB receptor subunit 2 gene (GABABR2) for association with ND in a sample of 600 families comprising an extensively phenotyped population of more than 1,400 smokers and non-smokers of both African- and Caucasian-American origin. The GABABR2 gene is a strong candidate for involvement in ND because GABA, the main inhibitory neurotransmitter in the brain, is involved in many neurochemical pathways that regulate physiological and psychological processes. Furthermore, the gene is located within a region on chromosome 9q22 that showed significant linkage to ND in our previous genome-wide screening. Single SNP analysis using PBAT-GEE indicated that 4 of the 12 SNPs covering the GABABR2 gene were significantly associated with smoking behavior in the African-American population, and 3 of the 12 SNPs showed significant results in the Caucasian-American population. Of interest is that the exonic SNP rs3750344 showed significant association with smoking-related phenotypes ($p = 0.000015$ in the Caucasian-American samples; $p = 0.0178$ in the African-American samples). Haplotype analysis using FBAT provided evidence for a positive association of the rs2491397(G)-rs2184026(A)-rs3750344(C) haplotype with smoking-related phenotypes in the overall sample ($Z = 4.02$; $p = 0.000058$). In summary, this study not only confirms previous data on the importance of the family of GABA receptor genes in addiction behavioral traits but provides insight into the genetics of ND, showing the importance of future studies of the GABABR2 gene as a critical candidate in regulating smoking behavior (Supported by DA-12844).

A variant within an intron of RAPTOR (regulatory protein of mTOR) at 17q25 is a modifier of PSORS1 (HLA class I) in psoriasis. *A.M. Bowcock, C. Helms, P. Taillon-Miller, N.L. Saccone, B. Pierce.* Genetics Dept., Wash. Univ. School Med., St. Louis, MO.

Psoriasis is a chronic inflammatory skin disease affecting ~2% of the Northern European population. Its frequency is elevated in HIV patients and 20-30% of patients have psoriatic arthritis. A major determinant of psoriasis maps to the HLA class I region (PSORS1), although its identification has been elusive. Moreover, its penetrance is only ~15% indicating a requirement for genetic modifiers or environmental triggers. PSORS2 maps to chromosome 17q25, and two peaks of association where TDT $p < 0.001$ lie within this region, separated by 6 Mb. The first peak harbors SLC9A3R1 and NAT9; genes involved in polarized epithelia/the immune synapse and acetylation respectively. One predisposing allele within this region and lying between the two genes leads to loss of RUNX1/AML1 binding (Helms et al. 2003). The second peak lies within an intron of RAPTOR (regulatory protein of mTOR). We have replicated the association with RAPTOR in an independent set of families from the U.K. This association is strongest when cases with a family history of disease are used (Capon et al. 2004). Recent analyses have revealed epistasis between RAPTOR and PSORS1: PDT p value for a previously associated marker within RAPTOR increased in significance from 0.009 to 0.0007 when trios were selected on the basis of cases harboring a variant upstream from HLA-C. These findings indicate that the RAPTOR-associated variant is a modifier of PSORS1, and also illustrates the power of epistasis studies to identify causative variants in regions with complex LD patterns such as the MHC.

Association study of CREB1 and childhood-onset mood disorders. *I. Burcescu¹, K. Wigg¹, N. King², A. Vetro³, E. Kiss³, L. Katay³, J.L. Kennedy², M. Kovacs⁴, C.L. Barr^{1,5}, The International Consortium for Childhood-Onset Mood Disorders.* 1) Cell and Molecular Division, The Toronto Western Hospital, Toronto, ON, Canada; 2) Neurogenetics Section, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 3) Department for Child and Adolescent Psychiatry, Szeged University, Szeged, Hungary; 4) University of Pittsburgh, Pittsburgh, Pennsylvania, USA; 5) The Hospital for Sick Children, Toronto, Ontario, Canada.

Several lines of evidence suggest that the cellular pathways involved in synaptic plasticity contribute to the risk of depression including the finding that chronic antidepressant treatment up-regulates the cAMP signal transduction cascade resulting in increased expression and function of the cAMP responsive element binding protein (CREB), a transcription factor that increases the expression of key growth factors involved in synaptogenesis and neurogenesis. Recently, linkage was reported for early-onset depression (onset < 25 years) to 2q33-35, in the region of the gene for CREB1, in families recruited from the Pittsburgh area. This finding was significant only in female sibling pairs from those families. Further, two specific DNA variants, -656G/A and a cytosine insertion/deletion in intron 8, were identified in this gene that co-segregated with depression in two of the families. We sought to replicate this finding by testing for an association between CREB1 and childhood-onset mood disorders (COMD) in a sample of 195 nuclear families (225 affected children) collected in Hungary. We genotyped the two CREB1 DNA variants previously identified as linked to depression as well as three additional polymorphisms spanning the gene. In addition, we genotyped the -656G/A DNA change and insertion/deletion polymorphism in intron 8, in a sample of 112 cases and matched controls collected in the Pittsburgh area, and examined the distribution of alleles and genotypes. The results of our study show no evidence for an association between COMD and CREB1, and no gender-specific transmission for any of the polymorphisms tested.

Association of TNF-, Corneodesmosin, SEEK1 genes with Psoriatic Arthritis. *C. Butt¹, F. Siannis², V. Farewell³, F. Pellett², L. Peddle⁴, C. Schentag², D. Gladman², B. Fernandez¹, P. Rahman¹.* 1) Faculty of Medicine, Memorial University of Nfld., St. John's, Newfoundland and Labrador, Canada; 2) University of Toronto; 3) Institute of Public Health, Cambridge UK; 4) Newfoundland Genomics, St. John's, Newfoundland and Labrador, Canada.

The MHC region has long been considered a strong candidate region for an underlying PsA susceptibility gene. In view of the location and proposed biologic effect of TNF-, corneodesmosin (CDSN), and SEEK1, we set out to determine if polymorphisms within these genes are associated with PsA in a founder and admixed population from the same country. We assessed PsA patients and ethnically matched healthy controls from a founder and an admixed population for the TNF, CDSN and SEEK1 SNPs. PsA subjects and controls were genotyped for TNF-, SEEK1, and CDSN by time-of-flight mass spectrometry. All five TNF- SNPs were in the 5 flanking region of TNF- gene at the following positions: -1031 (TC), -863 (CA), -857 (CT), -308 (GA) and -238 (GA). The following four SNPs were tested in the CDSN gene 619 (rs707913); 1215; 1236 (rs1042127); 1243 (rs3132554), and SNP +39604 of SEEK1. All primers were designed using Sequenom SpectroDESIGNER software, scanned using a mass spectrometry workstation (Bruker), and analyzed using the Sequenom SpectroTYPER-RT software. Results: There was no association observed between the CDSN SNPs and onset of psoriasis, PsA or arthritis pattern. An association between SEEK1 and PsA was noted in the founder population (OR 2.0, p=0.017); however by using logistic regression we determined that SEEK1 does not appear to be a further susceptibility factor if the HLA-Cw*0602 status is already known, and is likely in linkage disequilibrium with HLA-Cw*0602. A modest association was noted between the TNF- 238 A allele and PsA in the founder population (OR 2.5, p=0.02) which was not validated from the admixed cohort. None of the other SNPs tested were noted to have an association between TNF/CDSN/SEEK1 and onset of psoriasis, PsA or arthritis pattern in either population.

Association study of the spinocerebellar ataxia 1 gene located at 6p22.3 that show linkage with schizophrenia and bipolar disorder in multigenerational families from Eastern Quebec. *Y.C. Chagnon, C. Merette, M. Cayer, J. Lamarche, M-A. Roy, M. Maziade.* Molecular Psychiatry, Robert-Giffard Research Center, Beauport, Quebec, Canada.

BACKGROUND. Significant linkages with schizophrenia (SZ) at 6p24-p22 have been reported repeatedly in different populations. A risk haplotypes of the dysbindin (DTNBP1) gene located at 6p22.3 have been associated with SZ. We have observed a linkage (Lod=3.47) with SZ at 6p22.3 one centimorgan centromeric to DTNBP1. Our linkage directly involved the marker SCA1 located within the spinocerebellar ataxia 1 (ATX1) gene associated to the olivopontocerebellar atrophy. In a previous study, ATX1 has been shown to be also in linkage disequilibrium with SZ. **OBJECTIVE.** To evaluate a possible association with SZ and BP of the ATX1 microsatellite used in our linkage study. **SAMPLES.** 45 multigenerational families (~1 000 family members) with multiple cases of SZ and bipolar disorder (BP). 300 unrelated SZ and 150 controls. **METHODS.** Non-parametric linkage analysis, factorial analysis, and chi square and variance analysis tests. **RESULTS.** We observed potential differences between SZ and controls in genotype distribution ($p=0.0002$) with a borderline result for allele distribution ($p=0.07$), as well as between BP and controls ($p=0.03$ and $p=0.11$, respectively). Genotype and allele distributions in SZ appeared to be different of BP ($p=0.01$ and $p=0.04$, respectively). Four single nucleotide polymorphisms (SNP) located within DTNBP1 showed no significant differences ($p>0.09$) between the SZ, BP and control subjects, or between the 300 unrelated SZ patients and 150 controls ($p>0.30$). Using our factor analysis to derive continuous variables from symptoms of SZ and BP, three factors representing negative symptoms, psychosis, or depression, respectively, were detected. We compared the mean scores on these factors by ATX1 genotype using a variance analysis. A significant difference was observed between SZ and BP patients ($p=0.003$) underlying the ATX1 genotype effect on certain clusters of symptoms. This supports the difference in genotype and allele distribution observed for SZ in contrast to BP in our families.

Program Nr: 2268 from the 2004 ASHG Annual Meeting

Gene expression analysis in bipolar disorder using lymphoblastoid cell lines. *H. Chen, C.A. Ross, R. DePaulo, Jr., M.G. McInnis.* Psychiatry & Behavioral Sci, Johns Hopkins Univ Sch Med, Baltimore, MD.

Microarray analysis has made genome-wide testing gene expression feasible but the need for appropriate brain tissue has placed a serious limit on transcriptome-wide testing in complex disorders of the brain. To explore a potential strategy to surmount this limit, we examined the expression profiles in lymphoblastoid cell lines from bipolar I subjects (BP I) and corresponding unaffected first-degree relative controls on the Affymetrix Genechip platform (U133 plus2.0). Data analysis was performed using the Spotfire DecisionSite and Functional Genomics software. The mean expression value of each gene was determined in 11 BP I subjects and 11 unaffected controls. We analyzed the genes detected present in all 22 cell lines, and found that there were 70 genes with 1.3 fold changes or greater associated with a t-test p-value < 0.05 in BP I subjects compared to controls. Ten genes were selected for real-time quantitative RT-PCR verification using the TaqMan method. Nine genes showed similar changes (> 1.3 fold) in the BP I subjects that is consistent with microarray findings, however, only 3 were statistically significant using a two-tailed t-test. Our study suggests that lymphoblastoid cell lines are a potential powerful and accessible cellular system for the analysis of genes and expression in psychiatric disorders where availability of brain tissue is limited.

***MECP2* variation in Portuguese autistic patients.** A.M. Coutinho¹, G. Oliveira², C. Katz³, J. Feng³, J. Yan³, C. Yang³, C. Marques², A. Ataíde², T.S. Miguel², T. Temudo⁴, P. Maciel⁵, S.S. Sommer³, A.M. Vicente¹. 1) Instituto Gulbenkian de Ciência, Portugal; 2) Hospital Pediátrico de Coimbra, Portugal; 3) City of Hope National Medical Center and Beckman Research Institute, USA; 4) Hospital de Sto. António, Portugal; 5) Escola de Ciências da Saúde, Universidade do Minho, Portugal.

Mutations in the gene encoding the methyl-CpG-binding protein 2 (*MECP2*) are responsible for Rett syndrome (RTT). Autism is a neurodevelopmental disorder that shares symptoms with RTT, and therefore an association of *MECP2* with autism etiology as been questioned. Some *MECP2* mutations described in RTT have also been reported in autistic patients. In this study, the *MECP2* gene was scanned for mutations in a Portuguese autistic sample, to assess if the phenotypic spectrum of mutations can extend beyond the traditional diagnosis of RTT and X-linked mental retardation syndromes, possibly leading to a milder phenotype in males. The coding region and 3'untranslated region (3'UTR) were scanned in 172 autistic children and 143 controls, by detection of virtually all mutations-SSCP (DOVAM-S). Although the role of the 3'UTR is not clearly defined, this region is unusually long in *MECP2* and well conserved between human and mouse, suggesting an important regulatory role. We report a novel G206A missense change, found in an autistic boy with severe mental retardation and absence of language. The missense change leads to an alteration in aminoacid properties, which is likely to alter the secondary structure of the protein. Moreover, it's located in a highly conserved nucleotide inside a region implicated in an alternative transcriptional repression pathway, and therefore it is highly possible that this change leads to a functional alteration of MeCP2. Thirteen new 3'UTR variations not present in the controls, eight of which located in conserved nucleotides, were also found. The present results support the hypothesis that *MECP2* underlies several neurodevelopmental disorders, and that distinct mutations alter differently the MeCP2 function, leading to a diversity of clinical manifestations due to the differential abnormal expression of its target genes.

Assessing STRK1 and STRK2 in our independent cohort. *E. Evans*¹, *J. Meschia*², *M. Brown*³, *S. Rich*³, *S. Hague*¹, *R. Brown*², *B. Kissela*², *T. Brott*², *J. Hardy*¹, *A. Singleton*¹. 1) Lab of Neurogenetics, National Institute on Aging, Bethesda, MD; 2) Dept. of Neurology, Mayo Clinic, Jacksonville, FL; 3) Department of Public Health Sciences and Neurology, Wake Forest University School of Medicine, Winston Salem, NC.

A phosphodiesterase 4D (PDE4D) haplotype on chromosome 5q12 was associated with an increased risk of ischemic stroke last year. Earlier this year the same group published an additional risk locus for stroke, within the gene ALOX5AP, which encodes the 5-lipoxygenase activating protein (FLAP) on chromosome 13. We tested these two loci for linkage and association to stroke using two study designs, a concordant sib pair series and a case/control association series. The series comprised individuals age 18 years or older who either presented with ischemic stroke within 180 days after the onset of symptoms or were found to be neurologically normal. The sample series consisted of the SWISS series (Siblings with Ischemic Stroke Study), the ISGS series (Ischemic Stroke Genetic Study) and the PRE-SWISS series, totaling over 600 samples. To test their findings, we used the markers and SNPs previously linked to disease. For PDE4D, we typed markers AC008818-1, SNP-32, -45, -56, -83 and -87 and for ALOX5AP, we ran microsatellite markers D13S289 and D13S1238 and SNPs SG13S89, SG13S32, SG13S25, and SG13S114. For both loci we analyzed microsatellite markers using an ABI3100, and for each SNP we either designed a restriction digest assay or used an ABI Assay-by-Design allelic discrimination assay. After performing statistical analyses on each of the sample series for each marker, our data suggests that no significant linkage or association was identified in the SWISS, ISGS or PRE-SWISS series with any of the markers tested. Although both PDE4D and ALOX5AP were found to be associated with ischemic stroke in an Icelandic cohort, in a more diverse sample series, the two genes do not appear to associate strongly with disease.

The Adrenergic System and Attention-Deficit/Hyperactivity Disorder. *Y. Feng¹, K. Wigg¹, J. Crosbie², T. Pathare², A. Ickowicz², R. Tannock², W. Roberts², M. Malone², J.L. Kennedy³, R. Schachar², C.L. Barr^{1,2}.* 1) Cell & Molecular Biology Division, The Toronto Western Hospital, University Health Network; 2) The Hospital for Sick Children; 3) Neurogenetics Section, Centre for Addiction and Mental Health.

Considerable evidence suggests the involvement of noradrenergic mechanisms in attention-deficit/hyperactivity disorder (ADHD). The noradrenergic (norepinephrine) system is known to be involved in visual attention, modulation of vigilance (sustained attention), initiation of adaptive response, learning and working memory. Elegant work using both animal models and pharmacological probes has shown that the adrenergic system and particularly the alpha 2 adrenergic receptor, are critical for maintenance of visual-spatial information. Therefore the noradrenergic system may contribute more specifically to the cognitive deficits observed in ADHD, particularly working memory. Using a sample of 186 nuclear families including 50 siblings, we investigated the genes for the adrenergic receptors ADRA1A, ADRA1B, ADRA1C, ADRA1D, ADRA2A, ADRA2B, and ADRB1, ADRB2, ADRB3 as candidates for susceptibility to ADHD. Multiple markers across each gene were examined. First, we analyzed ADHD as a categorical trait using transmission disequilibrium test (TDT) analysis; we then applied a quantitative approach family based association test (FBAT) to examine symptom dimensions of inattention, hyperactivity/impulsivity and digit span forwards and backwards-as a proxy for working memory. Preliminary results indicate lack of evidence for a relationship between these genes and ADHD diagnoses, nor did we find any significant relationship between inattentive and hyperactive/impulsive traits and these genes. However, we did observe some preliminary evidence for an association with markers in the ADRA2A gene and working memory.

A Class II Cytokine Receptor Gene Cluster is a Major Locus for Hepatitis B Persistence. *A.J. Frodsham¹, L. Zhang¹, U. Dumpis², N. Mohd-Taib³, S. Best¹, A. Durham³, H. Whittle², H.C. Thomas³, M.R. Thursz³, A.V.S. Hill¹.* 1) The Wellcome Trust Centre for Human Genetics, Oxford, UK; 2) Medical Research Council, Fajara, The Gambia; 3) Imperial College School of Medicine, London, UK.

There are 350 million people with persistent hepatitis B virus (HBV) infection worldwide. Of these up to one third will die from complications of the infection such as cirrhosis and primary liver cancer. Furthermore current treatment for persistent HBV virus infection is poorly effective, expensive and impractical in developing countries where rates of persistence are at their highest. Host genetics have been shown to play a role in the outcome of infection. To further elucidate the role of host genetic factors in the resolution of infection, we performed a genome wide scan in a large set of Gambian families with children with persistent HBV infection. The most significant region of the genome found to exert a major effect on susceptibility to persistence was found on chromosome 21. This area contains a cluster of important genes belonging to the cytokine receptor 2 family. Polymorphisms resulting in amino acid changes in two of the genes within this cluster, the 2nd subunit of the interferon alpha receptor (IFNAR2) and the interleukin 10 receptor beta subunit (IL10RB), are significantly associated with the outcome of HBV infection in this population. Furthermore, haplotype analysis also shows a highly significant correlation with disease persistence. Additionally, we have evidence that these non-conservative amino acid substitutions have a direct functional effect on cell surface expression levels and work is now underway to clarify the exact nature of the role of this variation with respect to HBV persistence. Both of these genes are known to play a central role in host immunity and thus provide us with new avenues for identifying novel therapies for HBV infection for use in endemic areas where it will be most beneficial.

Polymorphisms in trace amine receptor 4 (TRAR4) are associated with susceptibility for schizophrenia on chromosome 6q23.2. *P.V. Gejman¹, J. Duan¹, A.R. Sanders¹, C. Hou¹, N. Saitou², T. Kitano², J. Comeron³, B. Mowry⁴, D.F. Levinson⁵, R.R. Crowe⁶, J.M. Silverman⁷, M. Martinez⁸.* 1) Dep. Psychiatry, ENH RI/ Northwestern University, Evanston; 2) Div. Population Genetics, National Institute of Genetics, Mishima, Japan; 3) Dept. Biological Sciences, The University of Iowa, Iowa City; 4) Dept. Psychiatry, University of Queensland, Brisbane, Queensland, Australia; 5) Dept. Psychiatry, The University of Pennsylvania, Philadelphia; 6) Dept. of Psychiatry, University of Iowa College of Medicine, Iowa City; 7) Dept. of Psychiatry, Mount Sinai School of Medicine, NY; 8) Méthodologie Statistique et Epidémiologie Génétique des Maladies Multifactorielles, Institut National de la Recherche et de la Santé Médicale, Evry, France.

Several linkage studies provide convergent support for chromosome 6q13-q26 as containing a locus for schizophrenia, and more recently for bipolar disorder. We genotyped 192 schizophrenia pedigrees across the MOXD1-STX7-TRARs gene cluster at 6q23.2, which contains a number of prime candidate genes for schizophrenia. Thirty-one screening SNPs were selected, providing a minimum coverage of at least 1 SNP per 20 kb. The association observed with rs4305745 ($P = 0.0014$) within the TRAR4 (trace amine receptor 4) gene remained significant after correction for multiple testing. Through database searching and sequencing genomic DNA in a 30 probands sub-sample, we obtained a high-density map of twenty-three SNPs spanning 21.6 kb of this gene. Single SNP and also haplotypic analyses revealed that rs4305745, and/or 2 other SNPs in perfect linkage disequilibrium (LD) with rs4305745, appears the most likely mutation underlying the association of the TRAR4 region with schizophrenia. Comparative genomic analyses revealed that rs4305745, and/or the associated SNPs in complete LD, can affect gene expression. Moreover, RT-PCR studies of various human tissues including brain confirm that TRAR4 is preferentially expressed in those brain regions implicated in the pathophysiology of schizophrenia. These data provide strong preliminary evidence that TRAR4 is a susceptibility gene for schizophrenia and await replication attempts in additional clinical samples.

Screening for mutations in exon 1 of the Rett syndrome gene, MECP2, among individuals with autism and with mental retardation. *C. Harvey*¹, *S.E. Alfred*¹, *G.N. Mnatzakanian*², *S.W. Scherer*², *W. Roberts*³, *B.A. Minassian*², *J.B. Vincent*¹. 1) Neuroscience Research, CAMH, Toronto, Ontario, Canada; 2) Program in Genetics and Genomic Biology, Hospital for Sick Children, Toronto, Ontario, Canada; 3) Childhood Developmental Centre, Hospital for Sick Children, Toronto, Ontario, Canada.

We recently identified and reported a new isoform of the Rett syndrome gene, MECP2, which results in a new coding region within the first exon. We also reported the identification of a mutation in a single female Rett patient within this new coding sequence- an 11 base pair deletion that results in a frameshift, causing a premature truncation of the protein, and thus supporting a role for this new isoform in the etiology of Rett syndrome. Previously, mutations in the MECP2 gene (exons 3 and 4) have also been identified in individuals with other neuropsychiatric disorders, including autism, mental retardation and Angelman syndrome. We hypothesized that, since this new coding region is clearly important for the correct function of MECP2 during neurodevelopment, this coding region would also be relevant for screening in cases of autism and mental retardation (and non-15q11 cases of Angelman). We have now screened this region in ~100 autism probands, and in ~100 patients with mental retardation. Direct DNA sequencing was used for mutation detection. No mutations were identified among the autism screening set, however 4 sequence variants were identified among the MR cases. We report here on the sequence variants identified, and their possible relevance to neurodevelopment and mental retardation.

Expression analysis in Parkinson Disease (PD), progressive supranuclear palsy (PSP), and frontotemporal dementia with Parkinsonism. *M. Hauser¹, M. Nouredine¹, R.W. Walters¹, C.M. Hulette¹, D.E. Schmechel¹, M.L. Bembe¹, J.M. Stajich¹, H. Xu¹, E.R. Martin¹, B.L. Scott¹, J. Stenger¹, Y-J. Li¹, R. Jensen³, C. Scherzer², S. Gullans², J.M. Vance¹.* 1) Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Brigham and Womens Hospital, Harvard Medical School, Boston, MA; 3) Department of Physics, Wesleyan University.

Parkinsons Disease (PD) is a progressive neurodegenerative disease characterized by the loss of dopaminergic (DA) neurons in the substantia nigra. We present gene expression profiling in the substantia nigra of six patients with PD, two with progressive supranuclear palsy (PSP), one with frontotemporal dementia with Parkinsonism (FTDP), and five controls. PSP and FTDP are related disorders that, like PD, show loss of DA neurons this allows us to identify expression changes that may be secondary to cell loss. All samples were analyzed with Affymetrix U133A microarrays, and a subset was analyzed by serial analysis of gene expression (SAGE). Genes from several metabolic pathways are significantly ($p < 0.05$) altered in PD (but not PSP and FTDP) patients. The molecular chaperones HSPA1A and HSPA1B are overexpressed. There are significant reductions in vesicle transport genes: 9 subunits of the vacuolar ATPase ATP6 are reduced, as are GDI1, STXBP1, SYT1, and VAMP1, proteins involved in docking of secretory vesicles. Mitochondrial gene expression is substantially altered: of the top 20 SAGE tags most significantly differentially expressed between PD and control, five map to the mtDNA. Overall, our SAGE data reveal a 1.5-fold increase in mtDNA-generated tags in PD SN compared to control. This increase was not matched by an increase in the number of tags that map to nuclear genes encoding mitochondrial proteins, indicating a possible disruption of mitochondrial homeostasis. Differentially expressed genes that map to regions of PD linkage are being investigated as susceptibility genes: family-based and case/control association analysis of tightly-linked polymorphisms will be presented.

Identification of Candidate Genes for Clubfoot. *J.T. Hecht*^{1,2}, *A. Heck*³, *M. Bray*³, *S. Watlington*¹, *A. Scott*², *S.H. Blanton*⁴. 1) Univ of Texas Medical School, Houston; 2) Shriners Hospital for Children, Houston, TX; 3) Univ of Texas School of Public Health, Houston; 4) University of Virginia, Charlottesville.

Idiopathic talipes equinovarus (ITEV), or more commonly, clubfoot, is a developmental deformity that is characterized by a rigid foot, adducted forefoot, cavus midfoot, equinovarus of the hindfoot, and hypoplastic calf musculature. This common birth defect is treatable but the etiology of ITEV is largely unknown. We have collected a large sample of ITEV probands and their families, including simplex trios, trios with a positive family history, and extended multiplex families, for use in genetic studies. We have tested two groups of candidate genes for linkage with and without association in this population. The first group consisted of CASP8, CASP10, and CFLAR. These apoptosis regulators were chosen because they map to the chromosomal region 2q31-33 which has been identified as significantly associated with translocations in ITEV. Typing of SNPs throughout the genes revealed positive linkage with association with a variant in CASP10 in the simplex trios ($p < 0.003$). The second group of candidate genes consisted of NAT1 and NAT2. These genes were chosen because they are involved in tobacco metabolism and smoking has been identified as a risk factor for ITEV. Of the 5 polymorphisms tested, only one in NAT2 yielded significant results ($p = 0.03$) under an additive model in the simplex trios. The polymorphisms in NAT2 are known to act in a recessive manner, with only individuals who have a variant form for both copies of the alleles having an altered acetylation rate. Therefore, a recessive model was also considered. The NAT2 polymorphism remained significant, with a p-value of 0.007, with a deficit of the normal allele. These results suggest that CASP10 and NAT2 may play a role in the etiology of ITEV. We are examining CASP10 for functional sequence changes. In addition, the CASP10 results provide a scientific foundation to further explore the contributions of other apoptotic genes in the etiology of clubfoot. The NAT2 results are especially important results as they have significant implications for pregnant women who smoke during pregnancy.

Characterization of an Osteoporosis Linkage Peak: A Case/Control study to validate genes targeted by BoneFusion modeling software. *K.E. Irenze¹, K. Ardlie¹, B. Jordan¹, J. Lemaire¹, P. Enrietto², L.T. Herren².* 1) Genomics Collaborative, a division of SeraCare Life Sciences, Inc., Cambridge, MA; 2) Kenna Technologies, Inc., West Chester, PA.

Osteoporosis is a common disease that affects both men and women as they age. One of the best predictors of risk for osteoporosis is bone mineral density (BMD). A linkage peak for low bone mineral density in the hip was identified on chromosome 1p36 (Devoto et al. 1998, *Eur J Hum Genet*, 6 151-157). This linkage peak contained nearly 100 genes spanning over 5 Mb of sequence. Our goal was to determine whether in silico analysis of putative candidate genes within molecular pathways, prior to testing those candidates, can enable us to more accurately target higher-likelihood candidates and reduce both the cost and time involved in identifying the genes associated with disease. To this end, Kenna Technologies applied BoneFusion to enhance the evaluation and prioritization of a subset of gene candidates for targeted analysis. BoneFusion knowledge diagrams and simulations were used to provide evidence for a role for these genes in bone remodeling and to evaluate the effects of modulating activity/levels of candidate genes on BMD through BoneFusion simulation. Seven genes were selected for further analysis including resequencing and association studies on samples from the GCI Global Repository. Resequencing of these genes, in 48 Osteoporosis Cases, resulted in discovery of 44 novel SNPs not previously reported in public databases. A cohort of 728 USA white/caucasian, non-Hispanic Cases was selected, and all Cases have confirmed Osteoporosis with at least one DEXA Scan T-Score reading of 2.5 or less, in addition to full spine and full hip Z-Scores, T-Scores, and BMD measurements available. All Cases were individually matched with healthy Controls having no Osteoporosis for at least one generation. Analysis of 130 single nucleotide polymorphisms that were selected and genotyped on the 728 Cases and 728 Controls will be presented.

Mutation, selection and evolution of the Crohns disease susceptibility gene, CARD15. *K. King¹, M. Sheikh¹, A.P. Cuthbert¹, S.A. Fisher¹, C.M. Onnie¹, M.M. Mirza¹, J. Sanderson², A. Forbes³, J. Mansfield⁴, C.M. Lewis¹, R.G. Roberts¹, C.G. Mathew¹.* 1) Dept Genetics & Development, GKT School of Medicine, London, UK; 2) Dept Medicine, GKT School of Medicine, London, UK; 3) St Marks Hospital, Harrow, UK; 4) Dept Gastroenterology & Hepatology, University of Newcastle, UK.

Crohns disease (CD) - a chronic inflammation affecting the gastrointestinal tract - is associated with mutations in the CARD15 gene. There is also evidence of an excess of rare CARD15 variants in CD. Mutation analysis of the coding region of CARD15 identified many missense variants of 5% frequency. The evolutionary conservation of CARD15 was investigated to help assess the candidacy of rare variants as potential disease susceptibility alleles (DSAs). CARD15 was sequenced in three non-human primates and bioinformatic analysis was performed to identify other orthologues, and the conservation of amino acid substitutions examined. Seven rare variants (R393H, A612T, R703C, R830Q, N852S, R896X and R1019G) were classified as potential DSAs and these were genotyped in 600 cases and 600 controls. The allele frequency of R703C was 0.6% in cases and 0% in controls ($p=0.0019$). The low frequency of the remainder did not allow formal statistical testing. Phylogenetic analysis of CARD15 revealed ambiguity concerning the N-terminus of the translation product. Human, chimpanzee and gibbon CARD15 all appear to possess an in-frame ORF upstream of the putative start site in rat, mouse, zebrafish and pufferfish, potentially coding for a further 27 amino acids. Use of both translation initiation sites (81 nucleotides apart) has previously been identified in human CARD15. Interestingly, we observed a homozygous frameshifting insertion in tamarins that would preclude use of the first translation initiation site. This particular species of tamarin (*Saguinus oedipus*) is susceptible to a spontaneous chronic colitis which has served as an animal model for related human diseases. We are currently testing constructs for expression in 293T cells to assess the functional significance of the primate-specific upstream open reading frame of CARD15, and the potential consequences of its disruption in tamarins and related New World monkeys.

Association of the SNAP25 gene with bipolar affective disorder and suicidality. T.A. Klempan¹, A.H.C. Wong², T. Armstrong¹, V. Deluca^{1,2}, C.L. Barr^{2,3}, F.M. Macciardi^{1,2}, J.L. Kennedy^{1,2}. 1) Neurogenetics Section, Centre for Addiction and Mental Health, University of Toronto, Toronto, ON, Canada; 2) Department of Psychiatry, Faculty of Medicine, University of Toronto, Toronto, ON, Canada; 3) Toronto Western Hospital, Toronto, ON, Canada.

The SNAP25 gene encodes one of three functionally conserved presynaptic molecules (SNAREs) comprising a core complex controlling generalized exocytosis and neurotransmission. Altered levels of the protein have been identified in several psychiatric conditions, as well as in rodent models of these disorders. Importantly, based upon the phenotype of the coloboma mouse (with a deleted Snap25 gene) and association studies, a link has been made between variation at this locus and attention deficit hyperactivity disorder (ADHD). We have investigated association of three transitions in the 3 untranslated region of SNAP25 within 283 nuclear families with bipolar affective disorder in conjunction with diagnosis and attempts at suicide, a frequent consequence of affliction with this disorder. Analyses conducted using TDT demonstrate significant overtransmission of the *DdeI* 1 allele to female probands ($\chi^2=4.654$, $P=0.031$). The family-based association test (FBAT) also suggests biases in allele transmission under a recessive model (*DdeI* 1 allele: $Z=1.694$, $P=0.090$; *MnII* 1 allele: $Z=1.821$, $P=0.069$), while the most frequent SNAP25 haplotype shows differential transmission ($\chi^2=4.72$, 1df, $P=0.030$). An effect of two of these variants on the likelihood of attempted suicide was observed for a subset of the probands using ANCOVA ($F[2,102]=3.327$, $P=0.040$ for *DdeI* polymorphism, $F[2,102]=2.470$, $P=0.090$ for *MnII* polymorphism), further pronounced when stratified by allele presence or absence ($F[1,103]=6.533$, $P=0.012$ for *DdeI* polymorphism; $F[1,103]=4.196$, $P=0.040$ for *MnII* polymorphism). These results suggest an association of SNAP25 sequence variants with both bipolar disorder and suicidal behavior, possibly through disequilibrium with further mutations affecting level of expression or function in neurotransmission. Further investigation of molecules governing synaptic vesicle fusion and release may be warranted in studies of suicide.

Case-control association studies of 122 candidate genes for idiopathic Parkinson's disease. *I. Mizuta^{1,2}, W. Satake¹, Y. Momose³, Y. Hirota¹, A. Oka⁴, H. Inoko⁴, M. Yamamoto⁵, N. Hattori⁶, M. Murata⁷, T. Toda^{1,2}.* 1) Div Functional Genomics, Osaka Univ Grad Sch Med, Osaka, Japan; 2) CREST, JST, Saitama, Japan; 3) Dept CBI, Grad Sch Med, Univ Tokyo, Tokyo, Japan; 4) Dept Mol Life Sci, Tokai Univ Sch Med, Kanagawa, Japan; 5) Dept Neurol, Kagawa Pref Central Hosp, Kagawa, Japan; 6) Dept Neurol, Juntendo Univ Sch Med, Tokyo, Japan; 7) Dept Neurol, NCNP, Tokyo, Japan.

Idiopathic Parkinson's disease (PD) is a complex disorder caused by multiple genetic and environmental factors. To disclose the genetic factors, we are doing case-control analysis by using single nucleotide polymorphisms (SNPs) in multiple candidate genes. We selected candidate genes from the viewpoints of familial PD, dopaminergic neurons, Lewy body, trophic factors, cytokines, oxidative stress, mitochondria, apoptosis, ubiquitin-proteasome, autophagy, etc. For initial screening, we genotyped 190 patients and 190 controls by Invader method. Of 267 SNPs in 122 candidate genes, 22 SNPs in 16 genes showed P values less than 0.05 (allele frequency, chi-square statistics). These included UCHL1, NDUFV2, CTSD, FGF2, BCL2, etc. We are now confirming these associations by increasing the number of samples to nearly 900 for patients and 900 for controls.

AQP1, selected by differential screening of gene initiation sequences, is associated with schizophrenia in Portuguese population. X. Ni^{1,2}, J. Trakalo¹, J. Valente³, M. Azevedo³, M. Pato⁴, C. Pato⁴, J. Kennedy^{1,2}. 1) Neurogenetics Section, Ctr Addiction & Mental Health, Toronto, ON, Canada; 2) Department of Psychiatry, University of Toronto, Canada; 3) Department of Psychiatry, University of Coimbra, Portugal; 4) Veterans Administration Hospital, Washington, D.C., USA.

Using differential screening of gene initiation sequences (GIS), the DNA sequences that surround the gene start codon, we identified a product, showing stronger signal in a pool of probands with schizophrenia compared with their parents. The sequence of this DNA fragment shows high homology with the aquaporin 1 gene (AQP1), which is located on human chromosome 7p14 and codes the aquaporin 1 (channel-forming integral protein, 28kDa). To confirm the association between AQP1 and schizophrenia we tested four markers in the AQP1 gene with TaqMan technique in 163 Portuguese trios and nuclear families with DSM-IV schizophrenia probands. The program HaploView (version 2.04) from the Whitehead institute was used to test for concordance with Hardy-Weinberg equilibrium (HWE), calculate the linkage disequilibrium (LD), create the LD blocks, and perform the transmission disequilibrium test (TDT). TDT for extended marker haplotypes (TRANSMIT version 2.5.2) was used to test for transmission disequilibrium between haplotypes of the four AQP1 polymorphisms and schizophrenia. The genotype distributions in probands were all in HWE ($p > 0.05$). In TDT analysis using each allele we found a significant association between schizophrenia and the marker rs2267719 in AQP1 ($p = 0.0285$), and a trend to significance with the polymorphisms rs2267720 ($p = 0.0588$). The markers rs2267719 and rs2267720 of AQP1 were in high linkage disequilibrium. In haplotype transmission analysis the rs1859840A-rs2267719C-rs1049305G of AQP1 transmitted often than the expected ($p = 0.0305$) though the global chi-square test showed a negative result ($p = 0.1137$). Our results suggest that the human AQP1 may be associated with schizophrenia.

The MTHFR polymorphism is associated with acute rejection in kidney transplantation. *W.S. Oetting¹, M.J. Brott¹, N. Li², W. Pan², R. Kandaswamy³, A.J. Matas³.* 1) Dept. Medicine and Institute of Human Genetics, Univ. Minnesota, Minneapolis, MN; 2) Dept. of Biostatistics; 3) Dept. of Surgery.

Introduction: Several DNA polymorphisms have been previously associated with acute rejection (AR) after transplantation. We have now expanded this work with the analysis of 17 polymorphisms in 14 genes to determine their association with AR in our own population. **Methods:** DNA was isolated from 301 recipients, all of whom received Ab induction and calcineurin inhibitors (CNI) with either mycophenolate mofetil (MMF) or sirolimus. 17 single nucleotide polymorphisms (SNPs) were genotyped including ACE (I/D), AGT (p.T174M and p.M235T), F2 (c.20210G>A), F5 (p.R506Q), F7 (p.R353Q), GNB3 (c.825C>T), ICAM (p.R241G and p.K469E), IL6 (c.-174C>G), IL10 (c.-1082G>A), ITGB3 (p.L33P), MTHFR (c.677C>T), PPP3CA (p.Q318K), TGFB (p.L10P) and TNFA (c.-238G>A and c.-308G>A). SNPs were analyzed using the ABI 7500 and TaqMan probes and the ACE polymorphism was analyzed by agarose gel electrophoresis. Fisher's exact test was used to investigate a possible association between AR within one year after transplant (n=27) and a SNP for each gene in the SAS statistical software package. **Results:** The methylene tetrahydrofolate reductase (MTHFR) polymorphism (rs1801133) was the only SNP to give a suggestive association (P = 0.0612) with AR for all three genotypes. Inheritance of either the TT or TC genotype increased the risk of rejection (P = 0.0213; odds ratio of 2.3 (1.2-4.9)). The MTHFR SNP is associated with altered enzymatic activity. The T allele (frequency = 0.29) has been shown to reduce catalytic activity, resulting in an increase in serum homocysteine levels. Individuals homozygous for the C allele appear to be protected from AR whereas individuals either homozygous or heterozygous for the T allele were found to be at greater risk for acute rejection. **Conclusions:** Determining the genotypes of polymorphisms that affect transplant outcome may be important in the individualization of immunosuppression therapy. Randomized trials will need to be done to determine if individuals with either the TT or TC MTHFR genotypes would benefit from increased immunosuppression.

Association of *CD40L* IVS4+121 AG polymorphism with risk for coronary artery lesions in male Kawasaki disease patients. *Y. Onouchi*¹, *S. Onoue*¹, *T. Kawasaki*², *Y. Nakamura*^{3, 4}, *A. Hata*^{1, 5}. 1) Lab. Gastrointestinal Diseases, SNP Research Center, RIKEN, Yokohama, Japan; 2) Japan Kawasaki Disease Research Center, Tokyo, Japan; 3) Lab. Molecular Medicine, Human Genome Center, Institute of Medical Science, the Univ. of Tokyo, Tokyo, Japan; 4) Research Group for Personalized Medicine, SNP Research Center, RIKEN, Yokohama, Japan; 5) Dept. Public Health, Graduate School of Medicine, Chiba Univ., Chiba, Japan.

Kawasaki disease (KD) is an acute systemic vasculitis syndrome of infants and young children. Although KD is a basically self-limiting disease, 15 to 20% of untreated patients could suffer coronary artery aneurysms, a risk factor for life-threatening complications. Epidemiological findings suggest that genetic factors play a role in the pathogenesis of KD. To identify genetic factors, affected sib pair analysis has been performed. One of the identified peaks was located on Xq26 region. A recent report of elevated expression of CD40 ligand (CD40L), which maps to Xq26, during the acute phase KD and its relationship to the development of coronary artery lesions (CAL), prompted us to screen for polymorphism of *CD40L* and to study the association of the gene to KD. 22 single nucleotide polymorphisms (SNPs) were identified in 12.2kb of *CD40L* region. Among them, a newly identified SNP in intron 4 (IVS4+121 AG) is marginally over-represented in KD patients as compared to controls (109/602, 18.1% vs. 111/737, 15.1%). The difference was significant when male KD patients with CAL were compared to controls as a patient group (15/58, 25.9%, vs. 111/737, 15.1%, OR=2.0, 95%CI=1.07-3.66, $p=0.030$). Comparison between male patients with CAL and those without CAL also showed a significant difference (25.9% vs 14.1%; OR=2.1, 95%CI=1.02-4.21, $p=0.041$). Interestingly, this variation was extremely rare in a control Caucasian population (1/145, 0.7%). Our results suggest a role of CD40L in the pathogenesis of CAL and might explain the excess of males affected with KD.

Mutation Screening of 130 Candidate Genes Reveals a Complex Molecular Inheritance for Adult-Onset Primary Open Angle Glaucoma (POAG). *M. Sarfarazi*¹, *A. Child*², *L. Welsh*^{1,2}, *S. Suriyapperuma*¹, *S. Monemi*¹, *T. Rezaie*¹. 1) Molecular Ophthalmic Genetics Laboratory, University of Connecticut Health Center, Farmington, CT; 2) Cardiological Sciences, St Georges Hospital Medical School, London.

POAG is a group of ocular disorders with diverse clinical presentation, variable age of onset and considerable genetic heterogeneity. By using several genome scans we identified potential POAG loci on chromosomes 1, 2, 3, 4, 5, 6, 8, 10, 17 and 20. The purpose of this study was to identify the causative genes at every one of these loci. Potential candidate genes were selected based on their ocular expression and screened for mutation in their respective linked families. For each gene, affected subjects were screened by bi-directional sequencing and observed variations were evaluated bioinformatically against public databases. Co-segregation with POAG phenotype was evaluated by restriction enzyme analysis, SSCP or direct sequencing. Absence of POAG-causative mutation was confirmed in a group of normal control subjects from an ethnically matched population. We screened 130 genes from 10 different regions, including those mapping to the known GLC1A-GLC1E loci. For 2 intervals, every single known gene mapping to that region is now fully sequenced. Candidate genes had up to 80 exons and their cDNA sizes varied from 1 to 10-kb. Mutation screening revealed a large number of sequence alterations including many new SNPs, insertions, deletions and duplications. Identification of novel isoforms in a number of these genes added further complexity to molecular identity and verification of their role in POAG. Only 3 of the 130 genes screened were confirmed as POAG disease-causing genes. Confirmation, familial segregation, population screening and disease-causing nature of other observed variations are currently in progress. In conclusion, screening of a large number of candidate genes is required before a definite glaucoma-causing gene can be identified. This task is further complicated by presence of many naturally occurring polymorphisms within these genes. Supported By EY-09947, EY-014959, M01RR-06192 and IGA.

Association of NOS2A polymorphisms and pulmonary tuberculosis. *W.K. Scott^{1,2}, M.C. Levesque¹, L. Zhang², W.F. Hulme², N.N. Wall², C.A. Browning-Large², S.G. Patillo¹, A.W. Mosher¹, C.J. Pozsik³, J.R. Gilbert^{1,2}, J.B. Weinberg², C.D. Hamilton^{1,2}.* 1) Department of Medicine, Duke University Medical Center, Durham, NC; 2) Center for Human Genetics, Duke University Medical Center, Durham, NC; 3) South Carolina Department of Health and Environmental Control, Columbia, SC.

Tuberculosis (TB) is a significant cause of premature mortality worldwide. Approximately 10% of exposed individuals develop active pulmonary TB, suggesting that host defense factors, partly under genetic control, determine development of active disease. The NOS2A (inducible nitric oxide synthase) gene has been implicated in the development of mycobacterial infections in mouse models and is an attractive candidate gene for human TB susceptibility. We examined five polymorphisms in the promoter region of the NOS2A gene for association with TB in a family-based association study. Individuals reported to the North Carolina and South Carolina TB Control programs between 1992 and 2004 were eligible for the study. Individuals older than 14 years with culture-confirmed pulmonary TB and children younger than 14 years with culture- or clinically-confirmed TB were enrolled along with unaffected sibling or parental controls. Genotypes were obtained for 228 individuals from 104 families (68 African-American and 36 white). The TRANSMIT program (Clayton 1999) was used to analyze each polymorphism for association with TB in each ethnic group. Associations were assessed using the bootstrap empirical p-value provided by TRANSMIT. No polymorphisms were significantly associated with TB in the white subset ($p > 0.05$). However, the minor allele (4% frequency) of one polymorphism (-5091C) was associated with TB in African-Americans ($p=0.01$). These results indicate that at least one rare polymorphism of this gene may be over-transmitted to African-Americans with TB. However, given the low allele frequency of the variant, the robustness of this association is unclear. We will continue to follow-up by genotyping additional families for these and other polymorphisms in NOS2A.

Investigation of the dopamine D5 receptor gene in adult Attention Deficit Hyperactivity Disorder. *A. Squassina*¹, *U. Jain*², *V. De Luca*¹, *M. Krinsky*¹, *P. Muglia*¹, *J. Kennedy*¹. 1) Neuroscience section, Centre for Addiction and Mental Health, Department of Psychiatry, Clarke site, Toronto, Ontario, Canada; 2) Division of Child Psychiatry, Centre for Addiction and Mental Health, Toronto, Ontario, Canada.

Attention Deficit Hyperactivity Disorder (ADHD) is a common childhood disorder characterized by inattention, hyperactivity and impulsivity. It affects 3-5% of school-aged children and persists into adulthood in about 30% of cases. Twin, family and adoption studies have shown a large genetic component in the etiology of ADHD. Several lines of evidence indicate that the dopaminergic system play a role in the aetiology of ADHD. Numerous studies have also shown positive association among various polymorphisms at the dopaminergic system genes and ADHD. Previous investigations have examined the association between a dinucleotide (CA)_n repeat polymorphism, located in the cosmid containing the DRD5 gene, and ADHD. Some reports have shown a preferential transmission of the 148 bp allele ADHD children. In the present study we tested the association between ADHD and the CA repeat in our sample comprised of 110 families and 88 cases with matched controls. The E-TDT results did not show significant biased transmission of the 148 bp allele however, there was a trend for the over-transmission of this allele to ADHD offspring (T=42, NT= 30, $2 = 2.00$, $p=0.15$). An excessive non transmission of the 152 bp allele was observed suggesting a protective effect of this allele ($2 = 6.00$, $p=0.01$). The quantitative trait locus analysis, performed comparing the different genotype groups among the Brown and Wender scales score, did not detect any significant difference. Our study didnt show a strong effect for the CA repeat at the DRD5 locus in increasing susceptibility to ADHD. However, further analysis on a bigger sample are warranted.

Systematic screening of PLA2G7 gene for polymorphic variants and a preliminary association study in coronary artery disease patients. C. Terranova¹, M. Gomez-Lira¹, L. Provezza¹, N. Martinelli², C. Bozzini², M.R. D'Apice³, S. Gambardella³, G. Novelli³, P.F. Pignatti¹. 1) Department of Mother and Child, Biology and Genetics University of Verona, Verona, Italy; 2) Department of Clinical and Experimental Medicine, University of Verona, Verona, Italy; 3) Center of Excellence for Genomic Risk Assessment in Multifactorial and Complex Diseases, School of Medicine, Tor Vergata University of Rome, Rome, Italy.

Elevated levels of lipoprotein-associated phospholipase A2 (Lp-PLA2, or platelet-activating factor acetylhydrolase, PAF-AH) have been shown to be an independent risk factor for patients with angiographically proven coronary artery disease (Caslake et al 2000, Packard et al 2000). The entire coding region, the 3' flanking region, and 3,500bp of the 5'flanking region of the gene for Lp-PLA2 (PLA2G7) were systematically screened using DHPLC analysis in 100 Italian subjects with (CAD, 50 individuals) or without (CAD-free, 50 individuals) angiographically documented severe coronary atherosclerosis. Nine polymorphic variants were identified in these individuals: three known missense mutations in the coding region (Arg92His, Iso198Thr, and Val379Ala), a known deletion polymorphism (1190-20_23delGATT) in intron 11, two newly described highly polymorphic dinucleotide repeats (1134+31TGmAGn) in the 3 flanking region, and three SNPs in the 5 flanking region (-402T>C and 209C>G, -280T>C) one of them (-280T>C) newly described. No statistically significant difference in frequency the of alleles or genotypes of these PLA2G7 polymorphisms was observed between CAD and CAD-free individuals, suggesting that these sequence variants do not play an important role in susceptibility to coronary artery disease in this small study group. References: Caslake MJ, Packard CJ, Suckling KE, Holmes SD, et al (2000) Lipoprotein-associated phospholipase A2, platelet- activating factor acetylhydrolase: a potent new risk factor for coronary artery disease. *Atherosclerosis* 150; 413-419). Support for EKN1 as the susceptibility locus for reading disabilities and attention deficit hyperactivity disorder

on 15q21. *K. Wigg¹, J. Couto¹, Y. Feng¹, J. Crosbie², B. Anderson², T. Cate-Carter², R. Tannock², M. Lovett², T. Humphries², J.L. Kennedy³, A. Ickowicz², T. Pathare², W. Roberts², M. Malone², R. Schachar², C.L. Barr^{1,2}.* 1) Cell & Molecular Division, Toronto Western Hospital, Toronto, Ontario; 2) Brain and Behaviour Programme, The Hospital for Sick Children, Toronto, Ontario; 3) Neurogenetics Section, Centre for Addiction and Mental Health, Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada.

Reading disabilities (RD) have been linked to a number of chromosomal regions including 15q. Recently a gene in the 15q region, EKN1, was identified via a translocation breakpoint in a family segregating with RD. Association studies in a small sample of families from Finland provided further support for this gene as a susceptibility locus for RD. In our sample of 148 families identified through a proband with reading difficulties, we found evidence for allelic association of polymorphisms in the EKN1 gene to the phenotype of RD identified as a categorical trait ($p=0.018$) and, using quantitative analysis, to reading related processes. There is considerable evidence from twin studies for shared genetic factors contributing to RD and attention-deficit hyperactivity disorder (ADHD), particularly inattention symptoms; therefore, we investigated the relationship of genetic markers in this gene to ADHD and the inattention and hyperactive/impulsive symptoms, in a sample of 186 nuclear families collected through a proband with the disorder. We found a trend for linkage to the ADHD phenotype as a categorical trait using the transmission disequilibrium test, and significant evidence for biased transmission of a haplotype containing this marker ($p=0.009$). Using quantitative analysis, we observed evidence for association of this haplotype to the inattention and hyperactive/impulsive symptoms, and a trend for association with the reading phenotypes of word identification and decoding. Our results provide preliminary support for the role of the EKN1 locus in RD and ADHD suggesting that this locus may be pleiotropic, contributing to both phenotypes.

Exclusion of TBX2 and TBX4 as candidate genes in MYP5-linked high myopia. *T.L. Young¹, P.C. Paluru¹, S. Nallasamy¹, W. Cole², E. Heon².* 1) Divisions of Ophthalmology and Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Ophthalmology and Vision Science Research Program, University Health Network, Toronto, Ontario, Canada.

TBX2 and TBX4 are T-box genes of the TBX2/3/4/5 subfamily of highly evolutionarily conserved putative transcription regulators that play critical roles in development. TBX2 and TBX3 are considered cognate genes, as are TBX4 and TBX5. TBX2 is known to be expressed in the human and mouse neural retina and mis-expression of TBX2 causes morphologic eye defects in *Xenopus*. TBX4, although primarily involved in hind limb development, may play a yet undiscovered role in eye development or in the regulation of TBX2 expression. Both TBX2 and TBX4 map within the high-grade myopia-5 locus (MYP5) located on chromosome 17q21-23. We screened individuals from the original MYP5 family for sequence variations in these genes. The genomic DNA from two affected individuals (proband spherical refractive error of -50.00 diopters in both eyes), two unaffected relatives, and one normal external control was screened by direct sequencing. Nine primer pairs spanning intron-exon boundaries and coding regions were designed for the 6-exon TBX2 gene. Similarly, 10 primer pairs were designed for the 8-exon TBX4 gene. Polymerase chain reaction products were sequenced and analyzed using standard fluorescent methods, and sequences were aligned with known database gene sequence for base pair change analysis. Sequencing of TBX2 amplicons revealed 10 polymorphisms, 6 of which were novel, and sequencing of TBX4 amplicons revealed 12 polymorphisms, 5 of which were novel. No polymorphism for either gene segregated with high myopia. TBX2 and TBX4 have been excluded as candidate genes for MYP5-associated high myopia.

Evidence for Gene Environment Interaction in HNF-3 Mediated MMP-7 Induction in Idiopathic Pulmonary Fibrosis. *Y. Zhang*¹, *A. Pardo*², *Y.P.P. Di*³, *B.S. Maher*⁴, *L. Wang*¹, *A.M.K. Choi*¹, *M. Selman*⁵, *N. Kaminski*¹. 1) Dept Medicine, Div PACCM, Univ Pittsburgh Sch Med, Pittsburgh, PA; 2) Facultad de Ciencias UNAM, Mexico DF, Mexico; 3) Dept Environmental and Occupational Health, Univ of Pittsburgh Sch public Health, Pittsburgh, PA; 4) Center Craniofacial and Dental Genetics, Univ Pittsburgh Sch Dental Med, Pittsburgh, PA; 5) Instituto Nacional de Enfermedades Respiratorias, Mexico DF, Mexico.

Idiopathic pulmonary fibrosis (IPF) is a devastating disease characterized by the expansion of fibroblasts/myofibroblasts, usually forming discrete subepithelial foci, and by the excessive accumulation of extracellular matrix which result in progressive and severe distortion of the pulmonary architecture. Although the etiology of IPF is unknown, a number of environmental exposures has been associated with elevated risks for IPF development. Particularly, a growing body of evidence strongly suggest that chronic exposure to cigarette smoke is a major risk factor to develop IPF. The genetic mechanisms that underlie the development of IPF and their association with environmental risk factors are unknown. Here we report evidence for gene-environment interaction in IPF based on our analysis of the matrix metalloprotease 7 (MMP-7) promoter single nucleotide polymorphisms, -181A/G and 153C/T. The 181A allele (homozygote or heterozygote) was significantly over-represented in Mexican smokers with IPF compared to normal Mexican smokers (95.7% vs 81.3%, $P = 0.0352$). The G to A transition resulted in a novel binding site for hepatocyte nuclear factor 3 (HNF-3). In-vitro, this transition led to allele specific HNF-3 binding to the MMP-7 promoter, and increased sensitivity of the MMP-7 promoter to HNF-3b. Interestingly, exposure to cigarette smoke extract induced expression of MMP-7 and HNF-3b. Our results suggest that the increased sensitivity of the polymorphic MMP-7 promoter to HNF-3b provides susceptibility to IPF in smokers carrying the 181A allele. In addition to being the first evidence for gene-environment interaction in IPF our results suggest a new general mechanism for smoking induced lung injury in humans.

SLE patients show low levels of CD4⁺CD25⁺CD45RO⁺ regulatory T cells which are extremely heritable and associated with the *CTLA4* gene. *M. Barreto*¹, *R. Ferreira*¹, *C. Fesel*¹, *M.F. Fontes*¹, *E. Santos*³, *M. Alves*³, *N. Cortez-Dias*³, *C. Pereira*², *B. Martins*², *R. Andreia*³, *J.F. Viana*³, *L. Mota-Vieira*⁴, *C. Vasconcelos*³, *C. Ferreira*³, *J. Demengeot*¹, *A.M. Vicente*¹. 1) Inst Gulbenkian Cincia, Oeiras, Portugal; 2) Instituto de Cincias Biomedicas Abel Salazar, Porto, Portugal; 3) Associacao dos Doentes com Lupus, Lisboa, Portugal; 4) Hospital Divino Esprito Santo, Ponta Delgada, Azorean Islands, Portugal.

Naturally occurring CD4⁺CD25⁺CD45RO⁺ regulatory T cells (Treg) play a key role in suppressing self-reactive T cells, contributing to the maintenance of immunologic self-tolerance and to autoimmune disease protection. With the purpose of investigating the involvement of these Treg in Systemic Lupus Erythematosus (SLE) pathogenesis, we have determined the relative numbers of CD4⁺CD25⁺CD45RO⁺ T cells in a population of 71 patients, 156 relatives and 193 healthy individuals. We found a significant difference in the distribution of the CD4⁺CD25⁺CD45RO⁺ T cell numbers among patients and controls ($H=37.49$, $p<0.0001$), with the patients showing significantly lower levels of Treg cells than healthy individuals. The numbers of Treg cells in SLE relatives showed an intermediate distribution between patients and controls and heritability for this trait was estimated as 85% ($p=0.0000002$). Given the high heritability of this trait, we searched for genetic factors determining the levels of Treg cells. Because cytotoxic T lymphocyte associated antigen 4 (CTLA-4) is a downregulator of the immune response and is constitutively expressed in regulatory T cells, we further investigated the involvement of the *CTLA4* gene in Treg levels. For this purpose we genotyped two polymorphic markers within the *CTLA4* gene. We found an association of a 3'UTR microsatellite and the levels of Treg cells ($H=19.320$ $p=0.023$). Individuals carrying a specific genotype, which had previously been found to increase risk for SLE, showed lower levels of these cells. These results suggest that *CTLA4* risk allele induces a reduced suppressive activity of these cells and consequently the proliferation of effectors, leading to the development of autoimmune disease.

Genetic Characterization of the CD40 P227A Polymorphism: A Gain-of-Function Polymorphism Associated with Human SLE. *P.M. Gaffney¹, A.C. Grammer², L. He², R.M. Plenge³, R.R. Graham³, W.O. Ortmann¹, P.K. Gregersen⁴, D.M. Altshuler³, P.E. Lipsky², T.W. Behrens¹.* 1) Department of Medicine, University of Minnesota School of Medicine, Minneapolis, MN; 2) Autoimmunity Branch, NIH/NIAMS, Bethesda, MD; 3) Broad Institute, MIT/Whitehead Institute for Biomedical Research, Boston, MA; 4) North Shore-Long Island Jewish Research Institute, New York, NY.

CD40 is a surface receptor on B lymphocytes and dendritic cells that plays a critical role in immunity against pathogens. CD40 is located within a region of genetic linkage to SLE on chromosome 20q13.1. To further investigate the role of CD40 in SLE we sequenced all coding exons and intron/exon boundaries and discovered a novel missense single nucleotide polymorphism (SNP) in the cytoplasmic domain of CD40, which results in a proline-to-alanine mutation at amino acid 227 (P227A). In P227A carrier families with SLE, P227A was preferentially transmitted to affected offspring (22 of 27, 81%, $p=0.0038$) suggesting a role for P227A in the pathophysiology of SLE. Our data also suggested an increased prevalence of P227A in Hispanic families (5 of 15, 30%) compared with Caucasian families (6 of 196, 3%). To investigate this, we genotyped P227A in unaffected Caucasian, African American and Hispanic control populations from the United States and the CEPH Diversity Panel, comprised of DNA from 51 indigenous populations in 60 geographic locations throughout the world. These analyses confirmed the increased allele frequency of P227A in Hispanics (3.6%) compared to Caucasians (0.41%) or African Americans (1.0%) in the United States. The results in the CEPH Diversity Panel revealed striking allele frequencies exclusively in populations from South and Central America (range 7.1%-46%) suggesting the influence of selective pressure. Importantly, functional studies show that the CD40 P227A receptor constitutively binds the adaptor protein TRAF2, which in turn leads to signaling through the mutant receptor in the absence of ligand-induced receptor aggregation. Thus, CD40-P227A is a common genetic variant with a gain-of-function phenotype that predisposes to SLE.

Mannose-binding lectin (MBL) genetic susceptibility for Alzheimers disease. *L. Nuytinck*¹, *M. Palmer*², *S. Schraen-Maschke*³, *M. Duhamel*¹, *M. Van Thielen*¹, *T. Van de Castele*¹, *A. Johansson*², *A. Delacourte*³, *B. Sablonniere*³, *K. Blennow*², *E. Vanmechelen*¹. 1) Innogenetics NV, Gent, Belgium; 2) Gteborg University, Sweden; 3) INSERM U422, Lille, France.

In sporadic Alzheimers disease (AD) it has been estimated that apart from ApoE4, a number of additional loci can determine AD genetic risk. As evidence has accumulated indicating a chronic inflammatory reaction in areas of the brain affected by AD, we explored the possible role of innate immunity in AD pathogenesis. As a first target, the gene encoding mannose-binding lectin (MBL) was studied due to its key role in innate immunity, and in view of reported decreased MBL levels in the cerebrospinal fluid of AD patients compared to controls. The main functions of MBL are the activation of the complement system through the lectin pathway and the modulation of inflammation. Six common *MBL2* DNA variants localized in the promotor, 5'UTR and exon 1 sequences, are known to result in considerable variations in the quantity and functionality of MBL in serum. In order to investigate the genetic susceptibility of common *MBL2* genotypes for the development of AD, a case-control study was performed consisting of 523 AD patients and 285 age-matched controls from Swedish and French centers. Genotyping was performed using the INNO-LiPA MBL2 and the INNO-LiPA ApoE assays (Innogenetics, Gent, Belgium). Using a logistic regression approach, it was tested if disease incidence changed depending on the presence of the 'promotor deficient' *MBL2*-haplotype LXPA, and the pooled 'non-functional' *MBL2*-haplotypes HYPD, LYPB and LYQC, as compared with the pooled *MBL2*-haplotypes HYPA, LYPA and LYQA. AD-incidence tended to increase with the presence of LXPA ($p=0.0657$, OR 1.34 [95% CI 0.98-1.84]) and significantly decreased with the presence of the non-functional haplotypes ($p=0.0304$, OR 0.72 [95% CI 0.53-0.97]). No significant interactions between ApoE and the *MBL2*-(pooled) haplotype(s) were observed ($p0.45$). Our results indicate that genetic variation in the *MBL2* gene could be associated with the development of AD. This may have important implications for the diagnosis and treatment of this disease.

Epigenetic alteration of Angelman syndrome gene (*UBE3A*) in autism brains. Y. Jiang, Q. Liu, L. Dai, A.L. Beaudet. Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX.

Numerous cytogenetic studies have indicated that chromosome 15q11-q13 and genomic imprinting may play an important role in the genetic etiology of autism. Maternally inherited interstitial duplications of 15q11-q13 and an isodicentric chromosome 15 of maternal origin are the two most common cytogenetic abnormalities found in autism patients. Two disorders of genomic imprinting, Prader-Willi syndrome (PWS) and Angelman syndrome (AS), involve abnormalities of the 15q11-q13 region. Maternal deficiency of chromosome 15q11-q13 and mutations in *UBE3A*, a brain-specific and maternally expressed ubiquitin protein ligase, are the major causes of AS. There are significant overlapping clinical features between AS and autism. We tested a hypothesis that *UBE3A* is a candidate gene from 15q11-q13 and that epigenetic alteration of *UBE3A* contributes to autism susceptibility. We have analyzed DNA methylation of CpG islands at the 5' ends of *SNRPN* and *UBE3A*, as well as a newly identified tissue-specific DNA methylation site at the 3' end of *UBE3A* in autopsy brain tissues and cell lines from autism patients. We have identified abnormal DNA methylation at the 5' *UBE3A* CpG island in 1 out of 17 brain tissues. The 5' *UBE3A* CpG island is completely unmethylated in 60 normal controls but became partially methylated in one autism brain. In addition, we also found a significant reduction of *UBE3A* protein in 7 out of 17 autism brain tissues by Western blot analysis. These findings are in press (Am J Med Genet). In subsequent work, abnormal DNA methylation at the 3' tissue-specific DNA methylation site was also identified in 1 out of 43 cultured lymphoblast cell lines from autism patients. Sequence alterations in the CpG island/promoter region of *UBE3A* were also identified in autism patients and the functional significance of these alterations is being investigated in an *in vitro* assay. The available data suggest that dysregulation of *UBE3A* gene expression in the brain may contribute to autism susceptibility and that epigenetic alterations may play an important role in autism.

Lack of association between VIPR2 gene variants and Autism Spectrum Disorders (ASDs) in Case-Control and Family Based Association Studies. X. Liu^{1,3}, J.J.A. Holden^{1,2,3}, ASD-CARC⁴. 1) Dept of Psychiatry; 2) Dept of Physiology, Queens University, Kingston, ON, Canada; 3) Autism Research Program, Ongwanada Resource Centre, Kingston, ON, Canada; 4) www.autismresearch.ca.

The etiology of ASDs is unknown, but widely accepted as resulting from the interaction of multiple genes and environmental factors. Vasoactive Intestinal Peptide (VIP) is a peptide hormone expressed in both the gastrointestinal tract and the brain. It has been shown to reduce autistic symptoms in children infused with secretin for the assessment of gastrointestinal complaints. A recent report of elevated levels of VIP in blood samples from newborns later diagnosed with autism has spurred an interest in this gene and its receptor in the etiology of ASD. Of genes involved in the VIP pathway, VIPR2 gene is of particular interest because of its abundant expression in the embryonic and postnatal brain and its location at 7q36, near the distal portion of the broad autism linkage peak found in several genome scans. A recent study with a small sample size suggested that the VIPR2 gene might play a role in susceptibility to autism. To determine whether these findings could be confirmed, we genotyped the same two polymorphisms in 180 multiplex families, 58 simplex families and more than 250 control samples. We performed both a case-control study and examined allele and haplotype transmission using FBAT, and did a genotype-phenotype association analysis based on the available ADI-R data. Our results demonstrated no deviation from the null hypothesis of no association of VIPR2 variants with autism susceptibility. We have also separately examined transmissions for paternal versus maternal alleles, transmission to affected boys versus girls, and subgrouped the multiplex families into groups with exclusively males and those with at least one affected girl. None of these subsets revealed significant deviation from the null expectation. Our interpretation of these findings is that it is unlikely that the VIPR2 gene plays a significant role in the genetic predisposition to autism. (Supported by CIHR and OMHF).

Genetic association studies in gallstone disease in North India. *B. Mittal, M. Dixit.* Dept of Genetics, Sanjay Gandhi Postgrad Inst, Lucknow, UP, India.

Background: Gallstone disease is common in western countries as well as in India. It is a multifactorial disease. The increased incidence and virulence in certain populations, high concordance in monozygotic twins, and clustering of gallstone disease in families suggest the possibility of a genetic predisposition to the disease. A prerequisite for the development of cholesterol gallstone is lithogenic bile, which is often the result of enhanced cholesterol synthesis or a reduced bile acid pool size, or both. Nucleation of cholesterol monohydrate crystals is an initial and essential step in the process of gallstone formation. In humans, several genetically derived phenotypes are responsible for variation in lipoprotein and lipoprotein metabolizing enzyme types, which in turn may affect the concentration of cholesterol in bile.

Aim: Present study was undertaken to reveal the association of apolipoprotein B XbaI, apolipoprotein HhaI, LRPAP1 intron 6 insertion (I)/ deletion (D), lipoprotein lipase HindIII, and LDL receptor AvaII polymorphisms with gallstone disease in North India.

Materials and Methods: Blood samples were collected from 100 gallstone patients and 200 ultrasonographically confirmed gallstone free healthy subjects. Genotyping was done by PCR-RFLP followed by agarose / polyacrylamide gel electrophoresis. In case of LRPAP1 insertion/ deletion polymorphism PCR products were electrophoresed directly.

Result: There were no significant differences in allele frequencies of LDLR AvaII polymorphism in patient and control group. In contrast to other studies no association of apolipoprotein 4 allele was found with gallstone disease. In LRPAP1, II genotype and I allele were significantly higher [(p=0.003) and (p= 0.013) respectively] in patients than in controls. X+ allele of Apolipoprotein B was significantly lower (p= 0.000) in patients as compared to controls. Frequency of L1L2 genotype (LPL HindIII polymorphism) was also significantly lower (p= 0.000) in patients than in controls.

Conclusion: Presence of I allele of LRPAP1 in homozygous or heterozygous form and absence of X+ allele and L1L2 genotype may confer higher risk for development of gallstones.

Serotonin System Genes and Childhood-Onset Mood Disorder (COMD). *S.A. Shaikh¹, J. Strauss¹, N. King¹, A. Vetro², E. Kiss², Z. Tamas³, C. George⁴, M. Kovacs⁴, C. Barr⁵, J. Kennedy¹.* 1) Neurogenetics, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2) Szeged University Medical Faculty, Department for Child & Adolescent Psychiatry; 3) Vadaskert Hospital, Budapest, Hungary; 4) Western Psychiatric Institute and Clinic, UPMC Health System, Pittsburgh, USA; 5) University Health Network-Toronto Western Research Institute, Department of Psychiatry, University of Toronto.

The serotonin system has been extensively studied and implicated in various neuropsychiatric disorders including mood disorders. We have investigated two of the receptors, 5HT1B and 5HT2A, and the serotonin transporter (SLC6A4). We have collected two independent samples of childhood-onset mood disorder (COMD), one in Pittsburgh consisting of 150 case-control pairs and the other in Hungary consisting of 218 small families. In our case-control analysis, we have found no association between childhood-onset mood disorder and the G861C polymorphism of 5HT1B and the T102C polymorphism of 5HT2A by allele frequencies ($\chi^2 = 0.01$; $p = 0.91$ and $\chi^2 = 1.35$; $p = 0.24$, respectively), or genotype frequencies ($\chi^2 = 0.37$; $p = 0.83$ and $\chi^2 = 1.63$; $p = 0.43$, respectively). Analysis of the 17 bp variable number tandem repeat in the second intron of the serotonin transporter gene, 5HTTVNTR, was not significant in the Pittsburgh sample (allele frequencies $\chi^2 = 3.10$; $p = 0.21$; genotypes $\chi^2 = 4.20$; $p = 0.32$).

Analysis of our Hungarian COMD families by transmission disequilibrium test (TDT) showed similar results to our case-control study with no association with 5HT1B (T102C) and 5HT2A (G861C) polymorphisms. However, analysis of the VNTR polymorphism showed preferential transmission of the 12 repeat ($\chi^2 = 4.72$; $p = 0.03$), and combining the Pittsburgh and Hungary samples for the 5HTT VNTR produced a Z score of 2.71, $p = 0.003$. Overall our examination of the serotonin 1B and 2A is mostly negative, however we found evidence that the 12 repeat allele of the 5HTTVNTR polymorphism may play a significant role in the pathogenesis of COMD. Further examination of the serotonin system, particularly the 5-HTTLPR polymorphism in a larger sample, may be warranted.

Association between the C-45T polymorphism of the Cholecystokinin Gene and Panic Disorder. S.

Tharmalingam¹, N. King¹, C. Rothe^{1,3}, D. Koszycki², J. Bradwejn², F. Macciardi¹, J.L. Kennedy¹. 1) Neurogenetics, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2) Department of Psychiatry, University of Ottawa and the University of Ottawa Institute of Mental Health Research, Royal Ottawa Hospital, Canada; 3) Department of Psychiatry, University of Munster, Munster, Germany.

Panic disorder (PD), affecting 1-3% of the population, is classified as an anxiety disorder, where individuals experience sudden onset of panic attacks and fear of future attacks. The cholecystokinin system has been previously implicated in PD, and is suggested to play a neurobiological role through its interaction with dopamine and its influence on dopamine-induced behaviour. We genotyped, using TaqMan assays and the ABI7000, the C-45T polymorphism in the Sp1 binding site of the promoter region of the CCK peptide gene located on chromosome 3pter-q12, along with four other polymorphisms found within intronic regions of the gene. We first investigated the five CCK polymorphisms in 297 individuals from 94 small nuclear families and found the C-45T promoter polymorphism to be significantly associated with PD. Our transmission disequilibrium test (TDT and s-TDT) analysing this gene in the families yielded a chi-square of 8.048 ($p=0.005$). In a second sample of case-control pairs using the same polymorphisms, individuals were matched for sex, age, and ethnicity. There was a significant difference in the distribution of alleles of the C-45T polymorphism between the 101 case-control matched pairs ($p=0.04$). The other four polymorphisms did not show any association with panic disorder. Our findings support the involvement of CCK gene in panic disorder, but further analysis of other polymorphisms in this gene or other genes of the CCK system is warranted.

Interaction of a Region on Chromosome 11q23 and the HLA-DPB1 Locus Influences Susceptibility to Ankylosing Spondylitis (AS). *J. Reveille*¹, *G. Zhang*², *M.H. Weisman*³, *J. Bruckel*⁴, *H.R. Schumacher*⁵, *M.A. Khan*⁶, *R.D. Inman*⁷, *W.P. Maksymowych*⁸, *T.M. Martin*⁹, *M. Stone*⁷, *J.T. Rosenbaum*⁹, *L. Jin*². 1) Div Rheumatology, Univ Texas Medical Sch, Houston, TX; 2) University of Cincinnati, Cincinnati, OH; 3) Cedars-Sinai Medical Center, Los Angeles, CA; 4) Spondylitis Association of America, Sherman Oaks, CA; 5) The University of Pennsylvania, Philadelphia, PA; 6) Case Western Reserve University, Cleveland, OH; 7) The University of Toronto, Toronto, ON, Canada; 8) The University of Alberta, Edmonton, AB, Canada; 9) Oregon Health & Science University, Portland, OR.

To study the interaction of chromosomal regions previously identified in a genomewide scan of familial AS susceptibility with genes of the major histocompatibility complex (MHC) and had available radiographs or reports thereof. All patients met modified New York Criteria for AS (1984). MHC genotypes were determined by oligotyping with high resolution DRB1 typing by sequence analysis. Interaction between chromosomal regions (with markers with NPL score > 1.5 identified in the genomewide linkage analysis) and MHC was studied by performing conditional analyses. The weighting of each family was based on their evidence for linkage at these markers. Two weighting schemes were used to model a positive (for gene-gene interaction) and a negative (for heterogeneity gene-gene interaction) relationship between loci on different chromosomes, respectively. Based on this conditioning scheme, the conditional allele-sharing model LOD scores were calculated by ASM computer program. 244 affected sib pairs from 180 pedigrees were analyzed, including 602 family members, of whom 424 had AS. An additional 39 pedigrees containing 129 family members (48 with AS) were included, of whom two had affected sib pairs but the other sib was not available for study and 37 were trio families (one affected proband with parents available). A region on chromosome 11 (11q23) showed statistically significant interaction with MHC.

Resegregating behaviors in the Silver Fox. A model system for mapping sociability. G.M. Acland¹, H.N. Erb¹, K. Chase², K.G. Lark², G.D. Aguirre³, L. Trut⁴, I. Oskina⁴, A. Kharlamova⁴, A.V. Kukekova¹. 1) College of Veterinary Medicine, Cornell Univ, Ithaca, NY; 2) Univ of Utah, Salt Lake City, Utah; 3) School of Veterinary Medicine, Univ of Pennsylvania, Philadelphia, PA; 4) Institute of Cytology and Genetics, Novosibirsk, Russia.

Silver Fox (*Vulpes vulpes*) strains have been bred to exhibit tame behavior like pet dogs (*Canis familiaris*), or wildtype aggressive behavior. These studies recapitulate the process in which dogs were domesticated from the Grey Wolf (*Canis lupus*), but were accomplished in 35 generations under carefully recorded observation. The resulting differences between tame and wildtype fox strains provide clear evidence for heritability of traits similar, in one case, to the normal sociability of human children, and in the other to autism and anxiety disorders. Informative pedigrees have now been developed by crossing tame and wildtype foxes, and backcrossing F1 individuals to mates from the tame population. A newly refined method of measuring behavior in these populations identified 50 binarily scoreable observations that nonredundantly and reliably distinguished behaviors of the reference populations (Tame, Wildtype, F1). Principal-components analysis was used to dissect out independent elements underlying these behaviors. PC1 accounted for 47.3% of total variance in measured traits; PC2 for 6.4 %. This system clearly discriminated tame foxes from wildtype foxes. F1 foxes yield intermediate values that extend into the ranges of both the tame and wildtype foxes. Behavioral scores PC1 and PC2 of backcross foxes cluster bimodally with one subgroup well within the tame range, and a second with values similar to those of F1 and wildtype foxes. Heritability and power analyses demonstrate strong support for a mapping project in progress to map QTLs underlying these resegregating traits. This project, utilizing microsatellite markers adapted from the canine genome and validated in the Silver Fox, holds considerable promise for identification of loci potentially important for both normal human behavior, and recognized hereditary disorders of human sociability.

Genome-wide linkage scan for the metabolic syndrome reveals a major quantitative trait locus on chromosome 15q: The Quebec Family Study. *Y. Bosse*^{1,2}, *J.-P. Després*^{2,3}, *Y.C. Chagnon*⁴, *T. Rice*⁵, *D.C. Rao*⁵, *C. Bouchard*⁶, *L. Pérusse*⁷, *M.-C. Vohl*^{1,2}. 1) Lipid Research Ctr, Laval Univ, Ste-Foy, PQ, Canada; 2) Department of Food Science and Nutrition, Laval Univ, Quebec, PQ, Canada; 3) The Quebec Heart Institute, Quebec, PQ, Canada; 4) Laval Univ Robert-Giffard Research Ctr, Quebec, PQ, Canada; 5) Division of Biostatistics, Washington Univ School of Medicine, St. Louis, MO, USA; 6) Pennington Biomedical Research Ctr, Baton Rouge, LA, USA; 7) Division of Kinesiology, Department of Social and Preventive Medicine, Laval Univ, Quebec, PQ, Canada.

The metabolic syndrome clusters multiple cardiovascular risk factors under one disorder entity. An autosomal genome-wide linkage scan was performed on 707 participants from 264 nuclear families of the Quebec Family Study in order to identify chromosomal regions harbouring genes predisposing to the metabolic syndrome. Maximum likelihood-based factor analysis was used to generate factors underlying the correlation structure among waist circumference, body mass index, plasma insulin and glucose levels, triglyceride and HDL-cholesterol levels, as well as systolic and diastolic blood pressure. Three major factors were identified and interpreted as metabolic syndrome, blood pressure and blood lipids. The metabolic syndrome factor had high factor loadings (0.4) for the eight metabolic syndrome-related phenotypes and explained 76.5% of the standardized variance. Family lines accounted for 45.6% of the metabolic syndrome factor variance. The most significant genome-wide variance component linkage with this composite factor was found on chromosome 15q, with a LOD score of 3.15 at 86 cM. Suggestive evidence of linkage (LOD 1.75) was also observed on chromosomes 1p, 3p, 3q, 6q, 7p, 19q, and 21q. These quantitative trait loci should be further explored as they may harbour genes that contribute to the underlying correlation structure among the phenotypes defining the metabolic syndrome.

Association of PTPN1 with coronary artery calcification in the Diabetes Heart Study. *K.P. Burdon^{1,2}, J.L. Bento^{1,2}, N.D. Palmer^{1,2}, C.E. Langefeld³, J.K. Campbell³, S.R. Beck³, J.J. Carr⁴, D.M. Herrington⁵, B.I. Freedman⁵, S.R. Rich³, D.W. Bowden^{1,2,5}.* 1) Center for Human Genomics; 2) Biochemistry; 3) Public Health Sciences; 4) Radiology; 5) Internal Medicine, Wake Forest University School of Medicine, Winston-Salem, NC.

The protein tyrosine phosphatase, non-receptor type 1 gene (PTPN1) encodes the PTP1B protein, a ubiquitously expressed tyrosine phosphatase involved in several pathways, including negative regulation of both insulin and leptin signaling as well as regulation of integrin and cadherin function. We have observed significant associations between PTPN1 SNPs and both diabetes and measures of insulin resistance in Caucasian and Hispanic American populations. In the Diabetes Heart Study (DHS), we have investigated the association of PTPN1 with diabetic cardiovascular disease in 706 individuals from 267 Caucasian families. Phenotypes studied include carotid intima-media thickness (IMT), coronary (CAC) and carotid (CarAC) artery calcification and lipid measures. A total of 23 PTPN1 SNPs were genotyped. A single (~88 kb) block of linkage disequilibrium (LD) was detected encompassing the entire coding region of PTPN1. To test for association, GEE1 modeling was used, with age, gender, diabetes status and smoking status as covariates. The majority of SNPs within the LD block were found to be associated with CAC (p-values ranging from <0.0001 to 0.066). Haplotypes were computed with the EM algorithm for a subset of 8 SNPs. The most frequent haplotype (frequency = 0.41) was found to contribute to increased calcium scores with a p-value of 0.039 under an additive model. This haplotype was also found to confer risk for diabetes and insulin resistance in previous studies. A second haplotype (frequency = 0.09) differed from the risk haplotype at 5 of the 8 loci and was found to contribute to decreased calcium scores also under an additive model (p = 0.027). No consistent association was detected with IMT, CarAC, or lipid measures. These results suggest that the PTPN1 locus contributes to arterial calcification and diabetic cardiovascular disease.

The interferon gamma (IFNG) gene and its interaction with smoking are associated with lung function in smokers. *K. Burkett¹, J. He¹, J.E. Connett², N.R. Anthonisen³, P.D. Paré¹, A.J. Sandford¹.* 1) James Hogg iCAPTURE Centre, UBC, St Paul's Hospital, Vancouver, BC, Canada; 2) Division of Biostatistics, School of Public Health, University of Minnesota; 3) Faculty of Medicine, University of Manitoba.

It has been suggested that interactions between genetic factors and environmental determinants such as smoking may lead to better understanding of the pathogenesis of chronic obstructive pulmonary disease (COPD), which is diagnosed mainly based on lung function. We hypothesized that the IFNG gene and its interaction with smoking are associated with lung function in smokers in the Lung Health Study (LHS). We studied 4 single nucleotide polymorphisms (SNPs) in IFNG in 1061 Non-Hispanic whites with the lowest (n = 530, FEV1 % predicted = 62.6 0.1) and the highest (n = 531, FEV1% predicted = 91.8 0.1) lung function at the beginning of the LHS. The four SNPs are rs2069707, rs1861493, rs2069718 and rs2069727. The associations were analyzed by chi-square tests and logistic regression to adjust for potential confounding factors including age, sex, research center and pack - years. The rs2069727 SNP, which is in perfect linkage disequilibrium with a polymorphism affecting IFNG expression level, was associated with low lung function. The frequencies of the higher IFNG expression GG genotype were 26.1% and 18.0% respectively in low and high lung function groups, which was significantly different before and after adjustment for confounding factors (unadjusted OR = 1.6, 95% CI 1.2 2.2, p = 0.002; adjusted OR = 1.5, 95% CI = 1.1 2.1, p = 0.009). There was a significant gene and smoking interaction with p = 0.001 for the interaction term. The ORs decreased significantly as pack-years increased; the ORs (95% CIs) were 3.3 (1.7-6.3) in smokers with 20 pack years, 1.5 (1.0-2.1) in smokers with 40 pack years and 0.8 (0.5-1.3) in smokers with 60 pack-years. There were no associations between the other three SNPs and lung function. In conclusion, cigarette smoking modifies the association between IFNG SNP and lung function in smokers. Supported by the NHLBI Lung Health Study and the Canadian Institutes of Health Research.

Mutation Analysis of DARPP-32 as a Candidate Gene for Schizophrenia. *C.-H. Chen^{1, 2}, C.-H. Li¹, H.-M. Liao¹.* 1) Dept Psychiatry, Tzu-Chi General Hosp, Hualien City, 970 Taiwan; 2) Institute of Human Genetics, Hualien City, 970 Taiwan.

Background: Dopamine- and cAMP-regulated phosphoprotein of relative molecular mass 32 kD (DARPP-32) plays a pivotal role in mediating the signal transduction of many neurotransmitters and neuromodulators in brain that are implicated in the pathogenesis of mental disorders. A recent study demonstrated significant reduction of DARPP-32 protein in the dorsolateral prefrontal cortex (DLPFC) of patients with schizophrenia when compared to controls, suggesting that DARPP-32 may be involved in the pathophysiology of schizophrenia. In view of the high heritability of schizophrenia, we hypothesized that DARPP-32 might be a plausible candidate gene for conferring schizophrenia susceptibility. Methods: We directly sequenced the genomic DNA from patients with schizophrenia to search for mutations in the exon and core promoter regions of the DARPP-32 gene and conducted a case-control association study. Results: Five molecular variants were identified, including a C-to-G substitution at the core promoter that obliterated an AP-2 transcription factor binding site; a G deletion at untranslated exon 2; a G-to-A and an A-to-G substitutions at intron 2 and intron 6, respectively; and a three-base pair deletion of AGA at exon 6 that resulted in a deletion of a glutamate at codon 135. However, no differences of allele or genotype frequencies of these variants between patients and controls were noted. Conclusions: Our data indicate that the DARPP-32 gene may not be a major susceptibility gene for schizophrenia, and the reduced DARPP-32 protein in the DLPFC of patients with schizophrenia is unlikely due to the mutations of the DARPP-32 gene.

Genetics of Gene Expression Variation in Radiation Response. *C. Correa*¹, *V.G. Cheung*². 1) School of Medicine, Univ. of Pennsylvania, Philadelphia, PA; 2) Depts of Pediatrics & Genetics, Univ. of Pennsylvania, The Children's Hospital of Philadelphia, PA. 19104, USA.

Humans are exposed to ionizing radiation (IR) through the environment and in medical settings. Much variation in IR response has been observed clinically among individuals. However, the genetic basis of this variation remains largely unknown. This is partly due to the lack of phenotypes that can be precisely measured and the difficulty of collecting family material for genetic studies. In this project, we are identifying the genetic contribution of variation in IR response by using the expression level of genes as phenotypes in lymphoblastoid cells lines from unrelated individuals and genetically identical monozygotic twins.

The focus of our study is a set of known IR responsive genes. First, we measured their expression levels at baseline and at two time-points post irradiation among unrelated individuals. We found extensive variation in the expression levels of these genes at baseline and in response to radiation. The extent of variation is greater after radiation. Second, to determine if there is a genetic component to the variation in IR-induced expression phenotypes, we measured the expression levels among 10 sets of genetically-identical monozygotic twins and compared the variance among twin pairs with the variance within twin pairs by means of the intraclass correlation coefficient (ICC). The ICC is the highest for three genes, PPM1D, FDXR and CDKN1A (ICC > 0.80). The induction of these genes is significantly ($P < 0.001$) greater among twin pairs than within twin pairs supporting that there is a genetic component to the variation in the expression levels of these genes. Further analysis shows that the distribution of the radio-response of ferredoxin reductase (FDXR), as measured by area-under-the curve for its expression level at baseline and post-IR, is distributed bimodally.

In this presentation, we will present our findings and describe our approach to dissect the genetic basis of radiation response. Similar study design can be applied to study the genetic architecture of other complex human quantitative phenotypes.

Bioinformatic assembly of the *GABRG3* gene and its role in autism spectrum disorder. *S. Curran, M. Kasahara, J. Powell, P. Bolton.* Psychological Medicine, Inst Psychiatry, London, United Kingdom.

Autism is a neurodevelopmental disorder with a significant genetic component of a complex nature. Genomic screens have demonstrated suggestive evidence for linkage to proximal chromosome 15q close to the cluster of gamma (γ)-aminobutyric acid receptor A (GABAA) subunit genes (*GABRB3*, *GABRA5* and *GABRG3*) and preliminary association studies support this. Cytogenetic abnormalities in this region have been described in several individuals with autism. The proximal portion of chromosome 15q is a complex region of the genome, containing an imprinting centre, numerous repetitive elements and duplicons. Developmental studies suggest that GABA plays an important role in neurogenesis. The subunits that make up the GABAA receptors have been shown to change during development, in particular the 3-subunit, which is present in embryonic cortex and spinal cord but not in significant amounts in adult tissues. Such transient expression of embryonic receptor types that respond to developmental signals rather than synaptic transmission may be important in neurodevelopmental disorders such as autism. The current assembly of the human genome (July 2003) for the chromosome 15 region that includes *GABRG3* is incomplete, only part of the gene is present. We have therefore attempted to assemble the complete sequence. Genome databases were searched for sequences highly homologous to *GABRG3* exonic sequences using the program *blastn* and a number of sequenced BAC and fosmid clones identified. Further searches with non repetitive sequences from the ends of these clones were used to identify additional sequences from the region. When manual assembly of these sequences was attempted, it was apparent that there is a large duplicated segment flanking exons 5 and 6. Similar low copy repeat elements can be associated with non homologous recombinational events leading to deletions and duplications. We are using a quantitative PCR dosage assay to examine copy number in this region in 145 well characterised individuals with autism spectrum disorders and their parents.

Association studies of schizophrenia with the ionotropic and metabotropic glutamate receptor genes. Y.

*Fukumaki*¹, *R. Kikuta*¹, *C. Makino*¹, *H. Shibata*¹, *H. Ninomiya*², *N. Tashiro*³. 1) Division of Disease Genes, Research Center for Genetic Information, Medical Institute of Bioregulation, Kyushu University, Fukuoka 812-8582, Japan; 2) Fukuoka Prefectural Dazaifu Hospital Psychiatric Center, Dazaifu 818-0125, Japan; 3) Department of Neuropsychiatry, Graduate School of Medicine, Fukuoka 812-8582, Japan.

Schizophrenia is a devastating neuropsychiatric disorder with a life time prevalence of about 1% of the world population. Since the glutamatergic dysfunction hypothesis was proposed for the pathogenesis of schizophrenia, we have been conducting a systematic study of associations between glutamate receptor (GluR) genes and schizophrenia. We report here genotype and haplotype association studies on two GluR genes, the NMDA receptor subunit NR2D gene, *GRIN2D*, and the metabotropic glutamate receptor mGluR5 gene, *GRM5*. [1]*GRIN2D*: We identified 13 SNPs by direct sequencing of the entire exons and the 5' upstream regions of the gene. We genotyped 200+ Japanese case-control pairs for 7 common SNPs selected from the 13 SNPs, with the average intervals, 8.35 kb. We observed no significant associations of any of the 7 SNPs with schizophrenia. However, we observed highly significant haplotype associations with the disease in 3 SNP-pairs out of all possible 21 pairs ($p = 1.09 \times 10^{-6}$, $p_{\text{corr}} = 2.29 \times 10^{-5}$, at the lowest). [2]*GRM5*: We genotyped 100 Japanese case-control pairs for 14 known SNPs of the gene with the average intervals, 42.4 kb. We observed no significant associations of any of the 14 SNPs with schizophrenia. However, we observed highly significant haplotype associations with the disease in one pair of the SNPs out of all possible 91 pairs ($p = 3.37 \times 10^{-4}$, $p_{\text{corr}} = 3.07 \times 10^{-2}$) We confirmed this significant association by expanding the sample size to 200+ ($p = 6.34 \times 10^{-5}$, $p_{\text{corr}} = 5.77 \times 10^{-3}$). We conclude that susceptibility loci for schizophrenia are probably situated within or very close to the *GRIN2D* and *GRM5* regions in Japanese.

Systematic mutation screening of protein phosphatase 1 catalytic subunit(PPP1CA) at 11q13.3 as a candidate gene for schizophrenia. *T.-W. Hung*¹, *C.-H. Chen*^{1,2,3}. 1) Institute of Human Genetics, Tzu-Chi University, Hualien, 970 Taiwan; 2) Department of Psychiatry, Tzu-Chi University Hualien, 970 Taiwan; 3) Tzu-Chi General Hospital, Hualien, 970 Taiwan.

Background: Dopamine- and cAMP-regulated phosphoprotein of relative molecular mass 32 kD (DARPP-32) was suggested to be involved in the pathogenesis of schizophrenia. Phosphorylated DARPP-32 is an inhibitor of protein phosphatase-1 (PP1). The PP1 is a major serine/threonine protein phosphatase in eukaryotic cells that regulates phosphorylation and activity of numerous physiologically important substrates, including neurotransmitter receptors, voltage-gated ion channels, ion pumps, and transcription factors. Previous studies reported that one of the catalytic subunit of PP1 is associated with schizophrenia, suggesting that PP1 is also involved in the pathogenesis of schizophrenia. The purpose of this study is to examine whether another one of the catalytic subunits of PP1-PPP1CA is also associated with schizophrenia. Methods: To test this hypothesis, we systematically screened the protein-coding sequences and promoter region of the PPP1CA gene in a sample of schizophrenic patients using direct sequencing. Results: In 48 patients we found six polymorphisms including two G to C substitution at the core promoter region (-132G/C, -63G/C); a C to G substitution at intron 3 (IVS3-8C/G); a A to G substitution at intron 4 (IVS4+48A/G); a C to T substitution at intron 5 (IVS5-10C/T) and a G to A substitution at 3' UTR (c.1113G/A), respectively. To determine their association with schizophrenia, we currently carrying out case-control study with a larger sample size.

Family-based Association Analysis of the Critical 3.4 Mb Region on 17q24 Reveals Association Between Multiple Sclerosis and the PRKCA Gene. *S.P. Kallio*¹, *J. Saarela*¹, *R. Asselta*^{1,2}, *D.C. Chen*³, *A. Jokiahho*³, *A. Palotie*^{3,4,5,6}, *L. Peltonen*^{1,7}. 1) Dept of Molec Med, National Public Health Inst, Helsinki, Finland; 2) Dept of Biol and Genet for Medic Sci, Univ of Milan, Italy; 3) Dept of Hum Genet, School of Med, UCLA, CA, USA; 4) Finnish Genome Center, Helsinki, Finland; 5) Dept of Clin Chem, Univ of Helsinki, Finland; 6) Dept of Pathology, School of Med, UCLA, CA, USA; 7) Dept of Med Gen, Univ of Helsinki, Finland.

Multiple sclerosis (MS) is a chronic neurological disorder of the CNS. An increased prevalence (200/10⁵) of MS has been documented in the region of Southern Ostrobothnia in Western Finland. We have established linkage in 28 Finnish multiplex MS families to four loci, one on 17q22-q24. We further restricted the initial 23 cM locus to a 3.4 Mb region by combining power of linkage, LD, and monitoring for haplotype sharing among affected individuals. A set of 61 SNPs covering this region was genotyped in 22 large and 42 trio families originating from the high-risk MS region. Seven SNPs showing nominal evidence for association were further genotyped in an independent set of 439 Finnish trios. A SNP located in a large intron of the PRKCA gene showed the strongest evidence for association in these trios ($p=0.003$) and in a combined subset of families originating from the high-risk region ($p=0.00009$). The association with PRKCA was recently replicated in an English MS study sample. To capture most of the variation in this region and identify the MS predisposing alleles, we genotyped 250 additional SNPs in PRKCA and 15 other genes located in the critical region and monitored for differential expression in peripheral blood lymphocytes of 8 MS cases and 9 family controls. Interestingly, in addition to the PRKCA SNP, 4 SNPs located 0.5 Mb apart, in the HELZ gene also showed some evidence for association in the complete data set. These SNPs were observed to be in LD with the originally identified PRKCA SNP. Preliminary expression data indicated no differences for the steady state transcript level of regional genes between MS cases and controls, suggesting that the associated allele does not have a direct effect on transcription, at least not in the analysed cells.

Linkage and association analyses of adiponectin serum level in Type II diabetes. *IP. Kovac¹, R.J. Havlik², D. Foley², R. Peila², A. Singleton², J. Hardy², J. Egan³, D. Taub³, B. Rodriguez⁴, K. Masaki⁴, D. Curb⁴, FW. Fujimoto⁵, AF. Wilson¹.* 1) Dept Genometrics, NHGRI, Baltimore, MD; 2) NIA, Bethesda, MD; 3) NIA, Baltimore, MD; 4) University of Hawaii, Honolulu, HI; 5) University of Washington, Seattle, WA.

Type 2 diabetes is a common genetically influenced multifactorial disorder, affecting an estimated 8.6 million Americans over age 60 alone. The expression of adiponectin, an adipocyte-derived protein, correlates negatively with total fat [Arita et al. 1999], and lowered plasma levels of adiponectin were found in patients with Type 2 diabetes [Hotta et al. 2000]. Evidence of linkage for serum levels of adiponectin (LOD = 3.2) was reported at the chromosome 14, 29cM [Commuzzie et al. 2001]. Our objective was to evaluate linkage and association of adiponectin serum levels in this candidate region, using an independent sample in which marker D14S297 (31.75cM) showed some evidence of linkage and association with Type 2 diabetes. The data were derived from a sample of older Japanese Americans with a high prevalence of diabetes living in Hawaii, including 529 siblings from 175 families. Model-independent sib-pair linkage analyses were performed on microsatellite markers D14S297, D14S1040, and D14S1032, with SIBPAL [SAGE 4.5]; covariates included age, sex, and body mass index (BMI). Allelic association analyses for each marker were performed with ASSOC [SAGE 4.5]. Genotypic association analysis compared genotypic distributions at each marker between approximate lower and upper 10-th percentile, e.g. adiponectin serum level ≤ 4 (N = 53) versus ≥ 21 (N = 52), using Monte Carlo simulation of Fisher's exact test [SAS]. There was no evidence of linkage. Some association results were nominally significant, i.e. marginal Monte Carlo genotypic association at the marker D14S1032, 23.2cM ($p = 0.05$; $p = 0.04$ when upper and lower 20%-ile were compared for this marker only). No statistical evidence persisted after adjusting for multiple testing. The relatively small sample size may contribute to the ambiguous results concerning the hypothesis that regulation of adiponectin expression may contribute to Type 2 diabetes in our population.

Independent association of the MICA and DRB1 genes with Graves' disease (GD) in Taiwanese children. *YJ. Lee^{1,3}, CY. Huang¹, MR. Chen¹, FS. Lo², CW. Dang¹, FM. Chang¹, HF. Liu¹, CC. Chu¹, M. Lin¹.* 1) Dept Pediatrics & Medical Res, Mackay Memorial Hosp, Taipei; 2) Division of Endocrinology, Department of Medicine, Chang Gung Children's Hospital, Taoyuan; 3) College of Medicine, Taipei Medical University, Taipei; Taiwan.

MICA-TM A5 and DRB1*09012 are associated with GD. This study investigated which renders the stronger association. **Methods:** 158 children with GD and 333 healthy adults were genotyped for MICA-TM microsatellite and DRB1 gene. The stronger association was investigated according to Svejgaard. **Results:** MICA-TM A5 (Factor **A**) and DRB1*09012 (Factor **B**) in patients and controls (only significant comparisons are listed in the Table. OR: odds ratio, Pc: corrected p)

Conclusion: MICA-TM A5 & DRB1*09012 are independently associated with GD & DRB1*09012 shows a stronger association.

Comparison	a	b	c	d	OR	Pc

Genome Wide Allelic Association Study of Alcohol Consumption Behavior in a Finnish Population. *P.A. Lind¹, C.J.P. Eriksson², K.C. Wilhelmsen¹*. 1) Dept Genetics, University of North Carolina, Chapel Hill, NC; 2) Department of Mental Health and Alcohol Research, National Public Health Institute, Helsinki, Finland.

Analysis of population isolates with increased allelic and locus homogeneity may facilitate the identification of genes that predispose to alcoholism. We are attempting to map susceptibility genes relevant to alcoholism phenotypes by allelic association analysis in a population from Finland. In this study, male subjects (n = 305) were either recruited during clinical treatment for alcoholism (104 cases) or by advertisements (97 cases, 104 controls). All were screened with the Alcohol Use Disorders Identification Test (AUDIT) and information regarding alcohol-related aggression was recorded. Factor analysis of the AUDIT data identified two principal components that reflect alcohol consumption and social consequences of drinking. DNAs were assembled into 23 pools based on the AUDIT factor analysis, traditional assessment of the AUDIT score and patterns of aggression. DNA pools were screened for allelic association with 811 microsatellite markers with an average spacing of 4.6 cM, and an average heterozygosity of greater than 77%. Genotype data were corrected for differential amplification, stutter peak and pool-size affects; and pair-wise analyses of pool allelic frequencies were performed. Nominally significant allele image pattern and allelic differences between pools were detected with approximately 100 microsatellites. The population was individually genotyped for 34 markers that showed the greatest evidence of allelic association ($P < 0.001$) between alcoholism phenotypes and concordance with respect to both the associated allele and the direction of association between related pools. Pool allele frequencies calculated from the individual genotype data validated the pooled results for 25 markers (74%) and a high false positive rate was observed with less robust microsatellites. We found evidence for allelic association in six chromosomal regions and the association was reinvestigated by fine mapping with additional microsatellite markers and single nucleotide polymorphism typing of eight candidate genes in these regions. SLC6A3 and ALDH1A1 showed the greatest association.

Investigation of IL-1 System Genes in Risk for Childhood-Onset Mood Disorders. *V.L. Misener¹, P. Luca¹, K.G. Wigg¹, N. King², A. Vetro³, E. Kiss³, K. Kapornai³, J.L. Kennedy², M. Kovacs⁴, C.L. Barr^{1,5}*, *The International Consortium for Childhood-Onset Mood Disorders.* 1) Toronto Western Research Institute, Toronto, ON, Canada; 2) Neurogenetics Section, Centre for Addiction and Mental Health, Toronto, ON, Canada; 3) Department for Child and Adolescent Psychiatry, Szeged University, Szeged, Hungary; 4) University of Pittsburgh, Pittsburgh, PA, USA; 5) The Hospital for Sick Children, Toronto, ON, Canada.

Inflammatory cytokines, such as IL-1, IL-6 and TNF-, induce a syndrome known as "sickness behaviour", the symptoms of which overlap considerably with symptoms typically seen in depression. This has led to the hypothesis that cytokine activity is a contributing factor in depression. While there are correlative findings to support this, the identification of functional variants of cytokine system genes conferring risk for depression would clearly establish causality. To this end, we are testing such genes as candidates for involvement in childhood-onset mood disorders, making use of a large sample of families identified through probands affected by depression in childhood, a highly familial and heritable form of depression. A study of IL-1 system genes is underway. Transmission/disequilibrium test analyses show no evidence for biased transmission of alleles of the intronic 86-bp VNTR polymorphism of the IL-1Ra gene (4-repeat: 68 times transmitted *vs.* 70 times not, $p=0.865$; 2-repeat: 71 times transmitted *vs.* 64 times not, $p=0.547$). However, for the promoter region -511C/T polymorphism of the IL-1 gene, transmission of the T allele is more uneven (91 times transmitted *vs.* 72 times not), although the transmission bias does not reach statistical significance ($p=0.137$). Interestingly, this allele was recently found to be associated with depressive symptoms in both Alzheimer's disease and schizophrenia. Based on these findings, we are now investigating a functional variant at position -31 of the IL-1 gene that is reported to be in linkage disequilibrium with the -511T allele. Additional polymorphisms of the IL-1Ra and IL-1 genes, and other IL-1 system genes, including IL-1 and the IL-1 receptors, are also being tested for association with depression in our sample.

Association studies of DTNBP1, NRG-1, RGS4, MRDS1, G72/G30 and DAAO in an extended Irish schizophrenia

case - control sample. *D.W. Morris¹, K.A. McGhee¹, K. Murphy¹, S. Schwaiger¹, J.M. Nangle¹, G. Donohoe¹, S. Clarke¹, P. Baldwin², P. Scully², J. Quinn², D. Meagher², J.L. Waddington³, M. Gill¹, A.P. Corvin¹.* 1)

Neuropsychiatric Genetics Group, Institute of Molecular Medicine, Trinity College Dublin, Ireland; 2) Stanley Research Unit, St. Davnets Hospital, Monaghan, Ireland; 3) Department of Clinical Pharmacology, Royal College of Surgeons, 123 St. Stephen's Green, Dublin 2, Ireland.

We have previously published association analyses of dysbindin (DTNBP1; Morris et al. Schizophr Res 2003, Williams et al. Arch Gen Psychiatry 2004), neuregulin-1 (NRG-1; Corvin et al. Mol Psychiatry 2004) and regulator of G-protein signalling 4 (RGS4; Morris et al. Am J Med Genet 2004) in a schizophrenia case - control sample taken from the Irish population. The sample consisted of 249 cases and 231 controls. We have since extended this sample to consist of 299 cases and 645 controls. A sample of this size provides 80% power with 95% confidence to detect association with an odds ratio of 1.6. We have used this more powerful sample to test associations we previously reported at the DTNBP1, NRG-1 and RGS4 loci. In addition we have tested for evidence of association at the MRDS1 (OFCC1) locus at 6p24.3, at the G72/G30 locus at 13q34 and at the D-amino acid oxidase (DAAO) locus at 12q24. The results in brief are; DTNBP1 association with the P1655-P1635-SNPA haplotype (sim p = 0.006). NRG-1 no association with the HapBIRE haplotype or the core haplotype first reported in the Icelandic population. RGS4 association with RGS4-4 RGS4-7 RGS4-18 haplotype (p = 0.04). MRDS1 no evidence of association. G72/G30 - single marker associations with rs3916965 (p=0.005) and rs2391191 (p=0.01) in addition to haplotype associations with these markers. DAAO - association with rs2111902 (p=0.02) and rs3918346 (p=0.003) and haplotype associations with these markers.

The dopamine transporter gene (DAT1) core promoter polymorphism -67T variant is associated with schizophrenia. *M. Ohadi¹, F. Fadaei², N. Khodayari¹, M. Garshasbi¹, A. Rahimi³, L. Hafizi¹, A. Ebrahimi¹, H. Najmabadi¹.* 1) Genetics Research Center, Social Welfare and Rehabilitation Sciences University, Daneshjoo Blvd. Koodakyar St., Evin, Tehran 19834, Iran; 2) Razi Psychiatric Center, Shahr-e-Ray, Tehran 18664, Iran; 3) Sina Hospital Psychiatric Center, Hamedan Medical Sciences University, Hamedan, Iran.

Dysfunction of the central dopaminergic neurotransmission has been suggested to play an important role in the etiology of schizophrenia. The dopamine transporter (DAT1) mediates the active reuptake of dopamine from the synapses and thereby plays a key role in the regulation of the dopaminergic neurotransmission. In this study, we sought to determine the possible association of the DAT1 gene core promoter polymorphism -67A/T with schizophrenia in a case/control study. The allele and genotype frequencies of the polymorphism were studied in 100 patients and 100 controls, which were matched on the basis of sex, age and ethnicity. The genotype frequencies in the patients group were as follows: AA 29%; AT 59%; TT 12% vs. the genotype frequencies in the control group: AA 57%; AT 38%; TT 5% [$\chi^2 = 16.54$, $df = 2$, $OR = 2.25$ (95% CI 1.46-3.45, $p = 0.0003$)]. For the first time, these findings provide tentative evidence for the contribution of the DAT1 gene core promoter polymorphism to the etiopathophysiology of schizophrenia at least in the Iranian male population that we studied. Replication studies of independent samples and family-based association studies are necessary to further evaluate the significance of our findings.

Further investigation of a potential psoriasis susceptibility locus on chromosome 5q31. *L. Samuelsson¹, C. Friberg¹, S. Nilsson², J. Wahlstrom¹.* 1) Clinical Genetic, Univ Gothenburg, Sahlgrenska Univ Hosp/East, Gothenburg, Sweden; 2) Chalmers University of Technology, Gothenburg, Sweden.

Psoriasis is a chronic inflammatory disease of the skin with both genetic and environmental risk factors. In a genome-wide screen on a Swedish family set several candidate regions were identified. With the aim of decreasing the heterogeneity of the family set a stratification criteria based on joint involvement was applied. This led to increased non-parametric linkage values (P 0.01) for five chromosomal regions including one on chromosome 5. On chromosome 5, the microsatellite marker reaching highest NPL-value in the genome scan (P = 0.008) was D5S816. This marker is located at chromosome 5q31, a region where many genes involved in immune and inflammatory system are located. The same region has also been suggested to harbor susceptibility genes for several inflammatory or autoimmune diseases including Crohn disease, atopic dermatitis, rheumatoid arthritis and celiac disease. Of these, both Crohn and celiac disease have been reported to have an increased prevalence in individuals with psoriasis. There is also a possibility of a shared disease-gene between rheumatoid arthritis and psoriasis arthritis since the highest linkage value was reached in the cohort of families with psoriasis and joint involvement. All these potential susceptibility loci are located within 12 cM from D5S816. We have therefore started to investigate the chromosome 5q31 region more closely in a psoriasis cohort with the attempt to confirm our first finding. We have genotyped additional microsatellite- and SNP markers across the region and evaluated the result by family-based linkage- and association analysis.

Maximizing the use of founder effect in search for genetic predisposing loci for schizophrenia. *T. Varilo*^{1, 2}, *R. Arajarvi*^{1, 2}, *T. Hiekkalinna*¹, *T. Partonen*^{1, 2}, *J.D. Terwilliger*³, *J. Lonnqvist*^{1, 2}, *L. Peltonen*^{1, 2, 4}, *T. Paunio*^{1, 2}. 1) Depts. of Molecular Medicine, and Mental Health and Alcohol Research, National Public Health Institute, Haartmaninkatu 8, 00290 Helsinki, Finland; 2) Depts. of Medical Genetics and Psychiatry, University of Helsinki, Haartmaninkatu 2b, 00029 HUS, Helsinki, Finland; 3) Dept. of Psychiatry and Columbia Genome Center, Columbia University, 1150 St Nicholas Ave, New York 10032, USA; 4) Dept. of Human Genetics, David Geffen School of Medicine, University of California, Los Angeles, 90095-7088, USA.

Anticipated allelic and locus heterogeneity hampers attempts to identify predisposing loci for common, polygenic diseases. We have previously carried out three genome-wide scans in samples of Finns ascertained for schizophrenia from highly extensive national epidemiological registers. We have focused on an outlying small founder municipality on the eastern border of Finland with a well established 300-year-old population history. Genetic analysis of schizophrenia families from this isolate have provided evidence of putative predisposing loci on several chromosomes 1q, 2q, 4q, 9q and X, a result typical for complex diseases. In order to diminish genetic and environmental heterogeneity to its minimum, we proceeded by selecting families from municipality level from separate villages, and divided our families based on the genealogy and established population history. We observed some divergence between the numbers of the alleles in the microsatellite markers of the Southern and the Northern villages implying for genetic diversity between these populations. 26 families informative for schizophrenia originating from the Southern villages highlighted the highest genome-wide evidence for linkage on chromosome 4q ($Z_{\max} = 3.3$ versus < 1 in the families from the Northern villages), whereas 15 families from the Northern villages provided most of the linkage information on 9q ($Z_{\max} = 2.64$ versus 1.18 in the Southern villages). The linkage to 4q23 is of particular interest since we recently reported a susceptibility locus for verbal learning and memory to the same chromosomal region (Paunio et al. 2004).

Lack of association of the mitochondrial aspartate/glutamate carrier *SLC25A12* gene with autism or with markers of mitochondrial dysfunction in autistic patients. A.M. Vicente¹, C. Correia¹, A. Coutinho¹, L. Diogo², M. Grazina³, C. Oliveira³, G. Oliveira². 1) Instituto Gulbenkian de Ciência, Oeiras, Portugal; 2) Hospital Pediátrico de Coimbra, Coimbra, Portugal; 3) Centro de Neurociências, Coimbra.

In a population-based study of autistic children, we have previously found hyperlactacidemia in 20.3% of the tested patients, suggestive of mitochondrial dysfunction. Altered mitochondrial function will result in defects in the brain bioenergetic metabolism and in impaired CNS development and functioning, and therefore may be underlying autism. Mitochondrial disease was confirmed in 7.2% of the autistic patients with hyperlactacidemia and the absence of mtDNA mutations, indicates involvement of nuclear genes. A strong association of autism with two SNPs within the *SLC25A12* gene, a nuclear gene encoding a mitochondrial aspartate/glutamate carrier (AGC1), has been found. AGC1 plays an important role in the malate/aspartate shuttle, which regulates the cytosolic redox state controlling lactate to pyruvate conversion. We examined the association of two *SLC25A12* polymorphisms, rs2056202 and rs11757, with autism and markers of mitochondrial dysfunction, namely hyperlactacidemia and high lactate/pyruvate ratio. We found no transmission disequilibrium of either SNP alleles (rs2056202: $Z=0.873$; $P=0.383$; rs11757: $Z=0.816$; $P=0.414$) or haplotypes ($\chi^2=3.05$; 3df; $P=0.384$) in a sample of 241 nuclear families. No association of either SNP with lactate levels (rs11757: $P=0.404$; rs2056202: $P=0.5323$) or with lactate/pyruvate ratio distribution (rs11757: $P=0.2561$; rs2056202: $P=0.8784$) was found in 199 autistic subjects. Finally, no significant differences in allele or haplotype frequencies were found between autistic patients with confirmed mitochondrial disorder and healthy controls. In conclusion, we show that *SLC25A12* polymorphisms can not explain the high frequency of mitochondrial dysfunction markers in our sample and we do not replicate the recent findings of an association of rs2056202 with autism.

Identification of a common 3' UTR haplotype in AQP5, a candidate gene for human asthma. *S.L. Zimmerman, A.A. Staton, C.M. Krane.* Dept Biol, Univ Dayton, Dayton, OH.

Aquaporins (AQPs) are water channels that allow for the vectorial movement of osmotically driven water across cell membranes. AQP5 is a water selective channel expressed in the lacrimal, salivary, and airway submucosal glands, corneal and airway epithelium, and in type 1 pneumocytes. Genetically targeted AQP5 knockout mice are hyperresponsive to cholinergic-stimulated bronchoconstriction, a hallmark of asthma. Therefore, we hypothesized that a subset of individuals with clinical features of asthma and bronchoconstriction will have DNA mutations within the AQP5 gene. SSCP was used to screen DNA from 100 asthmatic patients, and 50 individuals from the population (25 Caucasian and 25 African American) for nucleotide variation in 368 ntds. of the 5' flanking region, 5' and 3' UTRs, and exons 1-4 of the hAQP5 gene. Six nucleotide variants were identified. A TA-GC transition identified in intron 1 and a GC-CG transversion in intron 2 are present in the asthmatic population with allele frequencies of 3.0% and 0.5% respectively. A GC-AT transition in exon 4 (2.0%) results in a synonymous substitution (Thr-Thr). Three SNPs were identified in the 3' UTR; an AT-TA inversion (2.0%) and two AT-GC transitions. The AT-GC transitions occur in linkage disequilibrium with a haplotype frequency of 9.5%/10.0%/6.0% in the asthmatic/ Caucasian/ African American populations. The final A to G change alters a conserved adenosine residue located two nucleotides downstream of the polyadenylation-cleavage site, which is considered to be critical in the formation of the polyadenylation complex. No individual was identified as a compound heterozygote or homozygote for the variants screened. An allelic discrimination method using real-time PCR was also developed to identify the 3' UTR polymorphisms in large-scale screens. **CONCLUSION:** A genetic mutation screen of the human AQP5 gene identified six nucleotide variants, including a common 3' UTR haplotype for which 18.0% of the population is heterozygous. The AT-GC transition variant located within the region of assembly of the polyadenylation complex may be functionally important in the post-transcriptional regulation of the AQP5 gene.

Replication and CpG Methylation Mediate FRAXA (CGG)_n Deletions in Primate Cells. *M.R. Blondin^{1,2}, K. Nichol Edamura¹, C.E. Pearson^{1,2}*. 1) Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Molecular & Medical Genetics, University of Toronto, Toronto, Ontario, Canada.

Instability of the fragile X (FRAXA) CGG tract is known to be sensitive to both repeat length, purity and CpG methylation. Tracts 25 pure repeats can be unstably transmitted, but expanded and aberrantly methylated tracts (even heterogeneous patterns) are somatically stable. It has been suggested that for germline and somatic tissues, the absence of aberrant CpG methylation may enhance CGG deletions. For example, FRAXA males have only premutation CGG lengths in their sperm and rare high-functioning methylation mosaic FRAXA patients display high-levels of CGG length heterogeneity.

Using an SV40 primate DNA replication system, it was possible to investigate the effect of repeat length, direction and location of replication initiation, as well as CpG methylation upon CGG repeat stability in cells. Deletions were observed with 53 CGG repeats when replication was initiated proximal to the repeat tract using CGG strand as the lagging strand template. Replication mediated the presence of deletions, as no mutations were observed in the absence of replication. When replication was initiated further from the repeat while maintaining CGG as the lagging strand template or with templates using CCG as the lagging strand template, regardless of location of replication initiation, deletions were not observed. CpG methylation of the unstable template stabilized the repeat tract, decreasing the number and magnitude of deletion events. Templates with 20 CGG repeats were stable under all circumstances. These results reveal that CGG deletions occur during replication and are sensitive to replication fork dynamics, tract length, and CpG methylation.

Connections between FMRP and Rac1 pathways in mammalian cells. *M. Castets*¹, *A. Schenck*¹, *E. Bechara*¹, *H. Moine*², *E.W. Khandjian*³, *T. Rabilloud*⁴, *J.L. Mandel*¹, *B. Bardoni*¹. 1) Department of Molecular Pathology, IGBMC, ILLKIRCH, FRANCE; 2) IBMC, UPR 9002 CNRS, STRASBOURG, FRANCE; 3) Universite Laval, CHUQ, Quebec, CANADA G1L 3L5; 4) CEA, DRDC, LBCP, Grenoble, FRANCE.

Fragile-X syndrome, the most common form of inherited mental retardation, is caused by the absence of FMRP, a RNA-binding protein implicated in the regulation of mRNA translation and/or transport. A few hundreds of putative mRNA targets has been identified, but the specificity of interaction between FMRP and most of these mRNAs remains to be confirmed. Moreover, the consequences of the absence of FMRP upon expression of the corresponding proteins, as well as correlations with phenotypic features, are not fully determined. Using genetic analyses in *Drosophila*, we recently showed that dFMR1 is linked via dCYFIP, one of its interactor, to dRac1 pathway. Rac1 is a key regulator of actin cytoskeleton dynamics, with a well-established role in maturation and maintenance of actin-rich synaptic structures called dendritic spines. Strikingly, one of the main abnormalities observed in patients brain is an abnormal shape and number of these spines. To study Rac1-FMRP connection(s), we have established here a cellular model consisting of mouse fibroblasts cell lines stably expressing *FMR1* or not. Using this model, we demonstrate that FMRP-Rac1 link does exist in mammalian cells and we characterize parts of the molecular mechanisms connecting the two proteins. We show that activation of Rac1 by PDGF induces relocalization of FMRP and some of its partners close to actin structures called actin rings, which are involved in membrane protrusions. Moreover, Rac1-induced actin remodeling is enhanced in *FMR1* null fibroblasts. This phenotype is correlated with alterations in the level of proteins involved in Rac1 downstream signaling. FMRP binds with high affinity to the mRNA encoding one of these proteins, and is then very likely to negatively regulate its translation. Thus, we propose that the molecular mechanisms unraveled here, pointing to FMRP as a modulator of actin dynamics, could explain dendritic spine abnormalities and subsequently cognitive impairment in patients suffering from Fragile-X syndrome.

Association of Nucleotide Variations in The Apolipoprotein B48 Receptor Gene (APOB48R) with Plasma Total Cholesterol Levels in Hypercholesterolemic Individuals. *T. Nakajima*¹, *Y. Fujita*^{1, 2}, *Y. Ezura*¹, *A. Mi-i*^{1, 2}, *T. Bujo*³, *T. Kaneko*⁴, *K. Kamimura*⁴, *Y. Iino*², *Y. Katayama*², *S. Oikawa*², *Y. Saito*³, *M. Emi*¹. 1) Dept. Molecular Biology, Inst. Gerontology, Nippon Medical School, Kawasaki, Japan; 2) Dept. Internal Medicine, Nippon Medical School, Tokyo, Japan; 3) Departments of Genome Research and Clinical Application, and, of Clinical Cell Biology, Chiba University Graduate School, Chiba, Japan; 4) Awa Medical Association Hospital, Chiba, Japan.

Multiple factors predispose to the phenotypic features of high serum cholesterol levels, though details are not clearly defined yet. Here we investigated a possible association between the genotypes of variations in the apolipoprotein B48 receptor gene (APOB48R) and plasma cholesterol levels in 352 adult hypercholesterolemic patients in Japan. Six variations in APOB48R including c.1036-1062/del27 and A419P were analyzed for the phenotypic association to the age and gender-adjusted levels of total cholesterol (T-Cho), LDL-cholesterol (LDL-C) and HDL-cholesterol (HDL-C). Analysis of variance (ANOVA) with linear regression analysis detected a significant correlation between the genotypes of the A419P variation and the adjusted T-Cho levels ($r = 0.15$, $p = 0.007$). T-Cho levels among three genotypically categorized individuals, i.e., 265 homozygous A-allele carriers (243.4 \pm 21.4 mg/dl), 78 heterozygous carriers (247.9 \pm 23.7 mg/dl) and 9 homozygous P-allele carriers (263.1 \pm 21.1 mg/dl) indicate a co-dominant T-Cho highering effect of the minor C-allele. Similar effect was detected for c.1036-1062/del ($r = 0.13$, $p = 0.015$). Linkage disequilibrium (LD) analyzed on 8 variations including the neighboring loci indicated a significant LD within the locus. These results indicate that genetic variations in APOB48R are the important factors affecting lipoprotein phenotypes of the hypercholesterolemia. Our data providing a new insight for etiological studies of the hypercholesterolemic diseases may suggest a novel aspect of the mechanism that has to be considered in its pathogenesis and modifications in clinical manifestations.

***Drosophila* VDAC: A model system to study mitochondrial function.** *B.H. Graham, E. Alesii, W.J. Craigen.*
Department Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

Voltage-dependent anion channels (VDACs) are a family of small pore-forming proteins of the mitochondrial outer membrane found in all eukaryotes. VDACs play an important role in the regulated flux of metabolites between the cytosolic and mitochondrial compartments and three distinct mammalian isoforms have been identified. The specific physiologic and potential pathophysiologic roles of the various isoforms are not understood, but animal and cell culture experiments suggest that the various isoforms function in apoptosis, learning and reproduction. Annotation of the *Drosophila melanogaster* genome has revealed three putative VDAC isoforms (*CG17137*, *CG31722-PA*, *CG31722-PB*) closely linked to the previously reported *Drosophila* VDAC (*porin*). Molecular characterizations reveal complex developmental and adult sex-specific expression patterns for these genes. When expressed in yeast deficient for YVDAC, *porin* and *CG17137* rescue a conditional-lethal phenotype. Electrophysiological characterization of these proteins in reconstituted systems demonstrates a differential ability to permeabilize lipid bilayers and liposomes. Analysis of flies homozygous for hypomorphic P element alleles of *porin* or with knockdown of *porin* expression *in vivo* by RNAi reveal abnormal phenotypes including partial lethality and altered viability, neuromuscular dysfunction and male infertility-phenotypes reminiscent of mouse VDAC mutants. Transgenic expression of *porin* in the homozygous, hypomorphic background rescues the partial lethality and neuromuscular phenotypes. These studies demonstrate that *Drosophila* VDAC homologs have retained important aspects of VDAC structure and function, warranting further studies to utilize this genetic model system in delineating fundamental conserved roles of VDACs and mitochondria in eukaryotic cell function.

Investigation of polymorphisms in genes involved in mitochondrial function and oxidative phosphorylation for association to AD. *R.T. Perry¹, H. Wiener¹, L.E. Harrell¹, D. Blacker², R.E. Tanzi², M. McInnis³, S.S. Bassett³, R.C.P. Go¹.* 1) Univ Alabama at Birmingham, Birmingham, AL; 2) Massachusetts General Hospital, Charlestown, MA; 3) Johns Hopkins University, Baltimore, MD.

The brain is noted for its high oxygen consumption and the mitochondria is the location for cellular oxidative phosphorylation (OXPHOS). Normal mitochondrial function is important in neuronal development and structure, including affecting axonal and synaptic activity, however, mitochondrial respiration is the chief source of ROS in the cell. There is increased oxidative damage to nucleic acids and mitochondria in AD brains due to free radicals and ROS. Mitochondrial dysfunction is a hallmark feature of A-induced neuronal toxicity in AD. Recent studies using microarray technology to examine the differential expression of thousands of genes in the brains of mice overexpressing APP compared to normal mice, have identified a set of genes that are involved in mitochondrial energy metabolism and programmed cell death pathways. We recently reported the significant associations of two single nucleotide polymorphisms (SNPs) in the SOD2 gene, a key enzyme involved in the detoxification of the superoxide radical, to AD patients in the NIMH AD Genetics Initiative cohort and to an African-American case-control data set. Interestingly, the SOD2 gene is located at 6q27, a chromosomal candidate region of interest identified in AD genomic scans. Because of the above evidence, we have genotyped polymorphisms in additional genes shown to be important for normal mitochondrial function and nuclear and mitochondrial OXPHOS genes. Some of the nuclear genes reside in chromosomal candidate gene regions detected in the genomic scan we reported on last year. We will present the results of the genotypings of the SNPs in these genes at the meeting and discuss what role they may play in AD pathogenesis.

Genetic screen for mitochondrial phenotypes in mouse embryonic stem cells. *C. Stromberger, B.H. Graham, W.J. Craigen.* Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

Mitochondrial encephalomyopathies are important causes of mental retardation and multisystem disease in humans. Recent epidemiological evidence suggests that the minimal prevalence of mitochondrial diseases is 1 in 8500. Despite important insights into the clinical, biochemical, and molecular characterization of these disorders, specific genetic etiologies have been identified in only a minority of cases, and the underlying molecular pathogenesis remains poorly understood, with virtually no effective therapies available. We have devised a strategy for performing a genetic screen in mouse embryonic stem (ES) cells designed to identify genes that are important for mitochondrial function and that are potential etiological candidates for mitochondrial diseases. ES cells mutagenized by a retroviral-mediated promoter-trap strategy are screened by fluorescence-activated cell sorting (FACS) for abnormal mitochondrial phenotypes using fluorescent markers for mitochondrial mass and mitochondrial membrane potential. A small scale, pilot mutagenesis experiment has been performed and has resulted in the isolation of a promoter-trap clone that demonstrates a 31% decrease in the mean fluorescence for the mitochondrial mass marker and a 53% increase in mean fluorescence for the mitochondrial membrane potential marker. This result demonstrates that this approach can result in the isolation of mutant ES clones with potential aberrant mitochondrial phenotypes as suggested by fluorescent markers. By combining the genetic tractability of mouse ES cells with the high-throughput screening capacity of FACS, this proposal offers a novel, rapid approach for identifying genes important for mitochondrial function in a mammalian system well suited for studying mitochondrial biology. The identification of abnormal mitochondrial phenotypes in mutagenized mouse ES cells offers the promise of identifying candidate genes for human disease, generating new animal models for studying the pathophysiology of mitochondrial disease and delineating potential therapeutic targets.

Genetic evidence for a mitochondrial etiology of Alzheimer Disease (AD). *D. Wallace, E. Ruiz-Pesini, P. Coskun.* MAMMAG, Univ of California, Irvine, Irvine, CA.

The genetic etiology of late-onset AD remains unknown, though multiple studies have reported defects in mitochondrial oxidative phosphorylation (OXPHOS). We have discovered a germline mitochondrial DNA (mtDNA) mutation in the tRNA^{Gln} gene at np 4336 that is present in 5-7% AD patients but 0.4% controls, and that ancient cold-adaptive mtDNA missense mutations which uncouple mitochondrial OXPHOS and increase heat production are protective of AD, presumably because they reduce mitochondrial reactive oxygen species (ROS) production. Mitochondrial ROS induces somatic mtDNA mutations, and we have found a 15 fold increase in mtDNA rearrangements in AD brains. Moreover, we have discovered that the mtDNA control region (CR) mutation T414G, which affects the light (L)-strand promoter, is present in 65% of AD brains but 0% controls and that all mtDNA CR mutations are increased 63% in AD brains {79% in 59-69 year old (YO) patient brains, 18% in 70-79 YOs, and 130% in over 80 YOs}. Moreover, certain mtDNA mutations, such as the AD-specific T477C, can increase to 70-80% of the AD brain mtDNAs in the 70-79 YOs. Finally, the mtDNA L-strand transcript for ND6 and the mtDNA copy number are reduced 50% in AD brains. These observations indicate that AD is the result of the accumulation of somatic mtDNA mutations which result in OXPHOS deficiency, synaptic loss and dementia; a conclusion supported by recent reports that ApoE 4 and A increase mitochondrial ROS production.

Phenotypic, genetic and developmental characterization of recessive ENU-induced mouse models of cleft palate.

*B.C. Bjork*¹, *A.R. Vieira*², *L. Van Parijs*³, *J.C. Murray*², *D.R. Beier*¹. 1) Div. Genetics, Brigham & Women's Hospital, Boston, MA; 2) Dept. Pediatrics, The Univ. of Iowa, Iowa City, IA; 3) Center for Cancer Research, MIT, Cambridge, MA.

We observe a large spectrum of recessive phenotypes similar to human congenital disorders, including several craniofacial defects, in a late embryonic ENU mutagenesis screen. Clefting occurs in many known mouse mutants, but those with isolated clefts are ideal models of human non-syndromic cleft lip/palate (NSCL/P) (1/500-1000 live births). We have identified the *cleft palate only 1* (*cpo1*; isolated cleft secondary palate) and *curly tail/cleft palate* (*ctcp*; cleft secondary palate and/or a curly tail) mutations that are excellent such models.

The *cpo1* mutant phenotype is caused by a mutation that affects splicing efficiency of a zinc finger transcription factor on chr 4 (Hs. 1p36). A specific defect in palatal shelf elevation is evident upon histologic evaluation of *cpo1* mutants. *cpo1* gene expression during craniofacial development is consistent with its playing an important role in palatogenesis. 1p36, near *CPO1*, has been implicated in the etiology of human non-syndromic clefting. We identified three potential etiologic missense mutations in a screen of 200 NSCL/P cases from Iowa and the Philippines that are not observed in 200 controls. A *CPO1* haplotype is in strong linkage disequilibrium with Filipino non-syndromic cleft lip only and shows a weaker association with Iowa non-syndromic cleft palate only, thereby supporting an important role for the *CPO1* gene in the complex etiology of NSCL/P.

We identified a causative nonsense mutation in a novel protocadherin gene on chr 3 (Hs. 4q28) in *ctcp* mutants. *ctcp* gene expression during development is consistent with the mutant phenotype. Identification of downstream target genes and interacting proteins for these genes is in progress. We are also utilizing lentiviral-expressed RNAi to rapidly knock down these genes in mouse embryos and provide confirmation of the etiology of these ENU-induced mutations.

Mouse knockout analysis confirms and elucidates regulators of cell proliferation. *C. Friddle, R. Finch, A. Abuin.*
Lexicon Genetics Inc., The Woodlands, TX.

Deletion of Ku80 (aka Ku86) results in the decreased proliferative capacity of the affected cells (Vogel et al. 1999), illustrating the role of Ku80 as a positive regulator of cell proliferation. Loss of p53 allows fibroblasts to continue replicating past the point at which wildtype cells normally cease to divide (Reddell 1998), showing that p53 is a negative regulator of cell proliferation.

Despite the clear importance of these two proteins as regulators of cell proliferation, their mode of biological function, via protein-protein interactions, has proven very difficult to modulate by traditional pharmaceutical compounds (Chene 2004). We seek to circumvent this difficulty by identifying downstream members of the cell proliferation pathway that meet more traditional criteria for pharmaceutical intervention (i.e. 'druggable', Zambrowicz and Sands 2003).

Using the Affymetrix U74v2 chips, we screened for candidate genes that were up- or down-regulated in Mouse Embryonic Fibroblasts deficient in p53 or Ku80. Fibroblasts were cultured from p53 and Ku80 $+/+$ and $-/-$ embryos as previously described (Lim et al. 2000) and RNA was extracted. Comparison of RNA expression levels in two knockout samples versus four wildtype samples yielded dozens of genes whose expression levels were markedly changed. However, substantial changes in gene expression do not demonstrate a causative role in the pathway or disease.

Candidate genes that possess druggable protein domains in addition to substantial changes in gene expression were queued for mouse knockout analysis as part of our Genome5000 program. Knockouts were generated using either homologous recombination or our OmniBank library of gene-trapped mouse embryonic stem cells (www.mouseknockout.com). The phenotypic data presented here demonstrates that at least some of the candidate genes we identified as potential regulators of cell proliferation play a causative role and that the specific function of a gene in this pathway cannot be predicted by the direction and magnitude of the changes in gene expression. Mouse knockouts prove to be a powerful tool for both confirming the role of a gene in a disease process and determining its normal function.

A psoriasis-associated, synonymous SNP of the corneodesmosin (CDSN) gene affects transcript stability by altering the affinity for an RNA binding-protein. *F. Capon¹, P. Hobby², M. Allen³, A.D. Burden⁴, D. Tillman⁴, J.N. Barker³, R.C. Trembath¹.* 1) Dept of Genetics, University of Leicester, Leicester, United Kingdom; 2) The Randall Institute, King's College, London, United Kingdom; 3) St Johns Institute of Dermatology, Kings College, London, United Kindom; 4) Department of Dermatology, Western Infirmary, Glasgow, United Kingdom.

Psoriasis is a common skin disorder presenting with a multifactorial aetiology. Genome scans have provided compelling evidence for a major disease susceptibility locus on chromosome 6p21 (PSORS1) and refinement studies have defined a critical interval containing three highly polymorphic genes (HLA-C, HCR and CDSN) that carry psoriasis-associated alleles. We have previously obtained genetic evidence supporting a role for CDSN variation in psoriasis susceptibility. On this basis, we have now undertaken an assessment of CDSN SNP biological impact. We observed that the SNPs that are exclusive to psoriasis-associated CDSN haplotypes are located in gene regions implicated in the stabilization of RNA transcripts. CDSN being over-expressed in psoriatic lesions, we hypothesised that disease-associated intragenic SNPs may affect the rate of mRNA decay. Using transfection-based assays, we were able to demonstrate that the stability of mRNAs transcribed from CDSN risk haplotypes was increased by twofold. Site-directed mutagenesis showed that a single synonymous SNP (CDSN*971T) accounts for the augmented RNA stability. CDSN*971T localises to a RNA stability motif and UV cross-linking analysis demonstrated that it affects the affinity for a 39kDa RNA binding protein. Modelling of the corneodesmosin three-dimensional structure indicated that amino-acids modified by substitutions in cis of CDSN*971T are exposed on the protein surface, where they might alter corneodesmosin antigenicity. Finally, association analyses showed that haplotypes bearing CDSN*971T confer psoriasis susceptibility in a wide range of ethnic groups.

Hyperprolinemia is a risk factor for schizoaffective disorder. H. Jacquet¹, C. Demily^{1, 2}, E. Houy^{1, 2}, B. Hecketsweiler³, J. Bou¹, G. Raux¹, J. Lerond⁴, G. Allio², S. Haouzir², A. Tillaux⁵, C. Bellegou², G. Fouldrin², P. Delamillieure⁶, S. Dollfus⁶, T. D'Amato⁴, M. Petit^{1, 2}, F. Thibaut^{1, 2}, T. Frebourg¹, D. Champion^{1, 2}. 1) Inserm U614, Faculty of Medicine, Rouen, France; 2) Department of Psychiatry, Rouvray Psychiatric hospital and Rouen University Hospital, 76031 Rouen, France; 3) Department of Biochemistry, Rouen University Hospital, 76031 Rouen, France; 4) EA 3092, University Claude Bernard, IFR Neurosciences Lyon, 69677 Bron, France; 5) Dieppe Hospital, 76200 Dieppe, France; 6) Centre Esquirol, Caen University Hospital, 14000 Caen, France.

DNA sequence variations within the 22q11 DiGeorge chromosomal region (DGCR) are likely to confer susceptibility to psychotic disorders. In a previous report we identified several heterozygous alterations, including a complete deletion, of the proline dehydrogenase (*PRODH*) gene which were associated with moderate hyperprolinemia in a subset of DSM III schizophrenic patients. We have now conducted a case-control study including 114 control subjects, 188 patients with schizophrenia, 63 with schizoaffective disorder and 69 with bipolar disorder to determine whether hyperprolinemia is associated with increased susceptibility for any of these psychiatric conditions. We report that, taking into account a confounding effect due to valproate treatment, hyperprolinemia is a risk factor for DSM III schizoaffective disorder ($p= 0.02$, OR= 4.6, 95% CI 1.3-16.3). We did not detect 22q11 interstitial deletions associated with DiGeorge syndrome among the 320 patients included in this sample and we found no association between common *PRODH* polymorphisms and any of the psychotic disorder. In contrast, we found that five rare *PRODH* alterations (including a complete *PRODH* deletion and four missense substitutions) were associated with hyperprolinemia. In several cases, two variations were present simultaneously, either in *cis* or in *trans* in the same subject. Eleven from 30 hyperprolinemic subjects bore at least one genetic variation associated with hyperprolinemia. This study demonstrates that moderate hyperprolinemia is an intermediate phenotype associated with certain forms of psychosis.

Novel NOD2 Deletion in an Inflammatory Bowel(IBD) Patient. *R. Colliton¹, D. Melvin¹, E. Fan¹, R. Baldassano², B. Kamath², K. Loomes², D. Piccoli², C. Stolle².* 1) Pathology and Lab Medicine, Children's Hospital of Phil, Philadelphia, PA; 2) G.I. and Nutrition, Children's Hospital of Phil, Philadelphia, PA.

Crohn disease (CD) and ulcerative colitis(UC) are chronic inflammatory bowel diseases(IBDs)that are usually easily differentiated from one another based on clinical findings. In approximately 10% of cases, classification remains difficult. The NOD2 gene encodes a protein involved in bacterial recognition by monocytes and has been identified as one of the Crohn disease susceptibility loci. Three SNPs in the NOD2 gene,(R702W, G908R and 1007fs) have been associated with CD but not UC. We have screened a population of IBD patients for these SNPs using PCR and DNA sequencing analysis. In the course of screening, DNA from one patient with severe IBD failed to amplify with primers specific for the 3' end of exon 4 (ie. the R702W SNP), while exons 8 and 11 amplified. To determine whether a polymorphism under one of the primers was responsible for the PCR failure, primers for the 3' end of exon 4 were redesigned. The redesigned primer sets also failed to amplify suggesting a homozygous intragenic deletion of NOD2. Since primers for exons 5 and for the 5' end of exon 4 amplified, the breakpoints of the deletion must be limited to the 3' end of exon 4 and the 3' end of intron 4, a region of approximately 4.2 kb. To further delineate the extent of the deletion we designed a series of primers along IVS4. We have thus far been unable to amplify across the presumed breakpoint, indicating that most or all of this region is deleted. The exact breakpoints of this deletion are currently being determined but are likely to include the 3' end of exon 4 and at least 700bp of intron 4. A mutation of this nature has not yet been reported and we hypothesize that its effects would be similar to the 1007fs protein truncating mutation seen in CD patients, which is associated with a severe phenotype in homozygotes. The frequency of this mutation in the population is not known since heterozygotes would not be detected with the present SNP assay. However, inheritance of this mutation alone or together with another NOD2 variant may help explain the severity of the CD phenotype in some patients with IBD.

Lysyl oxidase genes in Cutis laxa. V. Hucthagowder^{1,3}, P. Coucke², K. Fong¹, K. Csiszar¹, Z. Urban^{1,3}, *The Cutis Laxa Consortium*. 1) Laboratory of Matrix Pathobiology, John A Burns School of Medicine, University of Hawaii, Honolulu, HI 96822, USA; 2) Department of Medical Genetics, Ghent University hospital, De Pintelaan, B-9000 Ghent, Belgium; 3) Department of Pediatrics, Washington University School of Medicine, St. Louis, MO 63110, USA.

Cutis laxa (CL) is a heterogeneous group of inherited or acquired disorders which shows distinct inheritance patterns (autosomal dominant, recessive and X-linked) suggesting that CL may be caused by mutations in multiple loci. Deficiency of lysyl oxidase activity has been reported to be associated with CL. The goal of this study was to investigate whether molecular defects in lysyl oxidase genes may cause CL. We collected 40 families with CL and applied the denaturing high performance liquid chromatography (DHPLC) methodology to screen lysyl oxidase (LOX) and lysyl oxidase-like (LOXL) genes for detecting mutations. The observed variants were also sequenced using ABI 3100 for further confirmation. We identified 21 variants in our CL probands. One variant in the exon 1 of the LOX gene was due to a G/A transition and resulted in a nonconservative arginine to glutamine substitution (R158Q). The genotype frequencies for R158Q were significantly different between CL patients (n=40) and controls (n=121), (chi square test, p 0.025). There were more R/Q heterozygotes and Q/Q homozygotes among the CL patients. In the LOXL gene 4 missense variants (R141L, G153D, A159S, A160P) and two silent variants (875CT and 960GT) were observed in exon 1. 14 other variants were located in different intronic regions and 3- untranslated region of the LOXL gene. Current studies include mutational analysis of the proline rich region of the LOXL, analysis of allele frequencies in normal individuals and functional studies on the expression and enzyme activity of lysyl oxidases in CL patients.

Searching for mutations in the *EFHC1* gene in patients with juvenile myoclonic epilepsy. P.A.O. Ribeiro¹, V.D.B. Pascoal¹, L.E. Betting², N.F. Santos¹, R. Secolin¹, S.B. Mory², C. Guerreiro², M. Guerreiro², F. Cendes², I. Lopes-Cendes¹. 1) Dept Medical Genetics, UNICAMP, Campinas, SP, Brazil; 2) Dept Neurology, UNICAMP, Campinas, SP, Brazil.

The idiopathic generalized epilepsies (IGE), for which a genetic cause is widely accepted, account for 39 to 59% of all epilepsies. The most common form of IGE is juvenile myoclonic epilepsy (JME). The first epilepsy locus was mapped in JME on chromosome (ch) 6p and ever since, in spite of almost two decades of study, the results are still conflicting. The *EFHC1* gene, mapped on ch 6p12-p11, could be responsible for the JME phenotype, since this gene contains an EF-hand motif, suggesting a role in neuronal calcium equilibrium. It spans approximately 63 kb, contains 11 exons and encodes 640 aminoacids. Recently, putative mutations were described in exons 2, 3, 4 and 5 of this gene in a few families segregating JME.

We investigated the relevance of the *EFHC1* gene in the etiology of JME in a large sample of patients.

All patients were diagnosed according to the ILAE classification of epilepsies and epileptic syndromes. We performed mutation analysis of the *EFHC1* gene in 20 patients with JME and 20 controls. All individuals were genotyped by PCR using five pairs of primers that amplified the entire coding region and exon/intron boundaries of exons 3, 4 and 5 of the *EFHC1* gene. PCR products were subsequently analyzed by the single-stranded conformation polymorphism (SSCP) method.

SSCP analyses did not detect any differences in pattern of migration between patients and controls.

We have not identified any mutations or sequence variants in the three exons of the *EFHC1* gene genotyped in our group of JME patients. We are still completing the mutation screening of the entire coding region of the *EFHC1* gene in order to better determine its potential role in the etiology of JME in our group of patients.

Evaluation of the FGF signaling pathway in nonsyndromic cleft lip and palate. *B.M. Riley, B. Trump, E. Russo, S. Santiago, A.R. Vieira, J.C. Murray.* Dept Pediatrics, Univ of Iowa.

Nonsyndromic cleft lip and palate (NS CLP) is a complex multifactorial birth defect resulting from a combination of genetic and environmental factors. In the Philippines, NS CLP has a birth prevalence of 1 in 500 and large families provide the opportunity for gene mapping and localization. A genome-wide linkage scan including 220 NS CLP Filipino families identified a novel region on chromosome 8p21, which includes the fibroblast growth factor receptor 1 (FGFR1) gene. Subsequent sequencing of candidate genes in the region in 90 Iowa NS CLP and 180 Filipino NS CLP patients identified three potential disease-causing mutations in FGFR1. Mutations in FGFR1 are known to cause craniosynostosis and the autosomal form of Kallman syndrome (anosmia/infertility) in which approximately 5% of patients have clefts. A nonsense mutation, R609X, was identified in a two-generation family from Iowa originally diagnosed with isolated CLP. Further contact with this family revealed that the proband developed features of Kallman syndrome but that her father, who has the R609X genotype, has isolated cleft lip and palate as a phenotype. Additionally, two missense mutations, M369I and E467K, have each been found in two NS CLP Filipino families and in 0 out of 1400 controls. Other identified mutations include 3 synonymous, 2 common non-synonymous, and 20 non-coding variants from introns and UTR. Conserved mouse-human homology regions lying 5' and 3' of FGFR1 were sequenced and 1 variant in 1000 bp of sequence was identified. Micro-deletion assays were also performed, however, there is no evidence of a deletion in the 200 cases screened. The interest in FGFR1 and its role in clefting extended the project to other interacting members of the family, including FGFR2, FGFR3, FGF2, FGF4, FGF8, FGF9, and FGF10. Two novel missense mutations have been identified in FGFR2 in Filipino families. We have also begun sequencing FGF10 and several variants have been found in the Filipino population. Further investigation of the FGF/FGFR family in NS CLP patients may reveal a role for FGF signaling in the development of cleft lip and palate and allow studies of gene-gene interaction.

Sequence analysis of MSX1 gene in brazilians patients with nonsyndromic cleft lip with or without cleft palate.
A.L. Silva¹, D. Moretti Ferreira¹, A. Richieri Costa², J.C. Murray³, L.A. Ribeiro². 1) Genetics, UNESP, Botucatu, Sao Paulo, Brazil; 2) Hospital de Reabilitacao de Anomalias Craniofaciais, USP, Bauru, SP, Brazil; 3) Department of Pediatrics University of Iowa - Iowa City, IA, EUA.

Cleft lip and/or palate (CL/P) are a major congenital structural anomaly that is notable for significant lifelong and complex etiology. Approximately 2/3 of cases does not show any others anomalies and are called non-syndromic (NS). The incidence of NS-CL/P is approximately 1 in 700 live born and the preliminary studies have suggested a handful of genes and/or loci in humans, as well as environmental disrupters appear to play a role in the genesis of such cases. The frequent occurrence as well as their extensive psychological, surgical, speech and dental involvement emphasize the importance of understanding the underlying causes. The MSX1 gene has been proposed as a gene in which mutations may contribute to NS-CL/P. Support to this comes from human linkage and linkage disequilibrium studies. Some previous sequencing studies revealed some mutations that can play a role in the etiology of the NS-CL/P. In this study we sequenced the MSX1 gene in 60 patients with NS-CL/P. The results revealed 2 missense mutations (75 G-) in a conserved block and (101 C-) and 1 polymorphism (48C-) on exon 1. This may show that mutations can be find identified in some subjects with NS-CL/P although it remain for future studies with parents and relatives to confirm if these particular mutations are causal.

Mutational studies on PRODH gene located in VCFS critical region of 22q11 in patients with schizophrenia. Y.

Zhang¹, R. O'Reilly², S.M. Singh¹. 1) Molecular Genetics Unit, Department of Biology & Division of Medical Genetics, University of Western Ontario, London, Ontario, Canada; 2) Department of Psychiatry, London Psychiatric Hospital, University of Western Ontario, London, Ontario, Canada.

The gene proline dehydrogenase (PRODH) encoding for 59 kDa protein is located in the low copy repeat regions of chromosome 22q11. PRODH is involved in the first step of metabolic conversion from proline to glutamate, making it a relevant protein in neural functioning. This along with the location of this gene in the VCFS region makes it a logical candidate for schizophrenia. In an earlier study Jacquet et al (AJHG 11: 2243-49) identified two rare mutations L441P (exon 12) and L289M (exon 8) in patients with schizophrenia that were not seen in the control samples. We have used their exon 12 primers (5'-TGACAATGTGACCCTGGACG-3' and 5'-CATGACATAAAAGCTGAGGAAATA-3') to assess any sequence variation in a group of schizophrenia patients from southwestern Ontario, Canada and their age, sex, ethnic group matched controls. All patients and controls were recruited and assessed by a single psychiatrist (R.O'Reilly) using DSM IV. We have identified a total of 8 missense mutations. Some of these mutations represent known SNPs and most of the amino acid substitutions involve phylogenetically conserved sites. 10 of 19 patients and 4 of 17 matched controls were found to have at least one base substitution. We report novel mutations at the E428G, A430V and R432H. One patient had 9 base changes, 7 of these involved amino acid substitutions, considered amplified of the pseudogene. This observation in repeated experiments from this patient only (and no other individual) however remains to be explained. We conclude that genetic variation in the PRODH gene is common. Based on their distribution, some of the substitutions (R431H) represent polymorphism, while others (A472T, A430V) remain logical causal mutations, but remains to be established. Supported by Schizophrenia Society of Ontario and Ontario Mental Health Foundation.

Polyglutamine-mediated changes in the biochemical function of TBP. *X.J. Li, M. Friedman, S.H. Li.* Human Genetics, Emory University, Atlanta, GA.

Transcriptional dysregulation has been proposed as a molecular mechanism for the pathogenesis of the polyglutamine (polyQ) diseases. Study of spinocerebellar ataxia 17 (SCA17), the most recently identified polyQ disease, may provide insight into this mechanism. The mutant protein in SCA17 is the TATA-binding protein (TBP), which mediates transcription by all three eukaryotic RNA polymerases as a fundamental component of several different complexes. To investigate the effect of the N-terminal polyglutamine tract on TBP function, we have generated TBP cDNA constructs containing 15, 31, 71, and 105 CAGs. When expressed in HEK 293 cells, only mutant TBP (71 and 105 CAGs) formed nuclear aggregates. Preliminary data from reporter assays suggest that the transcriptional impact of a polyglutamine expansion in TBP may be dependent on promoter strength and type. Specifically, for TATA-containing promoters, the effect of the polyQ expansion was inversely related to the strength of the promoter. We found that polyQ expansion alters the interaction of TBP with TATA-box DNA. Relative to the wild type protein, 71Q TBP bound less promoter DNA despite a reduced tendency for dimerization. However, expansion of the polyQ stretch increased the interaction of TBP with the transcription factor Sp1. These results indicate that polyQ expansion may affect multiple functions of TBP, thereby facilitating transcriptional dysregulation and ultimately contributing to SCA17 pathogenesis. Currently, we are trying to generate a transgenic mouse model of SCA17 in order to confirm these polyQ-mediated changes in TBP function in vivo.

POLYMORPHISMS IN FKBP5, A CO-CHAPERONE OF THE GLUCOCORTICOID RECEPTOR ARE ASSOCIATED WITH RESPONSE TO ANTIDEPRESSANT DRUGS. *M.A. Kohli¹, D. Salyakina¹, G. Wochnik¹, S. Lucae¹, M. Ising¹, B. Puetz¹, N. Kern¹, P. Lichtner², T. Bettecken², J.C. Mueller², E. Lohmussaar², T. Meitinger², T. Baghai³, B. Bondy³, R. Rupprecht³, M. Uhr¹, T. Rein¹, F. Holsboer¹, B. Mueller-Myhsok¹, E.B. Binder¹.* 1) Max-Planck Institute of Psychiatry, Munich, Germany; 2) Institute for Human Genetics, Technische Universitaet, Munich and GSF, Neuherberg, Germany; 3) Department of Psychiatry, Ludwig-Maximilians-University Munich, Germany.

It is hypothesized that antidepressants might all target a common final signaling pathway. Due to consistent dysregulations of stress hormones in the brain and peripheral circulation of depressed patients, the hypothalamic-pituitary-adrenal (HPA) system is considered a strong candidate. We found a strong association of SNPs in FKBP5, a glucocorticoid receptor (GR)-regulating co-chaperone of hsp90 with response to antidepressant drugs. By fine-mapping about 300kb around this gene, we could show that only SNPs located within the major LD-block containing FKBP5 were highly associated with response to antidepressant treatment ($p=0.00003$). We genotyped the three SNPs with the strongest association in our sample ($N = 280$) in a replication sample ($N = 85$). Two of the three SNPs showed a significant association with response to antidepressant treatment in the replication sample. In both samples, the association of response reflects an overrepresentation of homozygotes of the minor allele of the associated SNPs among the responders. Homozygosity for the minor alleles was also correlated with a higher protein expression of FKBP5 in lymphocytes and with a lower ACTH response in a neuroendocrine test assessing HPA-axis activity. The association of FKBP5 polymorphisms with response to antidepressant drugs appears to be independent of the primary pharmacological profile of antidepressants, as similar associations were obtained when dividing patients into three groups treated with different classes of antidepressants. These results support that FKBP5 and by extension the HPA-system may be involved in the common final signaling pathway of antidepressant drugs.

A major influence of CYP2C19 genotype on the metabolism of N-desmethylclobazam, an anticonvulsant of benzodiazepine class. *K. Kosaki¹, K. Maeyama³, K. Tamura¹, R. Sato², H. Samejima¹, Y. Tanigawara², T. Takahashi¹.*
1) Dept Pediatrics,; 2) Dept Pharmacy, Keio Univ, Tokyo, Japan; 3) Dept Pediatrics, Saitama Municipal Hosp, Saitama, Japan.

Introduction N-desmethylclobazam (NCLB), the major metabolite of the anti-epileptic drug clobazam (CLB), exerts a large influence on the therapeutic and adverse effects of CLB. A substantial inter-individual variability has been observed in the ratios of NCLB concentration/CLB dose and of the NCLB/CLB concentration. In the present study, we tested whether CYP2C19 genotype was associated with an altered metabolism of CLB and NCLB among 22 patients receiving CLB, giving careful consideration to a unique Japanese population structure in which the *2 and *3 alleles are the prevalent (35% altogether) and the exclusive mutant alleles. **Methods** A group of 22 patients (1.5 to 33 yrs, median=6.5 yrs) who had received oral administrations of tablets or granules of CLB with the dose unchanged at least for 4 wks at the time of study were studied after obtaining written informed consent. Genomic DNA was isolated from whole blood, and CYP2C19*2 and CYP2C19*3 mutations were detected by direct sequencing. **Results** The NCLB/CLB concentration ratio in 5 patients with two non-functional alleles (3 homozygotes for *2 or 2 compound heterozygotes for *2 and *3) were six-fold higher ($p=0.0001$) than those of 7 patients with normal alleles (*1 homozygotes). Patients with one non-functional allele (10 heterozygotes for *2 or *3) exhibited intermediate trait. Similarly, NCLB concentration/CLB dose ratio elevated as the allele count of the non-functional allele increased ($p<0.0001$). **Conclusion** We document here a genotype-phenotype correlation between CYP2C19 polymorphisms and those ratios. Patients with two mutated CYP2C19 alleles show significantly higher ratios than those with the wild type genotype: patients with one mutated allele exhibited intermediate an intermediate trait. That is, the degree of elevation in the ratios was dependent on the number of mutated alleles of CYP2C19 (gene-dose effect).

Association and Interaction Effects of Six Serotonin Pathway Genes to Fluoxetine Response in Major Depression.

*E.J. Peters*¹, *S.L. Slager*², *P.J. McGrath*³, *S.P. Hamilton*¹. 1) Dept. of Psychiatry, UCSF; 2) Dept. of Health Sciences Research, Mayo Clinic College of Medicine; 3) New York State Psychiatric Institute & Dept. Psychiatry, Columbia University College of Physicians & Surgeons.

Several lines of evidence suggest that indirect effects on the neurotransmission of serotonin are associated with the therapeutic action of SSRIs. Thus, it is plausible that genetic variants in serotonin receptors (i.e., HTR1A, HTR2A, and HTR2C) and enzymes responsible for the biosynthesis (TPH1 and TPH2) and degradation (MAOA) of serotonin may influence a patient's response to fluoxetine. We have previously reported an association between publicly available SNPs in a number of these candidate genes and antidepressant response phenotypes in our well-characterized clinical sample consisting of 96 subjects with major depression treated with fluoxetine. In order to capture further genetic diversity or functionally relevant variants in serotonin pathway genes in these samples, we resequenced the coding regions, intron-exon boundaries, and 5' proximal conserved non-coding regions of these 6 candidate genes in this well phenotyped clinical sample. In total, we analyzed 30kb per sample and identified 115 polymorphisms, 71 of which have not been previously described. The majority of SNPs uncovered via resequencing were rare, with 49 of them detected on only a single chromosome in our population. Genetic diversity and LD patterns were variable among the 6 candidate genes. Single locus association analysis was significant between global clinical antidepressant response and two SNPs (in TPH1 [p=0.02] and MAOA [p=0.02]). Our previously published haplotype associations seen with the HTR2A, TPH2, and TPH1 genes remained significant (p=0.03-0.0001) after addition of haplotype tagging SNPs uncovered during resequencing. In addition to single gene effects, we will present analysis of interaction/combined effects of polymorphisms in the serotonin pathway on fluoxetine response, using Classification and Regression Tree (CART) and multivariate logistic regression.

Program Nr: 2341 from the 2004 ASHG Annual Meeting

"Medication Response in Obsessive-Compulsive Disorder and the Genetics of Hepatic Enzyme CYP2C19 Metabolism". *M. Richter, T. Sicard, P. Arnold, E. Burroughs, J. Kennedy*. Centre for Addiction and Mental Health, University of Toronto, Toronto, Ontario.

There is considerable evidence supporting a genetic basis for Obsessive-Compulsive Disorder (OCD). To date, most work has focused on candidate gene hypotheses based on etiological models of the illness. An alternative strategy, little used to date, is to investigate the genetics of drug response. In this study, retrospective data regarding response to selective serotonin reuptake inhibitor (SSRI) medication trials was collected in a sample of 20 individuals meeting DSM-IV criteria for OCD. All individuals were genotyped for alleles 2 and 3 in the hepatic enzyme 2C19. In total, 12 of the 17 individuals with the common wild type genotype for alleles 2 and 3 were responders. One out of 3 individuals with a genotype characterized by at least one rare variant for allele 2 responded to medication. A rare mutant allele that has been identified for the 3 allele did not appear in our sample. There were no statistically significant between-group differences demonstrated in this small preliminary investigation (Fisher's exact test, $p=.270$). However, given the potential clinical benefits of identifying genotypes that predict response to medication, further work is merited.

Haplotypes of angiotensin II receptor genes are associated with blood pressure (BP) reduction in response to ACE inhibitor therapy in Chinese Hypertensives. X. Su¹, L. Lee², X. Li¹, J. Lu², Y. Hu², S. Zhan², W. Cao², L. Mei¹, Y. Tang¹, D. Wang¹, JI. Rotter¹, R. Krauss³, H. Yang¹. 1) Dept Medical Genetics, Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) Peking Univ, Health Sci. Ctr; 3) Children's Hosp. Oakland Res. Inst., Oakland, CA.

Angiotensin-converting enzyme inhibitors (ACEI) are among the drugs as first-line therapy for hypertension. However, there is marked inter-individual variation in BP response to ACEI. To identify genes that may contribute to this variability, we tested the relation of ACEI BP response to two candidates, the angiotensin II receptors AGTR1 and AGTR2, in a Chinese sample. The sample included 901 hypertensives who participated in a Chinese community based trial using ACEI benazepril for 3 yrs. We genotyped 6 SNPs from AGTR1 and 3 from AGTR2. Multivariate analyses were performed for single SNPs and haplotypes (HAPs), using BP reduction as the outcome variable, and age, gender, dose, and other medication as covariates. Of 26 AGTR1 HAPs, 3 were common: H1 59.9%/H2 20.7%/H3 17.1%. AGTR1-H2 was associated with increased BP reduction while H3 was associated with decreased BP reduction. Means of SBP/DBP reduction (mmHg) for AGTR1 H2 and H3 carriers were 16.0/9.4 (n=143), 3.6/4.1 (n=64), respectively, and for the remainder, 10.9/7.5 (n=680). In analysis with covariates, AGTR1 HAPs were independently associated with BP reduction (p<0.0002 for both SBP & DBP). Of 6 AGTR2 HAPs, 3 were common: H1 59.9%/H2 20.7%/H3 17.1%. In women, we observed an association between AGTR2 and BP reduction. Means of SBP/DBP reduction for AGTR2 H2 and H3 carriers were 9.6/4.9 (n=103) and 19.5/9.3 (n=81), respectively, and for the remainder, 12.8/6.0 (n=140) (SBP p=0.001; DBP p=0.004). In a model including all covariates, sex*AGTR2 interaction, and two genes, both AGTR1 and AGTR2 were independently associated with SBP (p<0.0003) and DBP (p<0.03). BP reduction response to ACEI is independently associated with both the AGTR1 and AGTR2 genes. These associations are being tested in a confirmatory sample from the same population with the goal of confirming that AGTR1 and AGTR2 haplotypes can be used to predict clinical response to ACE inhibitor therapy.

A novel cysteinyl leukotriene 1 receptor (*CysLT₁*) variant is associated with atopy and asthma in a Tristan da

Cunha isolate. *M.D. Thompson*^{1,2}, *N. Zamel*³, *A. Slutsky*^{3,4}, *C. Lilly*⁵, *W.M. Burnham*¹, *D.E.C. Cole*^{2,3}, *K.A.*

Siminovitch^{3,6,7}. 1) Dept of Pharmacology, Univ Toronto, Toronto ON; 2) Dept of Lab Medicine, Univ Toronto, Toronto ON; 3) Dept of Medicine, Univ Toronto, Toronto ON; 4) St. Michael's Hosp, Toronto ON; 5) Pulmonary & Critical Care Divn, Brigham & Women's Hosp, Boston MA; 6) Depts of Immunology and Medical Genetics & Microbiology, Univ of Toronto, Toronto ON; 7) Samuel Lunenfeld & Toronto General Hosp Institutes, Toronto ON, Canada.

Asthma is a complex trait with genetic and environmental components, while atopy is a well-defined phenotype of immune hyperactivity that often underlies asthma. The *CysLT₁* receptor gene has been implicated in atopy, because it is: 1) the target for the cysteinyl leukotriene ligands known to activate eosinophils and mast cells; and 2) the target for *CysLT₁* receptor antagonists (e.g., montelukast) used to treat asthma. Located at Xq13.2-21.1, *CysLT₁* variants could also contribute to gender-based differences in atopic asthma in some populations. Accordingly, we analyzed the *CysLT₁* receptor gene to identify candidate single nucleotide polymorphisms (SNPs) that might contribute to asthmatic or atopic phenotypes, and found a novel c.899GA SNP predicting a G300S amino acid substitution. Genotyping was then conducted to determine allele frequency in the Tristan da Cunha isolate with an excess prevalence of atopy (47% of 112 subjects). Overall, the frequency of the 300S variant in this Tristan da Cunha sample was 15% (25/167), but the odds-ratio (OR, unadjusted for kinship) for atopy in 300S carriers was more than 6-fold higher (OR=6.28, 95%CI:2.2-17.7, p.001) than for those with only wild-type G300 alleles. For asthma itself, the increase in risk was not as dramatic, but stratification by gender suggested that most of the risk was attributable to the heterozygous females (16/57 carriers: OR=4.0, 95%CI:1.2-13.3). This association was unchanged when General Linear Modeling was used to correct for gender and cigarette smoking covariates. Whether this finding can be generalized to other populations remains to be determined.

Molecular characterization of 22q11.2 microdeletions by real-time quantitative PCR: new insights. R. Weksberg¹, J.A. Squire², L. Moldovan¹, E. Chow³, A.S. Bassett³. 1) Div of Clin and Metabolic Gen, Hosp for Sick Children, Toronto, ON, Canada; 2) Ontario Cancer Institute and Depts of Lab Medicine, Pathology and Medical Biophysics, Dept Molecular & Medical Genetics, Univ Toronto, Toronto; 3) Clinical Genetics Research Prog, Centre for Addiction and Mental Health, and Dept of Psychiatry, Univ Toronto, Toronto.

Chromosome 22q11.2 deletion syndrome (22q11DS) encompasses a heterogeneous group of clinical disorders including congenital malformations and schizophrenia. Most individuals with 22q11DS carry either a ~3Mb or a ~1.5Mb deletion diagnosed by a standard FISH assay using the TUPLE1 (Vysis) probe. However, some cases of 22q11DS carry unique deletions not detected by the routine diagnostic assay.

We have developed a real-time quantitative polymerase chain reaction (qPCR) assay for 22q11.2, firstly to detect unique deletions/duplications and secondly to better characterize 22q11.2 deletion endpoints. Since the 22q11.2 genomic architecture is characterized by dense polymorphic segmental duplication, we used a combined bioinformatics (*in silico*) approach together with both qPCR and FISH. A physical map was generated to identify 36 single copy primer sets across 5Mb of 22q11.2 for real-time qPCR analysis.

We tested DNA from 4 controls, 1 patient trisomic for 22q11 and 72 patients with clinical features of 22q11DS. Our real-time qPCR assay robustly detected both deletions and duplications of 22q11.2. Of 46 interstitial deletions that were identified by qPCR, 2 were not previously detected by FISH analysis using the TUPLE1 probe. The position of these 2 unique deletions was confirmed by FISH analysis using the RP11-138C22 probe. The breakpoints of these unique deletions were localized to regions containing extensive blocks of homologous segmental duplications; a subset mapped to regions with large numbers of Alu repeats. This observation expands the range of repeat sequences involved in the destabilizing event that generates 22q11.2 microdeletions.

These data demonstrate that real-time qPCR can increase the sensitivity of detection for 22q11.2 deletions and duplications and can be utilized to study the molecular etiology of such genomic alterations.

FREQUENCY OF HINDIII (LPL) POLYMORPHISM IN PATIENTS WITH CORONARY ARTERY DISEASE IN MEXICAN POPULATION. *L. Arnaud Jr¹, M.P. Gallegos-Arreola¹, L.E. Figuera², G.M. Zúñiga-González¹.* 1) Medicina Molec, CIBO IMSS, Guadalajara, Mexico; 2) Genética, CIBO, IMSS, Guadalajara, Jalisco, México.

INTRODUCTION. The coronary artery disease (CAD) is one the most important cardiovascular disorders and the principal world cause of death. For a lot of time have been revaluated different risk factors (genetics and environmental). Between genetics factors we can find modifications in lipoprotein lipase levels leading to elevated triglycerides and reduced high density lipoprotein (HDL), both of then are risk factors for coronary artery disease. Some studies have described an association between HindIII polymorphism and Lipoprotein Lipase (LPL) and CAD, although this association is contradictory in others studies and its association is unknown in Mexican population. **METHODS.** In this study, genomic DNA from 153 CAD patients (abnormal coronariography), 106 controls with (normal coronariography) and 136 persons without CAD and background of CAD, diabetes mellitus and arterial hypertension were genotyped. **RESULTS.** HindIII -/- polymorphism shown statistical differences compared with others population. Lipidic profile components were higher in the HindIII -/- group with regard to +/- and -/-. When groups were classified by gender, HindIII +/+ was associated with masculine gender in the cases group. **CONCLUSIONS.** HindIII -/- genotype could play an important role as risk factor of CAD in the group studied.

No Association or Linkage of a common polymorphism in the Cyclooxygenase 2 gene with Alzheimer disease.

*O.G. Boutaud*¹, *N.C. Schmetz-Boutaud*², *J. Bartlett*², *M.A. Pericak-Vance*³, *J.L. Haines*². 1) Department of Pharmacology, division of Clinical Pharmacology, Vanderbilt University, Nashville, Tennessee; 2) Center for Human Genetic Research, department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, Tennessee; 3) Center for Human Genetics, Duke University Medical Center, Durham, North Carolina.

The potential contribution of cyclooxygenase (COX) in Alzheimers disease (AD) may be inferred from a number of studies. COX isoforms are expressed in the brain and are involved in physiological functions such as synaptic plasticity, prostaglandin production, and excitotoxicity. Individuals with no baseline dementia have a 60 to 80 % reduction in risk of developing AD when using non-steroidal anti-inflammatory drugs for at least two years. In addition, transgenic mice over-expressing COX-2 in neurons have accelerated deposition of amyloid in brain. Collectively, this evidence suggests that COX activity may be involved in the pathogenesis of AD. A recent study demonstrated that a common SNP polymorphism in the 3 untranslated region of COX-2 affects expression of COX-2. To test the hypothesis that COX-2 might be involved in AD, we genotyped 469 individuals affected with AD and 948 unaffected individuals from 249 families for this common polymorphism. We used the Pedigree Disequilibrium Test (PDT) to test for association between this locus and AD. The analysis of this SNP (hcv7550203 (rs5275)) did not show any significant linkage or association to AD. Although this polymorphism does not show an association with AD, we cannot exclude the possibility that other polymorphisms within COX2 might be related to AD. Other polymorphisms are currently being tested.

Investigating the role of prolactin and oxytocin system genes in childhood onset mood disorder. *J.M. Brathwaite¹, N. King¹, S. Shaikh¹, D. Voineskos¹, A. Vetr², E. Kiss², I. Baji³, C.L. Barr⁴, M. Kovacs⁵, J.L. Kennedy¹.*

1) Neurogenetics Section, Centre for Addiction and Mental Health, Department of Psychiatry, University of Toronto; 2) Szeged University Medical Faculty, Department for Child & Adolescent Psychiatry; 3) Vadaskert Hospital, Budapest, Hungary; 4) University Health Network Toronto Western Research Institute, Department of Psychiatry, University of Toronto; 5) Western Psychiatric Institute and Clinic, UPMC Health System.

Childhood onset mood disorder (COMD) is a serious affective illness that alters the normal development of a child. We examined the role of oxytocin and prolactin system genes in COMD probands. These hormones play a major role in the quality of parent-child bonding across species and are therefore relevant to regulation of emotion in childhood. Oxytocin has been shown to be involved in stress coping strategies, while prolactin has been seen to reduce stress response. We examined polymorphisms of the oxytocin (OXT), oxytocin receptor (OXTR), prolactin (PRL) and prolactin receptor (PRLR) genes. Our samples were 1) 197 Hungarian families with an affected proband, and both parents, and 2) 200 cases collected in Pittsburgh, and matched controls. Diagnosis in these subjects was determined using the Interview for Children and Adolescents - Diagnostic Version (ISCA-D). To test for biased allele transmission from parent to COMD patient in our families, we employed the sibling-Transmission Disequilibrium Test (s-TDT). We had significant results for PRLR(T/C) ($\chi^2=4.921$, $P=0.027$) and OXTR(T/G) ($\chi^2=4.900$, $P=0.027$). For the OXT(T/G) there was a tendency towards biased transmission ($\chi^2=3.76$, $P=0.053$). Associations were observed in the case-control study for markers OXT(G/A) ($\chi^2=7.099$, $P=0.003$), OXTR(T/G) ($\chi^2=8.645$, $P=0.013$) and PRL(C/A) ($\chi^2=6.925$, $P=0.031$). Combining Hungary and Pittsburgh samples Z-scores for OXT and OXTR indicated association with OXT ($Z=3.25$, $P=0.00058$) and OXTR ($Z=3.64$, $P=0.0001$). Results for the other markers were not significant. These results suggest a role for the involvement of prolactin and oxytocin in the pathogenesis of COMD, and there is a need for further studies.

Polymorphisms of Apolipoprotein E: Association with Susceptibility and Severity of Multiple Sclerosis. V.

Hadavi¹, D.D. Farhud¹, M.H. Sanati², M. Hushmand², S.M. Nabavi³, M. Seyedian⁴, M. Younesian¹. 1) Dept. of Human Genetics & Anthropology, School of Public Health & Institute of Public Health Research, Tehran University of Medical Science, P.O.Box 14155-6446, Tehran, Iran; 2) National Research Center for Genetic Engineering and Biotechnology, Tehran, Iran; 3) Shahed Medical University, Department of Neurology, Tehran, Iran; 4) Tehran University of Medical Sciences, Roozbeh Hospital.

The apolipoprotein E (APOE) polymorphism is known to impact on various neurologic disorders and has differential effects on the immune system and on CNS repair. Previous findings concerning a possible modulation of the clinical course of MS have been inconsistent, however. In a cross-sectional study, the authors investigated 81 patients with clinically definite MS and related their clinical and demographic findings to the allelic polymorphism of the APOE gene. The genotype distribution of patients with MS was compared with a cohort of 93 asymptomatic elderly volunteers. The authors found significant differences in the distribution of 4 allele between patients with MS and controls (9.3% vs. 0.5%; $\chi^2=15.2$; $df=2$; $p<0.001$). An analysis of disease progression in 81 patients with MS indicated that APOE-4 carriers are more likely to be affected with severe disease (61.5% with EDSS 7 vs. 7.7% and 30.8% with EDSS 3-7 and 3, respectively) ($\chi^2=7.88$; $df=2$; $p=0.019$). These results suggest effect of the APOE genotype on susceptibility to MS, and indicate an association of the APOE 4 allele with a more severe course of the disease.

ROR2 mutations in cleft lip and palate with limb defects. *M. Mansilla, S. Daack-Hirsch, J. Murray.* Dept Pediatrics, Univ Iowa, Iowa City, IA.

As part of a large cleft-candidate gene study conducted with subjects from the Philippines we have clinical data and biological samples from 49 individuals with orofacial clefting and some type of limb defect. Twenty-three of these subjects have amputation-type defects ranging from shortened terminal phalanges and nails to partial congenital limb amputation. Of the remaining 26 subjects, 7 have polydactyly, 5 mild syndactyly, 4 simian creases, 3 ectrodactyly, 3 clinodactyly, 2 club foot and 1 each joint contractures or broad thumbs. Many digital amputation-like defects appear similar to those described in the brachydactyly type B (BDB1) phenotype. In humans, mutations in ROR2 account for autosomal recessive Robinow syndrome and autosomal dominant BDB1 both include abnormalities of the limbs or digits. We detected 10 new variants. Eight are likely normal SNPs: two in the untranslated region A3734G and C3399T; four synonymous G1630A, C1885T, C2287T and C475T and two in the intronic region G223412A and G192488A. Two are missense mutations that are likely etiologic for the phenotype: E307L (exon 6) and G558S (exon 9). E307L was found in an affected proband, his affected cousin and his unaffected parents. This variant located at the extracellular domain, is likely to interfere ligand-receptor binding. G558S was found in a proband but not in her unaffected mother. This variant is located at the tyrosine kinase domain. Missense mutations in this region may inactivate the domain. We also examined a collection of nonsyndromic cleft lip with or without cleft palate (CL/P) cases. A 10-cM genome scan of 388 extended multiplex families with CL/P from seven diverse populations (2,551 genotyped individuals) revealed CL/P genes in six chromosomal regions, including a novel region at 9q21 (heterogeneity LOD score=6.6) near the ROR2 gene. To determine if ROR2 might contribute to non syndromic forms of CL/P we also sequenced exon 6 and exon 9 in 90 non-syndromic cleft samples and in 90 healthy controls, but did not find any etiologic variants. ROR2 mutations and genetic counseling should be considered in children with clefts and limb defects. ROR2 does not appear to be a common cause of isolated clefts.

ENDOTHELIAL NITRIC OXIDE SYNTHASE (eNOS) GENE POLYMORPHISMS IN CORONARY ARTERY DISEASE (CAD) PATIENTS OF MEXICAN POPULATION. *R. Mariaud-Schmidt¹, M.P. Gallegos-Arreola¹, L. Arnaud-López¹, L.E. Figuera², R. Arechavaleta³, T.J. Beltrán³, G.M. Zúñiga-González¹.* 1) Dept Medicina Molecular, CIBO, IMSS, Guadalajara, Mexico; 2) Dept Genética, CIBO, IMSS, Guadalajara, Jalisco, México; 3) Departamento de Endocrinología, HE, CMNO, IMSS, Guadalajara, Jalisco, México.

BACKGROUND: The vascular endothelium is now recognized as an important participant in a healthy cardiovascular system, and dysfunction of this cellular monolayer might be an initiating event in many or most cardiovascular disease states. eNOS gene polymorphisms have been associated inconsistently with cardiovascular disease. **OBJECTIVE:** Determination frequencies of three clinically relevant eNOS polymorphisms: T786C in the promoter, the variable number of tandem repeats (VNTR) in intron 4, and the Glu298Asp variant in exon 7 in Mexican population. **MATERIAL AND METHODS:** We study 205 CAD patients, subdivided in subgroup 1: 114 patients with coronary stenosis and subgroup 2: 91 patients without coronary stenosis and, a control group: 60 healthy individuals of the northwest Mexican population. For the polymorphisms analysis we amplified a 420bp segment of intron 4, a 180bp segment of promoter for T786C polymorphism, and a 248bp segment of exon 7 for Glu298Asp polymorphism. **RESULTS:** The genotype frequency of intron 4 (VNTR) were: 4a/4a, 27% in subgroup 1, 22% in subgroup 2, and 8% in the control group. The genotype frequency of T786C polymorphism were: C/C 16% in subgroup 1, 15% in subgroup 2 and 7% in the control group. The genotype frequency of Glu298Asp polymorphism were: 7% of T/T in subgroup 1, 4% in the subgroup 2 and 28% in the control group. **CONCLUSION:** This results suggest that the 4a/4a and C/C genotypes may be an important risk factors in CAD development in mexican population, and may be an useful in the effort to understand the polymorphisms associated with CAD and, its interpopulational diversity.

Two SNPs in the 5' and 3' end of the OPN (Osteopontin) gene contribute to susceptibility to Systemic Lupus

Erythematosus (SLE). *P. Momigliano-Richiardi¹, S. D'Alfonso¹, N. Barizzone¹, M. Giordano¹, A. Chiocchetti¹, C. Magnani¹, L. Castelli¹, F. Giacomelli², R. Scorza³, M.G. Danieli⁴, S. Migliaresi⁵, M.G. Sabbadini⁶, M. Galeazzi⁷, G.D. Sebastiani⁸, U. Dianzani¹.* 1) Univ. of Eastern Piedmont, Novara, Italy; 2) G. Gaslini Institute, Genova, Italy; 3) Milano Univ. , Milano, Italy; 4) Univ. Politecnica delle Marche, Ancona, Italy; 5) Napoli Second Univ., Napoli, Italy; 6) Vita e Salute Univ., Milano, Italy; 7) Siena Univ., Siena, Italy; 8) S. Camillo-Forlanini Hospital, Roma, Italy.

SLE is a multifactorial autoimmune disease. Several lines of evidence suggest that the early T-cell activation gene-1 (ETA-1) or osteopontin (OPN) has a role in the pathogenesis of SLE through its immunoregulatory effects. We tested the association of OPN with SLE by typing 394 Italian SLE patients and 479 matched controls for polymorphisms detected by scanning the coding, 5' and 3' flanking regions of the OPN gene by DHPLC in 23 SLE patients. Among the 13 detected SNPs, alleles -156G (0.714 vs 0.651, $p=0.006$, $p_c=0.036$) and +1239C (0.377 vs 0.297, $p=0.00094$, $p_c=0.0056$) were significantly increased in the patients. The presence of the associated allele in single or double dose conferred an OR=2.19 (95%CI 1.34-3.60) for SNP-156 and OR=1.53 (95%CI 1.14-2.05) for SNP +1239. A multivariate analysis showed that these effects were independent of each other. The risk associated to a double dose of susceptibility alleles at both SNPs was 3.8 (95%CI 2.0-7.4) fold higher relative to the complete absence of susceptibility alleles. A parallel and significant increase in OPN serum level (determined by ELISA) with increasing number of SLE susceptibility alleles was observed in 80 healthy individuals ($p=0.0019$). Considering individual clinical and immunological features, a significant association was seen for lymphadenopathy with -156 genotypes (overall $p=0.0011$; $p_c=0.046$). These data suggest the separate effect of a promoter (-156) and a 3'UTR (+1239) SNP in both SLE susceptibility and OPN serum production. We can speculate that these sequence variants (or others in perfect linkage disequilibrium) predispose to a high OPN production and that this in turn may confer susceptibility to SLE.

Investigation of a candidate gene for Inflammatory Bowel Disease on 12q23. *N.J. O'Callaghan¹, E.J. Walker¹, K.E. Peters¹, P.G. Board¹, J.A. Cavanaugh².* 1) John Curtin School of Medical Research, ANU, Canberra, AUSTRALIA; 2) MGRU, ANU Medical School, Canberra, AUSTRALIA.

Inflammatory bowel disease (IBD), encompassing Crohns disease (CD) and ulcerative colitis, is a group of debilitating diseases that involve chronic inflammation of the gut. Although the precise disease etiology of IBD remains unclear, numerous studies suggest a strong genetic component involved in disease susceptibility. One of the genomic regions identified as potentially harbouring IBD genes is the *IBD2* region on chromosome 12q. Here we report on suggestive linkage (NPL=2.1) at 12q23 in the Australian IBD population. This linkage is enhanced (NPL=3.0) in families carrying *CARD15* risk alleles. Seven polymorphisms within the region of maximal linkage were genotyped in 130 Australian IBD families. Single TDT (Transmission Disequilibrium Test) revealed a significant association with one polymorphism ($p < 0.05$) that is strongest in families carrying *CARD15* risk alleles ($p < 0.001$). The polymorphism is within an intron of a known gene involved in immune response. Quantitative Real-Time PCR analysis shows a disturbed pattern of expression; with an increase of mRNA levels detected in CD affected biopsy samples. We report the identification of a positional and functional disease candidate for IBD on chromosome 12. Our findings also suggest that this candidate interacts genetically with *CARD15*.

Association Analysis of 5HT Transporter Gene in Bipolar Disorder in the Colombian Population. *J.C. Prieto^{1,2}, C. Duran¹, A. Ordonez¹, J.F. Ortiz³, D. Patermina³, R. Tamayo³, F. Rivadeneira¹, C. Gomez².* 1) Inst de Genetica Humana, Univ Javeriana, Bogota, Colombia; 2) Hospital la Victoria; 3) Hospital San Ignacio.

Affective disorders are a common heterogeneous group of disease characterized by disturbances of mood. The bipolar affective disorder (BPD) is major psychiatric disorder that affects 1% of the population worldwide and it is characterized by episodes of mania and depression. Two polymorphisms in the serotonin transporter gene (5HTTR) have been examined in association studies of affective disorders. A polymorphic region linked to the gene 5HTTR has been associated with anxiety-related personality characteristics. A 17-bp repetitive element present in the second intron of the same gene also has been identified that consists of 9, 10, or 12 copies of the repeat sequence. In a Scottish study were found an association between the 9-repeat intronic VNTR allele, whilst in two other studies in European or British Caucasians the risk was associated with the 12-repeat allele. The objective of this study is to investigate association of the polymorphisms VNTR in intron 2 of 5HTTR gen. We have performed a case-control analysis in 75 cases with bipolar affective disorder and 81 control subjects. Allele frequencies for 12 and 10-repeat allele were different in the control subjects allele₁₂=0.43, allele₁₀=0.56 and cases allele₁₂=0.57, allele₁₀=0.42. Allele frequencies for 9-repeat allele were same in the control subjects allele₉=0.01 and cases allele₉=0.01. A significant association of the 12-repeat allele of the 5HTTR gene with bipolar disorder in Colombian population ($\chi^2=5.36$ $p<0.05$). Those results is similar an others studies in the European or British Caucasians. The 12-repeat allele may be a genetic risk factor in Colombian population.

Polymorphism interactions may influence asbestos-related disease development. *E.A. Putnam, A. Groves, K. Guttmanova, M.A. Pershouse.* Biomedical and Pharmaceutical Sciences/CEHS, University of Montana, Missoula, MT.

That polymorphisms contribute to phenotypic variation, disease risk, and response to the environment has long been hypothesized. A promising approach to dissect these contributions is the systematic exploration of the common gene variants that may be associated with disease. Although asbestos-related diseases (ARD) are among the most well studied occupational diseases, relatively little is known about the polymorphisms that may influence individual susceptibility. The goal is to investigate candidate genes, including those involved in inflammation and subsequent fibrosis, for polymorphisms that may be implicated in ARD development. DNA was isolated from 177 blood samples donated by Libby MT residents. Genotypes of GSTM1, GSTP1 and GSTT1, as well as TNF α (-308), IL1A, IL1B and IL1RA were determined. A general linear model of analysis was used to determine significance and possible interactions. A statistically significant main effect of IL1RA on disease scores was found ($F(2, 119)=3.127, p=.047$). Although no significant interactions were found, the interaction of GSTP1 and IL1RA accounted for 7% of the variance. The following four covariates were included in the model for their ability to predict disease: age, gender, exposure (0 to 3) and smoking as measured in pack/years. Gender had a statistically significant main effect ($F(1, 119)=4.823, p=.030$), as did smoking ($F(1,119)=8.050, p=.005$) and there was a significant interaction between age and exposure in the expected direction ($F(1, 119)=22.205, p<.001$). Overall the analyses have accounted for 40.4% of the variance; IL1RA by itself accounts for 5% of the variance. These data suggest that although the covariates play a large role in the development of asbestos-related diseases, they do not account for all of the variance. Results from the polymorphisms examined in the candidate genes thus far demonstrate the genetic contribution to ARD development, and analysis of the polymorphism interactions is promising. These studies demonstrate the need for a larger sample size to have enough power to detect significant contributions. Supported by ES011676.

Examination of several candidate genes on chromosome 10q in Alzheimer disease. *N.C. Schnetz-Boutaud¹, X. Liang¹, B.M. Anderson¹, J. Bartlett¹, E. Martin², W.K. Scott², M.A. Pericak-Vance², J.L. Haines¹*. 1) Center for Human Genetics Research, Vanderbilt University, Nashville, Tennessee; 2) Center for Human Genetics, Duke University Medical Center, Durham, North Carolina.

Alzheimer's disease (AD) is a genetically complex disorder that is the leading cause of dementia in the US. Although four genes have been identified that influence both early and late onset AD, these genes explain only part of the underlying genetic etiology. Numerous linkage studies have identified a large region on chromosome 10q that appears to segregate with AD. Despite follow-up efforts, the interval remains large and further localization has been difficult. Within this ~35 Mb region, numerous functional candidate genes have a strong biological rationale for examination in AD, and we chose five for additional analysis (Cdc2, Alpha Catenin, PLAU, TNFRSF6 and IDE). We used a dataset assembled from the NIMH repository, the NCRAD repository, Vanderbilt University, and Duke University. The total dataset consists of 4531 individuals (2491 affected, 1386 unaffected, 654 unknown) in 1184 families, 1152 cases and 320 unrelated controls. Multiple SNPs in each gene were selected for either their functional significance and/or their former use in other studies on AD. The combined analysis of the datasets identified a linkage signal in alpha-catenin with a lod=1.18 under a dominant model. The maximal lod score was 2.20, under the dominant model, in the NIMH subset. Association analyses using the Pedigree Disequilibrium Test did not demonstrate any significant results that survived even a modest correction for multiple comparisons. Additional SNPs in each gene, along with conditional analyses to account for the effects of APOE and family history, are ongoing. These data suggest that common polymorphisms in these candidate genes are not strongly associated with AD.

Genetic polymorphisms predict acute renal injury after coronary bypass graft surgery. *M. Stafford Smith, M. Podgoreanu, M. Swaminathan, B. Phillips-Bute, J.P. Mathew, R. Morris, M.F. Newman, D.A. Schwinn.* Dept Anesthesiology, Duke Univ Medical Ctr, Durham, NC.

Background: Post-cardiac surgery renal dysfunction is a common, serious multifactorial disorder, with inter-patient variability poorly explained by clinical, procedural, and biological markers. Therefore, we tested the hypothesis that selected gene variants are associated with acute renal injury after cardiac surgery.

Methods: 1671 patients undergoing aortocoronary surgery were studied. Clinical co-variables were recorded and DNA isolated from preoperative blood; MALDI-TOF mass spectrometry was used for genotype analysis. A model was developed relating clinical and genetic predictors to postoperative acute renal injury.

Results: A race effect was found so Caucasians and African Americans were analyzed separately. Overall, clinical factors alone are poor predictors of postoperative renal injury, although better in African Americans ($R^2=0.13$) than Caucasians ($R^2=0.03$). When 12 candidate polymorphisms are assessed, 2 demonstrate strong association with renal injury (>50% decrease renal filtration); these alleles include interleukin6 -572C and angiotensinogen 842C in Caucasians ($p<0.0001$ when they present together). Using less stringent criteria for significance ($0.01>p>0.001$), 4 additional polymorphisms are identified (apolipoproteinE 586T (2), angiotensin receptor1 1166C, and eNOS 894T in Caucasians; eNOS 894T and ACE D/I in African Americans). Adding genetic to clinical predictors resulted in the best model, with overall ability to predict renal injury increasing 4-fold in Caucasians and doubling in African Americans ($p<0.0005$).

Conclusions: In this study we identify, for the first time, genetic polymorphisms that collectively provide a 2-4-fold improvement over clinical factors alone in predicting post-cardiac surgery renal dysfunction. From a mechanistic perspective, most identified genetic variants are associated with increased renal inflammatory and/or vasoconstrictor responses.

Association of Proopiomelanocortin Gene Polymorphisms with Obesity in the IRAS Family Study. *B. Sutton*^{1,2}, *C. Langefeld*⁴, *A. Williams*⁴, *J. Norris*⁵, *M. Saad*⁶, *S. Haffner*⁷, *D. Bowden*^{1,2,3}. 1) Ctr Human Genomics, Wake Forest Univ Sch Med, Winston Salem, NC; 2) Dept Biochemistry, Wake Forest Univ Sch Med, Winston-Salem, NC; 3) Dept Internal Medicine, Wake Forest Univ Sch Med, Winston-Salem, NC; 4) Dept Public Health Sciences, Wake Forest Univ Sch Med, Winston-Salem, NC; 5) Dept Preventative Med and Biometrics, Univ Colorado Health Science Ctr, Denver, CO; 6) Dept Medicine, Univ California at Los Angeles, Los Angeles, CA; 7) Dept Medicine, Univ Texas Health Science Ctr at San Antonio, San Antonio, TX.

Proopiomelanocortin (POMC) has been found to be associated with rare Mendelian forms of obesity in children. In linkage studies the POMC region has been linked to leptin levels in Caucasian, Mexican American, and African American families. POMC polymorphisms have not been investigated in detail for association with obesity in the general population. Five single nucleotide polymorphisms (SNPs) were genotyped on 1049 Hispanic and African American individuals in the IRAS Family Study and tested for association with multiple obesity quantitative traits. General and family based association analysis of the data was performed using General Estimating Equations (GEE1) and haplotype analysis was performed using the quantitative pedigree disequilibrium test (QPDT). Five SNPs were genotyped (G-3460C, C17T, G3473A, C3755T, and A7069G). Evidence of association was seen primarily in Hispanics. SNP C3755T was consistently associated with P-values ranging from 0.011-0.045 for association with BMI, waist, visceral adipose tissue (VAT), and subcutaneous adipose tissue (SAT). G-3460C, G3473A, and A7069G were also found to be associated, though modestly, with additional obesity measurements (P-value 0.025-0.04). Results of haplotype analysis were consistent with single SNP analysis, with haplotypes containing C3755T showing the greatest evidence of association (P values ranging 0.024-0.048) for obesity traits. POMC polymorphisms show modest, but consistent evidence for association with obesity traits, consistent with the hypothesis that POMC contributes genetically to the development of obesity. Further studies will be necessary to clarify whether these or other SNPs are functional polymorphisms.

Genetic analysis of candidate modifier polymorphisms in α^0 thalassemia/HbE patients. *J.L. Whitacre¹, O. Sripichai^{1,2}, P. Winichagoon², K. Abel¹, A. Braun¹, S. Fucharoen².* 1) Sequenom, Inc., San Diego, CA; 2) Mahidol University, Nakornpathom, Thailand.

α^0 -thalassemia/HbE disease is one of the most common thalassemias in Southeast Asia and represents the main cause of childhood chronic disease. Recent worldwide migration has resulted in the appearance of abnormal hemoglobin alleles and associated disorders in other regions. Patients compound heterozygous for HbE and α^0 mutant alleles display remarkable variability in clinical expression, ranging from nearly asymptomatic to severe, transfusion-dependent disease clinically identical to homozygous α^0 -thalassemia. Given this clinical heterogeneity, additional genetic factors modifying disease severity remain to be discovered, themselves representing diagnostic targets for identifying at-risk individuals, or their products representing novel therapeutic targets.

Using an automated, chip-based platform for genetic analysis based on mass spectrometry (MassARRAY), we are examining to what extent genetic variation within the beta globin gene cluster contributes to disease severity in Thai/Chinese patients with α^0 thalassemia/HbE disease. A map of ~75 single nucleotide polymorphisms (SNPs) has been constructed spanning more than 80 Kb, including the locus control region (LCR) and all beta-like genes. These SNPs were identified through resequencing and from the public domain, including well-characterized RFLPs used in prior haplotype studies. Also included are assays for polymorphic sites reported to influence globin gene expression, specifically *Xmn-I* and the BP-1 binding sites upstream of α^G - and α -globin genes, respectively. Genotyping of other candidate modifier loci, including SNPs in genes encoding alpha hemoglobin stabilizing protein (AHSP), and the α -globin gene repressor BP-1, are underway. To date, almost 1250 patient DNAs have been collected and are being genotyped for the described assays. To identify additional modifier loci, carefully selected patient sub-groups representing the extremes in disease severity have been selected for DNA pool construction to be used in a genome-wide association study involving up to 100,000 gene-based SNPs.

Serotonin transporter SLC6A4 long promoter allele associated with suicide attempt in adults with a history of childhood-onset mood disorder. *N. Bulgin¹, J. Strauss¹, S. Shaikh¹, N. King¹, D. Goldman², X. Hu², C. George³, M. Kovacs³, J.L. Kennedy¹.* 1) Neurogenetics, Centre for Addiction and Mental Health, Toronto, ON; 2) NIAAA/NIH, Rockville, MD; 3) Department of Psychiatry, University of Pittsburgh School of Medicine, Western Psychiatric Institute and Clinic, Pittsburgh, PA.

Biological studies of suicide victims indicate altered central serotonergic function. However, results of serotonin system candidate gene studies have been less than consistent, especially those examining the serotonin transporter (SLC6A4) gene. Here we present the results of a unique genetic study examining differences in allele and genotype frequencies of the SLC6A4 gene variants between suicide attempters and non-attempters with a history of childhood-onset mood disorder (COMD). A total of 79 non-attempters and 97 attempters were genotyped for the intron 2 VNTR, the promoter insertion/deletion polymorphism (5-HTTLPR), and the long (l) G SNP described by Goldman et al. (2004). lG alleles were counted as s alleles to remain consistent with functionality. We first tested the sample for significant differences between attempters and non-attempters based on sex, affective disorder subtype, lifetime and current alcohol abuse/alcohol abuse or dependency (AD/AAD), and lifetime and current drug abuse. A history of at least one suicide attempt was significantly higher in females, those with a lifetime history of AD/AAD, and lifetime drug abuse ($p=0.04$, 0.01 , and 0.004 respectively). Intron 2 VNTR genotype frequencies did not differ significantly between the two groups when considering any of the covariates ($p>0.05$). In contrast, suicide attempters had a significantly higher frequency of the l/l 5-HTTLPR genotype than the l/s or s/s genotypes combined in both sexes (males: $p=0.02$; females: $p=0.03$), but not in those with lifetime drug abuse ($p>0.05$). Suicide attempt was significantly associated with the l/l genotype for AD/AAD subjects ($p=0.004$), but not for non-AD/AAD subjects ($p=0.21$). These results suggest that the l/l SLC6A4 genotype, in combination with AD/AAD, may have predisposed adults with a history of COMD to attempt suicide in our sample.

Structured association case-control and family-based association study on ADH4 gene and alcohol dependence.

X. Luo^{1,2}, H.R. Kranzler³, B.Z. Yang^{1,2}, J. Gelernter^{1,2}. 1) Dept Psychiatry, Yale Univ Sch Med, New Haven, CT; 2) VA CT Healthcare System, West Haven, CT; 3) Dept Psychiatry, Univ CT Sch Med, Farmington, CT.

Foroud et al. (2003) reported that alcohol dehydrogenase 4 (ADH4) gene might be a risk factor for alcohol dependence (AD) in European-Americans (EAs). We investigated the relationship between ADH4 gene and AD in additional populations, including EAs and African-Americans. Seven SNPs spanning the ADH4 gene were genotyped in 365 healthy controls, 432 AD cases, and 124 small families with AD offspring. Comparing cases and controls within populations, we found significant differences in genotype frequencies for four of the seven ADH4 markers (adjusted global $p=0.004$). To evaluate the effects of possible population admixture on these positive associations, we examined the ancestry proportions of each subject through the program STRUCTURE, using independent and highly ancestry-informative markers including 37 STR markers, FY, and one ADH4 marker (rs1984362). These ancestry proportions were then input into the STRAT program to run a structured association analysis, which suggested that the genotypes of six of the seven ADH4 markers were associated with AD after controlling for population admixture effects ($p=0.011-0.047$). To further control for potential confounding of associations by sex, and to explore more models including the interactions among markers, a backward stepwise logistic regression analysis was employed, with diagnosis as the dependent variable, and the ancestry proportion, sex, and either ADH4 allele, genotype, haplotype probability or diplotype probability as the independent variables. This analysis resulted in the C/C genotype for the ADH4 promoter SNP (rs1800759, $p=0.013$) and the homozygous seven-variant diplotype (CCGATCG/CCGATCG, $p=0.049$) being significantly associated with AD. TDT analysis for the independent family sample showed that the C allele of SNP hcv2033010 ($p=0.036$) and the seven-variant haplotype CCGATCG ($p=0.018$) were overtransmitted with AD. Our evidence confirms that the ADH4 gene is a susceptibility gene for AD. (Foroud et al. Am J Hum Genet. 2003;73(5 suppl.):#2066).

Genome-wide expression analysis in a mouse model of chronic inflammatory bowel disease. *D. Brudzewsky*¹, *L.A. Larsen*¹, *M. Claesson*², *M. Gad*², *N.N. Kristensen*², *S. Knudsen*³, *Z. Tmer*¹. 1) Wilhelm Johannsen Centre for Functional Genome Research, IMBG, The Panum Institute, University of Copenhagen (Denmark); 2) MAI, The Panum Institute, University of Copenhagen (Denmark); 3) CBS, Biocentrum, Technical University of Denmark.

Chronic inflammatory bowel disease (IBD) is a multifactorial disorder with two major clinical forms, Crohns disease (MIM 266600) and ulcerative colitis (MIM 191390) with unknown etiology. In order to investigate the gene expression levels in the T cell transfer SCID mouse model for colitis, we have screened Affymetrix GeneChips (MOE430A, containing 22600 genes, ESTs and non-ESTs) using colon cDNA prior to and after induction of colon inflammation. Based on histology, weight loss and results from a CD4⁺ T-cell anti-entero antigen proliferation assay the mice were categorised into a non-transplanted control group and two inflammatory groups with low and high levels of inflammation, respectively. Hierarchal clustering of the gene expression results supported this categorisation of the mice. We observed that ~40% of the 200 genes with most significant changes in expression are down-regulated. Two genes of interest were *15-Pghd* and *Gelsolin*. *15-PGHD* (-3.1 fold; p=3.3e-06) and has previously been found to be down-regulated during lipopolysaccharide-induced fever and systematic inflammation. The *Gelsolin* gene (-2.3 fold; p=1.4e-05) has been suggested to contribute to the pathophysiology of microvascular dysfunction during pulmonary inflammation when plasma Gelsolin is depleted. Among the up-regulated genes were the *S100a8* gene (78.1 fold; p=6.12e-07) and the *S100a9* gene (138.0 fold; p=6.29e-06) which together with the chemokines *Cxcl-5* (52.8 fold; p=2.6e-05) and *Cxcl-1* (8.2 fold, p=9.6e-06) are known to be involved in trafficking of inflammatory cells from the blood into the inflamed tissues. These results indicate that the SCID mouse model of colitis displays a gene expression profile, in accordance with conditions for chronic inflammation. This model can therefore be useful in identifying genes, pathways and perhaps new therapeutics involved and useful in IBD.

Quantification of the cystatin B gene expression pattern by real-time PCR. *M. Kuronen*¹, *T. Joensuu*¹, *L. Huopaniemi*², *A.-E. Lehesjoki*¹. 1) Folkhälsan Institute of Genetics, Department of Medical Genetics and Neuroscience Center, Biomedicum Helsinki, University of Helsinki, Finland; 2) Rational Drug Design Program, Biomedicum Helsinki, Finland.

Unverricht-Lundborg disease (EPM1, OMIM254800) is an autosomal recessive inherited disorder characterized by onset at the age of 6-15 years, severe stimulus-sensitive progressive myoclonus and tonic-clonic epileptic seizures. The mutated gene responsible for the EPM1 phenotype, cystatin B (*CSTB*), encodes a cysteine protease inhibitor of the cystatin family. The most common EPM1-associated mutation is an unstable expansion of a 12-mer repeat unit located in the promoter region of *CSTB*. Three of the other six known mutations affect conserved splice site sequences and predict severe splicing defects. Two mutations predict a truncated protein through creating a premature termination codon or causing a frameshift, while one is a missense mutation replacing a highly conserved glycine to arginine in exon 1. Expression of the *CSTB* mRNA was quantified in several human tissues, and in patients with different EPM1-associated mutations using TaqMan real-time quantitative PCR and comparative C_T method. Prior to the TaqMan-analysis RNA from control, patient and carrier lymphoblastoid cells were isolated and reverse transcribed. Human TATA binding protein mRNA was used as the endogenous control. The results of the EPM1-patients and mutation carriers were compared to three unaffected controls. *CSTB* mRNA is ubiquitously expressed in both fetal and adult human tissues having the greatest expression in the lung. Comparable with results in Northern analysis of lymphoblast cell RNA, *CSTB* was markedly reduced in the EPM1 patients homozygous for the expansion mutation, showing 3-8% of the expression of the unaffected control. Patients compound heterozygous for the repeat expansion and either a splice site mutation or a nonsense mutation also show reduced *CSTB* expression.

Social Supports and Maltreatment History Co-Moderate Expression of Serotonin Transporter Gene on Childhood Depression: Demonstration of Gene and Complex Environments Interaction. *B.Z. Yang¹, H. Douglas-Palumberi¹, S. Houshyar², D. Lipschitz¹, J.H. Krystal^{1,3}, J. Gelernter^{1,3}, J. Kaufman¹.* 1) Dept Psychiatry, Yale Univ Sch Medicine, West Haven, CT; 2) Dept Psychology, Yale Univ; 3) Natl Center, PTSD Res, VA, CT, West Haven, CT.

We investigated how complex environmental factors, such as social supports and maltreatment history, co-moderate the effects 5-HTTLPR, a functional polymorphism at the serotonin transporter protein gene locus (SLC6A4), on the development of childhood depression. Participants included 101 children: 57 maltreated children who were removed from their parents homes due to allegations of abuse or neglect, and 44 demographically-matched community-control (CC) children who had no prior history of maltreatment or exposure to domestic violence. These 101 children were from 67 families with various numbers of sibs and half-sibs in each family. 5-HTTLPR and 35 STR markers, previously shown to differentiate American populations effectively, were genotyped. Because of sibling relationships, the subjects were not necessarily genetically independent. We ran STRUCTURE (Pritchard et al 2000) multiple times (to cluster population groups empirically and infer ancestry) such that each STRUCTURE run included only one child from each family. The average ancestral proportions (AP) for each subject were defined as the mean of the APs from the STRUCTURE outputs. Generalized Estimating Equations (GEE) were used to model the effects of risk or protective factors while handling familial correlations between subjects resulting from the inclusion of siblings in the sample. Age, sex, and AP scores were entered in all the models as covariates. The main effects of 5-HTTLPR genotype (s/s; l/s; l/l), group (maltreatment; community control), and the social support indices were explored, together with all possible two-way and three-way interactions. The results showed that all the main effects, some two-way and three-way interactions were significant ($p < 0.04$ to < 0.0001). We conclude that maltreatment history and level of social support co-moderate the effect of 5-HTTLPR on development of depression in maltreated children.

Evidence for association of a *CBLB* variant with Type 1 Diabetes and genetic interaction with *CTLA4*. R.

Bergholdt, C. Taxvig, S. Eising, J. Nerup, F. Pociot. Steno Diabetes Center, Gentofte, Denmark.

Background and Aim. Due to an inhibitory role of Cbl-b in T-cell stimulation, dysregulation of Cbl-b may contribute to autoimmune diseases, including Type 1 Diabetes (T1D). The aim of the present study was to screen the human *CBLB* gene for mutations of importance in autoimmune disease and test for association to T1D and interaction with *CTLA4*.

Material and Methods. DNA from two collections of Danish T1D families, 1) 253 families and 2) 227 families, was used (Material 2 only for replication). Mutational screening, by sequencing, was performed in a subset of 24 individuals with T1D and at least one other autoimmune disease, as well as five controls without any autoimmune disease. Coding regions of the *CBLB* gene (Chr. 3q11-13.1) were screened. Genotyping was performed by RFLP-PCR, mutagenically separated PCR or primer extension method. SNPs were tested for association to T1D by Sib-transmission-disequilibrium test. To evaluate the degree of linkage disequilibrium (LD) in the region, the pairwise LD between the SNPs in *CBLB* was evaluated.

Results. Identified SNPs were genotyped in a T1D family material and tested for T1D association. A rare SNP in exon 12 (MAF:0.02) was associated to T1D. Replication of this observation in another Danish T1D family material was attempted, but did not reach significance. However, no difference existed between the two data sets, which were then pooled. When 480 families were evaluated significant association to T1D was still observed. Stratifying *CBLB* exon 12 data, according to genotypes of an established *CTLA4* SNP (*CT60*), strengthened T1D association in the *CT60* high risk subgroup. A high degree of LD in the region was demonstrated, three LD blocks included most of the gene.

Conclusion. We demonstrated T1D association of a rare polymorphism in exon 12 of the human *CBLB* gene. Gene-gene interactions probably play substantial roles in T1D susceptibility and evidence for genetic interaction between the *CTLA4* and *CBLB* genes, both involved in T-cell activation, was observed.

Tyrosinase is a phenotypic modifier of primary congenital glaucoma in Saudi Arabia. C. Bidinost¹, N. Hernandez^{1,2}, D. Edward³, A. Al-Rajhi⁴, J.R. Lupski⁵, R.A. Lewis⁵, B.A. Bejjani^{1,2}, D.W. Stockton⁵. 1) Washington State University, Spokane; 2) Sacred Heart Medical Center, Spokane, WA; 3) University of Illinois in Chicago; 4) King Khaled Eye Specialist Hospital, Riyadh, Saudi Arabia; 5) Baylor College of Medicine, Houston, TX.

Autosomal recessive primary congenital glaucoma (PCG) shows incomplete penetrance in the Saudi Arabian population. About 94% of individuals with PCG in Saudi Arabia have identifiable homozygous or compound heterozygous mutations in cytochrome P4501B1 (CYP1B1). We performed a genome-wide screen for modifier loci responsible for the incomplete penetrance, with both parametric and non-parametric analyses, which was unproductive. Recently, tyrosinase (*Tyr*) was found to modify the drainage structure phenotype in *Cyp1b1*^{-/-} mice, where *Tyr* deficiency caused more severe ocular dysgenesis. To test a possible modifying role for TYR on PCG in the Saudi population, we sequenced all five *TYR* coding exons in 60 individuals with homozygous and compound heterozygous *CYP1B1* mutations from Saudi families with incomplete penetrance, 50 unaffected Saudi controls, 50 unaffected non-Saudis, and 50 PCG-affected Saudis with homozygous and compound heterozygous *CYP1B1* mutations from fully penetrant families. We identified one polymorphism in exon 1 (575CA, S192Y) and a mutation in exon 4 (1205GA, R402Q) that results in a temperature-sensitive enzyme, TYR(R402Q). The exon 1 polymorphism showed similar distribution in all groups tested, but the frequency of heterozygosity for TYR(R402Q) is significantly higher in the fully penetrant families than in the nonpenetrant families ($p < 0.001$). There is no significant difference in the distribution of TYR(R402Q) between affected individuals and their nonpenetrant relatives. The heterozygotes for the R402Q mutation who have homozygous or compound heterozygous *CYP1B1* mutations have an 18-fold relative risk for PCG compared to individuals with an identical CYP1B1 genotype without the R402Q mutation. These data suggest that TYR(R402Q) is a susceptibility or liability allele for PCG in at-risk individuals with *CYP1B1* mutations in the Saudi population.

DIAPH2 is a susceptibility gene for POF. *S. Bione*¹, *C. Sala*², *F. Rizzolio*², *M. Goegan*², *R. Ricotti*¹, *A. Marozzi*³, *W. Vegetti*⁴, *R. Nappi*⁵, *D. Toniolo*^{1,2}. 1) IGM-CNR, Pavia, Italy; 2) DIBIT-HSR, milano, Italy; 3) Dept of Biology and Medical Sciences, University of Milano, Italy; 4) Dept of Obstetrics and Gynaecology, University of Milano, Italy; 5) Dept of Obstetrics and Gynaecology, University of Pavia, Italy.

Premature Ovarian Failure (POF) is a disorder characterized by lack of ovulation and elevated gonadotropin level before 40 years of age. POF has a frequency of about 1% among females, but with the increase of women reproductive age it has become a relevant cause of infertility. A genetic component of the disorder is demonstrated by the frequent finding of POF familial cases, but few responsible genes were identified accounting for a small proportion of cases. The DIAPH2 gene in Xq22 was proposed as a candidate gene for POF as it was found interrupted by the breakpoint of a balanced X/autosome translocation carried by a familial case of POF. Moreover the DIAPH2 gene is one of the two human homologue of the *Drosophila melanogaster* dia gene whose mutated alleles affect fruit fly fertility. To determine the contribution of the DIAPH2 gene in the pathogenesis of POF, we performed a case-control study on a panel of 248 Italian POF patients and 404 matched controls to identify allelic variants associated with the disorder. More than 30 single nucleotide polymorphisms (SNPs) spanning a region of about 1.5 Mb containing the DIAPH2 gene were genotyped and the haplotypic structure of the region was constructed using a pair-wise maximum likelihood estimation method. The region resulted split into three linkage disequilibrium (LD) blocks of about 540, 340 and 79 kb in length. One of the SNP analysed (L1) showed significant association to the POF condition ($p=0.0187$). The genotypes at the L1 locus resulted significantly different between patients and controls ($p=0.0053$) showing an excess of heterozygous individuals. The results can be explained by a reduction of male and homozygous female fertility. Experiments are in progress to verify the hypothesis. Our results demonstrated the involvement of DIAPH2 as a susceptibility gene for POF and provide new evidences in favour of a multifactorial pattern of inheritance of X-linked POF.

Identification and characterization of a Xp22.33 : Yp11.2 translocation causing a triplication of several genes of the PAR1 region in a XX male patient with severe Systemic Lupus Erythematosus. *P. Chagnon*¹, *R. Schneider*², *J. Hebert*^{1, 3}, *P. Fortin*⁴, *S. Provost*¹, *C. Belisle*¹, *V. Bolduc*¹, *M. Gingras*¹, *M. Lussier*⁵, *E. Silverman*², *L. Busque*¹. 1) Research Centre, Maisonneuve-Rosemont Hospital, University of Montreal, Montreal, Canada; 2) The Hospital for Sick Children, University of Toronto, Toronto, Canada; 3) The Leukemic Cell Bank of Quebec (BCLQ), Maisonneuve-Rosemont Hospital, Montreal, Canada; 4) University Health Network, Toronto, Canada; 5) HemaX Genome inc., Montreal, Canada.

The X;Y translocation breakpoint sequence of a XX male patient suffering from prepubertal Systemic Lupus Erythematosus (SLE) was characterized with the intention of identifying predisposing gene(s) for SLE. Spectral Karyotyping (SKY) of the patients metaphase chromosomes showed normal autosomes and two X chromosomes with one displaying a small portion of the Y chromosome. Fluorescence in situ hybridization (FISH) studies using a SRY gene-specific probe revealed that the breakpoint on the Y chromosome occurred downstream of this gene. Using a Y-chromosome PCR walking strategy and inverse PCR, we showed that the abnormal recombination occurred between retroviral long terminal repeats (LTR) of the pseudoautosomal regions of Xp22.33 (position 0.95 mb) and Yp11.2 (4.20 mb). The complete sequence of the breakpoint was determined. The recombination event caused a partial duplication of the pseudoautosomal region 1 (PAR1) in the derivative X chromosome. As a result, a portion of the genes of the PAR1 are found in three copies (partial trisomy) in the patients genomic DNA, which was confirmed by real time quantitative PCR. Gene expression analyses using TaqMan Assay also revealed an overexpression profile in the patient compared to normal individuals. The uniqueness of the translocation, the rarity of male severe prepubertal SLE, and the increased incidence of SLE in Klinefelter syndrome, who also have a triplication of the PAR1 region, point to a relationship between the partial triplication of the PAR1 region and SLE development in the patient. There is major interest to verify if one or more of the triplicated genes are involved in common SLE or other autoimmune disorders.

Association of the 5-*HTR1A* gene region with Autism Spectrum Disorders. C. Correia¹, A.M. Coutinho¹, C. Bento², C. Marques², A. Ataíde², T. Miguel², L. Borges², G. Oliveira², A.M. Vicente¹. 1) Instituto Gulbenkian de Ciência, Oeiras, Portugal; 2) Hospital Pediátrico de Coimbra, Coimbra, Portugal.

High levels of platelet serotonin have been consistently found in a proportion of autistic patients, suggesting that an abnormality in the serotonin (5-HT) system may be involved in autism etiology. We have previously found that 5-HT transporter gene variants are associated with an increased risk for hyperserotonemia. However, the reported association only accounts for a proportion of the total 5-HT variance. Other genes and environmental factors are likely involved in hyperserotonemia, and the somatodendritic autoreceptor 5-HT_{1A} is a strong candidate. In this study, we examined the association with autism and serotonin levels of two microsatellites in the 5-*HTR1A* gene region, D5S668 and D5S1956, in a sample of 221 autistic nuclear families. We found strong transmission disequilibrium of alleles at the D5S668 marker (Allele-wise TDT: $\chi^2=30.13$; $df=9$; $P=0.0004$), with preferential transmission of allele 1 ($\chi^2=6.898$; $P=0.0087$) and less frequent transmission of allele 2 ($\chi^2=3.903$; $P=0.048$). We examined the data for parent-of-origin effect and found significant results for paternal transmissions for D5S668 (Allele-wise TDT: $P=0.005$), which is suggestive of maternal imprinting. No transmission disequilibrium of D5S1956 was observed. In 144 trios, no significant association of serotonin levels was found with either marker, although a trend was found for D5S668 ($P=0.0596$ for D5S668; $P=0.0854$ for D5S1956). A larger sample size is necessary to confirm a possible role in the determination of serotonin levels. In conclusion, we obtained strong evidence for the existence of a susceptibility gene for autism in the region of marker D5S668, which might also be implicated in the regulation of serotonin levels. Further studies are being carried out with SNPs in the 5'UTR of 5-*HTR1A* gene to test our hypothesis that this gene is responsible for the observed association with autism and to clarify its possible role in the determination of serotonin levels.

Association of the DTNBP1 locus with schizophrenia in a US population. *B. Funke¹, C.T. Finn¹, A.M. Plocik¹, S. Lake², P. DeRosse³, J.M. Kane³, R. Kucherlapati¹, A.K. Malhotra³.* 1) Harvard Partners Center for Genetics and Genomics, Boston, MA; 2) Channing Laboratory, Brigham and Women's Hospital, Boston, MA; 3) Psychiatry Research, The Zucker Hillside Hospital, Glen Oaks, NY.

Linkage and association studies have recently implicated the dystrobrevin-binding protein 1 (DTNBP1) in the etiology of schizophrenia. We analyzed seven previously tested DTNBP1 single nucleotide polymorphisms in a cohort of 563 cases with schizophrenia or schizoaffective disorder and 649 control subjects. The minor alleles of three SNPs (P1578, P1763, P1765) were positively associated with the diagnosis of schizophrenia or schizoaffective disorder in the Caucasian subset of the study cohort (258 cases; 467 controls) with P1578 showing the most significant association ($p = 0.0026$). The same three SNPs were also associated in a smaller Hispanic subset (51 cases; 32 controls). No association was observed in the African American cohort (215 cases; 74 controls). A stratified analysis including the Caucasian and Hispanic subsets showed association with the minor alleles of four SNPs (P1578, P1763, P1320 and P1765). Again, the most significant association was observed for P1578 ($p = 0.0006$). Haplotype analysis supported these findings with a single risk haplotype significantly overrepresented in the Caucasian sample ($p = 0.005$). Our study provides further evidence for a role of the DTNBP1 gene in the genetic etiology of schizophrenia.

Narrowing down the haplotype association for preeclampsia on chromosome 2p25. *H. Laivuori*¹, *E. Kerkelä*², *H. Peterson*², *H. Jiao*², *K. Kivinen*², *V.-V. Mäkelä*², *R. Kaaja*³, *O. Ylikorkala*³, *J. Kere*². 1) HUSLAB Department of Clinical Genetics, Helsinki University Central Hospital, Helsinki, Finland; 2) Department of Biosciences at Novum, Karolinska Institutet, Huddinge, Sweden; 3) Department of Obstetrics and Gynecology, Helsinki University Central Hospital, Helsinki, Finland.

Preeclampsia, a potentially life-threatening disease during pregnancy, is characterized by hypertension and proteinuria. The epidemiology of preeclampsia suggests a genetic basis for the disorder. We have previously mapped a susceptibility locus for preeclampsia on chromosome 2p25 in 15 Finnish families, and the linkage of the previously mapped locus was verified with additional microsatellites (NPL score = 4.09, $p = 0.00036$). We continued finemapping using high-density single nucleotide (SNP) polymorphism genotyping. Further analysis of SNPs within the peak region revealed a significant association ($p = 0.0099$), and the region was narrowed down to 290 kb by a 3-SNP haplotype. Sequencing analysis of a 80-kb area around the peak marker in one woman homozygous for the haplotype yielded 57 SNPs. Twenty of the those SNPs were chosen (about 4 kb interval) for genotyping in all of the studied individuals, and the association was confirmed ($p = 0.0287$). The new peak region was centralized to eight SNPs with a haplotype (22112*11) showing more often in the affecteds than in the non-affecteds (22% vs. 9% of frequencies). The remaining SNPs found 13 kb upstream and 8kb downstream from the two peak markers will be genotyped for the final genetic dissection of the whole putative region.

Family-based and case-control association of Brain-Derived Neurotrophic Factor (BDNF) and adult ADHD. *M.B. Lanktree, P. Muglia, A. Squassina, M. Krinsky, U. Jain, F.M. Macciardi, J.L. Kennedy.* Centre for Addiction and Mental Health, Clarke Site, Toronto, ON, Canada.

Introduction: Studies have shown that adult ADHD has an increased prevalence in families, possibly due to a greater genetic liability. Neuroimaging, pharmacological data, and candidate-gene association studies indicate that the dopamine system plays a crucial role in the pathophysiology of ADHD. The Brain-Derived Neurotrophic Factor (BDNF) is a neurotrophin involved in survival, differentiation, and synaptic plasticity of several neuronal systems including the dopaminergic system and is expressed throughout the life of the neurons. **Methods:** In the present study we tested the association between six BDNF polymorphisms (five SNPs and one STR) and adult ADHD. The sample consisted of 119 trios comprised of an adult ADHD proband and their biological parents and an independent sample of 121 ADHD cases and a corresponding number of sex, age and ethnically matched controls. Association was tested using Haplotype Relative Risk (HRR), Haplotype Trend Regression (HTR) and quantitative tests using ANOVA. **Results:** Association was found at each marker ($p < .05$) with the strongest linkage at the STR ($p < .005$). Quantitative trait analysis was performed comparing core symptom Wender and BADDs mean scores across genotype groups. No significant differences were found in symptom scores between the genotype groups within cases. Subjects who met the criteria for depression were removed from the study, however, we examined the affective symptom scores on the BADDs scale to determine if our positive results were artifacts of comorbid depression and no association was found. Two common haplotypes were found and Haplotype Trend Regression (HTR) analysis of the six polymorphisms showed one was a risk haplotype and one was a protective haplotype ($p < 0.005$). **Conclusions:** While BDNF has been strongly implicated in affective disorders, no previous studies have investigated for the presence of association between ADHD and BDNF. Our results suggest that the BDNF gene may play a role in increasing the susceptibility to ADHD.

Association of a COMT promoter polymorphism with schizophrenia. *A.K. Malhotra³, C.T. Finn¹, A.M. Plocik¹, S. Lake², P. DeRosse³, J.M. Kane³, R. Kucherlapati¹, B. Funke¹.* 1) Harvard Partners Center for Genetics and Genomics, Boston, MA; 2) Channing Laboratory, Brigham and Women's Hospital, Boston, MA; 3) Psychiatry Research, The Zucker Hillside Hospital, Glen Oaks, NY.

Positional as well as functional evidence implicates the COMT gene in the genetic etiology of several psychiatric disorders, but results from previous association studies have been inconsistent. We genotyped four known COMT single nucleotide polymorphisms (SNPs) in 717 total cases (schizophrenia n=452, schizoaffective disorder n=111, mood disorder n=154) and 649 controls. The SNPs included the Val108/158Met polymorphism, which affects COMT activity and SNPs rs737865 and rs165599, which were highly associated in a previous study (1). In addition, we genotyped a SNP in the P2 promoter (-278A/G; rs2097603) as recent evidence suggests that cis-acting variation in the COMT gene may confer susceptibility to schizophrenia (2). In the Caucasian group including all affecteds (446 cases, 467 controls) the A allele of rs2097603 as well as the G alleles of the Val/Met polymorphism and rs165599 were significantly associated (p=0.0079; p=0.0096; p=0.0167), and one haplotype consisting of the three positively associated alleles plus the G allele for rs737865 (A-G-G-G) showed a trend towards significance (p=0.06). When the single SNP analysis was limited to subjects with schizophrenia and schizoaffective disorder, the promoter polymorphism remained significant while the Val/Met variant showed a trend towards significance in females. In the remaining set of patients (mood disorder), the Val/Met SNP and rs165599 yielded significant p-values of < 0.05. While our results confirm a possible contribution of cis-acting COMT variation to schizophrenia, they do not clarify the role of the Val/Met variant, which may reflect the difficulty of standardizing assessment of patients with psychiatric disease in the absence of objective biomarkers. 1. Shifman et al. (2002) *Am J Hum Genet* 71: 1296; 2. Bray et al. (2003) *Am J Hum Genet* 73:152.

A Pharmacogenetic Study of Bipolar Disorder: The CREB Family of Genes. *F. Mamdani, A. Sequeira, M. Alda, P. Grof, G. Rouleau, G. Turecki.* Douglas Hospital Research Centre, McGill University, Montreal, Quebec, Canada.

Bipolar disorder (BD) is a severe psychiatric disorder that affects 1% of the population. The importance of genes in BD has been enforced through studies using families, twins and adopted children. Recently, there have been many attempts to identify specific genes that are involved in BD; however, the task of finding susceptibility genes is not easy because BD is a complex disorder. One way to go about finding these susceptibility genes is using a pharmacogenetic approach, which implies looking at genes that may be involved in drug response. Pharmacogenetics has been increasingly used in the past 5-10 years and provides hope that eventually drug response will be a predictable factor. The most commonly used mood stabilizer in the treatment of BD, with approximately, 60% of patients showing some form of response. Unfortunately, lithium's mechanism of action has still not been defined, but studies have been consistently suggesting that lithium may act by modulating signal transduction pathways, and particularly, the cAMP pathway and CREB, which regulates transcriptional activity. An association study was carried out looking at the CREB1, CREB2 and CREB3 genes, located at ch 2q32.3-q34, 22q13.1 and 9pter-p22.1, respectively. A total of four promoter single nucleotide polymorphisms (SNP), 5 SNPs in the UTR, 5 exonic and 6 intronic SNPs were investigated for their frequency and haplotype distribution in a BD sample of 185 lithium responders and 57 nonresponders and 127 controls using a SNaPshot multiplex reaction. Our results suggest that the CREB1-1 SNP (A to T change, $P = 0.055$) and the CREB2-2 SNP (A to G change, $P = 0.034$) may have an effect on BD and lithium response.

Associations with schizophrenia over a 365kb region at Chromosome 3q13. *M.E. Talkowski¹, K.V. Chowdari¹, H. Mansour¹, J. Wood¹, M. Owen², M. O'Donovan², N. Norton², V.L. Nimgaonkar¹.* 1) University of Pittsburgh, Pittsburgh, PA; 2) University of Wales College of Medicine, Cardiff, UK.

We report on case-control and family based analyses consistent with SNP based associations over a 1.3mb region flanking the dopamine D3 receptor gene (*DRD3*). A ser9gly coding variant at exon1 of *DRD3* has been investigated extensively, but consistent associations have not been detected. We have investigated 69 SNPs at *DRD3*, as well as flanking regions.

We initially genotyped 15 SNPs spanning a 365 kb region centered on *DRD3* among 331 patients with schizophrenia/schizo-affective disorder (SZ), including 151 cases with available parents (case-parent trios). Cord blood samples from local live births served as unrelated, unscreened controls (n = 279). Transmission Disequilibrium tests (TDT) revealed significant associations with 5 SNPs. Significant case-control associations were also detected at 5 SNPs spanning 365kb about the *DRD3* locus, with case-control frequency differences ranging from 4.7% to 11%. Linkage disequilibrium (LD) patterns suggest four or more distinct associated haplotype blocks in this region.

To rapidly evaluate the bounds of the associated region, we next estimated allele frequencies among samples of pooled DNA from cases and controls using a novel re-sequencing protocol (n=200 per pool). We thus investigated 54 additional SNPs spanning a 1.3 mb region. We detected frequency differences over 7% for 11 additional SNPs across this region (range 7%-21%). Similar case-control differences were detected for 7 of these SNPs in an independent sample from Cardiff, UK (n=540 cases, 360 controls; range 4%-14%). The differences are particularly noticeable centromeric to *DRD3*.

Our analyses using individual and pooled genotyping assays thus suggest that associations with SZ exist over an extensive genomic region at chromosome 3q13. Further replicate studies are ongoing.

Further refinement of the susceptibility locus for migraine with aura on 4q24. *P.J. Tikka¹, M.A. Kaunisto¹, G. Oswell², M. Kallela³, J.C. Papp⁴, A. Presson⁴, E. Hämäläinen¹, T. Hiekkalinna⁵, H. Havanka⁶, J. Terwilliger⁷, M. Färkkilä³, L. Peltonen⁵, M. Wessman^{1,8}, A. Palotie^{1,2}.* 1) Biomedicum Helsinki, Research Program in Molecular Medicine and The Finnish Genome Center and Dept. of Clinical Chemistry, University of Helsinki, Finland; 2) Dept. of Pathology and Human Genetics, David Geffen School of Medicine at UCLA, USA; 3) Dept. of Neurology, University of Helsinki, Finland; 4) Dept. of Statistics, David Geffen School of Medicine at UCLA, USA; 5) Dept. of Medical Genetics, University of Helsinki and Dept. of Molecular Medicine, National Public Health Institute, Helsinki, Finland; 6) Dept. of Neurology, Länsi-Pohja Central Hospital, Kemi, Finland; 7) Columbia Genome Center, Columbia University, USA; 8) Folkhälsan Research Center, Helsinki, Finland.

Migraine is a complex neurovascular disease with a recurrent transient focal disabling headache as the main symptom. The neuronal dysfunction preceding the headache phase, which typically presents as visual symptoms, is the distinguishing feature in migraine with aura (MA). Migraine affects 10 - 15 % of adult females and 2 - 6 % of adult males, and 15 % of migraine attacks are of the MA type. Despite several genome-wide linkage and candidate gene studies predisposing genes for common types of migraine have not yet been identified. We have collected a large sample of Finnish MA families consisting of 600 families and more than 4000 DNAs. Using a subset of 50 families our group has reported linkage (HLOD 4.45) to 4q24, and subsequently restricted it to a 10 Mb (6.1 cM) region from D4S3006 to D4S1591. In order to further refine the position of an MA susceptibility locus, we performed fine mapping by genotyping 50 microsatellite markers and 110 SNPs. The -1 lod confidence interval highlighted the region between D4S1578 and D4S1572 as the most likely position. FBAT, Pseudomarker and Transmit analyses of 110 SNPs provided suggestive (p-values ranging from 0.0003 to 0.067), but not conclusive evidence for association in linked pedigrees. Further fine mapping using 400 additional SNPs and construction of combined microsatellite and SNP haplotypes is currently in progress.

Association of polymorphisms and haplotypes in the elastin gene in Dutch patients with sporadic aneurysmal subarachnoid hemorrhage. Z. Urban^{1, 2}, Y.M. Ruigrok³, S. Wolterink¹, S. Böhn^{1,2}, C. Wijmenga⁴, G.J.E. Rinkel³. 1) Biochemistry, JABSOM, Univ Hawaii, Honolulu, HI; 2) Pediatrics, Washington University Medical School, St. Louis, MO; 3) Neurology, University Medical Center, Utrecht, Netherlands; 4) Biomedical Genetics, University Medical Center, Utrecht, Netherlands.

A locus containing the elastin gene has been linked to familial intracranial aneurysms in two distinct populations. We investigated the association of single nucleotide polymorphisms (SNPs) and haplotypes of SNPs in the elastin gene with the occurrence of subarachnoid hemorrhage (SAH) from sporadic aneurysms in the Netherlands. We genotyped 167 SAH-patients and 167 matching controls for 18 exonic and intronic SNPs in the elastin gene. A Bonferroni correction was applied for multiple comparisons to all novel associations, with a correction factor derived from the number of SNPs tested (p_{corr}). There was a statistically significant association of SAH with a SNP in exon 22 of the elastin gene (minor allele frequency was 0.000 in patients and 0.028 in controls, OR 0.0, 95% CI 0.0-0.7, $p=0.004$; $p_{\text{corr}}=0.05$) and possibly with a SNP in intron 5 (minor allele frequency was 0.062 in patients and 0.128 in controls, OR 0.5, 95% CI 0.2-0.8, $p=0.007$; $p_{\text{corr}}=0.08$). Haplotypes of intron 5/exon 22 ($p_{\text{corr}}=0.002$), intron 4/exon 22 ($p_{\text{corr}}=0.02$), and intron 4/intron 5/exon 22 ($p=9.0 \times 10^{-9}$) were also associated with aneurysmal SAH. Variants and haplotypes within the elastin gene are associated with the risk of sporadic SAH in Dutch patients. Gradual increase of statistical power with the inclusion of 2 or 3 SNPs in the studied haplotypes supports the validity of our conclusion that the elastin gene is a susceptibility locus for SAH.

Obesity and genes of the dopamine system: A study of a Mexican population. *L. VanderBeek¹, M.B. Lanktree¹, R.D. Levitan¹, B. Camarena², H. Nicolini³, J.L. Kennedy¹*. 1) Centre for Addiction and Mental Health, Clarke Site, Toronto, ON, Canada; 2) National Institute of Psychiatry Ramón de la Fuente, Mexico City, Mexico; 3) Mexico City University, Mexico City, Mexico.

Introduction: We have recently reported a preliminary association between the 7-repeat allele of the dopamine-4 receptor gene and high lifetime body mass index in a Canadian sample of overeating women with Seasonal Affective Disorder (SAD). Particularly in high-risk populations, we speculate that dopamine genes may influence hedonic tone, establishing increased vulnerability to obesity in an environment where highly palatable, high caloric foods are plentiful. In the current study we examined whether genes coding for the dopamine D2 and D4 receptors (DRD2, DRD4) were associated with obesity in a sample of 44 small Mestizo families (people of mixed Spanish and Native Mexican ancestry) with an identified obese proband. **Methods:** The DRD4 VNTR and D2Taq1A polymorphisms were typed and quantitative measures were collected for all individuals (total N=123). ANOVA was used to compare quantitative measures in each of the genotypic groups using all individuals, while FBAT analysis was used to assess the transmission of quantitative phenotypes to affected probands. **Results:** In probands with obesity, FBAT found significant association between transmission of the 4-repeat allele of the DRD4 VNTR and increased BMI ($p=.04$). ANOVA analysis showed a non-significant trend associating the 4-repeat allele and high BMI ($p=.15$). These results were found with allele 4, as opposed to our prior finding in overeating women with SAD, in which the 7-repeat variant was the risk allele for obesity. **Conclusions:** The fact that different alleles of the DRD4 VNTR polymorphism may play a role in obesity in high risk Canadian vs. Mexican populations suggests that either the DRD4 VNTR polymorphism is in linkage disequilibrium with other genes contributing to obesity, or perhaps that different mechanisms are involved in obese patients where seasonality is or is not a strong environmental factor.

Functional polymorphisms of the human peroxisome proliferator-activated receptors gamma2 gene are associated to type 2 diabetes in African-Americans. *Q. Song¹, Q.W. Wang¹, Q. Xu¹, R. Kittles², G.H. Gibbons¹, C. Rotimi², The Africa America Diabetes Mellitus (AADM) Study.* 1) Cardiovascular Res Inst, Morehouse School of Medicine, 720 Westview Dr SW, Atlanta, GA 30310; 2) The National Human Genome Center, Howard University, Washington, DC 20059.

Peroxisome proliferator activated receptor gamma2 (PPAR γ 2) is a key transcription factor in adipocyte differentiation and lipid metabolism. No polymorphisms on this gene have been associated to diabetes in African-Americans. In this study, we systematically screened the 5-flanking region of human PPAR γ 2 gene and identified 11 novel single nucleotide polymorphisms (SNPs). Genetic association analysis in the Africa America Diabetes Mellitus (AADM) cohort showed that 2 SNPs, which are common in both African-Americans and Caucasians, are significantly associated with type 2 diabetes. Analysis of linkage disequilibrium (LD) and haplotype showed markedly divergent LD block structure, haplotype frequencies and single SNP frequencies among different ethnic US populations. These 2 common promoter SNPs are tightly in LD with Pro12Ala in Caucasians, but not in LD with Pro12Ala in African-Americans. Bioinformatic analysis using the VISTA program indicated that these 2 polymorphisms reside in an evolutionarily highly conserved region. Systematic functional analysis was performed by electrophoretic mobility shift assay (EMSA) and promoter-reporter assays. EMSA showed that these 2 SNP altered the DNA-protein binding intensities and may affect the recruitment of transcription factors during the PPAR γ 2 gene expression. Promoter deletion analysis showed that these 2 SNPs reside in regions that contain functionally important cis-elements of the PPAR γ 2 gene. Haplotype- and allele-specific PPAR γ 2 promoter reporter constructs showed that SNP-3 dramatically altered the PPAR γ 2 promoter activity in differentiated 3T3L1 adipocytes, and there is an interaction between alleles of SNP-3 and SNP-5 on their regulation of PPAR γ 2 transcription. Taken together, our data showed that there are functional-relevant genetic polymorphisms in the PPAR γ 2 promoter that are associated with the risk to develop type 2 diabetes.

Sensory deficiencies in a mouse model for Bardet-Biedl syndrome. A.J. Ross¹, H. May-Simera¹, J.P. Chapple², P.M. Munro², J. Hill¹, J.R. Lupski³, P.E. Scambler¹, N. Katsanis⁴, P.L. Beales¹. 1) Molecular Medicine Unit, Institute of Child Health, UCL, London, UK; 2) Department of Pathology, Institute of Ophthalmology, UCL, London, UK; 3) Dept of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 4) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

Bardet-Biedl syndrome (BBS) is a pleiotropic disorder with primary features that include age-related retinal dystrophy, obesity, polydactyly, renal dysplasia, reproductive tract abnormalities and cognitive impairment. It is genetically heterogeneous, with mutations identified in eight genes to date (*BBS1-8*). Recently there has been several lines of evidence to suggest that the BBS phenotype may result from a defect in cilia formation and/or function, or intraflagellar transport (IFT). Since, in addition to having visual impairments, 3% of BBS patients also have sensorineural deafness, together with our recent results of olfactory function showing that 47% of patients also manifest partial or complete anosmia, we were prompted to evaluate a mouse model of BBS for sensory deficiencies. We generated a mouse model null for the *Bbs6/Mkks* gene, which shows strong homology to the type II chaperonins. Null mice display age-related retinal degeneration that eventually leads to a complete loss of the photoreceptor layer. TUNEL staining showed that apoptosis occurs in the outer nuclear layer of the retina at ~2 weeks of age. Hearing was assessed using a 20KHz frequency generator and 31% of mice were identified to be impaired; olfactory function was tested by scoring the retrieval of buried food. We suggest that the sensory deficiencies displayed by *Bbs6*^{-/-} mice may result from ciliary dysfunction in sensory neurons and we present here data from structural analyses of cilia in the olfactory epithelia, cochlear hair cells and photoreceptors.

The role of NACP-Rep1 Polymorphic repeat in the regulation of -synuclein transcription. *O. Chiba-Falek*¹, *J.A. Kowalak*², *S.P. Markey*², *R.L. Nussbaum*¹. 1) GDRB/NHGRI/NIH, Bethesda, MD; 2) NIMH/NIH, Bethesda, MD.

Mutations and triplications of the α -synuclein gene have been implicated in familial Parkinson's disease (PD) while certain polymorphic alleles at a complex microsatellite repeat, NACP-Rep1, located ~10 kb upstream of the gene, have been associated with sporadic PD. Using luciferase reporter constructs, we showed previously that two domains flanking the repeat interact to enhance expression while the repeat acts as a negative modulator. Furthermore, we demonstrated that the expression levels among four NACP-Rep1 alleles of different lengths varied significantly, over a 3-fold range, in the neuroblastoma cells, SH-SY5Y. Subsequently, we showed previously that a NACP-Rep1 allele defined by length can differ in sequence due primarily to the intra-length variation of the TC-TA dinucleotides. However, analysis of two sequence variant alleles of size "1" using the luciferase reporter system showed only a slight expression difference between these 2 variants. This finding suggests that the length of the NACP-Rep1 allele, rather than minor sequence variation, plays the main role in the transcriptional regulation of α -synuclein expression. Next we studied the factors that bind to the NACP-Rep1 element and the region surround it. Proteins that bind to the NACP-Rep1 element were purified from SH-SY5Y nuclear extract and identified by mass spectrometry. One of the DNA-binding proteins detected is poly (ADP-ribosyl) transferase/polymerase (PARP). PARP was shown to play a role in MPTP-induced parkinsonism and dopaminergic neuronal cell death in a mouse model. Using electrophoresis mobility shift and super shift assay as well as chromatin immuno-precipitation assay we were able to further confirm the binding of PARP to the NACP-Rep1 element. Finally, we demonstrated the role of PARP in the regulation of α -synuclein expression and in modulating its promoter/enhancer activity. Given that even a two-fold increase in α -synuclein expression may, over many decades, cause PD, the association of different NACP-Rep1 alleles with PD may be a consequence of polymorphic differences in transcriptional regulation of α -synuclein expression resulting from different NACP-Rep1 alleles.

Friedreich ataxia in carriers of somatically unstable borderline GAA repeat alleles. *I. De Biase*¹, *R. Sharma*¹, *M. Gomez*¹, *M. Delatycki*², *T. Ashizawa*³, *S.I. Bidichandani*¹. 1) Biochemistry and Mol Biol, University of Oklahoma HSC, Oklahoma City, OK; 2) Murdoch Childrens Research Institute, University of Melbourne, Australia; 3) Neurology, University of Texas Medical Branch, Galveston, TX.

Friedreich ataxia (FRDA) is the most common recessive ataxia, typically caused by a large GAA repeat expansion within the first intron of the *FRDA* gene. Patients develop ataxia, hypertrophic cardiomyopathy and diabetes. Disease-associated repeats are reported to contain 66-1700 triplet-repeats. Rare alleles with 30-65 uninterrupted triplet-repeats, called premutations, do not normally cause disease, but may expand into the pathogenic range when transmitted from parent to child. However, given the rarity of alleles in this size range, the demarcation between normal and disease alleles remains poorly defined. We report two FRDA patients with delayed onset, hyperreflexia, and gradually progressive disease, who in addition to being heterozygous for large expansions, had alleles with 44 and 66 triplet-repeats, respectively. Using small pool PCR analysis of different tissue sources we demonstrate that these alleles, although not clearly in the disease range, were somatically unstable. As many as 15% (GAA-44) and 78% (GAA-66) of somatic cells contained alleles with >66 triplet-repeats, constituting a plausible mechanism for the atypically mild FRDA phenotype. In fact, 4.6% of somatic cells in the constitutive carrier of the GAA-66 allele contained >100 triplet repeats. The brother of the patient with the GAA-44 allele was found to carry a fully expanded allele and an allele with 37 triplet-repeats (GAA-37). Presently, in contrast to his sister, this subject does not show any clinical features of FRDA. By SP PCR, the GAA-37 allele showed no somatic variability. Our small pool PCR analysis of other carriers of borderline alleles indicates that the threshold for the initiation of somatic instability is between 40-44 uninterrupted GAA triplets. Our data indicate that somatic instability of borderline alleles (>40-44 uninterrupted triplets) may confer a risk of developing clinical disease by resulting in a significant proportion of cells bearing disease-causing expansions in pathologically affected tissues.

In vitro RNA interference against MHV-3 virus. *M.C. Grippo¹, T. Campos-Pereira¹, R. Gilioli², I. Lopes-Cendes¹.*
1) Med.Genet., UNICAMP/FAC. CIENCIAS MED, Campinas, SP, Brazil; 2) Animal Control, UNICAMP/CEMIB, Campinas, SP, Brazil.

RNA Interference (RNAi) has become a powerful used tool for the analysis of gene function and silencing mediated by double stranded RNA molecules. The first applications of the RNAi was demonstrated recently, including silencing of some viruses in vitro. The objective was to verify the efficiency of this new technique in the combat of the virus MHV-3 (hepatite murine type3). MHV belongs to the Coronavirus family, being the more frequently pathogen identified in mice used in experimental models. The Coronavirus is an enveloped virus with a large plus-stranded genome RNA. The MHV-3 codifies four structural proteins: protein S, which forms the petal-shaped spikes; protein M, which serves as a bridge between the nucleocapsid and the viral enveloped and the nucleocapsid protein (N) that wraps the viral genome into a long, helical nucleocapsid. This last one was choose, as our target to produce siRNAs molecules. Design of siRNAs was based on the sequence genome of MHV(GenBank AF 201929). We obtained 2 siRNAs, named 634 and 910, based in the position of the messenger RNA. A T7 promoter sequence was inserted upstream to the 21-mer MHV oligonucleotides to mallow in vitro Transcription. 1×10^4 L-929 cells, susceptible for MHV-3, were cultivated in 24 wells plates for 24 hours. 270 ng/well of each RNAs were tested for transfeccion with lipofectin. After transfection, cells were infected with 1 TCID₅₀ of the virus and observed in an interval of 24 to 48 hours, for the presence of citopatic effect through the formation of sincititions. We used three types of controls siRNA molecules: irrelevant, mutated and MEM-Eagle. The analysis of the results, clearly show reduction of the citopatic effect of the MHV-3 in the cellular cultures treated with siRNA910, while siRNA634 demonstrated not to have a significant effect. Molecular quantitative analysis for confirmation of the observed results is in progress and will be carried out by quantitative RT-PCR. Tests with siRNAs directed to other sequences of the MHV genome and in vivo experiments are also planned in order to better evaluate the potential use of RNAi in the treatment of MHV-3 viral infection.

Positional Candidate Gene Evaluation for Age-Related Maculopathy. *Y.P. Conley^{1,2}, D.E. Weeks², A. Thalamuthu², T.S. Mah³, R.E. Ferrell², M.B. Gorin^{2,3}.* 1) Health Promotion & Development, Univ Pittsburgh, Pittsburgh, PA; 2) Human Genetics, Univ Pittsburgh, Pittsburgh, PA; 3) Ophthalmology, Univ Pittsburgh, Pittsburgh, PA.

Age-related maculopathy (ARM) is a leading cause of visual impairment in elderly Americans with the prevalence expected to increase by approximately 60% over the next 20 years. Well-recognized as a complex genetic disorder, ARM is a major public health concern of unknown pathogenesis. Through the use of microsatellite-based genome wide scans with small ARM families, we have found consistent linkage for 1q31, 10q26 and 17q25 within 530 families consisting of 736 affected sib pairs. We have initiated association studies for 15 candidate genes based upon their localization within these intervals and/or their implicated roles in pathways that have been implicated in ARM pathobiology. The selected candidate gene products have functions associated with inflammatory processes, cholesterol/lipoprotein metabolism, and basement membrane integrity. We have conducted both family-based and case/control (330 well-characterized, age appropriate, non-ARM controls) association studies. Preliminary data analyses indicate that one gene involved with basement membrane integrity (HEMICENTIN) and one gene involved with cholesterol/lipoprotein metabolism (VLDLR) are putatively associated with ARM status based on our preliminary analyses. Additional analyses including replicate testing and haplotype analyses are currently being conducted to confirm these findings.

QTLs that modify light-induced retinal damage in albino mice; evaluation of the arrestin gene (*Sag*) for one

QTL. *M. Danciger*¹, *D. Worrill*¹, *J. Lyon*¹, *C. Yamashita*², *H. Yang*³, *D.B. Farber*², *M.M. LaVail*³. 1) Loyola Marymount Univ, Los Angeles, CA; 2) JSEI, UCLA Schl of Medicine, Los Angeles, CA; 3) Beckman Vision Center, UCSF School of Medicine, San Francisco, CA.

In a previous study of C57BL/6J-c^{2J} (B6a) and BALB/c albino mice, we found that ~50% of the genetic resistance to light-induced retinal damage shown by B6a was due to a QTL on distal Chr 3. There is strong evidence that the B6a, Met450 variant of RPE65 is the resistant allele underlying the QTL. However, the NZW/LacJ mouse carries the Met450 allele but is susceptible to light insult. One explanation is that NZW has other sensitive gene alleles that negate the protection conferred by RPE65-Met450. The purpose of this work was to test the above hypothesis. Progeny of an F1 intercross between NZW and B6a aged to ~3 months were exposed to 3 weeks of constant light at an in-cage illuminance of 20-70 ft-c. After exposure, retinal damage was quantified in a single 1- retinal section by averaging 12 measurements of the thickness of the outer nuclear layer in the posterior-superior retina. DNAs of 156 F2s were genotyped with 77 dinucleotide repeat markers spanning the genome; selected markers were typed in another 45 F2s. Sequencing and Western blot were done by standard methods. There was no QTL at distal Chr 3. There were QTLs on Chrs 1 (two), 10, 13, 14 and 16. The QTLs on Chrs 1 and 10 matched QTLs found in previous age-related and light-induced retinal damage studies. Sequencing of the arrestin gene in the mid Chr 1 QTL revealed two variants. One of these was an A/G variant 2 bp upstream of the start of translation. Although this variant did not predict a difference in translation, levels of arrestin were tested in the two strains before and after light exposure with Western blot analysis. No significant difference between strains could be detected.

The absence of a QTL at distal Chr 3 supports the hypothesis that RPE65 is responsible for the Chr 3 QTL found previously as both the B6a and NZW strains carry RPE65 Met450. The matching of QTLs from this study with QTLs in other studies suggests some commonality in retinal damage pathways.

Apolipoprotein E Gene Polymorphisms in Japanese Patients with Open Angle Glaucoma. *F. Mabuchi¹, S. Tang², D. Ando², M. Yamakita², J. Wang², K. Kashiwagi¹, Z. Yamagata², H. Iijima¹.* 1) Department of Ophthalmology, School of Medicine, University of Yamanashi, Yamanashi, Japan; 2) Department of Health Sciences, School of Medicine, University of Yamanashi, Yamanashi, Japan.

Objective: To date, it has been reported that the apolipoprotein E (APOE) gene have a role in the etiology of open angle glaucoma (OAG), with the 4 alleles being a risk factor. However, not all APOE studies have found an association, and among these the associations differ. Additionally, there has been no study about the association between them in the Japanese population. The current study was conducted to investigate whether the APOE gene polymorphisms were associated with OAG in the Japanese population. **Methods:** Genomic DNA was examined from 310 unrelated patients with OAG and 179 unrelated controls in the Japanese population. The presence or absence of the diseases in all patients and controls was based on clinical examination and/or ophthalmic records. The APOE allele frequency (2, 3, and 4 alleles) was studied by PCR-RFLP analysis, and compared between OAG patients and controls. **Results:** The average ages in the OAG patients and controls were 64.3 13.5 and 65.6 11.6 years (mean SD) respectively. The APOE genotype frequencies in the controls and OAG patients were 0% and 0% for 2/2, 10.1% and 4.5% for 2/3, 68.7% and 83.5% for 3/3, 0% and 0.7% for 2/4, 21.2% and 11.3% for 3/4, and 0% and 0% for 4/4 respectively, and there was a significant difference in the APOE genotype frequencies between these groups ($P < 0.001$ Chi-square test). The frequency of the OAG patients with 4 allele was significantly lower than those of the controls with 4 allele ($P = 0.009$ Fisher exact test). **Conclusion:** Contrary to the previous studies, the association between the 4 allele of the APOE gene and a reduced risk of OAG was found in the Japanese population. Further studies in the different racial population are desirable to understand more fully the relationship between the APOE gene polymorphisms and OAG.

Interaction of cigarette smoking and APOE genotype in age-related macular degeneration. *E.A. Postel¹, W.K. Scott², Y.-T. Fan², A. Agarwal³, J.R. Gilbert², J.L. Haines⁴, M.A. Pericak-Vance².* 1) Dept Ophthalmology, Duke Eye Center, Durham, NC; 2) Ctr Human Genetics, Duke Univ Med Ctr, Durham, NC; 3) Dept Ophthalmology, Vanderbilt Univ Med Ctr, Nashville, TN; 4) Ctr Human Genetics Research, Vanderbilt Univ Med Ctr, Nashville, TN.

Age-related macular degeneration (AMD) is a leading cause of vision loss in older adults and is caused by a complex interplay of genetic and environmental factors. Two well-replicated risk factors for AMD are history of cigarette smoking and APOE genotype. In an ongoing genetic-epidemiologic study of AMD, we examined these factors in a data set of 305 cases with AMD (65% female, mean age 75.9) and 176 rigorously examined controls (61.7% female, mean age 66.7). Smoking history was determined by a self-administered questionnaire. Several measures of smoking, truncated at 10 years prior to study enrollment, were examined for association with AMD. Of these, lifetime history (ever/never), duration, intensity and pack-years of smoking were significantly associated with risk of AMD after adjusting for age and sex in a logistic regression model ($p < 0.0001$ to 0.0007). Consistent with previous data, APOE-2 was positively associated with AMD and APOE-4 was slightly negatively associated, although neither effect reached statistical significance. Effects of APOE alleles as well as smoking measures became substantially stronger when cases were restricted to neovascular AMD only, and the risk increase due to APOE-2 became statistically significant (OR=2.1, 95% CI 1.1-4.2, $p=0.03$). To examine a potential gene-environment interaction of APOE-2 carrier status and lifetime smoking, separate models were constructed in smokers and non-smokers. In smokers, APOE-2 was significantly associated with neovascular AMD (OR=2.8; 95% CI: 1.1-7.2, $p=0.03$), adjusting for age and sex. In non-smokers, no significant effect of APOE genotype was detected. The increase in the strength of association between APOE-2 and neovascular AMD in the presence of smoking supports a role of gene-environment interaction in AMD etiology.

Molecular and clinical characterization of two Chinese families with maternally inherited Leber hereditary optic neuropathy. *J. Qu¹, R. Li², Y. Hu^{1,3}, X. Zhou¹, L. Yang², Y. Tong¹, F. Lu¹, M.X. Guan^{1,2,3}.* 1) Phthalmology and Optometry, Wenzhou Medical College, Wenzhou, Zhejiang, China; 2) Division and Program in Human Genetics, Cincinnati Children's Hospital Medical center, Cincinnati, Ohio; 3) School of Life Sciences, Wenzhou Medical College, Wenzhou, China.

Leber hereditary optic neuropathy (LHON) is a mitochondrial disorder that preferentially causes blindness in young adult males. We report here the molecular and characterization of two Chinese pedigrees with maternally transmitted LHON. In particular, five affected male of 29 matrilineal relatives in a four generation Chinese family (Family I) revealed a variable severity of bilateral vision dysfunction and age-of-onset. Sequence analysis of the complete mitochondrial genome in two pedigrees revealed the presence of G11778A mutation in the ND4 gene and a number of other nucleotide changes. Of these, four and seven known variants in the polypeptide coding genes lead to the replacements of amino acids in the family I and II, respectively. Other variants include polymorphisms in the D-loop region, 12S rRNA, 16S rRNA and silence mutations in the protein coding genes. None of these mtDNA variants are evolutionarily conserved and implicated to have significantly functional consequence. However, the novel A4435G mutation in the tRNAMet gene was identified in the family II. This mutation locates in the conventional position 34 of this tRNA. This position is evolutionarily conserved and critical site for tRNA function. Thus, it is implicated that the novel A4435G mutation may act as a secondary factor affecting the phenotypic expression of the G11778A mutation. Furthermore, incomplete penetrance in these families indicates the involvement of modulatory factors including nuclear modified genes in the phenotypic expression of vision impairment associated with the G11778A mutation.

Distribution of p53 haplotypes in primary open angle and low tension glaucoma. *J.L. Wiggs¹, D. Figueiredo¹, L.R. Pasquale¹, R.R. Allingham², M. Hauser³, E.A. DelBono¹, L.M. Olson⁴, M. Pericak-Vance³, J.L. Haines⁴.* 1) Dept Ophthalmology, Harvard Medical Sch, MEEI, Boston, MA; 2) Dept Ophthalmology, Duke University Medical Center, Durham, NC; 3) Center for Human Genetics, Vanderbilt University School of Medicine, Nashville, TN; 4) Center for Human Genetics, Duke University Medical Center, Durham, NC.

Primary open angle glaucoma (POAG) and low tension glaucoma (LTG) are characterized by retinal ganglion cell death associated with apoptosis. Many proteins participate in regulation of apoptosis including p53. The p53 codon 72 polymorphism has been evaluated in a Chinese POAG population (Lin et al., 2002) and an Indian POAG cohort (Acharya et al., 2002), with conflicting results. A third study of POAG patients from the UK found a difference in p53 codon 72 haplotype distribution between POAG and controls (Ressiniotis et al., 2004). Altered expression of p53 in lymphocytes from patients with low tension glaucoma has been demonstrated suggesting that p53 may have a greater role in retinal ganglion cell degeneration in these patients. The purpose of this study is to determine the distribution of the of p53 haplotypes in a population of individuals with POAG (n = 173) and a second population of individuals with low tension glaucoma (n = 84). Patients with POAG had an elevation of intraocular pressure associated with optic nerve damage and characteristic visual field defects. Patients with LTG had optic nerve damage and visual field defects without an elevation of intraocular pressure. Patients and age-matched controls (n = 106) were genotyped for two p53 polymorphisms, a 16 base pair insertion in intron 3, and the C/G substitution in exon 4 that changes the Proline at codon 72 to an Arginine. We observed a significant difference in the p53 haplotype distribution between LTG patients and controls (p < 0.01), but not between POAG patients and controls, suggesting that p53 may contribute to retinal ganglion cell degeneration in LTG patients.

Polymorphisms in the estrogen receptor (ESR2) gene are associated with peak bone mineral density in Caucasian men and women. *S. Ichikawa¹, D.L. Koller², M.L. Johnson¹, D. Lai², M. Peacock¹, S.L. Hui¹, C.C. Johnston¹, T. Foroud², M.J. Econs^{1, 2}.* 1) Medicine, Indiana University School of Medicine, Indianapolis, IN; 2) Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN.

Osteoporosis is a common multifactorial disorder, characterized by fragility fracture due to reduced bone mass. A major determinant of osteoporotic fractures is peak bone mineral density (BMD) achieved during young adulthood. Recently, we reported several quantitative trait loci (QTLs) for peak BMD identified by 9-cM genome scan. Significant linkage for trochanter BMD in Caucasian and African American sister pairs was found at chromosome 14q (LOD score = 3.5), where the estrogen receptor (ESR2) gene is located. Estrogens are necessary for the acquisition of optimal peak bone mass, and functional sequence variations in ESR2 are likely to influence acquisition of peak bone mass. To determine whether ESR2 polymorphisms are associated with peak BMD in our population, we tested eleven single nucleotide polymorphisms (SNPs) encompassing the entire ESR2 gene. Peak BMD at femur and lumbar spine was measured in 190 men (age 20-61) and 588 women (age 21-52) from Indiana. SNP genotyping was performed using matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry of allele-specific primer extension products. We found statistically significant association between ESR2 alleles and spinal BMD in both men and women. Five of the ten genetic variations reached statistical significance in men, whereas only two reached significance in women (p-value < 0.05). The strongest association in both sexes was found with the allelic variation present in the 5' untranslated region of ESR2 (p-value = 0.004). The alleles may account for up to 2.8% and 0.9% of the spinal BMD variation in healthy men and women, respectively. These results suggest that ESR2 polymorphisms are important in development of bone mass in both men and women.

Mutations of SLC26A4 gene is the second cause of non syndromic deafness. *S. Albert¹, H. Blons², F. Denoyelle¹, D. Feldmann², R. Couderc², E.N. Garabedian¹, C. Petit³, S. Marlin⁴.* 1) Dept of Pediatric ENT, Hosp A.Trousseau, AP-HP, Paris, France; 2) Dept of Biochemistry, Inserm U587, Hosp A.Trousseau, AP-HP, Paris, France; 3) Inserm U587, Institut Pasteur, Paris, France; 4) Dept of Clinical Genetics, Inserm U587, Hosp A.Trousseau, AP-HP, Paris, France.

Sensorineural hearing loss is the most frequent sensorial deficit in child, genetic origin accounting for up to 75% of the cases. It was shown that mutations of the SLC26A4 (PDS) gene were involved either in syndromic deafness characterized by congenital sensorineural hearing loss and goitre (Pendred syndrome), or in congenital isolated deafness (DFNB4). If the prevalence of SLC26A4 mutations in Pendred syndrome is clearly established, it remains to be studied in non syndromic deafness. In this report 101 patients, with non syndromic deafness and inner ear malformations, were genotyped for SLC26A4 using DHPLC molecular screening and sequencing. Seventy eight allelic mutations were observed and thirteen had never been reported. Most mutations were found in exons 6, 10, 16, 19 and 14, some of them had already been described in Pendred syndrome. Prevalence of patients with SLC26A4 mutations was 36.7% and prevalence of compound heterozygous patients was 16%. All patients included in this series had documented deafness (age of onset, severity, type, evolution status), associated with inner ear malformation (enlarged vestibular aqueduct, cochlear dysplasia). None had argument for syndromic disease. Clinical and genotypic data were collected in order to point out correlations. Among patients with PDS mutations, deafness was more severe and more fluctuant than patients with no mutations ($p < 0.05$). In conclusion, SLC26A4 mutations occurred frequently in patients with isolated deafness and inner ear malformation and represents up to 6% of non syndromic deafness cases. In terms of frequency, SLC26A4 is the second gene after GJB2 implicated in non syndromic deafness. Therefore deaf children with inner ear malformation should benefit from SLC26A4 molecular screening.

OPA1 gene mutations are frequently found in sporadic optic atrophies and are also responsible for auditory neuropathy. *P. Amati-Bonneau*¹, *C. Ayuso*², *F. Viala*³, *S. Joriot*⁴, *S. Odent*⁵, *A. Guichel*⁶, *M. Ferré*¹, *C. Hamel*⁷, *P. Belenguer*⁸, *Y. Malthièry*¹, *D. Bonneau*⁶, *P. Reynier*¹. 1) Service de Biochimie et Biologie Moléculaire, CHU Angers, France; 2) Genetic Department, Fundacion Jimenez Diaz, Madrid, Spain; 3) Service de Neurologie, CHU Toulouse, France; 4) Service de Neuropédiatrie, CHU Lille, France; 5) Service de Génétique Médicale, CHU Rennes, France; 6) Service de Génétique Médicale, CHU Angers, France; 7) INSERM U 583 Montpellier, France; 8) Laboratoire de Biologie Cellulaire UMR CNRS 5088, Toulouse, France.

Autosomal dominant optic atrophy (ADOA) (MIM 165500) is characterized by moderate to severe loss of visual acuity with an insidious onset in early childhood, blue-yellow dyschromatopsia and central scotoma. The penetrance of the disease may be as low as 40%. Most cases of ADOA are due to mutations in the OPA1 gene which encodes a dynamine-GTPase involved in the dynamics of the mitochondrial network. A total of 83 OPA1 mutations have been reported so far, and the spectrum of mutations supports the hypothesis that haploinsufficiency is a major mechanism of ADOA. We analyzed 308 unrelated patients affected with optic atrophy. Of these, 40% were familial cases and 60% sporadic. We found 71 (23%) different mutations, 63% and 37% in familial and sporadic cases respectively. A new database of OPA1 gene mutations and SNPs has been set up (<http://lbbma.univ-angers.fr/eOPA1>). We demonstrated that a specific mutation in OPA1 (R455H) was responsible for both optic and auditory neuropathy. The R445H mutation was found in 5 patients from 4 unrelated families affected with optic atrophy and retrocochlear perceptive deafness suggesting a strong genotype-phenotype correlation. This mutation, which affects a conserved amino acid in the GTPase domain of OPA1, was absent in 400 chromosome controls. We studied skin fibroblasts from patients and demonstrated that the R455H mutation leads to the hyperfragmentation of the mitochondrial network. Our results underscore the usefulness of OPA1 testing in sporadic optic atrophies and show that OPA1 mutation may lead to dysfunction in the optic as well as the auditory nerves.

GJB2 gene mutations: genotypic and phenotypic correlation. *D. Feldmann*¹, *H. Blons*¹, *F. Denoyelle*², *E. Garabedian*², *R. Couderc*¹, *C. Petit*³, *S. Marlin*⁴. 1) Dept Biochemistry and Inserm U587, A.Trousseau Hosp, AP-HP, Paris, France; 2) Dept ORL and Cervico-Facial Surgery, Inserm U587, A.Trousseau Hosp, AP-HP, Paris, France; 3) INSERM U587, Institut Pasteur, France; 4) Dept Clinical Genetics and Inserm U587, A.Trousseau Hosp, AP-HP, Paris, France.

GJB2 mutations represent the first cause of congenital non-syndrommic hearing loss in developed countries. We analysed the phenotype and the genotype of 265 patients presenting a homozygote mutation or double heterozygote mutations in GJB2, or the association of a GJB2 mutation with the GJB6 deletion : del(GJB6-D13S1830). Although the 35delG remains the most frequent mutation of GJB2 (68% of the alleles), we identified a total of 30 different mutations of this gene, of which 6 can be considered recurrent: del(GJB6-D13S1830), 310del14, E47X, Q57X, L90P, and V37I. We described 4 new mutations 355del9, 573-574delCA, M151R and Y115X. We have compared the deafness observed in patients homozygous 35delG and in patients with other genotypes. The mutations L90P and V37I were associated with a less severe phenotype than the phenotype of 35delG patients. Intrafamilial variation in the severity of the deafness was observed in 18/50 families (36%) and was not affected by the genotype. The clinical follow-up of the patients showed a hearing level that was stable in 76% (75/99), progressive in 21% (21/99) and fluctuant in 3% (3/99). The evolution of the disease was also independent of the genotype. This result is important for genetic counselling and pathologic studies of deafness caused by GJB2 mutations.

GJB6 and deafness in the Portuguese population. *M. Fialho¹, H. Teixeira¹, T. Matos¹, I. Galhardo², A.R. Santos², A. O'Neill³, S. Almeida⁴, H. Rosa⁵, J.C. Ferreira⁶, O. Dias², M. Andrea², H. Caria⁷, C. Connexins 26 (Cx26) and 30 (Cx30) are major proteins of gap junctions that play an important role in the process of intercellular communication, and are co-expressed in the cochlea. Half of the cases of nonsyndromic hearing impairment are caused by mutations in the gene encoding the gap junction protein connexin 26 (GJB2). However, 10 to 42 percent individuals, heterozygous for recessive mutations in this gene, are deaf, and no mutation in either the coding region or the splice sites of the other allele has been identified. GJB6, the gene encoding connexin 30, is an obvious candidate, due its structural and expression similarities with GJB2. Some deafness causing mutations were described, namely the T5M point dominant mutation and a 342 kb deletion responsible for recessive hearing loss. This deletion is the second most frequent mutation in the Spanish population and has thus become an important tool in the diagnosis of hereditary prelingual deafness. In the present study we have evaluated 15 Portuguese families with nonsyndromic sensorineural hearing loss in which the affected members have first been screened for GJB2 mutations and shown to have only one mutant allele. Molecular testing then focused on GJB6 gene. Mutation analysis was performed by PCR of the coding region, followed by SSCP. A specific PCR assay to amplify the break-point junction of the 342 kb deletion was used. This report presents the contribution of GJB6 gene for nonsyndromic hearing loss in Portuguese families monoallelic for GJB2 mutations.

Dominant and null alleles of *GJB2* segregating with a *PAX3* mutation in a family with hearing loss. *J.M.*

Gastier^{1,2}, *J. Frick*¹, *M.A. Springer*¹, *A. Sommer*^{1,2}. 1) Columbus Children's Hosp, Columbus, OH; 2) Ohio State Univ, Columbus, OH.

Mutations in the *GJB2* gene are the most common genetic abnormality associated with congenital nonsyndromic deafness. While most *GJB2* mutations are recessive, autosomal dominant mutations have also been reported which likely have a dominant negative effect by interfering with the formation of the connexon channels.

We describe a family in which a dominant *GJB2* mutation (R75W) is found in combination with a normal allele or a 35delG mutation. Counseling for this family is complicated by the segregation of a *PAX3* mutation (V29M). The mother of our family has nonsyndromic hearing loss while the father has Waardenburg syndrome. All of their children, three sons, are deaf. One has nonsyndromic hearing loss, and two have Waardenburg syndrome.

The genotypes in our family are complex. The mother is a compound heterozygote for the recessive 35delG(null) and dominant R75W mutations in the *GJB2* gene. One of her sons with Waardenburg syndrome also has both of these mutations, in combination with the *PAX3* V29M mutation. The other son with Waardenburg syndrome has the dominant R75W mutation in the *GJB2* gene and the V29M mutation in *PAX3*. Finally, the son with non-syndromic hearing loss is a 35delG homozygote for the *GJB2* gene.

The complex inheritance of *GJB2* mutations in this family provides an opportunity to characterize the phenotypic effect of a presumed dominant negative mutation (R75W) alone and in combination with a normal connexin 26 protein. The mother described above has isolated hearing loss due to the R75W mutation in combination with a null (35delG) mutation, consistent with the reported inability of the R75W to function properly. Two of the sons have paternally inherited 35delG mutations, yielding individuals who have mutations in two different hearing loss genes (*PAX3* and *GJB2*). This family demonstrates the difficulty in diagnosing and counseling when mutations are segregating in multiple genes.

Genetic basis of hearing loss associated with enlarged vestibular aqueducts (EVA) in Koreans. *S.K. Koo¹, H.J. Park², A.J. Griffith³, S.J. Lee¹, H.S. Jin¹, S.H. Go¹, S.C. Jung¹.* 1) Div Genetic Diseases, NIH, Korea, Seoul; 2) Soree Ear Clinic, Seoul, Korea; 3) National Institute on Deafness and Other Communication Disorders, MD, USA.

Sensorineural hearing loss associated with enlargement of the vestibular aqueduct (EVA) can be associated with mutations of the SLC26A4 gene. In western populations, less than one half of affected individuals with EVA have two mutant SLC26A4 alleles, and EVA is frequently caused by unknown genetic or environmental factors alone or in combination with a single SLC26A4 mutation as part of a complex trait. In this study we ascertained 26 Korean probands with EVA and performed nucleotide sequence analysis to detect SLC26A4 mutations. All subjects had bilateral EVA, and 20 of 26 were sporadic (simplex) cases. Fourteen different mutations were identified, including nine novel mutations. Five mutations were recurrent and accounted for 80% of all mutant alleles, providing a basis for the design and interpretation of cost-efficient mutation detection algorithms. Two mutant alleles were identified in 21 (81%), one mutant allele was detected in 3 (11%), and zero mutant alleles were detected in 2 (8%) of 26 probands. The high proportion of Korean probands with two SLC26A4 mutations may reflect a reduced frequency of other genetic or environmental factors causing EVA in comparison to western populations.

The *USH1C* 216GA splice site mutation results in a 35 base pair mutation. *J.J. Lentz¹, S. Savas¹, S-S. Ng¹, G. Athas¹, P. Deininger², B. Keats¹*. 1) Department of Genetics, Louisiana State University Health Sciences Center, New Orleans, LA; 2) Tulane Cancer Center, Tulane University Health Sciences Center, New Orleans, LA.

Usher syndrome is a heterogeneous group of disorders characterized by both deafness and blindness. The prevalence worldwide is reported to be between 1/16,000 and 1/50,000. Usher can be divided into three sub-types based on clinical severity and progression of sensorineural deafness, retinal degeneration and vestibular dysfunction. Usher type I is characterized by profound hearing loss at birth, vestibular dysfunction and progressive retinitis pigmentosa beginning in early adolescence. Genetic studies have determined the location of 12 genes associated with Usher (*USH1A-G*, *USH2A-C*, and *USH3A, B*). The *USH1C* locus was mapped to chromosome 11p by linkage analysis of Acadian families in Southwestern Louisiana and later shown to be caused by the *USH1C* gene, which encodes a PDZ-domain protein named harmonin. All Acadian patients were homozygous for both a cryptic splice site mutation in exon 3 (216GA), and a 45 base pair VNTR in intron 5 with nine repeats and a base pair change (GT) in the eighth position of the eighth repeat (9VNTR(t,t)). The finding of complete linkage disequilibrium between these events raised the possibility that homozygosity for both changes may be required for expression of the phenotype. Bitner-Glindzicz et al. (Nat. Genet. 26:56-60, 2000) reported that the 216GA mutation creates an in-frame deletion of 39 base pairs and results in an unstable transcript. In order to analyze the cause of this instability, we transfected HeLa cells with two constructs, one containing 216G and the other 216A. RT-PCR analysis demonstrated that the mRNA size difference is 35 bases not 39 bases, and this result was confirmed in lymphoblast cell lines from patients. A size difference of 35 base pairs means that the 216GA mutation results in a frame-shift and the transcript would encode a highly truncated, non-functional protein. Thus, the instability of the *USH1C* mRNA is explained by the out-of-frame cryptic splice site mutation in exon 3.

Otoferline : The trap of the neonatal hearing loss screening with evoked otoacoustic emissions. *A. Marcolla¹, H. Blons², D. Feldmann², F. Denoyelle¹, E.N. Garabedian¹, R. Couderc¹, C. Petit³, S. Marlin⁴.* 1) Dept of Pediatric ENT, Hospital A.Trousseau, AP-HP, Paris, France; 2) Dept of Biochemistry, Inserm U587, Hospital A.Trousseau, AP-HP, Paris, France; 3) Inserm U587, Institut Pasteur, Paris, France; 4) Dept of Clinical Genetics, Inserm U587, Hospital A.Trousseau, AP-HP, Paris, France.

Since 1994, more than 70 loci for non syndromic hearing loss NSHL have been identified and 35 different genes cloned. One of them, GJB2, encoding connexin 26, is involved in the most frequent form of NSHL: DFNB1. But the prevalence of the other genes in NSHL is unknown. The OTOF gene encodes otoferlin, a protein expressed in the inner hair cells and probably involved in the fusion of the synaptic vesicles in the cochlear neuro-epithelium. Mutations in OTOF are responsible for a congenital profound non syndromic deafness : DFNB9. The characteristic of DFNB9 is the transient persistence of evoked otoacoustic emissions (OAE), leading to either a false negative results in hearing loss screening programmes using this technique or to a diagnosis of auditory neuropathy. In two families with a DFNB9 phenotype, we have screened the OTOF coding sequence and identified two new mutations IVS44+1G->A and P490R associated in trans with Q829X, a frequent mutation in the Spanish population. In addition, Q829X was studied in 120 families showing prelingual, bilateral without inner ear malformation and severe or profound NSHL compatible with a recessive transmission and without GJB2 mutation. One homozygous patient was identified. In this patient OAE performed at 10 years of age were negative. Indeed, OAE usually disappear after one year of age. In conclusion, the OTOF gene was involved in 3/123 patients (2.5%) and should be screened in subjects with profound hearing impairment.

Screening of the *GJB2* (*Connexin 26*) Promoter Region Identifies a 10 Base Pair Deletion in Children with Bilateral Sensorineural Hearing Loss. *J. McCallum*¹, *C. Stolle*², *D. Yaeger*¹, *I.D. Krantz*¹. 1) Division of Human Genetics; 2) Division of Clinical Labs, The Children's Hospital of Philadelphia, PA.

Mutations in *GJB2* are the most common genetic cause of congenital bilateral non-syndromic recessive sensorineural hearing loss (BLSNHL). Individuals with BLSNHL and heterozygous mutations in *GJB2* have been consistently reported at higher frequencies than in the general population. It has been postulated that the second mutation necessary for BLSNHL in these individuals may be in other genes, or in regions of *GJB2* that are not routinely screened. In support of this, BLSNHL in some *GJB2* heterozygotes has been explained by a trans deletion of *GJB6* (*Connexin 30*). We hypothesized that, in individuals with BLSNHL and a single *GJB2* mutation, the second mutation may be in regulatory regions not presently screened. We have screened the promoter region of *GJB2* in 84 children with BLSNHL (8 *GJB2* homozygotes, 8 *GJB2* heterozygotes, and 68 with no identifiable *GJB2* mutations). A 10 nucleotide deletion (-3866 del 10) in the promoter encompassing part of a highly conserved consensus sequence for an MGF binding site was identified in 8 children, 6 of whom are *GJB2* mutation negative and 2 of whom are 35delG/M34T compound heterozygotes. The M34T change is now felt to represent a polymorphism. The -3866 del 10 was also seen heterozygously in 5/100 control samples. This indicates that heterozygous -3866 del 10 is not sufficient to cause BLSNHL. Protein binding to the MGF consensus sequence of *GJB2* in mammary cells up-regulates *GJB2* expression during lactation. Disruption of this site would likely down-regulate expression. If a similar mechanism occurs in the cochlea, the -3866 del 10 may account for some of the unfound changes in children with BLSNHL and no identifiable *GJB2* mutations or in trans with those with a heterozygous mutation. Alternately, the -3866 del 10 may itself be a polymorphism or might have a mild modifier effect on the phenotype of children with two pre-existing mutations. To date no homozygotes for this deletion have been identified. Studies are underway to determine the effect of this promoter deletion on *GJB2* gene expression and its role in the pathogenesis of BLSNHL.

Significance of the M34T variant of the GJB2 gene as a cause for deafness. *A. Pandya*¹, *K. Withrow*¹, *X-J. Xia*¹, *K.S. Arnos*², *V. Norris*², *W.E. Nance*¹. 1) Dept Human Genetics, Virginia Commonwealth University, Richmond, VA; 2) Dept. of Biology, Gallaudet University, Washington DC.

Mutations in the gap junction beta 2(GJB2) gene are the cause for more than 50% of profound pre-lingual genetic deafness. Although one specific mutation, 35delG accounts for 60%-70% of all pathogenic sequence variants, more than 80 mutations have been reported. Amongst these, the pathogenic role of the M34T substitution in GJB2 has been quite controversial. Early case reports and functional data in the xenopus oocyte system suggested that M34T might be a functionally significant dominant allele. Others have suggested that M34T may contribute to recessive hearing loss (HL). However, the presence of hearing compound heterozygotes with M34T and a known pathogenic GJB2 mutation, and similar frequencies of M34T in deaf and hearing control populations have raised the question of whether this change may represent a normal variant. To further evaluate the role of M34T, we have examined data from our national DNA repository from deaf individuals. In our repository, GJB2 alterations were found in 419 (37.2%) of 1125 deaf probands. The M34T allele was identified in 21(1.8%) deaf probands, including 18 heterozygotes, 1 homozygote, and 2 compound heterozygotes. Of these, 15 were from multiplex & 6 from simplex families. In 19 families with only M34T mutation, 42 family members were either known or obligate M34T carriers. In relatives who were not probands, 6 M34T carriers were deaf and 17 were hearing. If M34T is a dominant allele, our data suggest that it has a penetrance of 6/23 (26.1%). One 35delG/M34T compound heterozygote had unilateral HL as did his M34T heterozygote father and his paternal grandfather. The other compound heterozygote carried a H100Y allele in addition to M34T. The M34T homozygote was also deaf, although his HL was attributed to childhood meningitis. In all, 21 of 1125(1.87%) deaf or hard of hearing probands while 4 of 173 hearing subjects (2.3%) in the repository carried at least one M34T mutation. We conclude that the M34T allele is unlikely to be a cause of deafness, although the possibility that it may represent a hypomorph with low penetrance cannot be excluded.

SCAIP to identify Usher type 1 gene mutations in French patients: a pilot study. *A.F ROUX, V. FAUGERE, N. PALLARES-RUIZ, A. VIELLE, S. CHAMBERT, M. CLAUSTRES.* Genetics, CHU Montpellier, Montpellier, France.

Usher syndrome is the most common recessive disorder that associates hearing loss (HL) and retinitis pigmentosa (RP). It is both clinically and genetically heterogeneous. Current classification divides Usher syndrome in three distinct clinical types. Usher syndrome type 1 (USH1) is the most severe form characterized by profound congenital hearing loss, vestibular dysfunction and prepubertal onset of retinitis pigmentosa. To date seven loci, USH1A-G, have been mapped. Of them, 5 responsible Usher genes have been cloned: MYO7A, CDH23, PCDH15, USH1C and SANS. Most of MYO7A mutations are rare or private and mutation analysis requires the entire gene scanning. Therefore, we had initially chosen DHPLC to study the MYO7A gene. However, we encountered a high proportion of non pathogenic variants in our population. Moreover, too many domains of denaturation could be observed within one exon preventing thus any optimization of the analyses. Finally, we have applied the Single Condition Amplification/Internal primer method (SCAIP), initially developed for the dystrophin gene (Flanigan et al. 2003) to MYO7A and extended this performing approach to the CDH23 gene. One hundred samples are being currently analyzed: the screen already reveals recurrent mutations in our population for both genes (R1240Q and 223delG for MYO7A, IVS45-9G/A in CDH23) as well as new pathogenic mutations (IVS41 +1G/A ; A198T ; R1873W ; G163R in MYO7A). Our results also raise questions about the pathogenic status of some known mutations (T1566M and Y1719C). Because the whole coding region and intronic borders are analyzed, complex haplotypes are identified. These data will be integrated for genotype/phenotype correlations. This study shows that molecular diagnosis is becoming accessible to French patients and that prenatal diagnosis can be offered with an adequate genetic counseling.

Screening for mutations in alpha connexins in patients with hearing impairment that are negative for beta connexin genes. *M. Ventayol¹, E. Ballana¹, R. de Cid¹, P. Gasparini², X. Estivill^{1,3}*. 1) Genes and Disease, Center for Genomic Regulation, Barcelona, Spain; 2) Telethon Institute of Genetic and Medicine, Naples, Italy; 3) Experimental and Health Sciences Department,UPF, Barcelona, Spain.

Non-syndromic hearing impairment has a high incidence in general population affecting about 1 on 1000 newborns in developed countries, with genetic causes accounting for more than 60% of the cases. More than 80 loci and 30 genes have been related to non-syndromic hearing loss. Nevertheless mutations in a single beta-connexin gene (GJB2) are responsible for up to 50% of cases with an autosomal recessive pattern of inheritance, which is the most common one. Connexins are transmembrane proteins, the forming units of gap junctions that are basic for the maintenance of homeostasis in the cochlea. Twenty human connexin genes have been identified, they are subdivided in three groups: alpha, beta and gamma. Three beta connexins genes (GJB2, GJB6 and GJB3) and one alpha connexin (GJA1) have been associated with deafness, so far. Alpha connexins represent half of all connexins identified until now, therefore they should not be excluded as genes involved in hearing impairment. Gja4 is expressed in the mouse cochlea, being therefore a good candidate gene for deafness. We have performed a mutational screening in the alpha connexin 37 gene (GJA4) in 150 non related individuals belonging to Spanish families in which neither a mutation in the GJB2 gene nor the A1555G mitochondrial mutation have been identified. Denaturing high performance liquid chromatography methodology (dHPLC) has been used for the screening of mutations in GJA4 gene, where four single nucleotide substitutions have been identified so far. Two of these changes (132g>a, 147a>g) correspond to SNPs already described in public databases, while the other two (-8c>t, -37c>t) localise to the 5' UTR and have not yet been reported but they appear at very low frequencies (one individual for each change). Further studies should be performed in order to shed light on the potential role of this changes regarding the deafness phenotype. Other alpha connexin genes such as GJA1 or GJA10 are also under study to elucidate their role on hearing impairment.

A deafness associated Connexin allele that results in decreased expression. *E. Wilch*¹, *M. Zhu*², *S. Lebeis*⁶, *M. Regier*³, *J. Elfenbein*⁴, *R. Fisher*⁵, *K. Friderici*^{1,2,5}. 1) Genetics Program; 2) Department of Microbiology and Molecular Genetics; 3) Department of Epidemiology; 4) Department of Audiology and Speech Sciences; 5) Department of Pediatrics and Human Development, Michigan State University, East Lansing, MI; 6) Graduate Program in Microbiology and Molecular Genetics, Emory University, Atlanta, GA.

Mutations in GJB2, the gene coding for the gap junction protein Connexin 26 (Cx26), may account for 50% of cases of recessively inherited, nonsyndromic hearing loss (NSHL). Despite a current reported total of ~70 mutations of Cx26 causing recessive NSHL, screening efforts consistently reveal a significant number of deaf individuals bearing only one identified mutant Cx26 allele. In non-Jewish Caucasian populations, this mutation is most commonly 35delG, which is present at a carrier frequency of about 3% in these populations.

In our studies of a large extended Michigan family of northern European descent we identified several deaf individuals who are homozygous 35delG/35delG. However, four other deaf family members are 35delG heterozygotes; all share a common haplotype in the region containing the GJB2 gene on their non-35delG chromosome. Sequencing of the coding regions and splice sites of GJB2 and GJB6 did not reveal any potential additional mutation in the 35delG heterozygous proband. Heterozygosity of our proband at various markers within and around GJB2 indicates that this individual is not deleted for either GJB2 or the 342kb interval upstream of GJB2 and including the 5end of GJB6 that segregates with deafness when present in *trans* with 35delG. We developed a PCR-based, cDNA-specific assay to determine whether Cx26 was transcribed from the non-35delG chromosome. Buccal cells from the proband produce mRNA only from the 35delG chromosome.

This supports our hypothesis that an unidentified regulatory mutation of GJB2, when present in *trans* with 35delG, is responsible for hearing loss in these subjects. None of the previously reported mutations implicated in recessive Cx26 hearing loss affect regulation of Cx26 expression.

Mutations in the *VPS33B* gene, encoding a regulator of SNARE-dependant membrane fusion, cause ARC syndrome. *P. Gissen*^{1,2}, *C.A. Johnson*¹, *N.V. Morgan*¹, *E. Genin*³, *P.J. McKiernan*², *D.A. Kelly*², *E.R. Maher*². 1) Section of Medical and Molecular Genetics, University of Birmingham, Birmingham, UK; 2) The Liver Unit, Birmingham Childrens Hospital, Birmingham, UK; 3) INSERM U535, France.

Introduction: ARC syndrome (OMIM 208085) is an autosomal recessive disorder characterised by Arthrogryposis multiplex congenita, Renal dysfunction and neonatal Cholestasis with bile duct hypoplasia and low gamma glutamyl transpeptidase (GGT) activity. Platelet dysfunction is common. Affected infants fail to thrive and usually die in the first year of life. Methods and Results: We used autozygosity mapping to map the *ARC* locus to 15q26.1. We then screened the candidate genes in the region by direct sequencing and identified 9 germline mutations in the *VPS33B* gene in 14 ARC kindreds (Nat. Genet. 36 400-405 (2004)). One mutation was present in 8 unrelated Pakistani families, who shared haplotype around the gene. Haplotype analysis allowed us to calculate the age of this founder mutation to approximately 900-1000 years. *VPS33B* encodes a homologue of the class C yeast vacuolar protein sorting *Vps33* gene that contains a Sec1-like domain important in the regulation of vesicle to target SNARE complex formation. Immunofluorescence showed that overexpression of *VPS33B* caused perinuclear clustering of late endosomes, identifying a role in mobilising these membrane-bound organelles. Immunostaining suggested disordered trafficking of the polarised integral membrane proteins. Summary and Conclusions: ARC is the first human disorder associated with mutations in a gene involved in regulation of the SNARE-mediated mechanism of membrane tether and fusion. Studies to elucidate the function of the *VPS33B* gene product are in progress. *VPS33B*.

The mutational spectrum of *NSDHL* in CHILD syndrome: Functional implications. K. Grzeschik¹, L. Leveleki¹, A. König², D. Bornholdt¹, P. Rölle¹, R. Happle². 1) Zentrum für Humangenetik, Philipps-Universität, Marburg, Deutschland; 2) Klinik für Dermatologie und Allergologie, Philipps-Universität, Marburg, Deutschland.

CHILD syndrome (Congenital Hemidysplasia with Ichthyosiform Nevus and Limb Defects, MIM 308050), is an X-linked dominant, male-lethal trait characterized by an inflammatory nevus that usually shows striking lateralization with strict midline demarcation as well as ipsilateral hypoplasia of the body. Recently, we were able to demonstrate that this trait is caused by mutations in the gene *NSDHL* (NAD(P)H steroid dehydrogenase-like protein) encoding a 3-hydroxy-steroid dehydrogenase functioning in the cholesterol biosynthetic pathway. *NSDHL* maps to Xq28.

We report the results of mutational analysis in 30 familial and sporadic cases. The phenotype appears to be caused by loss of function because it can be associated with nonsense- and missense mutations as well as with deletions eliminating several exons or the complete gene.

Amino acids of *NSDHL* located outside the predicted functional domains (co-factor binding site, catalytically active site, transmembrane helix) which are highly conserved in evolution may pinpoint positions of potential functional importance. We generated by mutagenesis human *NSDHL* transgenes reflecting missense-mutations observed in CHILD patients or having altered other potentially functionally important sites. These constructs are transiently expressed in fibroblasts of a male CHILD patient containing either the mutated or the intact X-chromosome. The subcellular distribution of the protein is monitored. Complementation analysis by transfer of mutated human *NSDHL* into the *erg26^{ts}* yeast strain, which is mutated in the orthologous gene, *ERG26*, suggests functional differences between mutants, which are not reflected in the human phenotype.

***UNC13D* and *PRF1* mutations in childhood patients with hemophagocytic lymphohistiocytosis.** H.C. Hennies¹, K. Beutel², S. Schmidt¹, F. Oyen², S. Diler³, H. Kabisch², P. Nürnberg¹, R. Schneppenheim², G. Janka², U. zur Stadt². 1) Molecular Genetics and Gene Mapping Center, Max-Delbrück Center, Berlin, Germany; 2) Pediatric Hematology and Oncology, Childrens University Hospital, Hamburg, Germany; 3) Medical Biology and Bone Marrow Bank, University of Istanbul, Turkey.

Familial hemophagocytic lymphohistiocytosis (FHL) is an autosomal recessive disease affecting young children. It presents as a severe hyperinflammatory syndrome with activated macrophages and T lymphocytes. Mutations in the perforin 1 gene (*PRF1*) were reported in FHL-2 in 15-50% of all cases. Defective granule exocytosis caused by mutations in *UNC13D* has recently been described as the defect underlying FHL-3. Both types are phenotypically indistinguishable. We analyzed a large cohort of 61 patients with hemophagocytic lymphohistiocytosis from different geographic origins by linkage analysis and direct sequencing. We identified mutations in 28 samples investigated, 18 in *PRF1* (30%) and 10 in *UNC13D* (16%). Besides several known mutations, novel deletions, missense and nonsense mutations were detected in both genes throughout the coding regions. In 24 patients from Turkey, 13 had mutations in *PRF1* (54%) and 4 had mutations in *UNC13D* (17%). The mutation Trp374X, found in 11/13 patients with *PRF1* mutation from Turkey, was the only mutation observed repeatedly in patients from a common geographic origin. Surprisingly, only 7/28 patients from Germany showed mutations in either *PRF1* (3; 11%) or *UNC13D* (4; 14%). Furthermore, 4 out of 9 patients from other countries showed mutations in one of these genes. We detected only one mutation in *UNC13D* repeatedly in 10 heterozygous patients so far. Moreover, a genome-wide scan for a novel locus for FHL is under way using homozygosity mapping in a large consanguineous family from Turkey. Our results indicate that FHL-2 and FHL-3 account for more than 70% of FHL cases from Turkish origin, however, mutations were identified in only 25% of cases from German descent. Our data demonstrate extensive genetic heterogeneity in FHL, differences in epidemiology depending on the ethnicity, and the importance of further, yet unknown loci for the etiology of FHL.

Smith-Lemli-Opitz syndrome: Carrier frequency and spectrum of *DHCR7* mutations in Poland. *M. Krajewska-Walasek¹, E. Ciara¹, E. Malunowicz¹, B. Goryluk-Kozakiewicz¹, M. Witsch-Baumgartner², A. Jezela-Stanek¹, M. Piotrowicz³, K. Chrzanowska¹, J.S. Wayer⁴, M.J.M. Nowaczyk⁴, E. Popowska¹, G. Utermann².* 1) Dept. of Genetics, Childrens Memorial Health Institute, Warsaw, Poland; 2) Institute of Medical Biology and Human Genetics, Innsbruck, Austria; 3) Polish Mothers Hospital Research Institute, Lodz, Poland; 4) Dept. Pathology and Molecular Medicine, Faculty of Health Sciences, McMaster University, Hamilton, Canada.

SLOS is an autosomal recessive disorder of cholesterol biosynthesis caused by mutations in *DHCR7* gene. To date, most studies of SLOS carrier rates have dealt with Caucasians of Western European origins and were based on the observed carrier rates for the most common mutation in those populations, IVS8-1G>C. In Central Europe the most common mutations are W151X and V326L.

We performed a molecular analysis of the *DHCR7* gene 37 SLOS ethnic Polish patients. We identified 15 different *DHCR7* mutations. W151X (30% of alleles) and V326L (27.9%) accounted for 59% of all *DHCR7* mutations in Polish patients. Five missense mutations, I178N, M270V, G309S, L360P, R443H have only been observed in Polish patients. Using a previously described PCR-RFLP assay we screened 2900 anonymous blood samples from random newborn screening blood spot cards for the presence of the W151W (1650 blood spots) and V326L (1250) mutations. Thirty W151X carriers and 9 V326L carriers were identified. Given that these two mutations constitute 59% of the mutations observed in our population, the overall heterozygote carrier frequency may be as high as 3.32% to 5.22%, and the incidence of SLOS in Poland as high as 2.76 4.6 in 10,000. The discrepancy between calculated and observed incidence could be due to undiagnosed mild cases, misdiagnosed severe cases, or fetal loss of W151X homozygotes. In our series only one W151X/W151X infant was identified. More comprehensive incidence studies, including prenatal surveillance, are needed to determine if SLOS is as common as predicted by the very high 3-5% carrier frequency determined in this study.

2000 animal Bovine Research pedigree development and use; potential for human relevant gene discovery. *R.G. Snell¹, S. Berry¹, S. Davis¹, J. Pearson¹, P. Oxley¹, A. Stanfield¹, C. Ford¹, G. Stanley², S. Harcourt², J. Hooper², R. Spelman².* 1) Bovine Genetics, ViaLactia Biosciences, Auckland, New Zealand; 2) Livestock Improvement Corporation, Private Bag 3016, Hamilton, NZ.

The New Zealand dairy industry has a well developed molecular genetic program to identify markers and genes associated with both positive and negative traits. As part of our strategy we have generated a reciprocal cross of Holstein-Friesian and Jersey breeds to produce six F1 bulls and subsequently 850 F2 females. The complete pedigree has been genotyped with 200+ microsatellite markers for QTL and gene identification. Extensive phenotype recording of the F2 animals is in progress including milk production and milk composition. All the F2 animals have undergone three endocrine challenges, having been administered glucose, epinephrine and TRH. Growth rate, disease status and a large range of other characteristics have also been recorded. The soon to be released draft of the bovine genome will make the co-localisation of bovine and human traits simple. Although some genes will be discovered using this pedigree as a consequence of the dairy industries interests the potential to measure other characteristics which are possibly more relevant to human, exists. We are very interested in working with other researchers to take full advantage of this unique resource. The trial design and list of traits measured or currently being measured and results to date will be presented.

Mutations in human TBX4 cause lower limb malformations in small patella syndrome. *E. Bongers¹, P. Duijf¹, S. van Beersum¹, J. Schoots¹, A. van Kampen², A. Burckhardt³, B. Hamel¹, F. Loan⁴, L. Hoefsloot¹, H. Yntema¹, H. van Bokhoven¹, N. Knoers¹.* 1) Dept Human Genetics, Univ Medical Ctr, Nijmegen, Netherlands; 2) Dept Orthopaedic Surgery, Univ Medical Ctr Nijmegen, Netherlands; 3) Dept Orthopaedic Surgery, Kantonsspital Olten, Switzerland; 4) Dept Medical Genetics, Genetika Plzn, Czech Republic.

Small patella syndrome (SPS; MIM 147891) is an autosomal dominant skeletal dysplasia characterized by patellar aplasia or hypoplasia and pelvic anomalies, including disrupted ossification of the ischia and inferior pubic rami. In addition, femur and foot anomalies may accompany SPS. We identified an SPS candidate region of 5.6-cM on chromosome 17q22 by haplotype analysis. Inspection of genes in the SPS critical region revealed the TBX4 gene as a positional candidate. TBX4 belongs to the T-box gene family, encoding transcription factors characterized by a strongly conserved DNA-binding motif. Mutations in several T-box genes are associated with human developmental disorders, including TBX3 mutations in ulnar-mammary syndrome and TBX5 mutations in Holt-Oram syndrome, both characterized by severe malformations of the upper limb. Studies in model animals have indicated an important role for TBX4 in lower limb development. In chickens, misexpression of dominant-negative Tbx4 results in legless phenotypes and in deformed and hypoplastic pelvis. We found putative loss-of-function mutations in TBX4 in 6 families with SPS, including one nonsense, two missense-, one frameshift- and one splice-site mutation, and skipping of exon 7. Haploinsufficiency appears to be responsible for dominantly inherited SPS in at least some of the families. The phenotype associated with heterozygous TBX4 mutations suggest that this gene is involved in late stages of skeletal development. The present identification of TBX4 mutations in SPS patients emphasize the crucial role of TBX genes limb specification: TBX3 and TBX5 in upper limb development and TBX4 in development of the lower limb.

Screening for novel mutations in conserved intronic sequences of the CFTR gene in patients with cystic fibrosis.

J. Cheung¹, I. Aznarez^{1,2}, J. Zielenski¹, L-C. Tsui³, S.W. Scherer^{1,2}. 1) The Centre for Applied Genomics, and Program in Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, Canada; 2) University of Toronto, Canada; 3) University of Hong Kong, China.

Cystic fibrosis (CF) is a recessive disease affecting 1 in 2500 new born in the Caucasian population. It is characterized by obstructive pulmonary disease, pancreatic insufficiency and congenital bilateral absence of vas deferens (CBAVD) in males. CF is caused by over 1200 different mutations in the CFTR gene. The majority (83%) of such mutations are found in the coding region of the gene. However, a considerable number of CF patients have unknown mutations even after exhaustive sequencing of the entire coding sequence. The number of these unidentified cases is higher in patients presenting with milder forms of the disease such as pancreatic sufficiency (PS). We suspect that there are yet to be identified mutations in sites of intronic regulatory elements within the CFTR locus which currently fall outside the scope of standard CF mutation screening. We have identified conserved non-coding sequences by comparative DNA sequence alignment between human and other species to help pinpoint new genomic sites within the CFTR locus with putative functional significance. We scanned the 220 kb CFTR region and selected more than 40 segments of DNA, each larger than 50 bp in size, with high sequence conservation in a number of species including fugu. These conserved non-coding DNA segments might play roles in the regulation of proper expression of the CFTR gene. We performed mutation screening by DNA sequencing initially targeting 10 selected sites on 93 patient DNA samples (33 CBAVD, 27 PS, 33 PI patients) from whom there were only one or no mutations identified in the CFTR gene. So far, we have identified three different single-nucleotide alterations, each found in unrelated CBAVD patients with the following CFTR genotype: IVS8-5T/unknown, F508/unknown and unknown/unknown. We are currently mutation screening additional candidate regions and increasing our study population to include CF families with incomplete CFTR genotype as well as control samples consisting obligatory carriers and the general population.

Gene-Oriented File System: The Development of A Hermansky-Pudlak Syndrome Database (HPSD). *W. Li^{1, 3}, P. Liang², R.T. Swank¹.* 1) Department of Molecular & Cellular Biology, Roswell Park Cancer Institute; 2) Department of Cancer Genetics, Roswell Park Cancer Institute, Buffalo, NY 14263, USA; 3) Institute of Genetics & Developmental Biology, Chinese Academy of Sciences, Beijing, China.

Hermansky-Pudlak Syndrome (HPS, OMIM 203300) is a genetically heterogeneous disorder characterized by oculocutaneous albinism, prolonged bleeding and pulmonary fibrosis due to abnormal vesicle trafficking to lysosomes and related organelles such as melanosomes and platelet dense granules. This HPS database (**HPSD**) is to provide composite, annotative, and curative data that is distributed in a variety of public databases or predicted by bioinformatics servers for the recently cloned human and mouse HPS genes, as well as the genes responsible for HPS related syndromes, such as Chediak-Higashi syndrome (CHS), Griscelli syndrome (GS), Oculocutaneous albinism (OCA), and Ocular albinism (OA). This HPSD is designed by using a unique **gene-oriented file (GOF)** format. Seven blocks (genomic, transcript, protein, function, mutation, phenotype, and reference) are carefully curated in each user-friendly GOF entry. The HPSD emphasizes pair-wised human and mouse GOF entries. The genes included in this database (currently 56 in total) are arbitrarily divided into three categories: **(1) Human HPS, (2) Mouse HPS, (3) HPS Related Syndromes**. We believe that these very informative and peer-reviewed GOF files will be a shortcut to utilize the web-based information for the emerging interdisciplinary studies of HPS in *Genetics, Cell Biology, Biochemistry, Immunology, Neurology, and Medicine*. To access the HPSD, use this URL: <http://falcon.roswellpark.org/HPSD.htm/>.

A Novel Loss of Function Mutation in the *MSX2* Homeobox Gene in a Family with Foramina Parietalia

Permagna (PFM). V. Bernier¹, M. Ghassibé², L.M. Boon^{2, 3}, M. Vikkula². 1) Dept of Pediatrics, CHC, Liège, Belgium; 2) Lab of Human Mol Genetics, Christian de Duve Inst & Université catholique de Louvain, Brussels, Belgium; 3) Center of Vascular Anomalies, Université catholique de Louvain, Brussels, Belgium.

Parietal foramen is a normal osseous channel coursing through the three tables in the superior parietal region of the skull. Enlarged parietal foramina (PFM, FPP, MIM #168500) are secondary to an ossification default of the parietal fontanelles. They are bilateral and can be up to 2 cm or more in diameter. They may be familial, with an autosomal dominant inheritance. Surgical intervention is sometimes required. PFM can be caused by haploinsufficiency of the *ALX4* gene on 11p11.2, being part of the DEFECT 11 syndrome (MIM #601224), or as an isolated feature, due to loss of function and missense mutations in the *MSX2* gene on 5q34-q35. Altogether, 6 families with such mutations have been reported. *MSX2* belongs to the *MSX* homeobox gene family and codes for a transcription factor. *Msx2*-deficient mice show defects of the skull ossification and persistent calvarial foramen. In contrast, a gain of function mutation in *MSX2* was shown to cause autosomal dominant craniosynostosis type 2 (CRS2, #MIM 604757), also known as craniosynostosis Boston-type (CSB). CRS2 is characterized by the premature fusion of calvarial sutures leading to abnormal skull shape. Our aim is to characterize the PFM causing mutation in a family with 7 members showing persistent cranial foramina without associated symptoms except for a venous malformation in the foramen in one individual. A novel mutation was detected in all the affected members, a duplication of 17 nucleotides leading to a change in the open reading frame followed by a premature stop codon. This duplication is predicted to cause haploinsufficiency due to the abolition of the DNA binding domain. Moreover, two previously reported substitutions cause reduced *MSX2* affinity for DNA and thus lead to the formation of PFM due to haploinsufficiency. These results confirm the dosage effect of *MSX2* during development. (<http://www.icp.ucl.ac.be>) (vikkula@bchm.ucl.ac.be).

DTDST mutations in Finland and in the rest of the world: an unfolding story. *L. Bonafe*¹, *J. Hästbacka*², *A. Rossi*³, *A. de la Chapelle*⁴, *A. Superti-Furga*¹. 1) Div Molecular Pediatrics, Univ Lausanne, Lausanne, Switzerland; 2) Dept Medical Genetics and Hospital for Children and Adolescents, University of Helsinki, Finland; 3) Dept of Biochemistry, University of Pavia, Italy; 4) Human Cancer Genetics Program, The Ohio State University, Columbus, Ohio.

A small proportion of individuals with Diastrophic Dysplasia (DTD) in Finland are not homozygous for the common Finnish mutation IVS1+2TC. In 7 of these individuals we found a hitherto undescribed mutation, T512K, that was compounded with the Finnish mutation. This rare mutation was not found in 204 Finnish and in 150 non-Finnish controls. We then analyzed the Finnish family reported in 1970 as de la Chapelle dysplasia using blood DNA from parents and an unaffected sister and paraffin block-extracted DNA from the two affected stillborns. This family was found to segregate two mutations, T512K and R492W. The affected individuals were homozygous for T512K, father was heterozygous for T512K, mother and sister were compound heterozygous for T512K and R492W (*trans* phase confirmed by PCR cloning). This proved that T512K is pathogenic but, surprisingly, R492W is not in spite of its position in a transmembrane domain. We then re-screened our collection of families with DTDST dysplasias. T512K was not found in over 100 non-Finnish pedigrees with DTDST dysplasias. Conversely, R492W was found in 7 Finnish and 5 non-Finnish controls, and reanalysis of 3 DTD pedigrees in which R492W had been identified revealed the presence of still other, previously unidentified mutations that had gone undetected. We conclude that (1) T512K is a second, rare pathogenic mutation apparently restricted to the Finnish population; (2) T512K is seen mostly compounded with IVS1+2TC because of its higher frequency, the family reported here being the only example of homozygosity; (3) de la Chapelle dysplasia (MIM 256050) is indeed part of the DTDST dysplasia spectrum and corresponds to atelosteogenesis 2; (4) there is vast mutation heterogeneity in DTDST with 57 different pathogenic mutations identified today; in non-Finnish populations, 5 recurrent mutations account for 65% of pathogenic alleles.

No Mutation in the *VG5Q* Gene in Six Patients with Klippel-Trenaunay Syndrome. *L.M. Boon*^{1, 2}, *V. Wouters*², *A. Domp Martin*³, *E. Kajantie*⁴, *I. Kaitila*⁴, *F. Forzano*⁵, *E. Thompson*⁶, *M. Vikkula*². 1) Center for Vascular Anomalies, Clin Univ St-Luc, Université catholique de Louvain, Brussels, Belgium; 2) Lab of Human Molecular Genetics, Christian de Duve Institute & Université catholique de Louvain, Brussels, Belgium; 3) C.H.U-Dept of Dermatology, Caen, France; 4) Hospital for Children and Adolescents, Faculty of Medicine, University of Helsinki, Finland; 5) Clinical Genetic Unit, Galliera Hospital, Geneva, Italy; 6) Laboratory of Genetics, Womens and Childrens Hospital, North Adelaide, Australia.

Klippel-Trenaunay syndrome (KTS) is a rare congenital malformation characterized by cutaneous capillary malformations (port-wine stain), soft tissue and bony hypertrophy, and venous and lymphatic malformations. Alvoet *et al.* (1992) showed evidence that KTS occasionally shows familial aggregation. In addition, they found isolated vascular lesions to be overrepresented in relatives of KTS patients. The cause of the disorder is unknown. Whelan *et al.* (1995) reported a girl with symptoms reminiscent of KTS associated with reciprocal translocation (5;11)(q13.3;p15.1). This suggested that the disorder in this patient may be due to a single gene defect. Recently, in 5 individuals, Tian *et al.* (2004) identified an amino acid substitution (E133K), not present in 200 controls, in a gene they called *VG5Q* located in 5q13.3. The clinical characteristics of these individuals were not described, raising the question about the phenotype linked to the mutation. It is shown that *VG5Q* protein acts as a potent angiogenic factor in promoting angiogenesis, and suppression of *VG5Q* expression inhibits vessel formation. *In vitro*, *VG5Q* is expressed in blood vessels and is secreted as vessel formation initiates. On the basis of these results, we screened the *VG5Q* gene from blood DNA of six KTS patients with classical clinical characteristics, by SSCP (Single Strand Conformation Polymorphism) and HD (Heteroduplex) techniques and sequencing analysis. The results of the screening showed no mutation in the *VG5Q* gene. This suggests that the *VG5Q* gene is not the only gene involved in KTS and other causative genes should be implied. (vikkula@bchm.ucl.ac.be) (<http://www.icp.ucl.ac.be/vikkula>).

Involvement of *IRF6* in Van Der Woude Syndrome (VWS), Popliteal Pterygium Syndrome (PPS) and Isolated Cleft Lip and Palate (CL/P). M. Ghassibe¹, N. Revencu^{1, 2}, B. Bayet³, K. Devriendt⁴, L. Van Maldergem⁵, D. Genevive⁶, Ph. Pellerin⁷, O. Boute⁸, S. Manouvrier-Hanu⁸, R. Vanwijck³, Y. Gillerot^{2, 5}, C. Verellen-Dumoulin², M. Vikkula¹. 1) Lab of Human Mol Genetics, Christian de Duve Inst & Univ catholique de Louvain, Brussels, Belgium; 2) Center for Human Genetics, Clin Univ St-Luc & Univ catholique de Louvain, Brussels, Belgium; 3) Centre Labiopalatin, Clin Univ St-Luc, Brussels, Belgium; 4) Center for Human Genetics, Leuven, Belgium; 5) Centre de Génétique Humaine, Gerpennes, Belgium; 6) Génétique Médicale, Hôpital Necker-Enfants Malades, Paris, France; 7) Chirurgie plastique, Hôpital Roger Salengro, CHU, Lille, France; 8) Génétique Clinique, Hôpital Jeanne de Flandre, Lille, France.

Normal development of lips and palate is a dynamic, highly regulated, and complex process. From mouse models, human syndromes, association and expression studies, a wide range of proteins, such as transcription factors, growth factors and signaling molecules are shown to be involved in this process. When the structure or expression of one or more of these genes is modified, a cleft of the lip only (CL), palate only (CP), or lip and palate (CLP) may occur. Despite recent investigations on the mode of inheritance and interaction of different factors, genetics of orofacial clefts remains controversial. An important approach to study CL/P genetics is to evaluate genes known to contribute to syndromic forms of CL/P. They may be useful to demonstrate a significant overlap between syndromic and non-syndromic CL/P. Thus, we initiated our study on van der Woude syndrome (VWS, MIM #119300), an autosomal dominant disorder in which lower pits and occasional hypodontia are the only features distinguishing the disorder from isolated clefts. *Interferon regulatory factor-6 (IRF6)* gene, localized on 1q32.2, was recently shown to harbor mutations in patients with van der Woude and/or popliteal pterygium syndrome (PPS, MIM #119500). We screened *IRF6* for possible mutations in 22 families with VWS or PPS. Causative mutations in most of these families confirm that *IRF6* is the major VWS/PPS gene. (<http://www.icp.ucl.ac.be>) (vikkula@bchm.ucl.ac.be).

Identification of novel FGFR3 mutations in patients with hypochondroplasia. *S. Heuertz, M. Le Merrer, V. Cormier-Daire, L. Legeai-Mallet, A. Munnich, J. Bonaventure.* Department of Genetics, INSERM U393, Hopital Necker, 75743 Paris, France.

Hypochondroplasia (HCH) belongs to a family of chondrodysplasias of increasing severity including achondroplasia (ACH) and thanatophoric dysplasia (TDI and II). Most of these diseases are caused by heterozygous mutations in the Fibroblast Growth Factor Receptor3 (FGFR3) gene. While a recurrent mutation (G380R) in the transmembrane domain of the receptor accounts for more than 98% of ACH cases, a recurrent mutation (N540K) in the tyrosine kinase 1 (TK1) domain is responsible for only 55-60% of HCH cases. An additional mutation in the TK2 domain (K650N/Q/T) also causes HCH but remains extremely rare. Based on these results, genetic heterogeneity of HCH has been suggested but is still debated. To test this hypothesis we have sequenced the entire coding region of the FGFR3 gene in 24 patients with clinical features of HCH but lacking the common mutations in exons 13 and 15. Five novel missense mutations in exons 3, 5, 7 and 14 were identified. One mutation occurred in a familial form of HCH and segregated with the disease. The other cases were sporadic and the single base changes were absent both in the unaffected parents and in more than 100 controls. Two of these mutations created cysteine residues in the extracellular domain of the protein and are likely to induce constitutive activation of the receptor through formation of a disulphide bond. Interestingly, patients carrying cysteine substitutions had a phenotype similar to patients with the common N540K mutation, whereas the other novel mutations were associated with relatively mild phenotypes. We conclude that the spectrum of FGFR3 mutations causing HCH is wider than originally thought, but our inability to detect FGFR3 mutations in a significant number of cases further supports the idea that HCH is genetically heterogeneous. This work was supported by the European Skeletal dysplasia Network (ESDN), grant CE-QLG1-CT-2001-02188.

Clustering of mutations in the actin-binding domain of Filamin B leads to Atelosteogenesis types I and III. D.

Krakow¹, SP. Robertson³, ET. Sebald¹, V. Kirolova¹, S. Wachsmann-Fogiu², L. King¹, DL. Rimoin¹, DH. Cohn¹. 1) Medical Genetics Institute, Cedars-Sinai Medical Center, David Geffen School of Medicine at UCLA, LA, CA; 2) Minimally Invasive Surgical Technology Institute, Cedars-Sinai Medical Center; 3) University of Otago, Dunedin, New Zealand.

Mutations in Filamin B (*FLNB*) gene produce a spectrum of osteochondrodysplasias including autosomal recessive spondylocarpotarsal syndrome, and the autosomal dominant disorders, Larsen syndrome, Atelosteogenesis types I and III (AOI and AOIII). AOI and AOIII are lethal skeletal dysplasias characterized by multiple joint dislocations, abnormally formed bones, and disharmonic ossification of the tubular bones of the hands and feet. AOI is neonatal lethal and growth plate histology shows areas of acellularity with multinucleated cells in the resting zone. AOIII is not uniformly lethal, and cartilage histology shows areas of hypocellularity, but no multinucleated cells. Individuals with AOI and AOIII are heterozygous for missense mutations in the *FLNB* gene. In ten of eleven individuals, we found that mutations clustered in the calponin homology domain 2 (CHD2) of the actin-binding domain (ABD) of *FLNB*. Two mutations (G168S and M202V) were seen independently in unrelated individuals. In one familial case, the affected child with lethal AOIII was heterozygous for the G168S missense mutation, while the mother was mosaic for the mutation and manifested Larsen syndrome. This indicates that Larsen syndrome can result from somatic mosaicism for a *FLNB* structural mutation. In all cases of the AO, the predicted amino acid substitutions were in residues conserved among the three orthologous filamins and other similar actin-binding proteins (dystrophin, -spectrin, and -actinin-4). Although the mechanism by which these mutations produce disease is unknown, cultured fibroblasts from AOI/AOIII cases showed occasional multinucleated cells, reminiscent of chondrocytes in the growth plate, suggesting that one consequence of the mutation is a defect in cell division. Clustering of lethal AOI/AOIII mutations in the ABD of *FLNB* implicate a consistent mechanism by which the sequence and structure of this domain is essential for normal skeletogenesis.

Program Nr: 2417 from the 2004 ASHG Annual Meeting

Evaluating *ARSE*, an orphan enzyme in cartilage development, in which defects cause CDPX1. *M. Nino, S. Scheper, L. Chen, N. Braverman.* The McKusick-Nathans Institute of Genetic Medicine, Department of Pediatrics, Johns Hopkins Hospital, Baltimore, MD.

X-linked chondrodysplasia punctata (CDPX1), is characterized by abnormal bone and cartilage formation, midface hypoplasia, respiratory difficulties, and hearing loss. It is one disorder in a heterogeneous spectrum associated with epiphyseal stippling (chondrodysplasia punctata) on X-ray. Interestingly, the majority of these conditions are associated with defects in enzymatic pathways involving phospholipid synthesis, sterol metabolism, and vitamin K metabolism. CDPX1 is due to defects in the *ARSE* gene, which encodes the Golgi enzyme, arylsulfatase E (*ARSE*)¹. Although *ARSE* is expressed in many tissues, its function remains elusive. CDPX1 has been reported in over 100 patients, but relatively few have been studied at a molecular level. We are developing this project to improve the evaluation of patients with chondrodysplasia punctata, to offer molecular diagnosis of CDPX1 and to determine the functions of *ARSE* in normal skeletal development.

ARSE is located at Xp22.3 and spans 29.46 Kb. We have designed primers and amplified all 11 exons and boundary intronic regions, which we directly sequenced. In 4 new families with CDPX1 we identified 2 unique missense alleles, I40S, in one proband and his carrier mother and, T409M, in a 2nd proband and his carrier mother. We also identified a previously reported allele, G137A², in the 3rd proband and his carrier mother. The 4th proband has evidence of a de novo rearrangement of *ARSE*. Of the 3 missense changes, only the latter occurs at a conserved amino acid position. None are reported polymorphisms. In addition, we identified an alternative *ARSE* cDNA transcript by RT/PCR analysis of liver, kidney and fibroblast tissues. The transcript remains in frame but is lacking exon 2, which encodes the signal peptide and 2 metal coordination sites. Currently, we are planning additional functional studies of *ARSE* transcripts and proteins.

A recurrent mutation in the Dyggve-Melchior-Clausen/Smith-McCort dysplasia disease gene identified in families from Guam, Argentina and Chile. R. Pogue¹, N. Ehtesham¹, G. Repetto², R. Carrero-Valenzuela³, C. Bazan de Casella³, S. Pintos de Pons³, D. Cohn^{1,4}. 1) Medical Genetics Institute, Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) Universidad del Desarrollo-Clinica Alemana, Santiago, Chile; 3) Medical Genetics Center, UNT-FM, Tucuman, Argentina; 4) David Geffen School of Medicine, UCLA.

Dyggve-Melchior-Clausen dysplasia (DMC) and Smith-McCort dysplasia (SMC) are allelic autosomal recessive osteochondrodysplasias resulting from mutations in the *FLJ90130/dymeclin* gene (Cohn et al, 2003; El Ghouzzi et al, 2003). The two conditions have identical radiographic features and cartilage histology, but are distinguished by the occurrence of developmental delay and mental retardation in DMC. It was previously demonstrated that DMC results from homozygosity or compound heterozygosity for null mutations, compatible with absence of the gene product as the cause of the disorder. SMC in two families from Guam was shown to be produced by compound heterozygosity for a missense mutation (E87K) and a splicing mutation resulting in leaky skipping of exon 8. Although it was hypothesized that the milder SMC phenotype resulted from a small amount of normal gene product derived from the exon skipping allele, we have now identified two families in which DMC was produced by homozygosity for the exon 8 skipping mutation. These data suggest the alternative hypothesis that the E87K mutation is hypomorphic with the mutant protein retaining sufficient residual function to result in SMC rather than DMC. The occurrence of this sequence change in families from diverse geographic regions may imply a mutational hotspot, but the mutation does not occur within a sequence with a known increased mutation rate, such as a CpG dinucleotide. It is also possible that the mutations have a common ancestral origin in a colonizing population such as the Spanish, who were among the first explorers to visit all three countries during the first half of the sixteenth century and contributed to the current population of all of the countries in which the exon skipping mutation has been identified thus far.

Expression and functional gene analysis in periosteal fibroblasts from Apert syndrome patients. *A.L. Sertie¹, R.D. Fanganiello¹, N. Oliveira¹, S. Cavaleiro², N. Alonso³, M.R. Passos-Bueno¹.* 1) CEGH-IBUSP,Brazil; 2) UNIFESP,Brazil; 3) FMUSP,Brazil.

Apert syndrome (AS), the most severe of the craniosynostosis syndromes, is characterized by premature closure of coronal sutures, severe syndactyly of hands and feet and mental retardation. The majority of AS patients harbor one of two gain of function missense mutations localized in the fibroblast growth factor receptor 2 (FGFR2) region that forms the recognition site for FGF ligands: S252W and P253R, both related to ligand-binding inespecificity and increased ligand affinity. FGFRs are transmembrane tyrosine kinase receptors that play critical roles in skeletal development. Ligand activation of FGFRs initiates signal transduction through a diverse array of signaling pathways, which can lead to cell's proliferation, growth inhibition, or differentiation. Although it is known that AS osteoblast mutations cause overexpression of PKC pathway, premature differentiation and increased ossification, the abnormal FGFR2 signaling is not fully defined. We aim to gain further insight into signaling pathways and transcription factor networks derived from FGFR2 activation, as well as to identify genes involved in the molecular mechanisms of AS. As an experimental model we are examining the expression profile of primary cultured fibroblasts from the coronal suture periosteum (multipotent cells with the potential to differentiate into osteoblasts) of three AS patients (S252W) and comparing them to those of three wild type cultured periosteal fibroblasts. A set of 6 oligonucleotide arrays (CodeLink system) representing 20,000 human genes are being used. Differences in expression patterns of genes such as TGFB1, INTERLEUKIN 1, and in the transcription factors TWIST, MSX2, STAT1, DLX5 and SOX4, some of them previously showed in cells from AS patients, were observed. To further investigation we intend to use Real Time-PCR and RNA interference experiments. These studies may lead to a better understanding of the pathophysiology of AS, and may provide basis for future attempts to develop novel and effective therapies in order to ameliorate the clinical features.(FAPESP/CEPID - fanga@sti.com.br).

HOXD10 gene screening in cases with Congenital Vertical Talus (CVT) or Charcot-Marie-Tooth (CMT) Disease.

A.E. Shrimpton¹, E.M. Levinsohn², P. Debeer³, D. Katz⁴, C. Bryke⁵, R. Cady⁶. 1) Clinical Pathology, SUNY Upstate Medical Univ, Syracuse, NY; 2) Medical Imaging, Crouse Hospital, Syracuse, NY; 3) Center for Human Genetics, UZ Gasthuisberg, Leuven, Belgium; 4) Orthopedic Surgery, SUNY Upstate Medical University, Syracuse NY; 5) Comprehensive Genetic Services, Milwaukee, WI; 6) Pediatrics, SUNY Upstate Medical Univ, Syracuse, NY.

We have recently reported a mutation in a five generation Upstate (northern) New York Caucasian family of Italian descent with both Congenital Vertical Talus (CVT) and cavo-varus foot deformity consistent with Charcot-Marie-Tooth disease (CMT). Abnormal foot development segregated with an autosomal dominant mode of inheritance in this family. Twelve individuals had bilateral CVT, two individuals had bilateral CMT and two individuals had both CVT and CMT, one of whom had CVT in one foot and later developed CMT in the other. Whole genome linkage analysis using Affymetrix 10K Arrays defined a 7 Mb critical region on chromosome 2q31. Candidate gene sequencing of six homeodomain containing genes known to have a role in limb development (HOXD9, HOXD10, HOXD11, HOXD12, HOXD13, and EVX2) lead to the detection of a single missense mutation (M319K) in the HOXD10 gene (Shrimpton et. al.). This mutation is at a highly conserved base in the homeodomain and is located in the recognition helix at a position that projects into the major groove of the binding site on the target DNA. A LOD score greater than 6 was obtained from a linkage analysis on this family.

No additional mutations were detected from sequencing the HOXD10 gene in other cases which include: a. Non-familial CVT associated with skeletal muscular atrophy; b. CVT, developmental hip dysplasia and maternal clubfoot; c. CVT, developmental hip dysplasia and possible neuropathy; d. Probable CMT.

Shrimpton AE et al (2004) A HOX Gene Mutation in a Family with Isolated Congenital Vertical Talus and Charcot-Marie-Tooth Disease. *AJHG* 75:92-96. *HOXD10* *HOXD10*.

Balanced (9;11) translocation in a patient with non-syndromic craniosynostosis disrupts the SOX6 gene (11p15) and a conserved non-transcribed region (9q32). A. Tagariello¹, R. Heller², A. Greven³, V. Kalscheuer⁴, T. Molter¹,

W. Kress⁵, A. Winterpacht¹. 1) Inst Human Genetics, Univ Erlangen-Nuremberg, Erlangen, Germany; 2) Inst Human Genetics, Univ Cologne, Cologne, Germany; 3) Inst Human Genetics, Univ Hamburg, Hamburg, Germany; 4) Max-Planck-Institute for Molecular Genetics, Berlin, Germany; 5) Inst Human Genetics, Univ Wuerzburg, Wuerzburg, Germany.

Craniosynostosis is a congenital developmental disorder involving premature fusion of cranial sutures resulting in an abnormal shape of the skull. While significant progress has been made in understanding the molecular basis of syndromic craniosynostosis, little is known about the various forms of non-syndromic craniosynostosis. Here we report on a male infant with non-syndromic craniosynostosis presenting at birth with Crouzon-like brachycephaly, proptosis, midfacial hypoplasia and low set ears. Three-dimensional cranial computer tomography showed fusion of the lambdoid sutures and distal part of the sagittal suture with a gaping anterior fontanelle. Mutations in the genes for *FGFR1-3* were excluded. Standard chromosome analysis revealed a de novo balanced translocation t(9;11)(q32;p15). We have cloned the DNA fragment containing the chromosome 9 and 11 breakpoints. The breakpoint on chromosome 11p15 disrupts the *SOX6* gene, a gene known to be involved in skeletal growth and differentiation processes. Consequently, we have screened the complete *SOX6* gene in 102 patients with non-syndromic craniosynostosis. No causative mutation was found. Nevertheless, we can not rule out that the translocation may have lead to a truncated *SOX6* protein exhibiting a dominant negative effect. The breakpoint on chromosome 9 is located in a region without any known or predicted gene but, interestingly, disrupts patches of evolutionary highly conserved non-coding, non-transcribed DNA. Assuming a regulatory function of these sequences, we suggest that the translocation could have led to a dysregulation of flanking genes on chromosome 9 or 11 involved in cranial suture formation. Candidate genes have been evaluated.

Maffucci Syndrome and Olliers Disease are Not Allelic Disorders. V. Wouters¹, O. Enjolras², J.B. Mulliken³, C. Castellan⁴, L.M. Boon^{1, 5}, M. Vikkula¹. 1) Laboratory of Human Molecular Genetics, Christian de Duve Institute & Université catholique de Louvain, Brussels, Belgium; 2) Département de Dermatologie, Hôpital Lariboisière, Paris, France; 3) Division of Plastic Surgery, Childrens Hospital and Harvard Medical School, Boston, MA, USA; 4) Laboratory of Cytogenetica, Bolzano, Italy; 5) Center for Vascular Anomalies, Division of Plastic Surgery, Cliniques Universitaires St-Luc, Université catholique de Louvain, Brussels, Belgium.

Maffucci syndrome is characterized by multiple cutaneous venous-like anomalies (previously called cavernous angioma or hemangioendothelioma) in association with multiple enchondromas similar to those in Olliers disease, and a high incidence of malignancy. This rare congenital disorder is not inherited and has no sex prevalence bias. Severity of the disorder comes from the development of extreme and often grotesque deformation and, a 40% risk of cancerous transformation, especially to chondrosarcoma. About 200 cases have been reported. Our hypothesis is that Maffucci syndrome belongs to the group of contiguous gene syndromes, in which germline, or somatic deletion of several genes creates the combined phenotype. We have collected clinical data and/or blood/tissue samples from 37 Maffucci patients. Recently, two Olliers disease patients were discovered to carry a mutation (R150C) in the PTHR1 (parathyroid hormone receptor-1) gene (Hopyan *et al.*, 2003). One was somatic and the other germline. On the basis of these results, we carried out a germline screening and a somatic screening for *PTHRI* gene for Maffucci and Ollier patients by SSCP (Single Strand Conformation Polymorphism) and HD (Heteroduplex) techniques, combined with sequencing analysis. No mutation was identified in the *PTHRI* gene in Maffucci patients. This suggests that *PTHRI* gene is not the Maffucci syndrome gene and thus, despite their clinical overlaps, Maffucci syndrome and Olliers disease are not allelic disorders. Construction of a rat model for clubfoot malformation and initial analysis of diseases musculature proteome. H.

Zhou¹, J. Li-Ling¹, H. Zhu², X. Ji³, T. Wen¹, W. Fu¹, Y. Zhao¹, K. Sun¹. 1) Department of Medical Genetics, China Medical University, Shenyang 110001, CHINA; 2) Institute of Dermatology, First Affiliated Hospital, China Medical University, Shenyang 110001, CHINA; 3) Laboratory for Conservation and Utilization of Bio-resources, Yunnan University, Kunming 650091, CHINA.

Clubfoot (talipes equinovarus) is a common type of congenital malformation for which complex segregation analyses have suggested a genetic etiology. We have explored to construct a rat model for the disease using all-trans retinoic acid (ATRA) and analyze the variations in the relevant proteomes. Various doses of ATRA were given intra-gestically to Wistar rats on gestational day 10. Rat fetuses were removed through laparotomy on day 21, with proteins extracted and analyzed. Results: 1) Clubfoot malformation, together with other external abnormalities, were found among all experimental groups, with frequencies increasing with the dosage (11.29%, 15.28%, 60.98% and 68.18%, respectively, for 120, 130, 135 and 140 mg/kg body weight group). The highest incidence for isolated clubfoot malformation (29.27%) was seen in 135mg/kg group. 2) Analysis of the spinal cord, vertebrae and hind lower leg musculatures from abnormal rats showed significantly increased level of apoptosis ($P < 0.01$). 3) Total proteome of musculatures from hind lower legs of fetus rats were separated through 2-D gel electrophoresis. Approximately 600~1000 protein spots (mainly distributed within the range of pH 5~7 and 20~100 kD) were detected, respectively, on Coomassie Brilliant Blue or silver staining. 4) Compared with those of the normal controls, samples from model rat fetus showed gains and losses, in addition with varied strength (for 5-10 times or more) in a proportion of protein spots. However, only a few spots selected for mass spectrometry analysis had acquired consistent peptide mass fingerprints (cross-checked with PeptIdent, MS-Fit and Mascot). Comparing normal and abnormal proteomes has so far shown loss of slow skeletal muscle troponin T, significantly decreased X-linked inhibitor of apoptosis and gained expression of carboxylesterase AY034877 in the model rats.

Genetic variation in the TSC1 and TSC2 genes in 24 TSC families from India. *M. Ali¹, M. Markandaya¹, S.C. Girimaji², A.K. Shukla³, S. Sachhidanand⁴, A. Kumar¹.* 1) MRDG, Indian Institute of Science, Bangalore, India; 2) Department of Psychiatry, NIMHANS, Bangalore, India; 3) Department of Radiology, KIMS, Bangalore, India; 4) Department of Dermatology, Bangalore Medical College, Bangalore, India.

Tuberous sclerosis complex (TSC) is an autosomal dominant disorder with loci on chromosome 9q34.3 (TSC1) and chromosome 16p13.3 (TSC2). Genes for both loci have been isolated and characterized. Clinical symptoms of TSC include cortical tubers, subependymal nodules, mental retardation, seizures, autism, shagreen patches and angiofibromas on the skin, cardiac rhabdomyomas, retinal hamartomas, and angiomyolipomas in the kidneys. Several mutations have been reported in both TSC genes in patients mainly from the western and Japanese populations. However, there is no report on the mutation analysis of TSC genes in patients from the Indian population. We report here the mutational analysis of the TSC1 and TSC2 genes in 24 TSC families from India. Using PCR-SSCP and DNA sequence analyses, we have screened all 21 coding exons of the TSC1 gene and all 41 coding exons of the TSC2 gene in seven familial and 17 sporadic TSC cases. We have also sequenced promoters of both the TSC genes in 24 probands. We have identified a total of 12 mutations. Of these, seven mutations are novel. We have identified a single previously known deletion in the TSC1 gene. Of 11 mutations identified in the TSC2 gene, 3 are deletions, 2 are insertions, 3 are missense, 2 are splice site and 1 is a nonsense mutation. In addition, we have also detected three and eight variants/polymorphisms in the TSC1 and TSC2 genes respectively. Of these, three are novel SNPs. There was no correlation between the types of mutations (missense, nonsense, etc.) and the severity of the disease. As observed in the western and Japanese populations, the mutations were scattered across the TSC2 gene. DNA sequence analysis of promoter regions of both TSC genes in 24 families did not show any variation. (This work was financially supported by a grant from DBT, New Delhi to AK and SCG and a CSIR JRF to MA).

Molecular analysis of the PRKCG gene in Portuguese patients with spinocerebellar ataxia. *I. Alonso*^{1,2}, *C. Costa*³, *P. Coutinho*⁴, *I. Silveira*^{1,2}, *J. Sequeiros*^{1,2}. 1) Unigene, IBMC - Univ Porto, Porto, Portugal; 2) Lab. de Genética Médica, ICBAS, Univ. Porto; 3) Hospital Fernando da Fonseca, Amadora; 4) Hospital de São Sebastião, Feira; PORTUGAL.

Recently, mutations have been found in exon 4 of the PRKCG gene in families with spinocerebellar ataxia type 14 (SCA14), characterized by progressive incoordination of gait and limbs and by speech and eye-movement disturbances. The PRKCG gene encodes protein kinase C, a member of a family of serine/threonine kinases, which plays a role in diverse cellular processes such as signal transduction, synaptic transmission, cell proliferation and differentiation. Mutation screening in the PRKCG gene was performed in 366 Portuguese unrelated patients with ataxia. We ascertained 103 apparently autosomal dominant, 41 autosomal recessive families and 222 isolated cases with ataxia; 325 were of Portuguese origin, while 41 were from southern Brazil. Clinical manifestations in these patients included progressive gait ataxia, with or without associated symptoms, such as epilepsy, seizures, mental retardation or tremor. Mutation detection was carried out by PCR amplification, followed by SSCP and sequencing analysis. In one large family, a C-to-G heterozygous transversion in nucleotide 303 was detected, resulting in a new histidine-to-glutamine change at codon 101, located in Cys2, a cystein-rich region in the protein regulatory domain. This mutation was not detected in 400 chromosomes from a Portuguese control population. The His101 is evolutionarily conserved among PKC isozymes. No mutations were found in exon 4 in the remaining families or isolated patients. These results indicate that this and previously described SCA14 mutations are very rare.

Founder Effect in French Canadian Families with a Deletion Mutation in the CHAC Gene. *E. Andermann¹, A. Jansen¹, A. Al-Asmi¹, C. Dobson-Stone², A. Monaco², A. Lang³, F. Robert⁴, A. Badhwar¹, S. Mercho¹, F. Dubeau¹, A. Danek⁵, F. Andermann¹.* 1) Neurology & Human Genetics, McGill Univ, Montreal, PQ, Canada; 2) Monaco Group, Wellcome Trust Centre for Human Genetics, Oxford, UK; 3) Movement Disorder Clinic, Toronto Western Hosp., ON, Canada; 4) North Bay Genetics Clinic, ON, Canada; 5) Neurologische Klinik und Poliklinik-Groshadern, Klinikum der Univ. Munchen, Germany.

Background: Chorea-acanthocytosis (CHAC; OMIM 100500) is a neurodegenerative disorder characterized by the gradual onset of involuntary movements, dysarthria, areflexia, seizures and dementia, and the presence of acanthocytes. In the majority of CHAC families, the disease is inherited as an autosomal recessive trait due to mutations in the CHAC gene on chr 9q21. **Methods:** We have studied 4 French-Canadian kindreds. Medical and family histories were obtained. Biochemical tests, blood smears for acanthocytes, EEG, video-telemetry, MRI, volumetric and neuropsychological tests were performed. Bloods were collected for DNA studies in 75 individuals. **Results:** 11 patients in 6 sibships had clinical features of CHAC. 4 of the 6 sibships had clear parental consanguinity. 7 patients presented with epilepsy (6 temporal), years before developing involuntary movements including chorea, dysarthria, orofacial dyskinesia and unusual tics. The patients had mood disorders and slowly progressive cognitive and memory dysfunction. EEG confirmed temporal epileptic abnormalities. MRI of the brain showed caudate atrophy and abnormal signal in the basal ganglia. Peripheral blood smears showed acanthocytosis in all patients. All 4 kindreds were homozygous for a deletion mutation spanning exons 70-73 of the CHAC gene, and shared a common haplotype in the region. **Conclusion:** We describe four French-Canadian kindreds, three of which manifested familial mesial temporal lobe epilepsy as a presenting feature, delaying the diagnosis of CHAC. Parental consanguinity, the finding of a common haplotype and a shared deletion mutation, all suggest a founder effect. CHAC represents the first gene mutation associated with the clinical features of familial temporal lobe epilepsy, to our knowledge.

Parkin gene analysis in late onset autosomal recessive Parkinsons disease. *F. Annesi, D. Civitelli, E.V. De Marco, P. Spadafora, I.C. Ciro' Candiano, P. Tarantino, S. Carrideo, F.E. Rocca, G. De Cicco, G. Annesi.* Inst of Neurological Sciences, National Research Council, Mangone, Cosenza, Italy.

Early onset (>45 years) Parkinson's disease (EOPD) is an autosomal recessive neurodegenerative disorder characterized clinically by early onset of typical signs of parkinsonism. Three loci have been associated with early-onset, autosomal recessive parkinsonism: Parkin (PARK 2), DJ-1 (PARK 7), PINK 1 (PARK 6). The parkin gene, located on chromosome 6q25.2-27, contains 12 exons spanning 1.53 Mb and encodes an E2-dependent E3 ubiquitin protein ligase, that has a role in the proteasome-mediated degradation of target substrates. To date, a variety of mutations in the parkin gene have been reported, including exonic rearrangements (deletions and multiplications) and several missense mutations. **Material and Methods** For evaluating the role of the parkin gene in late-onset Parkinsons disease (LOPD), we performed a molecular screening of the 12 coding exons in 23 patients from 18 families from southern Italy, with probable autosomal recessive Parkinsons disease and an age at onset of 45 years or older. The conventional mutational analysis included polymerase chain reaction (PCR) and sequencing of the PCR products of the 12 exons on both strands. To identify exon rearrangements we performed gene dosage analysis using real-time PCR 7900 HT-SDS (Perkin Elmer-Applied Biosystems). We did not find any parkin mutations either by the conventional mutational analysis or with real-time PCR in all the subjects with late-onset PD. Our results suggest that parkin gene do not play an important role in development of LOPD.

E163L homozygous DJ-1 mutation in a family from southern Italy with amyotrophic lateral sclerosis-parkinsonism- dementia complex. *G. Annesi¹, G. Savettieri², P. Tarantino¹, F. Annesi¹, D. Civitelli¹, M. D'Amelio², P. Aragonese², I.C. Ciro' Candiano¹, B. Fierro², T. Piccoli², V. La Bella², F. Piccoli², E.V. De Marco¹, S. Carrideo¹, M. Zappia³, A. Quattrone^{1,3}.* 1) Inst Neurological Sci, National Research Council, Cosenza, Italy; 2) Dept of Neurology, Ophthalmology, Otorhinolaryngology and Psychiatry, University of Palermo, Italy; 3) Inst of Neurology, University Magna Graecia, Catanzaro, Italy.

To describe two patients with familial amyotrophic lateral sclerosis-parkinsonism-dementia complex and a novel mutation in the DJ-1 gene. Three siblings from a family having consanguineous parents were examined. In two patients and in three healthy relatives (the patients mother and two siblings), DNA samples were extracted by standard methods. The entire DJ-1 gene open reading frame was amplified and directly sequenced by means of forward and reverse primers. All the patients presented a syndrome characterized by akinetic-rigid parkinsonism moderately responsive to dopaminergic drugs, muscle weakness due to upper and lower motor neurons involvement with EMG findings of denervation, and cognitive impairment. The onset of the disease was at age of 24, 35 and 36 years old, respectively. Symptoms slowly progressed and one patient died at age 43 years old, after 7 years from the onset of the disease. Sequencing analysis of the DJ-1 gene in two patients showed an homozygous point mutation in exon 7 G-A at position 3385 nt (ref ALO34417) resulting in the substitution of a highly conserved E (glutamic acid) by a L (lysine) at position 163 of the DJ-1 protein. The patients relatives showed the E163L mutation in the heterozygous state. This mutation in homozygous state showed complete segregation with the disease in the family and it was not found in 300 normal chromosomes. We have identified a E163L homozygous point mutation in exon 7 of the DJ-1 gene in a family with autosomal recessive amyotrophic lateral sclerosis-parkinsonism-dementia complex. Our findings add further evidence on the pathogenic role of DJ-1 gene in early-onset familial parkinsonism and expand the clinical spectrum of the DJ-1 related disorders.

Refining the Marinesco-Sjögren syndrome locus on 5q31. A.-K. Anttonen^{1,2,3}, I. Mahjneh⁴, B. Udd^{1,5}, H. Somer⁶, M. Somer⁷, A.-E. Lehesjoki^{1,2}. 1) Dept of Medical Genetics, and Folkhälsan Institute of Genetics, Univ of Helsinki, Finland; 2) Neuroscience Center, Univ of Helsinki, Finland; 3) Clinical Genetics Unit, Helsinki Univ Central Hospital, Finland; 4) Dept of Neurology, Pietarsaari Hospital, Finland; 5) Neurology Dept, Vaasa Central Hospital, Finland; 6) Dept of Neurology, Univ of Helsinki, Finland; 7) The Family Federation of Finland, Helsinki, Finland.

The Marinesco-Sjögren syndrome (MSS) is a rare disorder with autosomal recessive inheritance. The main features of MSS are progressive myopathy, cerebellar ataxia, bilateral cataracts, hypergonadotrophic hypogonadism, and mild to moderate mental retardation. Recently patients with typical MSS features were linked to 5q31. Another locus for MSS with myoglobinuria has been localized on 18qter. We identified and clinically characterized a large inbred Finnish family with five patients, and two pairs of affected siblings. A candidate locus approach was undertaken to define the molecular genetic background of MSS in these families. Clinical information of the patients was gathered from medical records, and all the patients alive were examined by one clinician. Microsatellite markers were tested to evaluate the previously reported loci on 5q31 and 18qter. Haplotypes spanning the candidate regions were constructed and two-point LOD scores were calculated with MLINK program. All patients had classical MSS with generalized muscular weakness and hypotonia. Patients showed ataxia, bilateral cataracts, nystagmus, and dysarthria. Muscle weakness and wasting was most marked in the lower limb-girdle with both proximal and distal muscles involved. All patients had hypergonadotrophic hypogonadism and mild mental retardation. No linkage to markers on 18qter was detected, but significant linkage was observed between MSS and markers on chromosome 5q31. A maximum two-point LOD score of 6.55 (at =0.000) was obtained with marker *D5S414*. All the Finnish patients shared a homozygous, common haplotype over a subset of markers around *D5S414*. These data suggest that MSS in Finnish patients is caused by homozygosity of a founder mutation of an as yet unidentified gene on chromosome 5q31.

Two mutations in the *HSN2* gene explain the high prevalence of HSANII in French-Canadians. B. Brais¹, K. Roddier¹, T. Thomas¹, G. Marleau¹, A.M. Gagnon¹, M.J. Dicaire¹, A. Saint-Denis¹, I. Gosselin¹, A.M. Sarrazin², A. Larbrisseau³, M. Lambert³, M. Vanasse³, D. Gaudet⁴, G.A. Rouleau⁵. 1) CRCHUM, Univ. de Montréal, Montreal, Quebec, Canada; 2) Centre Hospitalier Régional de Lanaudière, Saint-Charles-Borromée, Quebec, Canada; 3) Hôpital Ste-Justine, Univ. de Montréal, Montreal, Quebec, Canada; 4) Centre de médecine génique communautaire de l'Univ. de Montréal, CH de la Sagouamie, Saguenay, Canada; 5) McGill Health Centre, McGill Univ., Montreal, Quebec, Canada.

Hereditary sensory and autonomic neuropathy type II (HSAN II, MIM 201300) is a rare childhood recessive neuropathy usually diagnosed in childhood or the early teens. It was first clearly described in 1973 in a French-Canadian (FC) kinship. The HSANII locus and the *HSN2* mutated gene have been uncovered. Through treating physicians we recruited 17 HSANII cases belonging to 13 families. Following informed consent, we extracted DNA of 17 patients and their relatives. Further to the identification of the responsible gene, we sequenced the whole *HSN2* gene in order to search for mutations. We have uncovered the largest international cluster ever described. They all originated from southern Quebec. Haplotype analysis predicted that two distinct mutations were responsible for HSANII in FC. Two distinct loss-of-function mutations were identified, both are predicted to lead to truncations of the protein. The higher prevalence of this condition in Quebec appears to be due to a relatively high carrier frequencies for both mutations. The following genotypes were uncovered in the different families: 58.3% of cases were homozygote for mutation 1 and 8.3% for mutation 2, and 33.3% were compound heterozygotes. 75% of chromosomes carried mutation 1 and 25% mutation 2. The comparison of clinical variables does not suggest any difference in phenotype between carriers of the two mutations. HSANII is more frequent in the FC population due to higher carrier rates for two distinct *HSN2* founder mutations. This is the first example of a FC recessive disease clearly more associated with a regional population of Southern Quebec. The uncovering of *HSN2* mutations will lead to better genetic counseling.

***FMRI* gene premutation is a frequent genetic cause of late-onset sporadic cerebellar ataxia.** A. Brussino¹, C. Gellera², A. Saluto¹, C. Mariotti², C. Arduino¹, B. Castellotti², N. Migone¹, F. Taroni², A. Brusco¹. 1) Genetics Biology & Biochem, University of Torino & Operative Unit of Medical Genetics, San Giovanni Battista Hospital, Torino, Italy; 2) Dept. Biochemistry and Genetics, National Neurological Institute IRCCS "Carlo Besta", Milano, Italy.

Premutation in the fragile-X (*FMRI*) gene has been associated with an increased incidence of premature ovarian failure in females and with a neurodegenerative disorder in males known as Fragile-X Tremor Ataxia Syndrome (FXTAS). We have collected a large cohort of 275 males affected by a sporadic form of spinocerebellar ataxia, referred for genetic analysis of *SCA* genes. The presence of pathological expansions was excluded in the *SCA1* and *SCA2* genes - accounting for over 90% of familiar *SCA* in Italy - together with *SCA3*, *SCA6*, *SCA7* and *FRDA1* gene expansions whenever a suggestive phenotype was present; age at onset ranged from 20 to 82 yr (mean 48.3 yr 14.5 S.D.). A novel fluorescent PCR analysis of the *FMRI* CGG repeat (able to detect up to 300-CGGs) was used to screen our patients: six were found carriers of a premutated allele (range 83-109 repeats). Clinical/neuroradiological findings were consistent with the FXTAS syndrome, and age at onset ranged from 53 to 69 yr. MRI showed cerebellar atrophy and T2-hyperintense middle cerebellar peduncles. Our results show that FXTAS is a frequent genetic cause of idiopathic ataxia accounting for 2.2% (6/275) of adult-onset cases. The frequency raises up to 4.2% (6/143) if one considers only cases with age at onset above 50 yrs, suggesting that it is a frequent genetic cause of late-onset sporadic ataxia. Since the analysis of the *FMRI* premutation is simple and rapid, genetic testing the CGG repeat number could be suggested as the first-choice investigation in all cases of late-onset idiopathic ataxia.

Mutations in the NHLRC1 gene are common in patients with Laforas progressive myoclonus epilepsy. D. Civitelli¹, F.E. Rocca¹, I.C. Ciro Candiano¹, R. Biondi², V. Sofia², G. Milana³, N. Cutuli³, E.V. De Marco¹, F. Annesi¹, P. Tarantino¹, S. Carrideo¹, G. De Cicco¹, G. Annesi¹. 1) Inst of Neurological Sciences, National Research Council, Mangone, Cosenza, Italy; 2) Institute of Neurology and Pediatrics, University of Catania, Italy; 3) Laboratory of Molecular Genetics, Dept of Services, University of Catania, Italy.

Lafora's progressive myoclonus epilepsy is an autosomal-recessive disorder caused by mutations in the EMP2A gene, which is located on chromosome 6q24. An ulterior causative gene for Laforas disease was recently identified on chromosome 6p22, termed NHLRC1 or EPM2B. It is a single-exon gene, encoding a putative E3 ubiquitin ligase (malin). In this study, we screened NHLRC1 gene in three patients. Examined probands are three Sicilian patients who received a diagnosis of LD after a comprehensive clinical and laboratory investigation. In two of them, age at onset of LD was 14 years, in the remaining patient LD started at the age of 11 years. Sequencing analysis of EPM2A did not reveal any pathogenic variant in all three patients. Then, we went on sequencing the NHLRC1 gene. We designed six primers pairs, to obtain six overlapping PCR fragments, spanning the whole NHLRC1 exon, including non-coding sequences. Amplified fragments were directly sequenced. In one patient we found a novel homozygous nonsense mutation (G199T, giving rise to a stop codon at aminoacid residue 67). The second patient carried a compound heterozygous for two mutations (C205G causing the P69A substitution, and G838A resulting in the E280K change). The last patient carried the heterozygous E280K mutation and a known polymorphism (C332T leading to the P111L substitution). All the mutations but the latter polymorphism were not found in 100 control chromosomes. The results of the present study provide evidence that mutations in the NHLRC1 gene may be a common cause of LD in populations of Mediterranean origin. Supported by Ministero della Sanit Progetto biennale Genetica dell'Epilessia.

Investigation for intragenic rearrangements of the PLP1 gene in patients with dysmyelinating leukodystrophies using MAPH. *P. Combes¹, C. Vours-Barriere¹, MN. Bonnet-Dupeyron¹, F. Gauthier-Barichard¹, J. Armour², O. Boespflug-Tanguy¹.* 1) UMR 384, Medecine Faculty, Clermont-Fd, France; 2) Institut of Geneticq, University of Nottingham, UK.

The PLP1 gene is known to be mutated in the X-linked myelination disorders, Pelizaeus-Merzbacher Disease (PMD) and Spastic Paraplegia type 2 (SPG2). The most common PLP1 mutation in PMD is a large duplication including the whole gene, whereas large deletions and punctual mutations can be responsible for PMD or SPG2 phenotypes. Semi quantitative PCR (only on 1 or 2 exons) has been used to quantify PLP1 gene copy number; looking only for large rearrangements. In the aim to search for small intragenic PLP1 rearrangements in patients presenting classical forms of PMD or SPG2 and not diagnosed as PLP1 mutated, we developed the MAPH (Multiplex Amplifiable Probe Hybridization) technique using 13 PLP1 specific probes distributed along the gene (2 promoter, 4 intronic and 7 exonic regions probes). This technique relies on the quantitative recovery and amplification of nucleic probes after hybridization to immobilized DNA. In a first approach, DNAs from 20 patients and 15 carrier mothers already diagnosed with duplications have been used to validate the technique and have shown that all the duplications encompass the entire PLP1 gene. Then, a total of 340 patients presenting with dysmyelinating leukodystrophies (including classical PMD, SPG2 and PMD or SPG like phenotypes) were screened. Whereas no duplications could be detected, two partial deletions of the PLP1 gene were identified. One deletion involves the 5 part of the gene (promoter to part of intron 1); the other one is a 3 gene deletion (exon 6 to 7). As it has been demonstrated for the DMD gene, MAPH is a powerful and cost effective tool to screen cohorts of patients for small intragenic or large genomic rearrangements.

Ataxia with oculomotor apraxia in a family from southern Italy: a clinical and genetic study. *E.V. De Marco, P. Spadafora, D. Civitelli, F. Annesi, S. Carrideo, I.C. Cir Candiano, P. Tarantino, F.E. Rocca, G. De Cicco, G. Annesi.* Inst of Neurological Sciences, National Research Council, Mangone , Cosenza, Italy.

Ataxia with oculomotor apraxia type 1 (AOA1) is caused by mutations in the aprataxin gene (APTX) which maps to chromosome 9p13 and codes for a nuclear protein involved in single-strand DNA break repair. Here we report on a family from southern Italian in which three members were affected by AOA1. There were three affected members: one 30-year-old man and two women of 39 and 37 years of age respectively. In all of them, symptoms started around the age of 15 months with progressive cerebellar ataxia. Important, the brother and the 39-year-old sister had also had repeated febrile convulsions around the age of 8 and 18 months respectively. From the time of the onset, the course of the disease was severe with appearance of cognitive impairment and all patients became wheelchair-bound. Oculomotor apraxia and severe axonal sensorimotor neuropathy were present in all patients. Laboratory investigation showed hypoalbuminaemia and hypercholesterolaemia; brain MRI revealed cerebellar atrophy. Genetic analyses for spinocerebellar ataxia types 1, 2, 3, 6, 7, 8, 12 and 17, for hereditary dentatorubropallidolusian atrophy, for Friedreich's ataxia and for ataxia-telangiectasia excluded the diagnoses of these disorders. Screening for mutations in the APTX gene was performed by sequencing exons 4, 5, 6 and 7. We found the patients bearing the homozygous W279X nonsense mutation which produces a protein truncated at aminoacid 279. As expected, their parents were both heterozygous for the mutation. We have described here the third Italian family with molecularly proven AOA1. Also our family carried a W279X substitution which is the most common mutation in Portuguese families.

ALS2/alsin detection in 26 patients with ALS2, JPLS, IAHS2 phenotypes. *E. Eymard-pierre¹, K. Yamanaka², P. Combes¹, D. Cleveland², E. Bertini³, O. Boespflug-Tanguy¹, and the European SPATAX consortium⁴.* 1) INSERM U 384, clermont-fd, France; 2) Ludwig Institute for Cancer Research, UC at San Diego, USA; 3) Bambino Gesu Childrens Hospital, Roma, Italy; 4) A. Durr, Inserm U289, Paris, France.

Non-sens mutations in the ALS2 gene have been reported in autosomal recessive forms of juvenile Amyotrophic Lateral Sclerosis (ALS2), juvenile primary lateral sclerosis (JPLS), and infantile ascending hereditary spastic paralysis (IAHS2). These 3 disorders are characterised by a progressive ascending spastic paralysis due to a retrograde degeneration of the upper motor neurons with (ALS2) or without (JPLS, IAHS2) involvement of the lower motor neurons. Using an antibody against RCC1 domain of the ALS2 protein, we demonstrated that ALS2 protein can be detected by western blot from lymphoblastes or fibroblasts and is absent in patients with ALS2 mutations. We screened for ALS2 a cohort of 26 families with primary involvement of the upper motor neurons. The ALS2 locus was excluded by haplotype analysis in 6 families. In the remaining 20 families, presence of the ALS2 protein was detected by western blot of lymphoblasts. ALS2 protein was detected in 13 patients and absent in 7. In only four out of these seven ALS2 negative patients, mutations were detected by direct sequencing of cDNA. We will quantify in these patients the ALS2 transcripts. Clinical analysis of the 35 patients demonstrated that the ALS2 positive patients tend to have a later age of onset, a slower progression, more frequent cognitive and SEP abnormalities and less frequent MRI abnormalities and display a lower motor neuron involvement in 20 percent; which was never observed in the ALS2 negative group. In conclusions, early onset, autosomic recesive forms of primitive degeneration of the upper motor neurons are genetically heterogenous. ALS2 mutations are found in only 12 percent of patients where an additionally 8 percent demonstrated an absence of ALS2 protein in lymphocytes. Therefore detection of ALS2 proteins in lymphocytes by western blot could be an interesting screening to look for ALS2 involvement in patients with ALS2, JPLS and IAHS2 phenotypes .

An expanding deletion on chromosome 14 in a family with dopa-responsive dystonia and ptosis. *K. Hedrich^{1,2}, R. Saunders-Pullman^{3,4}, K. Wiegers^{1,2}, F. Hinrichs¹, Y. Hellenbroich¹, K. Kabakci^{1,2}, V. Pulijaal⁵, K. Habermann³, L.J. Ozelius⁴, E. Schwinger¹, S.B. Bressman³, C. Klein^{1,2}.* 1) Hum. Genet., Univ. Luebeck, Germany; 2) Neurology, Univ. Luebeck, Germany; 3) Neurology, Beth Israel Medical Center, New York, NY; 4) Mol. Genet. and Neurology, A. Einstein College of Medicine, Bronx, NY; 5) Reprod. Genet., A. Einstein College of Medicine, Bronx, NY.

Dopa-responsive dystonia (DRD) is a childhood-onset movement disorder with an excellent response to L-Dopa. Most DRD is autosomal dominantly inherited with reduced penetrance and associated with mutations in the GTP cyclohydrolase I (GCHI) gene on chromosome 14q22. More than 80 different point mutations and, more recently, five different heterozygous deletions involving one or more exons have been described in GCHI. We present a three-generation family with four DRD patients and six unaffected who were tested for mutations in GCHI by sequence and quantitative duplex PCR analysis. No alteration in the GCHI gene was found by sequencing, however, we identified a heterozygous deletion of all six GCHI exons by quantitative PCR in all four affected and one unaffected individual, confirming reduced penetrance. Surprisingly, one obligate carrier, whose sister and son are both affected, did not carry this deletion. We confirmed paternity, however, haplotype analysis of the 14q22 region revealed several incompatibilities. Using 30 microsatellite markers, we demonstrated that this obligate carrier and his mother had another smaller deletion of 700kb localized downstream of GCHI. This deletion expanded independently twice in this family to a deletion of about 3600kb involving about 20 genes including GCHI. We verified these results by FISH analysis, using three different BAC clones from the RZPD (Berlin, Germany) that allowed us to distinguish between the two different deletions. Interestingly, all five carriers of the larger deletion also presented with ptosis, regardless of their DRD status. The deleted gene responsible for the ptosis remains to be identified, as do the break points of the deletions to understand the underlying mechanism of the deletion expansion.

A novel CAG/CTG repeat expansion in a patient with a progressive sensory neuropathy. *S.E. Holmes¹, J.S. Wentzell², C. Callahan¹, C.A. Ross¹, R.L. Margolis¹.* 1) Dept of Psychiatry, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Colby College, Waterville, ME.

CAG/CTG repeat expansions cause at least 12 different movement disorders, and our data suggests that additional disorders of this type may exist. Using the repeat expansion detection (RED) assay, we identified an expanded CAG/CTG repeat in a 50 year old woman with a progressive sensory neuropathy. The father, brother, and cousin of the proband are affected with a similar disorder. All known causes of CAG/CTG repeat expansions were excluded in the proband. To identify the locus of the expansion, we used PCR to test the repeat length of 267 CAG repeats in the human genome 8 or more triplets in length. The expansion was localized to an intron of a Genscan-predicted gene, approximately 200 bp downstream of an exon which is conserved in mouse. The closest experimentally verified gene in the region (encoding a serine/threonine kinase) occurs approximately 63 kb downstream from the repeat. We examined the repeat length, using an automated genotyping protocol, in the proband, her affected cousin, 255 control individuals and 219 patients with movement disorders of unknown cause. DNA from the brother and father is currently unavailable. The length of the expansion in the proband, verified by sequencing, was 98 triplets. The proband's cousin did not have an expanded repeat, and no expansions were detected in the patient group or the control group. The repeat length ranges from 5 to 27 triplets, with 8 triplets the most common allele. Heterozygosity is 59.5%. Our results suggest that this new repeat expansion is rare and probably is not the direct cause of the phenotype in our proband. Whether the repeat contributes to the patient's phenotype, or is associated with another phenotype, remains to be determined.

Purkinje cell degeneration and 1C2 positive neuronal intranuclear inclusions in SCA8 patients. *Y. Ikeda¹, M.L. Moseley¹, J.C. Dalton¹, M.T. Su², H.M. Hsieh-Li², G.J. Lee-Chen², H.B. Clark¹, J.W. Day¹, L.P.W. Ranum¹.* 1) Inst of Human Genet, Univ of Minnesota, Minneapolis, MN; 2) Department of Life Science, National Taiwan Normal University, Taipei, Taiwan.

Spinocerebellar ataxia type 8 (SCA8) is a dominantly inherited neurodegenerative disorder caused by a CTG repeat expansion. To investigate SCA8 pathogenesis we performed neuropathological studies of two postmortem human SCA8 brains. The first patient, from the large SCA8 family we initially described, had an expansion of 110 combined repeats. Moderate-to-severe loss of Purkinje cells, mild granule cell loss, and neuronal loss with gliosis in the olivary nuclei was found, with no evidence of degeneration in other parts of the brain. The second unrelated patient had approximately 140 combined repeats. Severe loss of Purkinje cells, granule cells and inferior olivary neurons was observed. Immunohistochemical analysis using the 1C2 antibody revealed panuclear staining in selected Purkinje cells and nuclear and cytoplasmic staining in selected medullary neurons with occasional neurons having discrete intranuclear inclusions. TATA-box binding protein (TBP) staining was negative for these neurons, indicating it is unlikely that the 1C2-positive inclusions represent TBP accumulation. Similar immunohistochemical findings are also found in BAC transgenic mice that we have developed with the SCA8 expansion but not in BAC control lines. It was recently demonstrated that the 1C2 antibody recognizes both homopolymeric glutamine and leucine expansions. These results suggest the following models: 1) short ORFs in the polyleucine or the polyglutamine direction are translated, although only polyleucine encoding transcripts have been detected; 2) CUG containing SCA8 transcripts induce inclusion formation similar to the model proposed for FXTAS in which CGG containing transcripts are associated with 1C2 negative but ubiquitin positive inclusions, although CUG containing RNA foci have not been detected in SCA8 human or mouse brains. Our inclusion data provide the first molecular link between the human disease and our BAC transgenic expansion mice and indicate a pathogenic mechanism involving intranuclear inclusions.

Disease mechanism for the SOX10 extension mutation that causes a novel neurocristopathy, PCWH. K. Inoue^{1, 2}, T. Ohyama², M. Khajavi², S. Rehberg³, Y. Goto¹, M. Wegner³, J.R. Lupski². 1) Dept MR & BD Res, Ntnl Inst Neurosci, NCNP, Kodaira, Tokyo, Japan; 2) Dept Mol Hum Genet, Baylor Coll Med, Houston, TX; 3) Inst Biochem, Univ Erlangen-Nürnberg, Erlangen, Germany.

SOX10 is an essential transcription factor for development and maintenance of neural crest and myelin lineages. Individuals with *SOX10* mutations can present with multiple defects including (1) peripheral demyelinating neuropathy, (2) central dysmyelinating leukodystrophy, (3) Waardenburg syndrome and (4) Hirschsprung disease. Most *SOX10* mutations result in premature termination codons (PTCs) and cause either PCWH, a combination of all four diseases, or WS4, a combination of the latter two. Previously, we identified that mRNAs with PCWH-causing *SOX10* mutations escape the nonsense-mediated decay (NMD) pathway, leading to a stable translation of dominant-negative mutant proteins. Meanwhile, mRNAs with WS4-causing mutations trigger NMD, resulting in haploinsufficiency due to the degradation of mutant mRNAs. However, the first case of PCWH had a unique 12 bp deletion that results in an 82 amino acid extension without disruption of the wildtype SOX10 protein, and the mutation mechanism for the extension mutant still remains unknown. To investigate the mechanism by which the extension mutation causes a PCWH phenotype, we performed functional analyses. We found a diminished transcription activity of the SOX10 extension mutants. A 10 amino acid peptide in the extension was found to be critical to diminish the transcription activity. This peptide sequence affected the binding of SOX10 to its target *in cis* when present downstream of the HMG domain. Either SOX10 mutants with the 10 amino acid peptide or the peptide alone do not interfere with wildtype SOX10 function *in trans*, thus excluding dominant-negative as the mutational mechanisms at least *in vitro*. Furthermore, an addition of the peptide to SOX11 dramatically diminished its transcription activity, but not on SOX9. From these findings, we conclude that the extension mutant may behave as a gain-of-function allele to cause PCWH rather than through a dominant-negative mechanism as appears to be the case for other PCWH-causing *SOX10* mutations.

Familial Spastic Paraplegia and the ALS2 gene. A. Jansen^{1,2}, I. Meijer^{3,4}, D. MacGregor⁵, F. Gros-Louis³, G. Rouleau³, F. Andermann¹, E. Andermann^{1,2,6}. 1) Dept Neurology & Neurosurgery, McGill University, Montreal, PQ, Canada; 2) Neurogenetics Unit, Montreal Neurological Institute, Montreal, PQ, Canada; 3) Centre for Research in Neuroscience and McGill University Health Centre Research Institute, Montreal, PQ, Canada; 4) Dept of Biology, McGill University, Montreal, PQ, Canada; 5) Hospital for Sick Children and University of Toronto, Toronto, ON, Canada; 6) Dept of Human Genetics, McGill University, Montreal, PQ, Canada.

Infantile onset ascending hereditary spastic paraplegia (IAHSP) is an autosomal recessive neurodegenerative disorder with early involvement of corticospinal and corticobulbar pathways and absence of lower motor neuron signs. We present a large consanguineous Pakistani kindred with IAHSP and mild intrafamilial phenotypic variability.

Fourteen patients presented with spastic paraplegia in the lower limbs before age 2, extending to the upper limbs by the end of the first decade. Tetraplegia, anarthria and dysphagia developed in the second decade. Disease progression was slow, resulting in death by the fourth decade, with relative sparing of intellectual skills. At age 13, CT, MRI and MRS of the brain, EMG, NCV and BAER in the proband were normal. VER, SSEP and MEP were abnormal. Muscle biopsy showed atrophy of type II-B fibers. A 1bp deletion (4844delT) in exon 32 of the ALS2 gene on chromosome 2q33 cosegregated with the disease. The deletion was located at the beginning of the VPS9 domain, and functional studies demonstrate that absence of a functional VPS9 domain of alsin is sufficient to cause neurodegeneration.

The IAHSP phenotype overlaps with complicated HSP, but severe upper arm and bulbar disabilities are generally absent in the latter. ALS2 mutations were originally reported in patients with juvenile ALS (ALS2). However, muscle atrophy, fasciculations or denervation on EMG were rare. Mutations in ALS2 were also found in families with early onset primary lateral sclerosis and phenotypes closely resembling IAHSP. These findings suggest that all patients with mutations in ALS2 have the same disease, rather than IAHSP, ALS2 and juvenile PLS representing 3 different allelic disorders.

Novel mutations and a frequent mutation in Japanese patients with MLC. *N. Kanazawa¹, E. Nakagawa², S. Hayakawa³, Y. Suzuki⁴, A. Shibata⁵, M. Kubota⁶, T. Kibe⁷, F. Sakai⁸, S. Tsujino¹.* 1) Department of Inherited Metabolic Disease, National Institute of Neurosciences, NCNP, Tokyo, Japan; 2) Division of Child Neurology, National Center Hospital for Mental, Nervous and Muscular Disorders, NCNP, Tokyo, Japan; 3) Department of Pediatrics, Toyohashi East Hospital, Aichi, Japan; 4) Department of Neuropediatrics, Aichi Welfare Center for Persons with Developmental Disabilities, Aichi, Japan; 5) Department of Pediatrics, Tokyo Women's Medical University Daini Hospital, Tokyo, Japan; 6) Department of Pediatrics, Tokyo University, Tokyo, Japan; 7) Department of Pediatrics, Seirei Mikatahara Hospital, Shizuoka, Japan; 8) Department of Neurology, Kitasato University, Kanagawa, Japan.

Megalencephalic leukoencephalopathy with subcortical cysts (MLC or van der Knaap disease), is an autosomal recessive disorder clinically characterized by macrocephaly, ataxia, spasticity, and mental decline. MRI shows swollen brain with diffuse white-matter abnormalities and subcortical cysts.

After informed consent was obtained, we analyzed the *MLC1* gene of six Japanese patients with MLC, suspected by clinical symptoms and MRI findings. Two of them were homozygous for a previously-described mutation, S93L. Three were heterozygous for S93L, and the other allele is unexpressed, aberrant splicing, and unknown, respectively. The remaining one was a compound heterozygote for two novel mutations, A275E and 436GA, which leads to aberrant splicing.

Combining our data with previous reports allows us to estimate the molecular genetic basis in a total of fourteen Japanese patients. S93L was observed in 12 of 14 (85.7%) patients at least in one allele, and in 19 of 28 alleles (67.9%). Therefore, S93L appears to be fairly frequent in Japanese patients with MLC, and analysis for this mutation in DNA isolated from leukocytes would provide for an easy and precise diagnosis of this disorder in Japanese patients.

PANK2 mutations in a Japanese girl with motor and emotional problems. *I. Kondo¹, Y. Nakadoi², N. Jyofuku², T. Iwai², K. Miyamoto¹, H. Yamagata¹, Y. Tabara¹, S. Endo².* 1) Dept Medical Genetics, Ehime Univ Sch Medicine, Ehime, Japan; 2) Dept. of Pediatrics, Kagawa Children's Hospital, Kagawa, Japan.

Pantothenate kinase-associated neurodegeneration (PKAN) is a rare autosomal recessive disorder characterized by progressive dystonia, rigidity and pigmentary retinopathy. MRI is the most distinct diagnostic test in patients with PKAN and all patients with characteristic MRI finding, called the eye of the tiger sign, have pantothenate kinase 2 gene (PANK2) mutations. At present, over 50 different mutations have been reported in PANK2. However, clinical phenotypes in patients with PKAN have shown a wide spectrum even in the same family members and a genotype-phenotype association has not been established. Pathogenic findings in autopsy brains were reported in several Japanese patients with Hallervorden-Spatz syndrome before identification of disease gene, but PANK2 mutations have not been studied. We report here the first Japanese patient with PANK2 mutations. She was an only one child from unrelated healthy parents. Her birth and developmental history were normal by the age of four years. She began having walking difficulty with drop feet and rigidity at five years of age. The mother noted that the patient had night blindness at the same age. At the age of seven years of age, poor performance and emotional problems were noted at school and she was diagnosed having PKAN based on a retinitis pigmentosa and the eye of the tiger sign in her MRI findings. Molecular analyses confirmed two mutations in PANK2, 4 bp deletion in exon 3 derived from her mother and a missense mutation, E444K, in exon 6 derived from her father. This missense mutation was not detected in 104 unrelated healthy controls. Variable onset of disease and symptoms often delay the diagnosis of PKAN. In our case, symptoms might begin at four years of age and characteristic MRI findings presented at the age of seven years. Further PANK2 analysis in patients with walking difficulty and night blindness is very important for establishment of early diagnostic criteria for PKAN before school of age.

Selected mutations in ASPM and Microcephalin excluded as candidates in 6 Iranian families with microcephaly.

P.A. Krakowiak¹, D.M. Fair¹, A. Jankhah², A. Parsian¹. 1) Pediatrics, UAMS, Little Rock, AR; 2) Shiraz Medical Genetic Counseling Center, Shiraz, Iran.

Background: Primary autosomal recessive microcephaly (MCPH) is a rare, genetically heterogeneous disorder that results in a structurally normal but reduced in size, cerebral cortex and mental retardation. At least six different loci have been shown to be linked to this defect and mutations in two genes have been identified in families with MCPH. At least 23 families have mutations in the *ASPM* (abnormal, spindle-like, microcephaly-associated) gene and two families sharing a common ancestral haplotype have mutations in the *Microcephalin* gene. Most of the reported families with identified mutations were from Northern Pakistan; however, one Jordanian, one Saudi Arabian, two Yemeni, and two Dutch families were also studied. **Methods:** We have examined 6 families with MCPH from South Central Iran (Fars Province). Each of the probands has one or more affected relatives, is a result of 1st cousin marriage, and meets the classic criteria for this defect with head circumferences of 3-7 standard deviations below normal, and mild to moderate retardation. We have screened each proband for mutations in portions of the *ASPM* and *Microcephalin* genes using genomic sequencing. The analyzed regions included exon 2 of the *Microcephalin* gene and exons 15, 16, 23 and part of exon 3 of the *ASPM* gene. The exons selected for this initial mutation screen were chosen because they contain mutations that have been identified in more than one family. **Results:** We have found no genetic mutation or variation that would change the amino acid sequence or result in protein truncation in the coding regions examined; however, we have identified 2 single nucleotide polymorphisms (SNPs) present in both affected and unaffected individuals. **Conclusion:** This study expands on the currently reported group of families to include a new region of the world. Our future studies will include screening of additional exons of the *ASPM* gene where mutations have been found and linkage analysis studies to test current and/or identify additional loci for MCPH.

A novel missense mutation in the ND gene in a child with Norrie disease and severe neurological involvement. *D. Lev^{1,2}, M. Hasan², Y. Weigel³, E. Gak³, C. Vinkler¹, T. Lerman-Sagie², N. Watemberg².* 1) Inst Medical Genetics, Wolfson Medical Ctr, Holon, Israel; 2) Pediatric Neurology Unit, Wolfson Medical Ctr, Holon, Israel; 3) Danek Gartner institute for human genetics, Sheba Medical Center.

Norrie disease is an X-linked recessive disorder characterized by congenital blindness and in some cases mental retardation and deafness. Neurologic abnormalities including myoclonus have rarely been described. We report a novel mutation identified in a patient with Norrie disease and severe neurological involvement. The patient was diagnosed at the age of 6 months due to congenital blindness. At the age of 8 months he developed myoclonic movements and convulsions and his EEG demonstrated hypsarrhythmia. He has marked developmental delay. His head circumference is on the 50 centile. Mutation analysis of the ND gene (NDP) of the affected child and his mother revealed a novel missense mutation T>A at position 134 resulting in change at codon 45. Some studies have suggested that epileptic seizures and growth retardation in patients with ND are the consequence of loss of contiguous genes, because most such patients have had deletions extending beyond the Norrie locus. The fact that the affected child and his mother carry this missense mutation does not support a contiguous gene effect, but favors the pleiotropism of NDP, at least as far as the epileptic manifestations are concerned. This has been suggested by another report of 2 families with NDP missense mutation where 3 affected patients suffered from epilepsy. The severity of the phenotype may suggest the functional importance of this site as was previously suggested for a nearby missense mutation.

Familial temporal lobe epilepsy preceded by febrile seizures is not associated with mutations in GABA-A receptor subunit genes. *S. Ma¹, B. Abou-Khalil¹, G.T. Lee¹, J.S. Sutcliffe^{2,3}, J.L. Haines^{2,3}, P. Heder^{1,2}.* 1) Department of Neurology, Vanderbilt University, Nashville, TN; 2) Program in Human Genetics, Vanderbilt University; 3) Department of Molecular Physiology and Biophysics, Vanderbilt University.

The genetics of temporal lobe epilepsy (TLE) associated with febrile seizures (FS) remains incompletely understood. TLE preceded by FS has been traditionally considered an acquired disorder, even though several specific syndromes with TLE and FS have been recently characterized with autosomal dominant or digenic inheritance. FS in these patients may represent initial manifestation of inherited tendency towards seizures. Mutations in different genes encoding GABA A receptor subunits have been identified as a rare cause of some idiopathic generalized epilepsy syndromes. We investigated the possible contribution of alpha1 (GABRA1), beta1 (GABRB1), gamma 2 (GABRG2) and delta (GABRD) subunit genes to familial TLE preceded by FS. We have screened probands from 46 kindreds with a positive family history of FS and TLE, and 40 individuals with sporadic TLE preceded by FS. Each exon was screened by single strand conformation polymorphism analysis and samples showing abnormal mobility shifts were sequenced. We did not identify any disease causing mutations in these genes. We found 3 novel syndromic changes in coding sequence of GABRA1 gene, 1 novel syndromic change in GABRG2 and one novel single nucleotide polymorphism (SNP) with an insertion in a 5UTR region of GABRA1, that was present in 3 kindreds but not in 200 normal controls; however, this sequence change did not fully segregate with the disease. We also identified several novel SNPs in intronic regions of all four genes analyzed. Our preliminary results indicate that TLE preceded by FS is not caused by mutations in GABA-A receptor subunit genes. We identified several novel SNPs in coding regions that need to be further investigated as possible susceptibility factors for this type of familial epilepsy.

Identification of FOXP2 truncation as a novel cause of nonsyndromic developmental speech disorder. K.D.

Forkhead-box transcription factors play important roles in embryogenesis. A point mutation in FOXP2 segregates with speech and language deficits in a 3 generation family (known as KE). This mutation, a G-to-A transition in exon 14, causes an Arg-to-His substitution within the DNA-binding motif. In addition, a translocation disrupting FOXP2 was found in an unrelated child with a similar phenotype. Extensive studies of children with autism and with specific language impairment failed to identify further FOXP2 coding changes. However, an overt feature of disorder in the KE family is verbal dyspraxia (problems co-ordinating mouth movements underlying speech), and, as yet, no study has fully examined FOXP2 in children with the appropriate phenotypic profile. Thus, in the present study we searched for mutations in all known FOXP2 exons in 43 probands with verbal dyspraxia. 7 probands had sibs who were also affected. All children had normal karyotype, no dysmorphic features, no mental retardation or additional diagnosis of medical/genetic disorder. A heterozygous mutation was identified in one proband, his affected sib, and their mother. This C-to-T change creates a stop codon in exon 7, yielding a dramatically truncated FOXP2 protein. Our data support the hypothesis that reduced FOXP2 dosage during neuronal development leads to disrupted speech. Moreover, they suggest that FOXP2 mutation is more frequent in children with verbal dyspraxia than in other language-related disorders.

CMT caused by EGR2 mutations: a natural history study of 10 patients. *P. Mancias*¹, *K. Szigeti*², *W. Wiszniewski*², *G.M. Saifi*², *G. Miller*³, *L. Keppen*⁴, *D.L. Daentl*⁵, *J.R. Lupski*². 1) Neurology, Univ TX Health Sci Center Med, Houston, TX; 2) Dept Genetics, Baylor Col Med, Houston, TX; 3) Dept Neurol, Baylor Col Med, Houston, TX; 4) Dept Ped and Adol Med, The Univ of S Dakota Sch of Med; 5) Shriners Hosp N Calif.

We have ascertained 10 consecutive patients with various EGR2 mutations and collected follow-up information regarding disease progression and respiratory compromise. The mean follow-up was 16.4 years. Three patients were from an AD, 3 from an AR family and in 4 patients CMT was caused by de novo mutations. Respiratory compromise in the form of documented restrictive pulmonary disease was present in 5/10 (50 %) of the patients, in one case it resulted in respiratory failure and death at 6 years of age. Cranial nerve findings were present in 60 %, and involved facial nerve, cranial nerve III, IX and XII. The progression of the disease was rapid, moderate or mild, depending upon the various mutations. Interestingly the toxic gain of function mutations resulted in mild, moderate or severe progression depending on the mutation, while the homozygous loss of function mutation in the recessive family with three affected children had minimal if any progression of the neuropathy. We have performed in vitro functional studies, including transcriptional activity, localization and function in apoptosis in transient transfection experiments utilizing constructs generated by in vitro mutagenesis. We correlated the in vitro data with severity of disease as measured by age of onset and rate of progression. We did not find a correlation between mutations and outcome, thus it is extremely difficult to prognosticate patients with EGR2 mutations. However our study confirmed that respiratory compromise and cranial nerve dysfunction are commonly associated with EGR2 mutations and can be useful in guiding molecular diagnosis.

ANALYSIS OF FIVE GENES IN BRAZILIAN PATIENTS WITH NONSYNDROMIC MENTAL RETARDATION. *C.M.C. Maranduba, A. Vianna-Morgante, M.R. Passos-Bueno.* Centro de Estudos do Genoma Humano, Instituto de Biociências, Universidade de São Paulo, São Paulo, Brazil.

carlosmaranduba@yahoo.com.br.

X-linked Mental Retardation affects approximately 1 in 600 males, comprising syndromic (MRXS) and nonsyndromic forms (MRX). To date 13 genes have been found to be associated with MRX. Four of these genes (*TM4SF2*, *IL1RAPL1*, *GDII*, *AGTR2*) and *ARHGEF9* gene, a functional candidate, were selected in this study. *TM4SF2* and *IL1RAPL1* mutations appear to account for 5-10% of MRX, while the other mutations are associated with less than 1% of the cases. We screened the coding region and the exon-intron boundaries of *TM4SF2*, *IL1RAPL1*, *GDII*, *AGTR2* and *ARHGEF9* genes, through SSCP/ dHPLC analysis and sequencing, in 118 male patients (25 familial and 93 isolated cases) who were shown not to carry the fragile X mutation. We found two polymorphisms in *TM4SF2* gene: c.237 CT (frequency of 3%) e c.441CT (5%), and a missense mutation c.515 CA (P172H), possibly pathogenic (Maranduba *et al.*, 2004). In the *IL1RAPL1* gene, we found one polymorphism (GA in 5UTR; 2% in our population) and an apparent silent mutation c.1200 GA (exon 9) not found in 221 control chromosomes. The analysis of this mutation in the RNAstructure 4.0 program (Nucleic Acids Res. 31:13, 3406-15, 2003) suggests that it changes the structure of the RNA and its possibly pathogenic. In order to further investigate if the mutation c.1200 GA in *IL1RAPL1* affects the processing of mRNA, we are currently conducting in vitro studies using the *pSPL3* vector (Exon trapping system, Invitrogen). We also identified the polymorphism IVS910GT in *GDII* gene and R248K in *AGTR2* gene, both already described. We did not find any pathogenic or polymorphic change in the *ARHGEF9* gene. In conclusion, our results suggest that the mutations P172H/*TM4SF2* and c.1200 GA/*IL1RAPL1* are possibly pathogenic, and that mutations in these genes account for approximately 1% of MRX cases. In this moment, *TM4SF2*, *IL1RAPL1*, *GDII*, *AGTR2* and *ARHGEF9* genes should not be considered in the routine diagnosis of mentally retarded individuals. Supported by: FAPESP/CEPID, CNPq.

Characterization of the mental retardation gene *FACL4* and analysis of a cellular Knock-out model. *I. Meloni¹, I. Longo¹, M. Bruttini¹, M.D. Ledesma², B. Hellias², C. Dotti², A. Renieri¹*. 1) Department of Molecular Biology, Medical Genetics, University of Siena, Siena, Italy; 2) Cavalieri Ottolenghi Scientific Foundation, University of Torino, Torino, Italy.

In 2002 we identified a new gene responsible for non-syndromic X-linked mental retardation (MRX): *FACL4* (fatty acid-CoA ligase 4), recently renamed *ACSL4*. The gene encodes for a protein which adds Coenzyme-A to long chain fatty acids, with high preference for arachidonic acid. It is expressed in all tissues except for liver and presents a brain-specific isoform resulting from alternative splicing and containing 41 additional N-terminal hydrophobic aminoacids. In order to establish how a mutation in this protein causes mental retardation we have characterized *ACSL4* expression in normal neuronal and non-neuronal cells. Western blot analysis was performed on protein isolated from brain, lymphoblasts and the neuronal cell line SH-SY5Y. This analysis demonstrated that in lymphoblasts *ACSL4* is present with two different isoforms. On the contrary, in brain and the neuronal cell line there is a third isoform with higher molecular weight, presumably corresponding to the brain-specific isoform. Immunofluorescence experiments in SH-SY5Y cells demonstrated that the protein is located in the medium compartment of Golgi apparatus. Analysis of cholesterol and ceramide content of membrane lipid extracts (total and from rafts) failed to demonstrate any difference between patients and control lymphoblasts. In order to define the possible role of *ACSL4* protein in neurons we have analyzed the consequences of its absence on neuronal differentiation in SH-SY5Y cells by employing antisense technology. This analysis has shown that differentiating cells lacking *ACSL4* expression present significantly longer cell processes with respect to cells expressing the protein, suggesting a role for *ACSL4* in membrane synthesis and/or recycling processes.

Program Nr: 2450 from the 2004 ASHG Annual Meeting

Mental retardation in Norrie disease due to vascular defects in the brain? *J. Neidhardt, U. Luhmann, B. Kloeckener-Gruissem, E. Glaus, W. Berger.* University of Zurich, Institute of Medical Genetics, Division of Medical Molecular Genetics and Gene Diagnostics, Schorenstrasse 16, 8603 Schwerzenbach, Switzerland.

Norrie disease (ND) is an X-linked recessive form of congenital blindness, progressive deafness and mental retardation. The disease is caused by mutations in the gene encoding Norrin, a ligand of the receptor Frizzled 4 of the Wnt signaling pathway. Norrie disease pseudoglioma homologue (*Ndph*) knockout mice closely resemble the human phenotype in eye and ear. They show defects in the vasculature of the inner retina and cochlea, while gross brain morphology is normal. In humans, at least one third of all ND patients show mental retardation with psychotic features, but its reasons are not yet understood. We studied the vasculature of different brain regions in our mouse model for ND, to elucidate a possible correlation between vascular defects in brain and mental retardation. The vascular network of the cerebellum, cortex, and hippocampus was stained by immunohistochemistry on cryosections of 8 month old mice and blood vessels were counted. We found a significantly reduced vascular content (~ 20 %) in the cerebellum of knockout mice. In addition, we observed an ~ 8 % decrease in the amount of blood vessels in both, cortex and hippocampus. These results were correlated with the transcription level of *Ndph* in different brain regions, examined by quantitative RT-PCR. We found that *Ndph* is expressed three times higher in the cerebellum than in cortex and hippocampus. Our results suggest a dosage dependent correlation between transcriptional activity of the *Ndph* gene and the amount of blood vessels in different brain regions. These data provide a first hint towards a possible cause of mental retardation in Norrie disease patients.

Program Nr: 2451 from the 2004 ASHG Annual Meeting

Identification of genetic basis in Korean patients with Charcot-Marie-Tooth disease type 1 (CMT1). *H-K. Park, C-S. Ki, E-J. Kim, J-W. Kim.* Department of Laboratory Medicine, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, Korea.

Charcot-Marie-Tooth disease type 1 (CMT1), the most common hereditary neurological disorder in humans, is characterized by clinical and genetic heterogeneity. About 70~80% of CMT1 patients have been associated with the duplication of 1.5 Mb region on chromosome 17p11.2-p12 including the PMP22 gene (PMP22-DUP), while remaining patients have been due to mutations in the PMP22, MPZ, GJB1, EGR2, and LITAF genes. In the present study, we tried to reveal the genetic basis of Korean patients with CMT1. Thirty-six index cases with CMT1 were included and tested for the PMP22-DUP by the pulsed-field gene electrophoresis (PFGE)-Southern blot analysis. Patients without PMP22-DUP were further investigated for the presence of point mutations in PMP22, MPZ, GJB1, EGR2, and LITAF genes by direct sequencing of all coding exons and their flanking intronic regions. Twenty-seven patients (75%) were confirmed to have the PMP22-DUP by the PFGE-Southern blot analysis, which was concordant with the previous reports. Among the patients with PMP22-DUP, 6 (17%) patients had point mutations: two in the PMP22 gene (T23R and 179-2A_G) and four in the GJB1 gene (D46G, V95M, Y151H, and F180L), in which three mutations were novel. No mutation was found in the MPZ, EGR2, and LITAF genes. In summary, the PMP22-DUP is also predominant in Korean patients with CMT1. It is of note that there was no patients with MPZ, EGR2, and LITAF mutation, which have been associated with about 25% of CMT1 patients.

Autosomal dominant early-onset Alzheimer's disease: an update. G. Raux¹, L. Maréchal^{2, 3}, C. Martin², J. Bou¹, C. Penet⁴, A. Brice⁴, D. Hannequin^{1, 3}, T. Frebourg^{1, 2}, D. Campion¹. 1) Inserm U614, Faculty of Medicine, 76183 Rouen, France; 2) Department of Genetics, Rouen University Hospital, 76031 France; 3) Department of Neurology, Rouen University Hospital, 76031 France; 4) Inserm U589 la Salpêtrière Hospital 75013, Paris, France.

Autosomal dominant early-onset Alzheimer's disease (ADEOAD) is a rare condition which is genetically heterogeneous. Missense mutations in three genes, encoding for the presenilin 1 (*PSEN1*), presenilin 2 (*PSEN2*) and amyloid precursor protein (*APP*) have been identified in ADEOAD. Mutational analysis of these 3 genes in 34 families had previously allowed us to estimate that 71 % of ADEOAD families were attributable to mutations of *PSEN1* and *APP* genes. However, other groups have recently reported lower estimates on smaller samples. To further clarify the respective contribution of these genes to ADEOAD, we analyzed 25 novel families ascertained by using the stringent criteria that we had previously defined (i. e. the occurrence of probable or definite AD cases with onset before age 60 in three generations). We identified *PSEN1* mutations (including 7 previously unreported mutations) in 19 families and *APP* mutations in 4 families. We failed to detect any *PSEN2* mutation. The new mutations cosegregated with the disease in two families with multiple living affected members. Two *PSEN1* mutations (Pro264Leu and Phe386Ser) were associated with an atypical presentation including spastic paraparesis. The Glu318Gly variation, which has been described either as a non pathogenic polymorphism or as a mutation with reduced penetrance was present in three families. Finally, 78 % of the affected subjects had an *APOE* 3-3 genotype and none had the *APOE* 4-4 genotype. When these data are combined with those previously published, and taking into account that the diagnosis of AD was not confirmed by neuropathological examination in two previously negative families we conclude that among 59 ADEOAD families, 65% are attributable to *PSEN1* mutations (59% if the Glu318Gly variation is considered as a non pathogenic polymorphism) and 15 % to *APP* mutations while 20% of the ADEOAD remain unexplained.

Mutations in the DLG3 gene cause non-syndromic X-linked mental retardation. *F.L. Raymond¹, P. Tarpey², J. Parnau¹, M. Blow², H. Woffendin², J. Moon¹, M. Partington⁴, G. Turner⁴, R. Stevenson⁵, C. Schwartz⁵, I. Young⁶, M. Bobrow¹, P.A. Futreal², M.R. Stratton², J. Gecz³, R. Wooster², on behalf of the Genetics of Learning Disability Study.* 1) Dept Medical Genetics, CIMR, Cambridge, United Kingdom; 2) Sanger Institute, Hinxton, Cambridge UK; 3) Womens and Childrens Hospital and University of Adelaide, Adelaide, Australia SA 5006; 4) Hunter Genetics and University of Newcastle, PO Box 84, Waratah, New South Wales, Australia 2298; 5) Greenwood Genetics Centre, 1 Gregor Mendel Circle, Greenwood, South Carolina USA 29646; 6) Department of Medical Genetics, Leicester Royal Infirmary, Leicester LE1 5WW, UK.

We have identified truncating mutations in the human gene DLG3 the homolog of Drosophila discs large 3 gene in 4 out of 329 families with moderate to severe X-linked mental retardation. DLG3 encodes synapse-associated protein 102 (SAP102), a member of the membrane associated guanylate kinase (MAGUK) protein family. Neuronal SAP102 is expressed during early brain development and is localised to the post-synaptic density of excitatory synapses. It is composed of 3 amino terminal PDZ domains, a src homology (SH3) domain and a carboxyl terminal guanylate kinase (GK) domain. The PDZ domains interact directly with the NR2 sub-units of the NMDA glutamate receptor, and with other proteins responsible for NMDA receptor localization, immobilization and signaling. The mutations identified in this study all introduce premature stop codons within, or before the third PDZ domain, and it is likely that this impairs the ability of SAP102 to interact with the NMDA receptor and/or other proteins involved in downstream NMDA receptor signaling pathways. The disruption of NMDA receptor targeting or signaling due to loss of SAP102, may lead to altered synaptic plasticity, and offers a mechanism which may explain the intellectual impairment observed in DLG3-mutated individuals.

Identification of a more common founder mutation in the *senataxin* gene responsible for AOA2 in French-Canadians. K. Roddier¹, A. Duquette¹, J. Mc Nabb-Baltar¹, I. Gosselin¹, A. Saint-Denis¹, M.J. Dicaire¹, L. Loisel¹, L. Marchand², J. Mathieu³, J.P. Bouchard⁴, B. Brais^{1,2,3}. 1) Laboratoire de neurogénétique, Centre de recherche du CHUM, Université de Montréal, Montreal, Quebec, Canada;; 2) Clinique d'ataxie du CHUM, Centre Hospitalier de l'Université de Montréal, Montreal, Quebec, Canada; 3) Clinique des maladies neuromusculaires, Carrefour de la Santé de Jonquière, Saguenay, Quebec, Canada; 4) Service de neurologie de l'Hôpital de l'Enfant-Jésus, Université Laval, Quebec, Quebec, Canada.

Recessive ataxias are a heterogeneous group of neurodegenerative diseases. At least one form of ataxia is more frequent in the Quebec population: the autosomal recessive spastic ataxia of Charlevoix-Saguenay (MIM 270550). In 1980, Jean-Pierre Bouchard described seven members of a large family who presented a rare recessive form of ataxia (MIM 606002). In this study, we further characterized this family and described 17 additional cases from nine families. The gene *senataxin* responsible for this disease has recently been identified. Following informed consent, we extracted DNA of 23 patients and their relatives. We completed a linkage analysis using standard methods. Further to the identification of the responsible gene, we sequenced all the exons and the intron/exon junctions in order to search for mutations in the French-Canadian cohort. Linkage analysis has demonstrated that all families are linked to the 9q34 locus for the recessive Ataxia with Ocular Apraxia type 2 (AOA2, MIM 606002). A maximum LOD score of 9.86 was obtained at = 0 for marker D9S2157. We sequenced the *senataxin* gene responsible for the AOA2 and identified four mutations in the French-Canadian population, including two novel missense mutations. The most common founder mutation is shared by 85% of the carrier chromosomes. AOA2 becomes the second recessive ataxia to be identified to be more frequent in the French-Canadian population due to the higher prevalence of a founder mutation.

***SIMPLE/LITAF* mutations in Charcot-Marie-Tooth disease and the potential role of the protein products in peripheral nerve transcriptional regulation and protein degradation.** *G.M. Saifi*¹, *K. Szigeti*¹, *W. Wiszniewski*¹, *M.E. Shy*², *K. Krajewski*², *I. Hausmanowa-Petrusewicz*³, *A. Kochanski*³, *S. Reeser*⁴, *J.R. Lupski*^{1,5,6}. 1) Dept Molec & Human Genetics, Baylor College of Medicine, Houston 77030, TX; 2) Dept Neurology, Wayne State University, Detroit, MI; 3) Neuromuscular Unit, Medical Research Centre, Polish Academy of sciences, Warsaw, Poland; 4) WellSpan Health System, York Hospital, York, PA 17505; 5) Dept Pediatrics, Baylor College of Medicine, Houston, TX; 6) Texas Childrens Hospital, Houston TX.

Charcot-Marie-Tooth (CMT) disease is a clinically and genetically heterogeneous group of inherited peripheral neuropathies characterized by progressive weakness and atrophy of distal limb muscles. Recently, a transcription factor gene, *SIMPLE/LITAF*, was shown to be responsible for an autosomal dominant demyelinating form of CMT linked to 16p (CMT1C). We screened this gene for mutations in a cohort of 192 patients with CMT or related neuropathies, each of whom tested negative for other known genetic causes of CMT. In 16 unrelated CMT families we identified nine different nucleotide variations in *SIMPLE/LITAF* that were not detected in control chromosomes. *SIMPLE/LITAF* mutations can occur *de novo* associated with sporadic CMT1. Bioinformatics analyses of LITAF and its cognate recognition sequence suggest involvement in global peripheral nerve transcription. We propose that a WW domain containing protein, most likely NEDD4, activates LITAF by the regulated ubiquitin/proteasome-dependent processing (RUP) pathway. Bioinformatics analyses and other observations of SIMPLE, an alternatively spliced isoform of LITAF, suggest that it could be a member of the RING finger motif-containing subfamily of E3 ubiquitin ligases that are associated with the ubiquitin-mediated proteasome processing pathway. It is thus likely that the transcriptional regulation by LITAF or the E3 ubiquitin ligase activity of SIMPLE may underlie the pathogenesis of Charcot-Marie-Tooth disease.

Hereditary Spastic Paraplegia 3A: a novel Atlastin-1 mutation causes aggregate formation in mammalian cells.

N. Sambuughin^{1,2}, M. Nakada², H. Holley², R. Bien-Willner², D. Baasanjav³, M. Berens⁴, K. Sivakumar², L. Goldfarb¹.

1) National Institute of Neurological Disorders and Stroke, NIH, Bethesda, MD; 2) Barrow Neurological Institute, Phoenix, AZ; 3) National Institute of Health, Ulaanbaatar, Mongolia; 4) Translational Genomics Research Institute, Phoenix, AZ.

Hereditary Spastic Paraplegia is a heterogeneous group of disorders characterized by progressive lower extremity weakness and spasticity. Thus far, twenty-two SPG loci have been mapped and ten genes identified. Recently, autosomal dominant mutations in the Atlastin-1 gene have been found to be associated with SPG3A which account for 10% of all known SPGs. Atlastin-1 is a 64 kDa member of the dynamin/Mx/guanylate-binding protein superfamily of large GTP-ases having two predicted transmembrane domains. Based on sequence homology and cellular localization, a functional involvement in Golgi membrane dynamics and vesicle trafficking have been proposed for Atlastin-1. We analyzed a five-generation Mongolian family in which SPG3A segregates with a novel mutation Thr156Ile in the Atlastin-1 gene. Four family members were diagnosed with definite SPG and had severe spastic gait and lower extremities hyperreflexia. The oldest affected member, a 47 year old female, had in addition, cognitive problems, severe bilateral weakness in the lower and distal muscles of the upper extremities, brisk reflexes, markedly increased muscle tone, up-going plantars, pes cavus. Other patients had hand tremor, urinary urgency and incontinence, and distal hypesthesia for pain and touch. Evidence is presented that mutant Atlastin-1 leads to formation of aggregates in the mammalian cells. Formation of aggregates may occur due to protein misfolding and disruption of oligomerization of Atlastin-1, which in turn may have deleterious effects on neuron survival. Immunoblots and immunocytochemical studies revealed that Atlastin-1 is associated with alpha-tubulin and endoplasmic reticulum (ER).

Respiratory and bioaminergic alterations in *Mecp2*-deficient adult mice, an experimental model for Rett

Syndrom. V. Saywell¹, H. Burnet², J.C. Roux², M. Bevorgut², M. Barthélémy², A. Moncla³, J. Mancini⁴, L. Villard¹, G. Hilaire². 1) Inserm U491, Faculté de Médecine Timone, Marseille, France; 2) GERM, FRE CNRS 2722, 280 Bd Ste-Marguerite, Marseille, France; 3) Dpt de Génétique Médicale, Hôpital d'Enfants de la Timone, Marseille, France; 4) Dpt de Neurologie Pédiatrique, Hôpital d'Enfants de la Timone, Marseille, France.

Rett syndrome is a severe X-linked neurological disorder, in which most patients carry a mutation in the gene encoding methyl-CpG binding protein 2 (MECP2). The clinical course of the disease consists of normal in utero and neonatal development followed by a period of regression showing signs of neurodevelopmental defects (arrest of brain development, loss of acquisitions such as speech and walk, apparition of behavioural troubles). One of the most life-threatening symptoms is the presence of severe breathing alterations consisting of a combination of hyperventilation and apneas when the patient is awake. These alterations disappear when the patient is sleeping. Several hypothesis have been proposed to explain these observations such as a defect in autonomic functions, brainstem immaturity and/or altered neurotransmitter systems. Studies of bioaminergic levels have been performed but revealed inconsistent results : normal concentration of noradrenaline, serotonin and dopamine in the spinal fluid whereas brain autopsy showed reduced levels of these substance. We performed experiments on wild-type and *Mecp2*-deficient mice to understand the role of the *Mecp2* gene in respiration and bioaminergic systems. Using plethysmography to record breathing, high pressure liquid chromatography to measure the concentration of bioamines and immunolabelling to study the catecholaminergic neurons, we show that the deficiency in the *Mecp2* gene lead to an altered respiratory rhythm and an abnormal medullary bioaminergic content.

Analysis of the GABA-A receptor gene in Japanese patients with Acute encephalitis or encephalopathy with refractory, repetitive partial seizures. *N. Shiroma, H. Minema, K. Katsuren, S. Fukuyama, T. Ohta.* Pediatrics, University of the Ryukyus, Okinawa, Japan.

<Background> Acute encephalitis or encephalopathy with refractory, repetitive partial seizures (AERRPS) is a rare disease caused by unknown etiology. In some case, overdose benzodiazepine which acts on GABA-A receptor, is effective to control of seizure. Recent studies conformed that some mutations in GABA-A receptor alpha1 subunit (GABRA1) gene alter the functional properties of GABA-A receptors. <Objective> To evaluate the genetic contribution of cloned human GABA-A receptors to AERRPS. <Methods> Informed consent was obtained from all the patients in this study. We analyzed GABRA1 gene in 6 patients with AERRPS. <Results> We found no mutation in the exons of GABRA1, we did identify two single nucleotide polymorphisms (SNPs) in exon 4 (471 C > T) and exon 6 (679 C > T). We postulate that the GABRA1 gene might not be a susceptibility gene for AERRPS.

Neuronal inclusions are not pathogenic in HD: a YAC mouse expressing a truncated fragment of huntingtin (shortstop) with 128 CAGs displays widespread neuronal inclusions but no behavioural changes or neurodegeneration. *E. Slow*¹, *R. Graham*¹, *A. Osmand*², *R. Wetzel*², *R. Devon*¹, *G. Lu*¹, *Y. Deng*¹, *J. Pearson*¹, *K. Vaid*¹, *N. Bissada*¹, *B. Leavitt*¹, *M.R. Hayden*¹. 1) Medical Genetics, CMMT, University of British Columbia, Vancouver, BC Canada; 2) Graduate School of Medicine, University of Tennessee, Knoxville, TN.

A YAC mouse model expressing full-length human huntingtin (htt) with 128 CAGs (YAC128) under the control of 24 kb of upstream promoter, exhibits behavioural and neuropathological changes that accurately recapitulate Huntington disease. During the development of other full-length YAC128s, a mouse expressing a short fragment of htt (shortstop) was serendipitously created. The shortstop mouse which expresses exons 1 and 2 of the HD gene, producing a protein of 117 amino acids with an expanded polyglutamine tract, possesses the identical regulatory region, polyglutamine repeat and level of transgenic protein as the full-length YAC128 on the identical FVB strain. This has allowed for the first time the opportunity to compare and contrast the effects of both full-length and truncated mutant htt *in vivo*. Htt inclusion analysis in the shortstop mice revealed 6-9 month earlier onset and more widespread inclusion formation both in percentage of neurons (65-95% more in 18 month shortstop compared to age-matched YAC128s) and in neuronal tissue types affected in the shortstop compared to the full-length YAC128. In addition, aggregation foci, a precursor of htt inclusions, are present at a higher density in certain tissues of the shortstop compared to the YAC128. The YAC128 model demonstrates reproducible decreases in rotarod performance ($p < 0.001$), brain weight ($p < 0.01$), striatal volume ($p < 0.05$) and striatal neuronal count ($p < 0.05$) compared to wild-type littermates. Surprisingly, shortstop does not demonstrate deficits in any of these measures, despite widespread inclusion burden. The role of inclusions in HD pathogenesis is controversial. These results indicate that htt inclusions and precursors, although part of the disease sequelae, are not pathogenic, and can exist completely separate from HD-related neuronal dysfunction and degeneration.

Aberrant striatal phosphatidylserine decarboxylase gene expression in the HPRT-knockout mouse. *S. Song, T. Friedmann, D. Smith.* Pediatrics, Univ. Calif. San Diego, La Jolla, CA.

There is virtually no detailed understanding of the mechanisms responsible for the dopamine deficit in the basal ganglia of the HPRT-knockout mouse, a model of Lesch Nyhan disease. We have used microarray transcriptional profiling methods in wild type and HPRT-knockout mice to examine the possibility that secondary genetic aberrations play a role in the altered CNS function in this disease model. We have identified a small number of genes whose expression in the striatum is aberrant during the development of the dopamine deficient from 2-6 weeks of post-natal life. One of the principal differentially expressed genes is the gene encoding phosphatidylserine decarboxylase (PSD) which, together with several other members of the PSD-like family, is significantly down-regulated in the striatum of the HPRT-knockout mice. The microarray results were confirmed by quantitative PCR analysis and by in-situ hybridization. Specifically, these results suggest suggest a potential role for altered phospholipid metabolism in the development of the CNS phenotype in the Lesch Nyhan disease. More generally our results suggest that complex gene expression defects may be responsible for parts of the phenotype of even "monogenic" and that at least some classical monogenic disorders may be functionally multigenic.

Modeling of spinocerebellar ataxia 7 in *Drosophila melanogaster* as a model of polyglutamine diseases. G.

Stevanin^{1,3}, *M. Latouche*¹, *E. Martin*¹, *V. Monnier*², *A. Mouatt-Prigent*¹, *A. Brice*^{1,3}, *H. Tricoire*². 1) Inst des Neurosciences, INSERM U289-NEB, Paris, France; 2) Institut Jacques Monod, UMR7592 CNRS, Paris, France; 3) Department of Genetics, Cytogenetics and Embryology APHP, Hopital Salpetriere, Paris, France.

Spinocerebellar ataxia type 7 (SCA7) is one of the 6 autosomal dominant cerebellar ataxias (SCA1, 2, 3, 6, 7 and 17) belonging to the group of the polyglutamine (poly-Q) diseases, which also includes Huntingtons disease, spinobulbar muscular atrophy and dentatorubral-pallidoluysian atrophy. Poly-Q diseases are all neurodegenerative disorders caused by the expansion of a translated (CAG)_n repeat in the corresponding gene and they share several features including the presence of neuronal intranuclear inclusions (NIIs) in patients brains. The mechanisms of neuronal death and the role of the NIIs remain unclear. In order to identify the pathways involved in the physiopathological process, we generated SCA7 transgenic flies expressing a truncated form of wild type or expanded Ataxin7 (polyQ-Ataxin7), the protein encoded by the SCA7 gene. Several transgenic lines were established and expression of the transgenes was targeted to the nervous system, muscles or ubiquitously, and was analyzed by western blot, real time RT-PCR, immunofluorescence, immunohistochemistry and electron microscopy. Preliminary results indicate that expanded Ataxin7 aggregates within the nucleus and induces late-onset lethality, early adult death, reduced viability and larval lethality according to the targeted tissues. Based on these results, we will use this model to identify modifier genes and pharmacological compounds that might prevent or modulate the toxicity of polyQ-Ataxin7.

Evaluation of Parkin mutations in a large familial PD cohort: The GenePD Study. *M. Sun¹, G. Xu², J. Latourelle², R. Prakash², J. Maher², R.H. Myers², J.F. Gusella¹, for the GenePD Study.* 1) Molecular Neurogenetics Unit, Center for Human Genetic Research, Massachusetts General Hospital, Harvard Medical School Boston, MA; 2) Department of Neurology, Boston University School of Medicine, Boston, MA.

Mutations in the Parkin gene are the most commonly identified cause of young onset parkinsonism with autosomal recessive inheritance. The frequency and spectrum of Parkin mutations have been extensively studied in ethnically mixed patient populations. Overall, the frequency of Parkin mutations was estimated at up to 50 percent in ARJP, 10-25 percent in early onset, and 2 percent in late onset families. However, the mutation rate reported varied by PD samples tested and detection methods employed. The purpose of this study was to evaluate the burden of Parkin mutations in 329 families with at least two PD affected members collected in the GenePD Study. We comprehensively screened all 12 coding exons and the corresponding exon-intron boundaries by both conventional mutation screening and gene dosage analysis. We narrowed the focus of our screen to the subset of families most likely to have Parkin mutations. We genotyped the microsatellite marker D6S305 which lies within the intron7 of the parkin gene in our entire sample set containing 715 individuals from 329 families. The 83 families where affected siblings shared both allelic IBS at the parkin locus plus an additional 99 families containing at least one member with onset age earlier than 52 years. In total, we screened 182 index patients (selecting the youngest onset subject in each family). We performed SSCP and sequencing to detect point mutations in the index patients combined with quantitative duplex PCR using Lightcycler to detect alterations of gene dosage (exon deletions and duplications). Mutations were found in 29/182 patients. Seven were compound heterozygous; 2 were homozygous; and 20 were heterozygous. We identified 5 known point mutations in 7 patients and 9 gene dosage alterations in 25 patients. In conclusion, Parkin mutations are not rare in this sample of PD patients (16%) and screening reduces genetic heterogeneity in the study of familial PD.

DJ-1 gene in late-onset recessive Parkinsons disease. *P. Tarantino, F. Annesi, D. Civitelli, E.V. De Marco, I.C. Ciro' Candiano, S. Carrideo, F.E. Rocca, G. De Cicco, G. Annesi.* Inst of Neurological Sciences, National Research Council, Mangone, Cosenza, Italy.

Three loci have been associated with early-onset, autosomal recessive parkinsonism: Parkin (PARK 2,) DJ-1 (PARK 7), PINK1 (PARK 6). Recently, mutations in DJ-1 were described as a novel cause of early-onset parkinsonism. We analysed the DJ-1 gene in 23 subjects with late onset (after the age of 45 years) Parkinsons disease (PD) screened from 18 families originating from Southern Italy with autosomal recessive PD (LORPD). These patients were evaluated previously for the presence of parkin mutations (PARK2) by a combination of gene dosage and sequencing and were found to be negative. The 18 families with LORPD were selected according to the following criteria: reported parkinsonism in two or more siblings; a mode of inheritance compatible with autosomal recessive transmission (affected siblings without affected parents); an age at onset of 45 years or older in all the affected siblings. Genomic DNA was extracted in all subjects from peripheral-blood leukocytes according to standard procedure. The entire DJ-1 open reading frame was amplified from genomic DNA, and PCR amplified were directly sequenced by means of forward primers. We did not find any pathogenic mutation in the DJ-1 gene in all patients with LORPD. We identified at codon 98 (exon 5) a G/A heterozygous substitution in four patients; this change was confirmed by Msp I restriction analysis, and was found in 10 out of 700 control chromosomes. Moreover we identified an 18 bp insertion/deletion variant in the promoter region of DJ-1(g.168_185del) in six patients; this variant was also found in 3 out of 600 control chromosomes. Our results indicate that mutations in DJ-1 are not common cause of LORPD. Further studies by using quantitative PCR assay are needed to exclude heterozygous exons rearrangements in subjects with LORPD.

An unusual cosegregation of CMT1A duplication and HNPP *PMP22* point mutation in a family with CMT1 disease. *F. Taroni, M. Milani, D. Pareyson, D. DiBella.* Div. of Biochemistry & Genetics, Ist. Naz. Neurologico C. Besta, Milan, Italy.

The common CMT1A duplication and HNPP deletion arise from unequal crossing over and homologous recombination during meiosis between flanking repeats (CMT1A-REP). CMT1A and HNPP thus result from an altered copy number of the dosage-sensitive myelin gene *PMP22* which is included in the duplicated/deleted tract. However, both diseases can also be caused by rare *PMP22* point mutations. We report here a unique family carrying both the CMT1A duplication and a HNPP *PMP22* point mutation. A CMT1 child (III-1), the only affected member of her family, was found to carry the duplication. Surprisingly, the mutation was also found in the mother (II-2) who had normal clinical and electrophysiologic phenotype. *PMP22* sequence analysis in both individuals uncovered a truncating frameshift mutation (Leu145fs) in the healthy mother but not in the affected child. In the mother, this mutation, which had been previously identified by us in 3 other HNPP families, would inactivate the extra copy of the *PMP22* gene, functionally compensating the effects of the duplication. Further investigations in the family demonstrated that the healthy maternal grandmother (I-1) also carried both the duplication and the point mutation, while her other son (II-1) had neither of them, which indicates that both mutations were harbored by the same chromosome. Microsatellite analysis suggests that a meiotic intrachromosomal homologous recombination event of maternal origin has occurred in the affected child, replacing the mutated *PMP22* copy with a functional one and resulting in CMT1 phenotype. [Supported by grants from Ministero della Salute (RF 2002/160) and Fondazione Mariani to F.T.]

Toward a clinical and molecular genetic description of a new form of autosomal recessive spastic ataxia in the French-Canadian population. *I. Thiffault^{1,2}, M.F. Rioux¹, J. Poirier¹, J. Mathieu³, G. Rouleau⁴, J.P. Bouchard⁵, B. Brais^{1,2}.* 1) Dept of Neurogenetics, Room M411L, CHUM-Notre-Dame, Montreal, PQ, CANADA; 2) Dept of Molecular Biology, Université de Montreal, PQ, CANADA; 3) Carrefour de la santé de Jonquière, Jonquière, PQ, CANADA; 4) MUHC-Montreal General hospital, Montreal, PQ, CANADA; 5) CHUL, Quebec, PQ, CANADA.

Recessive spastic ataxia are a very heterogeneous group of neurodegenerative disorders characterized by symptoms and signs of progressive gait, ataxia, spasticity, peripheral neuropathy, pyramidal and/or extrapyramidal signs and in certain cases cardiomyopathy, hypermyelinated retinal nerve fibers, and dysarthria. Relying on a network of Ataxia and Neuromuscular clinics that cater to more than 500 ataxic patients, we have recruited 26 affected individuals and their unaffected relatives from 20 unrelated French-Canadian families with an original form of autosomal recessive ataxia which do not have a precise molecular diagnosis; all patients were negative for Friedreich ataxia and Spastic ataxia of Charlevoix-Saguenay (SACS) by linkage analysis. Neuroimaging (MRI) shows cerebellar atrophy in 100% of the cases; more severe cases presented mild to moderate cerebral atrophy (42.9% of the cases) and leukodystrophy (52.4% of the cases). The major clinical features are the presence of ataxia, dysarthria, spasticity and hyperreflexia. The age of onset is variable (mean 8 years; range 3-20). The more severe cases have scoliosis, dystonia and mild cognitive impairment. There is a great intrafamilial and interfamilial variability in the severity of the phenotype. The clinical phenotype of the families is consistent with an autosomal recessive form of inheritance and geographic distribution of the cases suggests a French-Canadian founder effect. Using a homozygosity mapping approach, we performed a systematic 10cM genome wide scan (GWS) which did not reveal the responsible locus for this recessive ataxia. However, microsatellite analysis is on-going to refine the GWS map and to exclude 8 different known loci of other disorders which could overlap with this new form of autosomal recessive spastic ataxia. This study could lead to the identification of the mutated gene responsible for approximately 20% of recessive ataxia in Quebec and possibly in other populations with founder effect.

Refinement of the locus for pyridoxine-dependent epilepsy on chromosome 5q31. *B. Uhlenberg¹, P. Koehne², J. Herrmann², B. Lucke¹, M. Schuelke¹, B. Weschke¹.* 1) Department of Neuropediatrics, Charite, Berlin, Germany; 2) Department of Neonatology, Charite, Berlin, Germany.

Pyridoxine-dependent epilepsy (MIM 266100) is an autosomal recessive disorder characterized by different types of convulsions starting in the neonatal period, infancy or even in utero. Seizures exclusively respond to immediate administration of pyridoxine hydrochloride (vitamin B6). Interruption of pyridoxine supplementation usually leads to the recurrence of seizures which makes pyridoxine dependence permanent. Hypo- or dystonia, jitteriness, a high-pitched cry, abdominal distension, frequent vomiting, hypothermia as well as moderate motor and mental retardation are possible associated symptoms. The pathogenesis of pyridoxine-dependent seizures is not known, but a reduction in the synthesis of gamma-aminobutyric acid (GABA) as a result of diminished activity of the glutamic acid decarboxylase (GAD) has been postulated. However, linkage to the GAD1 (2q31) and GAD2 genes (10p23) was previously excluded in 4 consanguineous families and genome-wide scanning revealed linkage of the underlying gene to markers on chromosome 5q31.2-q31.3. In the absence of an appropriate candidate gene the responsible gene defect has not been unraveled so far. In this study we investigated a consanguineous Turkish family with two affected sons with unequivocal symptoms of pyridoxine-dependent epilepsy. We performed homozygosity mapping by microsatellite markers and confirmed linkage to the 5q region. We narrowed the critical region by detection of a recombination event proximal to marker D5S2033. The two patients were homozygous at loci D5S658 to D5S436. Thus the region encompassing the disease-underlying gene now comprises 4.5 cM. Work is in progress in order to identify a mutation in a possibly disease-related gene.

Search for rearrangements at the Golli-MBP locus in patients with undetermined leukodystrophies (UL) using different genomic quantification techniques. *C. Vaurs-Barriere¹, MN. Bonnet-Dupeyron^{1, 2}, P. Combes¹, F. Gauthier-Barichard¹, P. Vago², O. Boespflug-Tanguy¹.* 1) UMR384, Medicine Faculty, Clermont-Fd, France; 2) Cytogenetics Laboratory, Medicine Faculty, Clermont-Fd, France.

Leukodystrophies represent a heterogeneous group of rare inherited disorders that involve primarily the white matter of the central nervous system (CNS). The PLP gene is implicated in the etiology of the hypomyelinating X-linked forms of leukodystrophies; large rearrangements of the PLP genomic region being the predominant mutation. Nevertheless, we found that almost half of the patients with a hypomyelinating leukodystrophy have no identified PLP mutation, suggesting that other genes important for brain myelination may be implicated. The myelin basic proteins (MBP) correspond to the second most important class of CNS myelin proteins. The MBP gene, localized on chromosome 18, is included in a more complex gene structure called the Golli-MBP complex. Rearrangements within the MBP gene have been found in spontaneous dysmyelinating mutants as the shiverer mouse and the long evans rat. Patients with 18q- syndrome displayed also abnormal myelination pattern on MRI correlated with a genomic minimal interval including the MBP gene. Therefore, the Golli-MBP locus could be considered as a good candidate gene in the etiology of UL. We first searched for rearrangements at the Golli-MBP locus in 340 patients without identified PLP mutations. After using FISH in a pre-screening step, we have adapted the Multiplex Amplifiable Probe Hybridization (MAPH) and the Quantitative Mutiplex PCR of Short Fluorescent fragments (QMPSF) quantification techniques to the study of the Golli-MBP gene in our large cohort. Although preliminary results obtained by FISH led us to think that there may be duplication events in a mosaic form, no rearrangement has been finally found by QMPSF and MAPH, neither by FISH using a different labeling protocol. This work highlights the difficulty to use FISH for rearrangement detection (particularly duplications) and has allowed us to compare advantages and disadvantages between QMPSF and MAPH. Finally, rearrangements at the Golli-MBP locus seem not involved in the etiology of UL.

SCA8 EXPANSIONS ARE NOT FREQUENTLY ASSOCIATED WITH OTHER SCA EXPANSIONS IN SPANISH SERIES. *V. Volpini¹, J. Corral¹, I. Banchs¹, J. Armstrong^{1, 2}, H. Nicolas¹.* 1) Medical and Molecular Genetics Centre, Cancer Research Institute, Hospitalet de LL, Barcelona, Spain; 2) Neuropathologic Institut, Bellvitge Hospital, Barcelona, Spain.

The spinocerebellar ataxias (SCAs) belong to a group of genetic disorders caused by repeat expansion of a specific tandem DNA repeat. Several SCA loci cause dominantly inherited ataxia by the expansion of a CAG repeat which is translated into polyglutamine tracts. In contrast, SCA 8 is reported to be caused by an unstable transcribed but untranslated CTG repeat expansion in the 3 exonic region of a gene on chromosome 13q21, and large alleles above the disease threshold have been observed in healthy individuals who have no family history of ataxia. Additionally, the coexistence of SCA8 expansions with other expansions such as FRDA, SCA6 or SCA1 have also been reported elsewhere. We have studied a total of N = 203 patients with ataxia from families with a dominant pattern of inheritance and in which we have detected their respective SCA expansions: 38 SCA1; 47 SCA2; 91 SCA3; 5 SCA6 and 22 SCA7. We performed a PCR analysis in all cases using 5-fluorescent SCA8-F3 and SCA8-R4 primers as described and none of them also have the SCA8 expansions in the reported pathogenetic range. We have not found either great or giant expansions as reported in healthy individuals in other SCA series. In conclusion we have not found coexistence of SCA8 expansions with other SCA expansions in our SCA series. Such a situation seems to be a rare event although it has been detected in other SCA or FRDA series but it should be taken in account to explain the etiopathogenesis of dynamic mutations disorders.

Clinical and molecular genetic study of six Japanese families with familial hemiplegic migraine/ episodic ataxia type 2. T. Wada¹, T. Go², H. Tsukahara³, M. Kanayama³, Y. Suzuki⁴, Y. Fukushima¹, S. Saitoh⁵. 1) Medical Genetics, Shinshu Univ Sch Medicine, Matsumoto, Nagano, Japan; 2) Tokyo Women's Medical College, Tokyo, Japan; 3) Nagoya City Medical College, Nagoya, Japan; 4) Aichi Welfare Center for Persons with Developmental Disabilities, Kasugai, Japan; 5) Hokkaido Univ. Sch. Med., Sapporo, Japan.

Introduction Familial hemiplegic migraine (FHM; MIM#131500), episodic ataxia type 2 (EA2; MIM#108500) and spinocerebellar ataxia type 6 (SCA6; MIM#183086) are allelic disorders caused by mutations of the *CACNA1A* gene at 19p13. *CACNA1A* encodes a pore-forming Cav2.1 subunit of a P/Q-type voltage-dependent calcium channel. We reported here clinical and molecular genetic study of six Japanese families in which patients were clinically diagnosed as FHM or EA2. **Subjects** Patients from two FHM and four EA2 families, and 50 normal controls. **Methods** Genomic DNAs extracted from peripheral blood were amplified by PCR using primers designed for 47 exons of the *CACNA1A* gene, and the entire coding region including exon-intron boundaries was sequenced. Mutations were confirmed by DHPLC and/or PCR-RFLP. **Results** Two nucleotide substitutions (Thr666Met and Arg1057Cys) in two FHM families, and three nucleotide substitutions (Ala236Pro, Gly1105Ser and Gly1479Val) and one nonsense mutation (Arg1665stop) in four EA2 families were identified. **Discussion** We concluded that Thr666Met and Arg1665stop were pathogenic mutations. Arg1057Cys and Gly1105Ser were considered to be polymorphisms, because the polymorphisms did not cosegregate with affected family members, Therefore, the *CACNA1A* gene was not linked to the EA2 phenotypes in these families, suggesting that EA2 could be genetically heterogeneous, and some genes other than the *CACNA1A* gene might be involved in EA2. We have not decided yet whether Ala236Pro or Gly1479Val are pathogenic. Because FHM/EA2 has genetic heterogeneity and wide clinical spectrum in each family, comprehensive genetic analysis including functional study is mandatory to determine the pathological significance of the nucleotide substitutions. Our results should contribute to establishment of genotype and phenotype relationship in FHM/EA2.

Are the 5-hydroxytryptamine (5-HT) Receptor Genes HTR2B and HTR2C (Serotonin Receptor 2B and 2C) Modifier Genes for the Neurological Phenotype in Tuberous Sclerosis Complex? *C.H. Ward, H. Northrup, A.T. Williams, K.-S. Au.* Pediatrics, Univ of Tx at Hou, Houston, TX.

Tuberous sclerosis complex (TSC) is an autosomal dominant neurocutaneous disorder involving benign growths in the skin, brain, heart and kidneys of affected patients. The neurological phenotype of these patients is variable even within families and may be severe with early onset of seizures and significant mental retardation. We hypothesize that the action of modifier genes influences the phenotype of patients with mutations in the TSC1 and TSC2 genes. The 5-hydroxytryptamine (5-HT) receptors are a family of receptors for the neurotransmitter serotonin that act via stimulation of phospholipase C to produce a variety of central and peripheral effects. The HTR2B receptor is primarily involved in vasoconstriction, and possibly associated with pulmonary hypertension. HTR2C has been implicated in control of neuroendocrine function, body temperature and food intake. Polymorphic variants of the HTR2B and HTR2C have been tested for possible roles in a variety of psychiatric disorders, obesity, and neuronal hyper-excitability and seizure activity. The variant in HTR2B involves a change in amino acid 421 from valine to methionine (V421M) and the one in HTR2C involves a change in amino acid 23 from cysteine to serine (C23S). The rare polymorphic variants create unique restriction enzyme sites for TspR1 (V421M) in HTR2B and Hpy118I (C23S) in HTR2C for easy genotyping. To investigate both polymorphisms for possible modifier gene effects in TSC patients, we decided to genotype DNA from 490 phenotypically characterized TSC patients who had previously been tested by SSCP and/or direct sequencing for all exons of the TSC1 and TSC2 genes. Subtle mutations were identified in 77% (22% in TSC1 and 55% in TSC2) leaving 23% of the TSC-affected individuals with no mutation identified (NMI). After genotyping 237 individuals, it was discovered that only three individuals carried the V421M in HTR2B and we did not pursue this further. For HTR2C, 41 of 201 (20%) individuals tested to date have the 23Ser variant. Upon completion of genotyping, we will assess for genotype-phenotype correlation.

Molecular heterogeneity in segmental NF1. *L. Messiaen*^{1, 2}, *H. Brems*³, *O. Maertens*², *T. Callens*¹, *A. Helderman-van den Enden*⁴, *R. Sciot*⁵, *M. Flour*⁶, *B. Korff*¹, *E. Legius*³. 1) Dept Genetics, Univ Alabama Birmingham, AL; 2) Dept Medical Genetics, Univ Hosp Gent, Belgium; 3) Dept Human Genetics, Univ Hosp Leuven, Belgium; 4) LUMC, Leiden, The Netherlands; 5) Dept Pathology and; 6) Dept Dermatology, Univ Hosp St Raphael Leuven, Belgium.

We studied 3 patients who developed in adulthood multiple histology-proven cutaneous neurofibromas as the only NF1-related signs. We found 3 different mechanisms underlying their disorder. Somatic mosaicism for a NF1 total gene deletion was found in lymphocytes and neurofibroma-derived Schwann cells (SC) from the 1st patient. Selective culture of SC from 4 neurofibromas w/wo forskolin allowed identification of the 2nd hit in all tumors. In the 2nd patient, who presented with 2 discrete patches of cutaneous neurofibromas, a conserved missense mutation S139P was found in lymphocytes and fibroblasts. As this patient did not develop any NF1 related signs before his thirties, S139P may be a hypomorphic allele. In each of 6 neurofibromas studied, NF1^{+/+} SC carrying the S139P missense mutation only as well as NF1^{+/-} SC with a 4-bp deletion (6789-6792delTTAC) in addition to the S139P mutation were present. Fibroblasts from the neurofibromas only harbored the S139P mutation, indicating that 6789-6792delTTAC arose during development in a neural crest precursor cell. Furthermore, in all 6 neurofibromas studied, a different 2nd hit was found in the NF1^{-/-} SC cultures besides S139P and 6789-6792delTTAC. In the 3rd patient no NF1 mutation was found in the lymphocytes after comprehensive mutation analysis. However, a different 1st hit was found in the NF1^{+/-} SC cultures of each neurofibroma studied, indicating the presence of a mutator phenotype. A 2nd hit was identified in the NF1^{-/-} SC cultures of 2 out of 3 neurofibromas. None of these NF1 mutations was identified in blood lymphocytes. No microsatellite instability was observed in the neurofibromas. Further work is needed to understand the pathogenesis of this new condition. Although segmental NF1 is generally presumed to be a manifestation of somatic mosaicism for a NF1 mutation, the current study shows that the disorder is more complex and exhibits molecular heterogeneity.

Patients with Rothmund-Thomson syndrome and juvenile cataracts (Type I RTS) lack mutations in the *RECQL4* gene. L.L. Wang, R.A. Lewis, M.L. Levy, R. Davis, B. Chong, M. Hegde, S.E. Plon. Baylor College of Medicine, Houston, TX.

Rothmund-Thomson Syndrome (RTS) is an autosomal recessive disorder with a heterogeneous clinical profile characterized by skin rash (poikiloderma), small stature, sparse hair, gastrointestinal disturbance, skeletal abnormalities, and a significant risk for developing osteosarcoma. The original description of this disorder in 1868 by Auguste Rothmund, a German ophthalmologist, was notable for rapidly progressive bilateral juvenile cataracts in his patients. A recent study of a cohort of RTS subjects showed that two-thirds of subjects carried deleterious mutations in the *RECQL4* gene, which encodes a RECQ DNA helicase. Subjects carrying constitutional mutations in *RECQL4* were at a significant risk of developing osteosarcoma compared to subjects lacking *RECQL4* mutations. The previously studied cohort of RTS subjects had a low prevalence of cataracts (6 percent), and none developed the bilateral cataracts in childhood as described by Rothmund. We have subsequently identified four subjects with diagnostic features of RTS including bilateral cataracts diagnosed before the age of 6 years similar to Rothmunds patients. Three of the subjects were adults from the Mennonite community (two sisters ages 44 and 46 years and an unrelated 21 year old woman). The fourth subject was a 2 year old Caucasian child who also had small stature. All four subjects had the characteristic poikilodermatous rash, sparse or absent scalp hair, eyebrows and eyelashes, but none has developed cancer. DNA samples from the four subjects were evaluated by PCR and sequencing of the *RECQL4* gene, and no deleterious *RECQL4* mutations were identified. The Mennonite sibling pair was found to be discordant for multiple intragenic *RECQL4* single nucleotide polymorphisms, providing further evidence for genetic heterogeneity in this disorder. These data suggest that RTS subjects with bilateral juvenile cataracts have the Rothmund (Type I) form of RTS, and that they are likely to carry mutations in a gene other than *RECQL4*. Further studies using homozygosity mapping of the Mennonite patients are aimed at identifying the gene responsible for this Type I form of RTS associated with juvenile cataracts.

Genetic Basis of Familial Hypercholesterolemia Among Filipinos. *E.C. Cutiongco*¹, *E.R. Punzalan*², *R. Sy*², *R. Santos*², *E. Fadrigulan*², *S. Gosengfiao*², *P.M. George*³, *A. Laurie*³. 1) Institute of Human Genetics, National Institutes of Health, University of the Philippines Manila; 2) Department of Internal Medicine, University of the Philippines College of Medicine, Manila, Philippines; 3) Canterbury Health Laboratories, Christchurch, New Zealand.

Almost all heart disease results from susceptibility genes, defective single genes or genes interacting with various environmental factors. Discovery of these genes has led to a better understanding of the various types of heart disease prior to its onset, and more importantly, to development of strategies for its intervention. Familial hypercholesterolemia (FH) ranks as one of the most common genetic disorders affecting about 1 in 500 persons. It is transmitted as an autosomal dominant disorder involving the low-density lipoprotein (LDL) receptor gene. It is characterized phenotypically by extremely elevated levels of plasma LDL-cholesterol, tendon xanthomas, arcus cornealis and premature onset of atherosclerosis. To date, approximately 700 different mutations have been described in the LDL-receptor gene. These mutations lead to impaired function of the receptor by preventing proper cellular binding and uptake of LDL-cholesterol. Most mutations occur rarely and often only in single families although there are mutations described as prevalent in certain ethnic groups. Most heterogenous populations, however, carry a wide variety of mutations. Screening of exons 1-7 of the LDL receptor gene using DHPLC and subsequent DNA sequencing were done for the 60 Filipino subjects included in the study. We report the presence of mutations (D69N, H562Y, C308Y) previously documented in either Chinese or Malaysians. Novel mutations (intron 2 190+4A>T 5splice donor; exon 10b A480E; intron 8 1187-10G>A 3 splice acceptor) were also detected. This is the first study showing the heterogenetic basis of FH among Filipinos.

Normal and mutated fibrillin-1 alleles as modifiers of phenotypic severity in the Marfan syndrome. *M. Godfrey*^{1,2}, *J. De Backer*¹, *P. Van Acker*¹, *P. Coucke*¹, *A. De Paepe*¹. 1) Dept Medical Genetics, Ghent University Hospital, Ghent, Belgium; 2) Dept Pediatrics, Univ Nebraska Medical Center, Omaha, NE.

Background: The Marfan syndrome (MFS) is caused by mutations in the gene encoding fibrillin-1 gene (FBN1). Despite many hundreds of known FBN1 mutations no clear genotype/phenotype correlation has been identified. The high degree of inter- and intra-familial variability is likely due to a combination of genetic and environmental factors. It has been suggested that the expression of the normal FBN1 allele in affected individuals can influence the phenotypic severity of MFS. To test this hypothesis we studied the expression of the normal and mutant alleles in a large MFS family with high clinical variability.

Methods: Quantitative analysis of RNA expression in 10 affected members of the same family carrying a splice site mutation (IVS 8 -1 G>C) was performed on an ABI 3100 prism. The clinical severity in each individual was estimated using a grading system in which the phenotypic severity in each organ system was scored.

Results: Analysis showed the presence of 1 normal and 2 abnormal fragments. Sequencing of the abnormal fragments demonstrated that the splice site mutation creates both exon skipping (exon 9) and alternative splicing (in-frame deletion of 12 basepairs: c989-1000delATGTTCCGCCAG; p331-334del). The ratios of both normal and alternatively spliced fragments to the exon skipped fragment shows a possible relationship between their relative expression and clinical severity. The higher the expression of the normal and alternatively spliced fragments, the milder the phenotype. The higher the expression of the exon skipped fragment, the more severe the phenotype.

Conclusions: There appears to be a modifying effect on the severity of the phenotype by both the normal and mutant alleles. Patients with milder phenotypes appear to have higher expression levels of both the normal and alternatively spliced fragments compared to the exon skipped fragment. A more thorough examination for alternative spliced fragments should be considered in cases with mis-splicing mutations.

Study of the modifying role of androgens and androgen receptor in cardiac hypertrophy. *B. Gopinath, R.J. Trent, B. Yu.* Molecular and Clinical Genetic, Royal Prince Alfred Hospital, Sydney, NSW, Australia.

Cardiac hypertrophy is associated with increased cardiovascular morbidity and mortality, and it has been suggested that testosterone may be important in modulating cardiac mass. The steroid 5- reductase type 2 gene (*SRD5A2*) is a potential modifier, as it is the major enzyme that converts testosterone to dihydrotestosterone. The V89L change in *SRD5A2* has been found to be associated with lower levels of testosterone (Schatzl et al. 2002). Additionally, androgen receptors (AR) are present in myocardial tissue, which may permit androgens to modify the hypertrophic process via direct receptor-specific actions. In this study, we determined the distribution of the *SRD5A2* SNP (V89L) in 158 probands with familial hypertrophic cardiomyopathy (FHC) and 298 controls and characterised AR expression in a rat model with cardiac hypertrophy. This model was subsequently used to study the effects of testosterone stimulation on AR and one of its target genes, the β -myosin heavy chain gene. We found the V89L change in *SRD5A2* to be twice as frequent in FHC cases (10.8%) compared to controls (5.0%), but this was not significant perhaps due to small numbers tested. AR mRNA levels were 11-fold lower in neonates with cardiac hypertrophy compared with controls at postnatal day 1 (P 0.01). Testosterone treatment resulted in a slight increase in β -myosin heavy chain expression in both control and cardiac hypertrophic neonates, but this was not significant. In summary, the V89L change was higher in FHC cases although not conclusive. Further studies of *SRD5A2* haplotypes may confirm its role in cardiac hypertrophy. In our rat model, a unique decrease in AR expression was found in neonates with cardiac hypertrophy.

Lymphocytic Vasculitis in the Vaso Vasorum in Thoracic Aortic Aneurysms in patient with marfan syndrome, familial and sporadic disease: restricted usage of T-cell receptor BV genes suggests an autoimmune vasculitis.

D.C. Guo¹, R. He¹, W. Sun⁴, A.L. Estrera², H.J. Safi², T.T. Huynh², J. Lin¹, L.M. Buja³, J. Zhang⁴, Y.J. Geng¹, D.M. Milewicz¹. 1) Dept Internal Medicine, Univ Texas/Houston Med Sch, Houston, TX; 2) Dept Cardiovascular Surgery, Univ Texas/Houston Med Sch, Houston, TX; 3) Dept Cardiovascular Pathology, Univ Texas/Houston Med Sch, Houston, TX; 4) Dept Neurology, Baylor College of Medicine, Houston, TX.

The histopathologic abnormality underlying ascending thoracic aortic aneurysm (TAA) was thought to be due to noninflammatory loss of smooth muscle cells and elastic fibers. The mouse model of Marfan syndrome (MFS) suggested that inflammation was a component of the aortic disease. We hypothesized that an autoimmune mechanism may be involved in the recruiting T lymphocytes and contributing to the pathogenesis of TAA. Aortic specimens were obtained from patients undergoing surgical repair of TAA with MFS (n = 9), FTAA (n = 7), sporadic TAA (n = 15), along from aortas from age matched controls (n = 6). Immunohistochemistry indicated that CD3+ cells significantly increased in the aortic media of TAA patients compared to those of controls (p<0.001) and in aortic media of patients with MFS and FTAA compared to those of sporadic TAA (p<0.05). In addition, CD68+ cells were also increased in the aortic media in the patients compared with controls. The number of infiltrating T lymphocytes and macrophages in the aortic media of TAA aortas were inversely correlated to the age of patients at the time of the repair (r = -0.83, p value <0.001; r = -0.70, p value <0.01, respectively). The gene expression profiles of T cell receptor chain variable region (TCRBV) was investigated using the real-time quantitative RT-PCR. The results indicated that there was a highly restricted use of BV22 and/or BV25 in the T cells in the aneurysm aortas, while control aortas and peripheral blood had diverse distribution of BV usage. The restricted usage of TCR BV gene by infiltrating T cells in the aortas with ascending aortic aneurysms suggest that autoimmune mechanism may be involved in the pathogenesis of TAA from patients with MFS, FTAA, and sporadic TAA.

Establishing the disease gene for TAAD1. *P. Gupta, D.G. Guo, D.M. Milewicz.* Dept Internal Medicine, Univ Texas Houston Med Sch, Houston, TX.

Ascending thoracic aortic aneurysms leading to aortic dissections (TAAD) can be inherited in an autosomal dominant inheritance in the absence of an associated syndrome. We have mapped a major locus for this disorder to 5q13-14, TAAD1, encompassing nearly 6cM. This is a major locus for TAAD based on studies using American and Finnish families, and this locus is responsible for up to 40% of all familial TAADs. The aim of this study is to identify the disease gene at the TAAD1 locus. Methodology used was direct sequencing in the forward and reverse direction of exons, as well as the splicing sites and intronic region adjacent to the exons. Using the public databases, we were able to identify 26 currently known genes according to RefSeq. Gene prediction programs like Twinscan, Genscan, MGC, etc identified a larger number of coding regions. These genes and coding regions were prioritized based on the known or putative function of the gene. The first genes to be sequenced were those involved in the extracellular matrix (ECM) because Marfan syndrome, a syndrome with TAAD, is due to mutations in fibrillin 1, an ECM protein. We sequenced versican, thrombospondin 4, SCAMP1, EDIL3, and cmya5, all of which are known ECM proteins or interact with the EDM, but known disease causing mutations were identified. Subsequently genes that are implicated in the intracellular protein trafficking were sequenced. These genes included HOMER1, TPO1, APG10L, and JMY. No disease causing alterations were identified in this set of genes. The next group of genes targeted was transcription factors, and LHFPL2, PAPD4, ZFYVE16, NYD-TSP1, and ZCCHC9 were sequenced. Finally, we investigated membrane bound proteins including RASGRF2, ZFYVE16, MGC23909, and UNQ9217, however, no disease causing mutations were identified. We are also identifying splice variants of all of these genes and sequencing the alternative exons. Other genes and coding regions have been selected based on known vascular expression patterns. We sequenced all of the exons in each known and predicted gene in the forward and reverse direction. While we have not identified the gene that is responsible for TAAD, we have found a number of novel SNPs not in the current databases.

No live individual homozygous for a novel endoglin mutation in a consanguinous Arab family with hereditary hemorrhagic telangiectasia. *A. Karabegovic*^{1, 2}, *M. Shinawi*³, *U. Cymerman*², *M. Letarte*^{1, 2}. 1) Immunology, University of Toronto, Toronto, Ontario, Canada; 2) Cancer Research Program, The Hospital for Sick Children, Toronto, Ontario, Canada; 3) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas.

Hereditary Hemorrhagic Telangiectasia (HHT) is an autosomal dominant vascular dysplasia characterized by dilated vessels and arteriovenous malformations (AVMs). It is associated with mutations in the Endoglin (ENG; HHT1) or Activin-like receptor kinase-1 (ALK1; HHT2) genes. Mice expressing a single allele of either of these genes can develop signs of disease whereas embryos lacking both alleles die at mid-gestation of cardiovascular defects. We have performed mutation analysis in a large Arab family with a known history of HHT and consanguinity. A novel ENG exon 7 missense mutation (c.932T>G) was found in the proband, who suffered from daily epistaxis and pulmonary and cerebral AVMs. The mutation was also present as a single allele in ten other individuals (age 5-56) with clinical signs of disease and an infant without symptoms. No mutation was found in 21 unaffected family members, strengthening the genotype/phenotype correlation. Marriage between two affected first cousins yielded five children, four affected and one normal. Two miscarriages occurred at 6-8 weeks of gestation. We propose that these fetuses were homozygous for the mutant allele, and died in utero at a time when endoglin is essential for cardiovascular development.

Screening for mutations in the gene encoding the regulatory protein FKBP12.6 in Finnish patients with catecholaminergic polymorphic ventricular tachycardia. *P.J. Laitinen^{1,2}, H. Swan³, K. Kontula^{1,2}*. 1) Research Program in Molecular Medicine, University Helsinki, Helsinki, Finland; 2) Department of Medicine, University of Helsinki, Helsinki, Finland; 3) Department of Cardiology, University of Helsinki, Helsinki, Finland.

Catecholaminergic polymorphic ventricular tachycardia (CPVT) is a severe inherited cardiac arrhythmic disorder. CPVT is highly penetrant and manifests with exercise-induced episodes of polymorphic ventricular tachycardias and sudden deaths. The onset of the symptoms is in adolescence or young adulthood and no structural abnormalities of cardiac muscle can be observed. If left untreated, CPVT results in high mortality. We previously mapped the gene underlying autosomal dominant CPVT to chromosome 1q42-43 and consequently identified mutations in the gene coding for cardiac calcium release channel, the ryanodine receptor (RYR2). Soon thereafter, the autosomal recessive form of the disease was shown to result from mutations of cardiac calsequestrin gene (CASQ2), which encodes an intrasarcoplasmic calcium storage protein. Even though mutations in RYR2 and CASQ2 account for a significant portion of familial CPVT, many families affected with CPVT do not harbor a mutation in either of these genes. FKBP12.6 (encoded by the FKBP1B gene) is a regulatory protein of RYR2 channel. We considered the FKBP1B gene a particularly intriguing candidate as defective RYR2:FKBP12.6 interaction has recently been suggested to occur in heart failure and CPVT. Therefore we aimed at investigating whether genetic alterations of the FKBP1B gene contribute to the molecular basis of CPVT in Finnish patients. Thirty index patients affected with CPVT were included in this study. We directly sequenced the complete coding region and exon flanking sequences of the FKBP1B gene. Several intronic SNPs, but no obvious disease-causing mutations were detected. We are currently determining the frequencies of these SNPs in a control cohort. In conclusion, the gene encoding the regulatory protein FKBP12.6 appears to play a minor, if any, role in the molecular pathogenesis of the Finnish CPVT patients included in this study.

Genetic Modifiers of Alagille Syndrome. *R. McDaniel¹, J.J.D. Morrissette¹, B.M. Kamath¹, M. Devoto², N.B. Spinner¹.* 1) Div. Human Genetics, Children's Hospital of Phila., Philadelphia, PA; 2) The Nemours Childrens Clinic, Wilmington, Delaware.

Alagille syndrome (AGS) is a complex dominant, multi-system disorder involving the liver, heart, and other systems. Penetrance of JAG1 mutations is close to 100%, but expressivity is highly variable both between and within families. Mutations in Jagged1 (JAG1), a ligand in the Notch signaling pathway are found in over 90% of patients. The Notch signaling pathway is critical for determination of cell fate decisions during development. Liver disease in AGS is a consequence of intrahepatic bile duct paucity, and ranges from minimal liver test abnormalities to end stage liver disease requiring transplantation. Possible contributors to variability include genetics factors (e.g. variation in the normal JAG1 allele or in other genes downstream of JAG1) and environmental factors. To study the contribution of allelic variation of JAG1 and other members of the Notch signaling pathway, we identified 13 families with multiple affected siblings. All had inherited a mutant JAG1 allele from an affected parent. We stratified family members according to disease severity and genotyped them to determine which JAG1 allele they inherited from their unaffected parent. To date, stratification and genotyping are complete for 7 JAG1 polymorphic markers in 7 families. Six of 7 sib pairs were discordant for both liver phenotype (one mild and one severe) and JAG1 genotype (i.e. they inherited different alleles from their unaffected parent). In the 7th sib pair, the male sibs had a maternally inherited JAG1 mutation, but they inherited different JAG1 alleles from their unaffected father. Both siblings had moderate to severe liver disease, although only one sibling required a transplant. These studies provide preliminary support for the hypothesis that polymorphisms on the non-disease JAG1 allele influence severity of liver disease, although the numbers are small and analysis is continuing. Similar analysis is being carried out for alleles of other potential modifier genes (e.g. Notch1 and Notch2 receptors).

Investigation on mutations of the MYH7 gene in Iranian hypertrophy cardiomyopathy (HCM) patients. *M. Montazeri¹, M. Ghani Kakhki^{1,3}, G. Estahbanati², DD. Farhud³, F. Nouhi², M. Peyghambari², N. Givtaj², M. Houshmand¹.* 1) Medical Genetic Department, National Institute for Genetic Engineering and Biotechnology, Tehran, Iran P.O.Box:14155-6343; 2) Tehran heart Hospital (Shaheed Rajaei); 3) Tehran University of medical Sciences, School of Public Health.

Hypertrophy cardiomyopathy (HCM) is a genetic disorder typically inherited in an autosomal dominant fashion with variable penetrance and variable expressivity. The disorder has a variable presentation and carries a high incidence of sudden death. The disorder has been estimated to occur in 0.05-0.2% of the population. While still in the early stage of research development, genetic testing can be used to identify a symptomatic family member with the same mutation as the proband (i.e. index case). HCM may occur at any age from newborn to elderly. In this study our patients have been selected according to their history (sudden cardiac death, physical signs, electrocardiography, cardiac catheterization and in some cases electro physiology. Our investigation is focused on mutation detection in the bMHC gene in exons that commonly have mutations. PCR is carried out using 13F and 15R primers and 19F and 21R primers to amplify 847bp and 799bp fragments, respectively. These amplimers were sent for sequencing. Other exons which have more common mutations such as exons 13, 14, 15, 19, 20 and 21 were sequenced. If there is a high-risk mutation in the patient, s family they would be referred to cardiologists for implanting ICD or drug therapy. In this study 52 HCM affected patients have been evaluated for mutations in exons 13-14-15-19-20-21 of the MYH7 gene with the aid of PCR and sequencing. Results showed that 14 of 52 patients had mutations after study their sequencing chromatogram. Four of these 14 patients had mutation in exonic regions and the other patients in the intronic region. Founded exonic mutations in patients were G10I95A in exon 13, A1041C in exon14, C13430T, C13978A in exon 19. Further study of patients families is needed to reveal the role of these mutations. It seems that mutation diagnosis in the MYH7 gene can give a good prognosis to prevent sudden death of affected ones.

Cardiac specific missense mutations in Jagged1: dosage or differential signaling? *J.J.D. Morrissette¹, D.A. Ross², E. Goldmuntz³, N.B. Spinner¹*. 1) Div Human Genetics, Children's Hosp Phila; 2) Dept Genetics, U. Penn School of Medicine; 3) Div. of Cardiology, Dept of Pediatrics, Children's Hosp Philadelphia, Phila, PA 19104.

Haploinsufficiency for the Notch Signaling Pathway ligand Jagged1 (JAG1) causes Alagille syndrome (AGS), a variably expressed, pleiotropic, dominant disorder. Liver and cardiac disease accounts for most of the morbidity in this disorder. JAG1 mutations have also been implicated in the etiology of isolated cardiac disease leading us to carry out a mutation screen of 126 patients with tetralogy of Fallot and 50 patients with pulmonic stenosis in which we identified 3 unique JAG1 missense mutations. We present molecular analysis of these mutations. The mutations (P810L, C664S, R937Q) were analyzed for their subcellular localization and ability to signal the Notch receptor. P810L did not reach the cell surface, and was inactive, similar to AGS associated missense mutations. However, C664S and R937Q retained partial activity, and some protein reached the cell surface. This was similar to previous findings on the mutation G274D, associated with dominantly inherited, isolated cardiac disease. To study downstream effects of decreased JAG-Notch signaling, quantitative RT-PCR experiments were carried out to assay levels of HES1 and HRT1, two genes activated by functional JAG1. There was differential activation of these genes, depending upon the mutant. Both HES1 and HRT1 were expressed in cells containing the Notch receptor, after stimulation with the C664S. However, the R937Q mutant differed in that HES1 was activated, but activation of HRT1 was greatly reduced. Since the HRT genes are considered essential regulators in heart development, loss of activation may be important in the development of heart disease. We suggest that the developing heart is more sensitive than other organ systems to decreases in JAG1 dosage. This may be due to different thresholds for transcriptional activation in heart sensitive tissues or the missense mutations in individuals with isolated cardiac disease may differentially signal to the various Notch receptors, leading to a cardiac specific phenotype.

Identification and characterization of a novel mutation in SCN5A and a common variant carrying risk for arrhythmia in Han Chinese population. *D. Niu*^{1,2}, *H. Hwang*³, *B. Hwang*¹, *S. Lau*¹, *C. Liao*¹, *J. Chen*³, *R. Shieh*³, *J. Wu*³, *Y. Chen*³. 1) Dept Pediatrics, Taipei Veteran General Hospital, Taipei; 2) Inst Clinical Medicine, National Yang-Ming University, Taipei, Taiwan; 3) Inst Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

A four-generation family with five instances of sudden cardiac death was identified. One of the surviving family members received pacemaker insertion because of severe bradycardia. Other affected family members have cardiac conduction abnormalities such as prolonged PR interval and/or prolonged QRS duration. In all family members who underwent clinical evaluation, there were no signs of Brugada syndrome on resting ECGs, and structural abnormalities were excluded by conventional echocardiography. Using candidate gene approach, direct sequencing of SCN5As coding region (28 exons) revealed that two nucleotide changes present in this family. The first one, a G-to-A transition, leads to a non-synonymous amino acid change of R1192Q. The other, also a G-to-A transition, leads to a nonsense mutation (W1420X) and results in a shortened polypeptide. While the former was previously reported to be associated with Brugada syndrome and acquired long QT, the latter was a novel mutation and found to be associated with all affected members of this family. These two mutations were screened in ninety-four randomly selected Han-Chinese subjects. The nonsense mutation was not detected in any of the control subjects; however, the R1192Q mutation was present in 11% of the subjects with allele frequency of 0.06. Of those nine R1192Q carriers available for further cardiac studies, two had electrocardiographic abnormalities. One had frequent ventricular premature complexes and the other had prolonged QT interval. We concluded that W1420X mutation in the SCN5A is the cause of sudden death/cardiac conduction defects in this family. However, R1192Q, a Brugada/long QT mutation reported in other population, is a polymorphism in Han Chinese and individuals carrying the mutation may have an increased risk for arrhythmia.

Characterization of a mouse model for Hutchinson-Gilford Progeria Syndrome. R. Varga¹, M.R. Erdos¹, R. Virmani², F.D. Kolodgie², H. Avallone², W. Hagen³, E.G. Nabel⁴, F.S. Collins¹, M. Eriksson⁵. 1) NIH/NHGRI Genome Technology Branch, Bethesda, MD; 2) Armed Forces Institute of Pathology, Department of Cardiovascular Pathology, Washington, DC; 3) University of California at Irvine, Department of Medicine, Irvine, CA; 4) NIH/NHLBI Cardiovascular Branch, Bethesda, MD; 5) Karolinska Institutet, Department of Medical Nutrition, Huddinge, Sweden.

Hutchinson-Gilford Progeria Syndrome (HGPS) is a rare disorder characterized by symptoms of accelerated aging such as alopecia, growth retardation, sclerodermal skin changes and loss of subcutaneous fat. The average age of death is 12 years, commonly due to myocardial infarction or stroke. Cardiovascular pathology includes vascular smooth muscle cell depletion and myocardial hypertrophy and fibrosis. We recently discovered a *de novo* mutation, 1824C>T (G608G), in the lamin A gene (LMNA) in 90% of classical HGPS cases that creates a novel splice donor site in exon 11 (Eriksson et al., *Nature*, 423: 293-298, 2003).

In order to characterize this mutation's effects *in vivo*, mouse models have been created using two different strategies. In one approach, a 164 kb human BAC containing the LMNA gene has been recombineered in a bacterial host to incorporate the 1824C>T (G608G) mutation. In a second approach, a LMNA minigene is under the control of a tetracycline-regulated promoter that limits expression to specific tissues.

RT-PCR and western blotting from tissues of G608G BAC transgenic lines have revealed expression of the mutant LMNA RNA and protein gene products. Two founders died early without offspring and display pathologic changes in the heart and blood vessels that may indicate a progeric phenotype due to the mutant LMNA transgene. Histologic analysis revealed cardiac hypertrophy and fibrosis as well as arterial medial thickening in the heart and kidney.

These data provide interesting evidence of an analogous phenotype in these mice as compared with published data on human HGPS patients and suggest that these mice may provide a good model for studying accelerated atherosclerosis.

A locus for autosomal dominant isolated noncompaction of the ventricular myocardium maps to chromosome 11.

M.V. Zaragoza¹, M. Johnson², A. Lynn², D. Newkirk¹, L. Christ², L.B. Smoot³, D.R. Sperling⁴, M.E. Bocian¹, S. Schwartz², N.H. Robin⁵, F. Brozovich⁶, T. Huang¹. 1) Dept of Pediatrics, Div of Genetics, UC Irvine, Irvine, CA; 2) Dept of Genetics, CWRU, Cleveland, OH; 3) Children's Hosp, Dept of Cardiology, Boston, MA; 4) OC Pediatric Cardiology, Orange, CA; 5) Dept of Genetics, UAB, Birmingham, AL; 6) Dept of Medicine, Div of Cardiology, Univ Hosp, Cleveland, OH.

Isolated noncompaction of the ventricular myocardium (INVM) is a cardiomyopathy characterized by loose, trabeculated myocardium, thought to arise from a block in the process in which myofibrils compact during cardiogenesis. Clinical manifestations are variable; some affected individuals are asymptomatic whereas others may develop ventricular dysfunction or arrhythmias. INVM is genetically heterogeneous; mutations in *G4.5/TAZ* on Xq28, *DB* on 18q12 and *ZASP/LDB3* on 10q22-q23 have been found in a small proportion of patients. Recently, genetic linkage to 11p15 has been reported in a single family. Thus, the etiology for most cases is still unknown. This report describes clinical and molecular studies of two unrelated families with INVM: the first consists of affected twin girls who carry a balanced translocation involving chromosomes 10 and 11, and the second, a four-generation family with multiple affected members. To identify the disease-causing gene, we mapped the chromosomal breakpoint in the first family and conducted genetic linkage analysis in the second family. By FISH using BACs and long range PCR-derived probes, the breakpoints on chromosome 10 and 11 have been localized to approximately 30 kb and 10 kb regions, respectively. Linkage analysis using markers spanning the chromosomal regions demonstrate strong linkage (LOD 3) with chromosome 11. The interval size varies from 15 cM to 50 cM depending upon how individuals with milder phenotypes are classified; all possible intervals include the breakpoint region. Our results provide evidence for a common genetic etiology in the two families and suggest that an additional locus for INVM exists on chromosome 11. Determination of the genetic basis will enhance our understanding of INVM and cardiogenesis.

Aceruloplasminemia Causing Brain Iron Overload and Dementia. *D.G. Brooks¹, J. Dunaief, MD, PhD², J.F. Schenck, MD, PhD³, E.A. Zimmerman, MD⁴.* 1) Div Medical Genetics, Univ Pennsylvania, Philadelphia, PA; 2) Dept Ophthalmology, Univ Pennsylvania, Phila, PA; 3) General Electric Research, Schenectady, NY; 4) Neurology, Albany Medical College, Albany NY.

Loss of function mutations in the ceruloplasmin (Cp) gene cause the rare, adult-onset disease aceruloplasminemia (aCp). Deficiency of Cp, the major serum and astrocyte ferroxidase generating Fe³⁺ for binding to apotransferrin, there is impaired iron recycling and iron-deficiency anemia. Excess iron accumulates in the pancreas, retina and brain contributing to the hallmark clinical triad of diabetes plus degeneration of brain and retina. A 57 year old man was evaluated for aCp after presenting with diabetes, macular degeneration, dementia and iron-deficiency anemia in spite of marked liver iron overload. Serum Cp was below the limit of detection in the proband and at half normal levels, consistent with recessive inheritance, in 3 healthy first degree relatives: father, sister and daughter. MRI showed markedly decreased signal in brain, liver > pancreas consistent with heavy iron accumulation. Mean T2 values were more than three standard deviations below the means of age-matched controls in caudate, putamen and hippocampus (p<0.0001) and markedly reduced in other regions including white matter and thalamus. Fundoscopic evidence of drusen and hyperpigmentation in both maculas were consistent with sub-clinical macular degeneration. Mutation analysis of the Cp gene is ongoing; the proband carries a C282Y mutation at the HFE locus which might protect against iron-deficiency anemia and/or contribute to his iron overload. This case emphasizes that a treatable risk factor for disease, iron overload, underlies three common conditions: dementia, diabetes and macular degeneration. Chelation and antioxidant therapies are ongoing however available iron chelators do not offer optimal penetration of the blood brain barrier. By presenting with dementia, this case highlights the need for better drugs to rid the brain of excess iron and/or neutralize the effects of redox-active metals in the brain. (Study Supported by: Neurosciences Institute of Albany Medical Center and GE Global Research).

Long QT syndrome: Identification and characterization of compound heterozygous patients. *H. Fodstad¹, M. Vukicevic³, J-B. Rougier³, I. Gautschi³, H. Abriel³, L. Schild³, K. Kontula¹, H. Swan².* 1) Biomedicum Helsinki, University of Helsinki, Finland; 2) Department of Cardiology, University of Helsinki, Finland; 3) Institute of Pharmacology and Toxicology, University of Lausanne, Switzerland.

Long QT syndrome (LQTS) is an inherited arrhythmic disorder, characterized by a prolonged QT interval on the ECG, ventricular arrhythmias and risk of sudden death. To date mutations in six voltage-gated cardiac ion channels, or the adaptor protein ankyrin B, have been shown to cause LQTS. Phenotypic variability exists both within and between families carrying the same mutation. Comprehensive knowledge of the underlying mechanisms for this variability is missing. The aim of this study was to search for possible compound heterozygous LQTS patients among affected Finnish families, and to find out whether this status contributes to phenotypic variation. We have identified three common mutations: A185T and R190G in the SCN5A gene, and R176W in the HERG gene. These mutations were studied in an extended cohort of 563 suspected LQTS families. In altogether 127 (23%) of these families we had previously detected an apparent disease-causing mutation in one of the LQTS genes. In seven families we identified twelve subjects who, in combination with an established LQTS mutation, had either the HERG R176W or the SCN5A R190G mutation. In addition, SCN5A A185T was found in eight, SCN5A R190G in three and HERG R176W in eight families as the sole mutation. The SCN5A A185T and R190G mutations alone seem to associate with normal QTc intervals (<440 ms), suggesting that their clinical impact on LQTS phenotype is limited, or that they represent some alternative and yet unknown disease mechanism. In contrast, the HERG R176W mutation alone seems to prolong the QTc interval: the QTc intervals in 37 mutation carriers versus 50 non-carriers were 44039 ms vs. 41022 ms, respectively. Functional in vitro studies of the SCN5A R190G and HERG R176W mutations are presently ongoing. Additional studies are required to clarify the impact of the compound heterozygosity on the LQTS phenotype and clinical outcome.

A novel heterozygous cDNA change in the Mre11 gene affects the stability of the MRN complex, ATM-dependent events, and karyotyping. *K.M. Gamo, S.A. Nahas, H.H. Chun, L. Eng, N.P. Rao, R.A. Gatti.* Department of Pathology, The David Geffen School of Medicine at UCLA, Los Angeles, CA.

Following exposure to ionizing radiation (IR), the ATM protein and the Mre11/Rad50/Nbs1 (MRN) complex play crucial roles in the cellular response to DNA double strand breaks (DSBs). In addition to the role of Mre11 as a substrate of ATM, it has recently been suggested that the MRN complex is involved in recruiting ATM to the site of DNA damage, where phosphorylation of ATM protein targets occurs. Here, we present an individual with a novel heterozygous cDNA change in the Mre11 gene (469delGTAA). While this individual does not display any clinical symptoms associated with either ataxia-telangiectasia (A-T) or ataxia-telangiectasia like disorder (A-TLD), we have observed an abnormal cellular phenotype including reduced expression of nuclear ATM and Mre11, reduced ATM kinase activity, *in vitro* radiosensitivity, impaired S-phase arrest, reduced Mre11 and phospho-Nbs1 (S343) IR-induced foci (IRIF), and chromosomal instability (t7;14). Thus, we demonstrate that even a heterozygous change in Mre11 can lead to definitive cellular aberrations, such as *in vitro* radiosensitivity and translocations of chromosomes 7 and 14.

Aprataxin gene mutations in a cohort of patients presenting with infantile onset cerebellar ataxia. *C. Gellera¹, S. Caimi¹, D. Di Bella¹, B. Castellotti¹, T. Granata², I. Moroni², G. Uziel², C. Mariotti¹, S. Di Donato¹, F. Taroni¹.* 1) Dept. of Biochemistry and Genetics, Istituto Nazionale Neurologico Besta, Milano, Italy; 2) Dept. of Child Neurology, Istituto Nazionale Neurologico Besta, Milano, Italy.

Ataxia with oculomotor apraxia type 1 (AOA1) is an autosomal recessive disease characterized by early-onset and slowly progressive cerebellar ataxia, areflexia, and peripheral neuropathy. Ocular apraxia is most prominent in early stage of the disease, by contrast, hypoalbuminemia, hypercholesterolemia and cognitive impairment are present in adult stage. AOA1 is caused by mutation in the APTX gene (9p13.3) encoding a nuclear protein (aprataxin) involved in the mechanism of DNA repair. We screened 130 unrelated patients (96% of Italian origin) for mutations in the APTX gene, including 110 sporadic cases and 20 patients presenting an autosomal recessive pattern of inheritance. All patients had progressive cerebellar ataxia with onset before 25 yrs., and were negative for the Friedreich ataxia GAA expansion. Mutational screening was performed by DHPLC analysis of exons 5, 6 and 7, coding for two functional motif of the protein, where the APTX mutations have been identified so far. We identified APTX gene mutations in aprox. 6% of cases: 10 patients belonging to 8 unrelated families (7 from Italy and 1 from Pakistan). Six patients belonging to 4 families carried the most frequent nonsense mutation identified so far: the W279X in homozygous form; 2 unrelated patients carried two different previously described missense mutation in homozygous form: the W279R and P206L; while 2 other unrelated patients carried two newly identified nonsense mutations: the R247X in homozygous form in a patient from Pakistan and the R306X in heterozygous form in a compound heterozygote patients carrying the W279X on the other allele. We report the identification of two novel nonsense mutations, one is the first mutation identified in exon 7. Our study indicate that APTX mutations are a relative frequent cause of disease in sporadic and recessive early-onset progressive ataxia. (Partially supported by grant Ministero Salute RF2002/160 to FT).

Mechanism and timing of mitotic rearrangements in the subtelomeric D4Z4 repeat involved in FSHD. *R.J.L.F. Lemmers¹, P.G.M. van Overveld¹, L.A. Sandkuij¹, H. Vrieling², G.W. Padberg³, R.R. Frants¹, S.M. van der Maarel¹.* 1) Human & Clinical Genetics, LUMC Leiden, Leiden, Netherlands; 2) 2.Department of Toxicogenetics, LUMC, Leiden, The Netherlands; 3) Department of Neurology, UMC, Nijmegen, The Netherlands.

Facioscapulohumeral muscular dystrophy (FSHD1A, MIM 158900) is an autosomal dominant myopathy displaying large inter- and intrafamilial variability. FSHD is associated with contractions of the polymorphic D4Z4 repeat on chromosome 4qter. Almost half of the new FSHD mutations occur post-fertilization, resulting in somatic mosaicism for D4Z4. Detailed D4Z4 analysis of eleven mosaic FSHD individuals revealed a mosaic mixture of a contracted FSHD sized allele and the unchanged ancestral allele in eight cases, which is suggestive for a mitotic gene conversion without crossover. However, in three cases the D4Z4 rearrangement resulted in two different sized D4Z4 repeats, indicative for a gene conversion with crossover. In all cases DNA markers proximal and distal to D4Z4 showed no allelic exchanges, suggesting that all rearrangements were intrachromosomal. We propose that D4Z4 rearrangements occur via a synthesis-dependent strand annealing (SDSA) model that relatively frequently allows for crossovers, which was recently confirmed by the detection of two other complex mosaic cases among eight new identified mosaic FSHD cases. Furthermore, the distribution of different cell populations in mosaic FSHD patients suggests that mosaicism here results from D4Z4 rearrangements occurring during the first few zygotic cell divisions after fertilization. Current investigations aim at the identification of chromatin factors associated with D4Z4 repeat instability.

Molecular analysis of the *LITAF/SIMPLE* and *PRX* genes in patients with demyelinating Charcot-Marie-Tooth (CMT) disease. *M. Milani*¹, *M. Cesani*¹, *S. Baratta*¹, *C. Caccia*¹, *M.R. Balestrini*², *D. Riva*², *J. Sepcic*³, *D. Pareyson*¹, *F. Taroni*¹. 1) Div of Biochemistry & Genetics, Ist Naz Neurologico C. Besta, Milan, Italy; 2) Div of Child Neurology, Ist Naz Neurologico C. Besta, Milan, Italy; 3) Dept of Neurology, University of Rijeka, Rijeka, Croatia.

At least 20 genetic loci and 13 genes have been associated with the demyelinating form of CMT disease (CMT1) and related disorders (DSD, CH). Mutations in the *LITAF/SIMPLE* gene (CMT1C; 16p13.1-12.3) have been recently suggested to be a relatively common cause of CMT1 after the CMT1A duplication and *GJB1/Cx32* mutations (Saifi *et al.*, ASHG 2003). We have screened for *LITAF* mutations by DHPLC and sequence analysis a group of 200 CMT1 patients negative for the CMT1A duplication and *MPZ*, *PMP22*, and *GJB1/Cx32* mutations. We have identified 2 relatively frequent polymorphisms, 3 rare polymorphisms, and 3 novel mutations. These latter were identified in heterozygous form in 3 unrelated adult patients (1 familial dominant case and 2 apparently sporadic cases) affected with moderate-to-severe forms of CMT1. Our data indicate that mutations in the *LITAF/SIMPLE* gene are not a frequent cause of demyelinating CMT.

Unlike the dominant forms, only a limited number of loci have been linked to the rare recessive forms (AR-CMT). The 4.9-kb coding region of the periaxin gene (*PRX*, CMT4F) was scanned for mutations by DHPLC and sequence analysis in a group of 30 CMT1A/*MPZ*/*PMP22*/*GJB1*-negative patients with severe demyelinating neuropathy. Three novel frameshift and nonsense mutations were identified in two AR families with 2 affected siblings in each family. Interestingly, in one family, the two siblings exhibited different disease severity and were found to be compound heterozygotes for two mutations affecting the long (L-periaxin) but not the short (S-periaxin) variant of the protein, suggesting that S-periaxin expression may account for clinical variability in these patients. [Supported by grants from Ministero della Salute (RF 2002/160) and Fondazione Mariani to F.T.].

Walker Warburg syndrome phenotype in Egyptian proband with mutation in the Fukutin gene. A. Pai¹, H. Van Bokhoven², G. Ryan¹, D. Chitayat¹. 1) Mount Sinai Hospital, Prenatal Diagnosis and Medical Genetics, Toronto, Canada Toronto, ON,; 2) Department of Human Genetics University Medical Center, Nijmegen, The Netherlands.

Walker Warburg syndrome (WWS) is an autosomal recessive disorder characterized by congenital muscular dystrophy, ocular and complex brain abnormalities. WWS along with muscle-eye-brain disease (MEB) and Fukuyama-type congenital muscular dystrophy (FCMD) are believed to share a similar pathomechanism. Clinical resemblance between the WWS, MEB and FCMD phenotypes can make diagnosis difficult. However, FCMD and MEB show striking Founder effects in Japanese and Finnish populations respectively, while WWS has been seen in different populations. At the molecular level, different MEB causing mutations have been identified in Japanese, Korean as well as Caucasian patients who were given diagnoses of either MEB or WWS or FCMD. We describe an Egyptian couple who had previously lost a child diagnosed with WWS. The couple presented to us prenatally with a recurrence WWS. Subsequent investigations performed in the neonatal period confirmed a clinical diagnosis of WWS with classic features of hydrocephalus, microphthalmia, hypotonia and cloudy cornea. DNA analysis revealed a homozygous frameshift mutation in the Fukutin gene, which has been associated with FCMD patients from the Japanese population. Genotype-phenotype correlations in this case are of particular interest due to the location of the mutation. The above case emphasizes the complexity of this group of congenital muscular dystrophies and makes a case for examining additional WWS patients who may also have mutations in the Fukutin gene versus the POMT1 gene in which mutations in WWS patients have already been described along with detailed genotype-phenotype correlations.

Allelic heterogeneity of NF1 gene mutations and phenotypic variations in 9 Korean NF1 kindreds. *S.J Park, H.J. Kim.* Medical Genetics, Ajou Univ. School of Medicine, Suwon, kunggi-do, Korea.

Neurofibromatosis type 1 (NF1) is one of the most common inherited disorders and is characterized by highly variable expressivity. The NF-1 gene is located at 17q11.2, contains 60 exons spanning approximately 350kb of genomic DNA, and encodes a 12kb transcript. The gene product, neurofibromin, has an estimated molecular weight of 327kDa and is widely expressed in many tissue. The mutation rate in NF1 gene is one of the highest reported human disorders. As of June 2004, the Human Gene Mutation Database(HGMD, Cardiff) listed more than 547 different NF1 mutations. The majority of them lead to a truncated protein product. To understand the molecular basis of phenotypic characteristics of Korean NF1 pts., we studied delineation of clinical phenotype and pedigree analysis of 14 pts. in 9 Korean family and NF1 mutation screening of 9 unrelated pts. by means of PCR, RT-PCR, microsatellite analysis and direct cycle sequencing for mutations in the whole coding sequence and the splice sites of the NF1 gene. 7 different mutations were identified in 3 sporadic and 4 familial cases with 6 single base substitutions (one missense, four nonsense and one splicing region mutation) and 1 single base insertion including 5 previous reported mutations (2446C>T R816X in exon 16, 4537C>T R1513X in exon 27, 3827G>A R1276Q in exon22, IVS8+1G>A and 6792C>G Y2264X in exon 37) and 2 novel ones (IVS21+2-3insT in exon 21 and 532G>T E178X in exon 4). Three mutations were detected in the GAP related domain(GRD) which is known functional domain of the NF1 gene and spans exons 20-27 and four mutations in exon 4, 8, 16 and 37. 9 affected members in 4 familial cases showed wide range of phenotypic variation. We found that affected members of same family sharing an identical mutant NF1 allele have different disease phenotypes. Intrafamilial phenotypic variation suggest that unlinked modifying genes may be involved in the development of particular clinical features of NF1.

Detection of Six Novel *RASA1* Mutations in Patients with Capillary Malformation-Arteriovenous Malformation.
N. Revencu^{1, 2}, *L.M. Boon*^{1, 3}, *O. Enjolras*⁴, *M.R. Cordisco*⁵, *E. Baselga*⁶, *E. Lauritzen*⁷, *A. Troilius*⁷, *J.B. Mulliken*⁸, *M. Vikkula*¹. 1) Lab of Human Molecular Genetics, Christian de Duve Inst of Cellular Pathology & Université catholique de Louvain, Brussels, Belgium; 2) Center for Human Genetics, Clin Univ St-Luc, Université catholique de Louvain, Brussels, Belgium; 3) Centre for Vascular Anomalies, Clin Univ St-Luc, Université catholique de Louvain, Brussels, Belgium; 4) Consultation des Angiomes, Lariboisière Hospital, Paris, France; 5) Dept of Dermatology, Hospital Nacional de Pediatria, Buenos Aires, Argentina; 6) Dept of Dermatology, Hospital de la Santa Creu I, Sant Pau, Universitat Autònoma de Barcelona, Spain; 7) Dept of Dermatology, University Hospital of Malmö, Malmö, Sweden; 8) Vascular Anomalies Center, Div of Plastic Surgery, Children's Hospital, Harvard Medical School, Boston, MA 02115, USA.

Capillary Malformation-Arteriovenous Malformation (CM-AVM) (MIM 608354) is a recently identified phenotype characterized by atypical capillary malformations (CM) associated with either arteriovenous malformation, arteriovenous fistula, or Parkes Weber syndrome (Eerola *et al.*, 2003). In this phenotype, CM are usually multiple, small, round to oval in shape and pinkish red in color. Eerola *et al.*, have shown that the CM-AVM phenotype is caused by mutations in the *RASA1* gene and reported 6 different mutations. The aim of this study was to consolidate the involvement of the *RASA1* gene in CM-AVM patients. For this, we have screened novel families exhibiting CM-AVM phenotype for mutations in the 25 exons of *RASA1* by single-strand conformational polymorphism and heteroduplex analyses. The fragments with abnormal migration were analyzed by sequencing. We identified 6 novel mutations in the *RASA1* gene: one deletion, one insertion of 3 nucleotides, 2 missense and 2 nonsense mutations. The deletion caused reading-frame shift and is predicted to result in a truncated protein. This data confirms that inactivating mutations in the *RASA1* gene are responsible for the CM-AVM phenotype. (vikkula@bchm.ucl.ac.be) (<http://www.icp.ucl.ac.be/vikkula>).

Study of the Ferritin light Polypeptide (*FTL*) gene, including the cis-acting Iron-Responsive Element (IRE), in Portuguese patients with Huntington-like symptoms. A. Teixeira-Castro¹, M.C. Costa¹, M. Constante-Pereira², J. Sequeiros³, M.M. Santos², P. Maciel¹. 1) ICVS/Health Sciences School, University of Minho, Braga; 2) Dept. Medicin, CHUM, Univ. Montreal, Canada; 3) UnIGENE, IBMC, Univ. Porto, Portugal.

Iron metabolism dysregulation has been associated with several neurological disorders. An insertion (460-461 InsA) in the coding region of the ferritin light polypeptide (*FTL*) gene was reported in patients of English and French ancestry causing neuroferritinopathy. These patients presented extrapyramidal symptoms, choreoathetosis, dystonia, spasticity and rigidity similar to Huntington disease (HD) but without cognitive decline, as well as low ferritin plasma levels. The content of cytoplasmatic ferritin is regulated by the translation of ferritin H and L mRNAs in response to an intracellular pool of iron by interaction between RNA binding proteins to the iron responsive element (IRE) localized on the conserved 5' UTR of ferritin H and L mRNAs, that appears as a stem-loop secondary structure. Several mutations have been described on the IRE of *FTL* (18 different nucleotide substitutions, two small deletions, two gross deletions and a double point mutation), all of these causing Hereditary Hyperferritinemia-Cataract Syndrome (HHCS). In order to verify (i) if mutations in the *FTL* gene explained the phenotype in a significant proportion of patients with movement disorders and (ii) whether mutations in the IRE of this gene could also be associated to neurological dysfunction, we assessed a group of 86 Portuguese patients with clinical manifestations partially overlapping with HD, in whom the CAG expansion in the HD gene had been excluded - HD-like patients. In our series, 50% of the patients had typical HD symptoms, whereas the remaining presented either only a movement disorder (77%) or only psychiatric alterations (23%). We have found one novel missense mutation in the *FTL* gene (474GA, leading to the A95T substitution) in a patient with early onset bilateral pallidal involvement and in his mother. No mutations have been found in the *FTL* IRE of the 86 patients, excluding this as a major cause of HD-like phenotype.

Identification of the Genetic Defect Causing Bleeding Disorder, East Texas Type (OMIM:605913). *L.M. Vincent, D.M. Milewicz.* Division of Medical Genetics, Dept of Internal Medicine, University of Texas-Houston Medical School, Houston, TX.

A novel bleeding disorder exhibiting an autosomal dominant mode of inheritance has been identified in a large kindred from east Texas (Bleeding Disorder, East Texas Type, OMIM:605913). The disorder is clinically characterized by easy bruising, life-threatening bleeding with trauma or surgery, and menorrhagia in affected women. Laboratory studies demonstrated prolongation of the prothrombin time (PT) and/or activated partial thromboplastin time (aPTT) in affected individuals. Paradoxically, assays of all known coagulation factors were within normal levels. Using candidate gene linkage, we mapped the critical interval containing the defective gene to a 13.4 Mb region on 1q24-25. After recruiting more individuals, we have further prioritized the critical interval to 7.8 Mb. We are systematically identifying and screening candidate genes for the disease causing mutation. To date, eleven candidate genes, including antithrombin III and coagulation factor V, have been sequenced, and no disease causing alterations have been identified. In addition, a biochemical assay has been developed in order to monitor the defect protein in plasma samples taken from affected individuals. This assay is being used to test the stability and activity of the defect after subjecting the affected plasma to varying experimental conditions. For example, after subjecting affected patient plasma to aluminum hydroxide, we found that the assay yielded normal results. Thus, we discovered that the defect binds either directly to aluminum hydroxide or indirectly to a protein that is vitamin K-dependent. When all proteins that bind to aluminum hydroxide were electrophoresed under reducing conditions, a novel 250kDa band was observed in all affected patients, but absent from controls. This band was excised, and is currently being sequenced. Elucidation of the genetic defect causing Bleeding Disorder, East Texas Type will advance our understanding of coagulation, potentially revealing a novel protein involved in the coagulation cascade, and may provide insights for novel therapy to delay or prevent coagulation.

Mutation analysis of *DNAI1* in patients with Primary Ciliary Dyskinesia (PCD). M. Zariwala¹, M.P. Kennedy¹, M.W. Leigh¹, P.G. Noone¹, R.U. de Jongh², L.M. Morgan², J. Rutland², J. Horvath³, H. Omran³, U. Prada⁴, R. Chodhari⁵, E.M.K. Chung⁵, H.M. Mitchison⁵, M.R. Knowles¹. 1) UNC-Chapel Hill, NC; 2) Concord Hospital, Sydney; 3) the Universitäts-Kinderklinik, Freiburg; 4) University of Verona, Verona; 5) Royal Free and University College Medical School, London.

Primary ciliary dyskinesia (PCD) is characterized by oto-sino-pulmonary disease and half the patients have situs inversus. It is usually inherited as an autosomal recessive trait. It is caused by abnormalities in the structure and function of cilia of respiratory tract and flagella of sperm. Ultrastructure analysis shows defective outer and/or inner dynein arms in ~ 90% of the patients. The disease is genetically heterogeneous and mutations have been reported in *DNAH5* (n=8 families) [Olbrich et al., Nat. Genet. 30: 143, 2002] and *DNAI1* (n=6 families) [Pennarun et al., AJHG; 65: 1508, 1999; Guichard et al., AJHG; 68: 1030, 2001; Zariwala et al., AJRCMB; 25: 577, 2001]. Both of these genes encode outer dynein arm (ODA) proteins. Genetic heterogeneity makes it challenging to identify disease-causing mutations in PCD patients. We analysed 78 unrelated PCD patients with ODA defects for genetic mutations in *DNAI1*. Thirteen families were excluded from linkage to *DNAI1* by using 'exclusion mapping'. The remaining 65 families were sequenced for all 20 exons. We identified 10 unrelated patients who harbored mutations in *DNAI1*. Six patients had mutations on both alleles, whereas 4 patients had mutations on one allele. Testing for splice mutation by RT-PCR is underway in these 4 patients. Of these 16 mutated alleles, 5 were novel mutations. Thus far, 121 patients (published and current study) have been tested, and 17 (14%) unrelated patients are known to harbor mutations. Despite locus heterogeneity, 15 mutant alleles carried the 219+3insT mutation and 6 mutant alleles were in exon 17. Since the majority of *DNAI1* mutations detected thus far are 219+3insT and in exon 17, screening PCD patients for these mutations can be used to expedite the mutation detection process and will help in devising a clinical test panel. This abstract is funded by GCRC #00046, M01 RR00046-42, NIH HL04225, NIH/NHLBI HL071798-01A1 and Wellcome Trust (UK).

Clinical and molecular characterization of Sotos syndrome in Spanish patients. *J. Del Valle*¹, *M. Del Campo*¹, *I. Delicado*², *E. Gabau*⁵, *F. Ramos*⁴, *C. Mellado*³, *I. Lopez Pajares*², *M.C. Roche*², *R. Gracia*², *L.A. Perez Jurado*¹, *P. Lapunzina*². 1) Genetics Unit. Dept of Experimental Science, Universitat Pompeu Fabra, Barcelona, Spain; 2) Genetics, Pediatric Neurology and Endocrinology, University Hospital La Paz, Madrid, Spain; 3) Dept of Pediatrics. Universidad Catolica de Chile, Santiago, Chile; 4) Dept of Pediatrics. Universidad de Zaragoza, Spain; 5) Dept of Pediatrics, Hospital Parc Tauli, Sabadell, Spain.

Sotos syndrome is an overgrowth syndrome characterized by pre and postnatal overgrowth, advanced bone age, developmental delay and mental retardation of variable severity, macrocephaly and a characteristic facial gestalt with a prominent forehead, apparent hypertelorism, downslanting palpebral fissures, receding hair line and pointed chin. The major cause of Sotos syndrome, an autosomal dominant condition, is haploinsufficiency for the NSD1 gene (nuclear receptor binding SET-domain 1). Microdeletions encompassing the NSD1 gene, likely mediated by unequal homologous recombination between flanking segmental duplications, are common in Japanese patients with Sotos syndrome, whereas point mutations in NSD1 have been predominant in all European published series. In this study, we report on a series of 18 Spanish and 2 Chilean patients with a firm clinical diagnosis of Sotos syndrome and molecular confirmation of NSD1 mutation. In search of common deletions, we used FISH and microsatellite markers inside and flanking the gene. Only two patients showed deletions encompassing NSD1. Screening for point mutations was performed using dHPLC and SSCP, and/or direct sequencing. Point mutations or small rearrangements have been identified in 18 additional patients. Sixteen are located in exons (>50% in exon 5), all but one causing either early stop-codons or frameshift, and 2 affect splicing signals, all predicting truncated proteins. None of these mutations have been previously reported, confirming the absence of mutational hotspots in European studies. In conclusion, this study confirms the clinical specificity to predict mutations in NSD1, the infrequent occurrence of deletions in European Sotos patients, and the mutational heterogeneity of the disorder.

Partial and variable recapitulation of the human BBS phenotype in the *Bbs4* null mouse. *E.R. Eichers*¹, *R.A. Lewis*^{1, 2, 3, 4}, *N. Katsanis*⁶, *J.R. Lupski*^{1,3,5}. 1) Depts of Mol & Human Genetics; 2) Ophthalmology; 3) Pediatrics and; 4) Medicine, Baylor Col of Med, and; 5) Texas Children's Hospital, Houston, TX; 6) Inst of Genetic Medicine and Wilmer Eye Inst, Johns Hopkins Univ, Baltimore, MD.

Bardet-Biedl syndrome (BBS) is a rare oligogenic disorder exhibiting clinical heterogeneity and complex inheritance. Although the BBS phenotype is variable both between and within families, the syndrome is characterized by mental retardation, polydactyly, obesity, hypogenitalism, renal abnormalities, retinal dystrophy, and several secondary features. Eight genes mutated in BBS patients have been identified. To investigate the etiopathogenesis of BBS, we created a mouse null for one of the *Bbs* genes, *Bbs4*, to analyze the contribution of one gene to the pleiotropic BBS phenotype in mouse.

Evaluations of these null mice have shown phenotypes with incomplete penetrance and various levels of expressivity, with partial recapitulation of the human phenotype. Heterozygous N2 matings have yielded 359 pups, with significantly distorted ratios (0.27 wild-type : 0.57 heterozygous : 0.16 null), suggesting partial embryonic lethality. Two of the 3 homozygous males and 3 of 3 females tested are fertile. Unlike the obesity characteristic of affected humans, all *Bbs4* null mice are significantly runted compared to their littermates when the animals are young. Most null mice attain a weight similar to their littermates over time, but several remain underweight. Only 3 null animals are obese (N = 38 (N2F1 and N2F2), age \geq 7 weeks). No null mice have polydactyly. We also observed ocular abnormalities in 7 of our homozygous mice, but these changes are variable in age of onset. No renal disease has been noted by autopsy.

Our data indicate that absence of *Bbs4* alone is insufficient to recapitulate fully the BBS phenotype, suggesting that additional alleles are required for the expression of specific phenotypic features. This interpretation is consistent with the variability seen within and between BBS patients and families and further supports the complex inheritance patterns in this syndrome and the possible influence of genetic background.

Analysis of atypical polydactyly patients: Surprisingly high yield of *GLI3* mutations in patients with mild Pallister-Hall and Greig cephalopolydactyly syndrome features. *J.J. Johnston, L.G. Biesecker, Clinical Collaborators. GDRB, NHGRI, Bethesda, MD.*

Mutations in the *GLI3* zinc finger transcription factor on chromosome 7p14.1 cause the Pallister-Hall (PHS) and Greig cephalopolysyndactyly (GCPS) syndromes. Mutations in *GLI3* have also been described in three types of apparently isolated polydactyly, PAP-A, PAP-A/B, and PPD-IV. It is unclear whether the apparently isolated polydactyly disorders represent the mild end of the disease spectrum for PHS and GCPS or if they are distinct clinical entities. In order to understand the clinical variability resulting from mutations in *GLI3* we have studied a cohort of patients who have features of PHS and GCPS. These patients do not fulfill the clinical criteria for either disorder. The group consisted of six individuals without preaxial polydactyly who had postaxial polydactyly and craniofacial features consistent with GCPS, and 12 individuals with postaxial polydactyly and features consistent with PHS including hypothalamic hamartomas and bifid epiglotti. In addition we analyzed four individuals with hypothalamic hamartomas without polydactyly (two isolated hamartomas and two with oral frenulae), and three individuals thought to have non-syndromic polydactyly. We identified a total of nine mutations and one missense alteration. Three individuals with postaxial polydactyly and craniofacial features consistent with GCPS had mutations in *GLI3* (50%) and another had a missense alteration that segregated with the disease in the family (17%). Six individuals with postaxial polydactyly and features consistent with PHS had mutations in *GLI3* (50%). Although the mutation yield is lower than that found in individuals who fulfill the diagnostic criteria (75%) mutation analysis in this set of patients suggests that clinicians should have a high index of suspicion for *GLI3* mutations in such patients. None of our patients with hamartomas in the absence of polydactyly, or isolated polydactyly, had mutations in *GLI3*. Our results suggest that individuals with polydactyly in combination with other features of PHS or GCPS should be screened for mutations in *GLI3*.

PTPN11 mutations in patients with LEOPARD syndrome : French Multicentric Experience. *B. Keren¹, Y. Sznajder¹, S. Saba¹, A. Hadchouel¹, D. Bonneau², B. LeHeup³, D. Lacombe⁴, A. Toutain⁵, S. Marlin⁶, G. Mortier⁷, C. Baumann¹, H. Cave¹, A. Verloes¹.* 1) Genetic Depts, Hopital R Debré, Paris; 2) Angers University Hospital; 3) Nancy University Hospital; 4) Bordeaux University Hospital; 5) Tours University Hospital; 6) Armand Trousseau Hospital, Paris, France; 7) Ghent University Hospital, Belgium.

LEOPARD syndrome (LS) is an autosomal dominant disorder characterized by Lentigines and caf-au-lait spots, EKG anomalies, Ocular hypertelorism, Pulmonary stenosis, Abnormal genitalia, Retardation of growth and Deafness. Insofar, 3 distinct mutations of the PTPN11 gene have been reported in 15 patients with LS. Screening of 14 unrelated propositi with a clinical diagnosis of LS from the French Multicentric Noonan Study yielded four different nucleotidic changes in PTPN11. The two previously described recurrent mutations Y279C in exon 7, and T468M in exon 12 were identified respectively in 6 and 4 unrelated patients. Two new mutations were identified. A substitution Y279S was found in 1 child who developed acute myeloid leukemia. A missense variation Q510P was found in 2 unrelated patients. Among 8 parents whose parental DNA was available, 3 mothers and 1 father were carriers and clinically affected. No mutations were found in 1 atypical, familial case who further exhibited marfanoid habitus. Comparing T468M and Y279C phenotype showed a significant difference for EKG anomalies, and a trend for heart defect, growth retardation, and deafness. AML, a probably not so rare complication of Noonan syndrome, is reported here for the first time with LS.

No evidence of SARA2 gene mutation in our patients with Marinesco-Sjogrens syndrome (MSS). *J. Lee¹, B. Chodirker², A.E. Chudley², S.R. Sanders², C. Carriles², C. Powell², J.J. Mulvihill¹, S. Li¹.* 1) Dept Pediatrics, BSEB #224, OUHSC Genetics Lab, Oklahoma City, OK; 2) Section of Genetics and Metabolism, Department of Pediatrics and ChildHealth, Children's Hospital, University of Manitoba, Winnipeg, Manitoba, Canada.

MSS is an autosomal recessive disorder with full penetrance that causes cerebellar ataxia, cataract, short stature, mental subnormality, hypergonadotropic hypogonadism and myopathy. Recently, SARA2 has been considered as a candidate gene responsible for MSS. However, no mutation was found in another study of 4 families with multiple affected individuals with a classical diagnosis of MSS. Because of contradictory data, we investigated 2 unrelated patients with MSS. Total genomic DNA was isolated and direct DNA sequencing utilizing primers covering all 7 exons was performed. No disease-causative mutation was found in either patient. A silent mutation was identified in one of the patients. The findings suggest that the SARA2 gene mutation is not the cause of MSS in our two patients.

Evidence for a second molecular mechanism resulting in the predominantly ocular form of Stickler syndrome : Alternative missplicing of a COL2A1 pathogenic mutation. *A.J. Richards¹, S. Meredith², P.W.P. Bearcroft², A. Poulson², G. Crossland², D.M. Baguley², J.D. Scott², M.P. Snead².* 1) Dept Pathology, University of Cambridge, Cambridge, United Kingdom; 2) Addenbrooke's NHS Trust, Hills Road, Cambridge, United Kingdom.

Type 1 Stickler syndrome is caused by mutations in COL2A1 the gene for type II collagen. It usually exhibits both eye and systemic features including myopia, retinal detachment, osteoarthritis, cleft palate and deafness. Certain mutations in exon 2 of COL2A1 result in a predominantly ocular form of the disorder, as this exon is alternatively spliced and excluded from the mature transcripts in cartilage. **Purpose:** To characterise the mutation in a family with predominantly ocular Stickler syndrome, but with a normal exon 2 sequence. **Methods and Results:** A family with the type 1 membranous phenotype of Stickler syndrome were assessed for skeletal and hearing traits associated with the disorder. None were found. Exon 2 of COL2A1 had a normal sequence. Mutation screening detected a T>C mutation converting the donor splice site of intron 51 from GT to GC. Amplification of illegitimate transcripts from cultured skin fibroblasts showed retention of intron 51 and premature termination of translation. Donor splice sites with GC dinucleotide sequences are often involved in alternative splicing. To determine if cartilage cells could splice this mutant allele normally, an expression vector containing minigenes with various mutant IVS51 donor splice sites were transfected into cultured cells. Mini genes with IVS51G+1T, G+1A and T+2C mutations were all misspliced (exon skipped) when transfected into cell lines derived from ocular tissue (MIO-M1, corneal, and scleral cells). Whereas the G+1T and G+1A mutants were misspliced in all cell lines derived from skeletal tissue, in contrast the T+2C mutant was spliced correctly in 2 of 3 (Saos-2 and SW1353) of these cell lines. **Conclusion:** The systemic features associated with Stickler syndrome are lacking in the family with the intron 51 T+2C mutation probably because cartilage cells are, at least partially, capable of splicing the mutant allele normally, whereas ocular tissue cannot.

Phenotype of SGCE mutations in a large sample of French patients. *S. Tezenas du Montcel*¹, *F. Clot*², *M. Vidailhet*^{2,3}, *P. Jedynek*⁴, *P. Damier*⁵, *F. Durif*⁶, *G. Ponsot*⁷, *C. Tranchant*⁸, *L. Vercueil*⁹, *A. Brice*². 1) Service de Biostatistique, Hopital Pitie-Salpetriere, AP-HP, Paris; 2) INSERM U289, Paris; 3) Service de Neurologie, Hopital Saint-Antoine, AP-HP, Paris; 4) Departement de Neurologie, Hopital Pitie-Salpetriere, AP-HP, Paris; 5) Service de Neurologie, Hopital Laennec, Nantes; 6) Service de Neurologie, Hopital Gabriel Montpied, Clermont-Ferrand; 7) Service de Neuropediatrie, Hopital Saint Vincent de Paul, Paris; 8) Hopital Universitaire de Strasbourg, Strasbourg; 9) Service de Neurologie, CHU de Grenoble, France.

Myoclonus Dystonia Syndrome (MDS) is an autosomal-dominant movement disorder characterized by rapid muscle contractions (myoclonus) and sustained twisting and repetitive postures (dystonia). The MDS gene (SGCE) encodes - sarcoglycan. We have evaluated the frequency of SGCE mutations and the corresponding phenotype in a large cohort of French patients with myoclonic syndromes. We performed SGCE screening in 74 index cases, half with family history of myoclonus or dystonia, with myoclonic/dystonic syndromes including patients with classic myoclonus dystonia, essential myoclonia, dystonia with myoclonus, dystonia, begin hereditary chorea. All coding exons of the SGCE gene were analyzed by direct sequencing and the DYT1 mutation was tested. We found 9 SCGE mutations (all of them novel) in 10 (29%) of the 34 patients with myoclonus dystonia, but found no mutation in any of the 50 patients with other phenotypes. There were 24 affected among 29 carriers. Penetrance was 100% in paternal and 0% in maternal transmissions. Myoclonus-dystonia patients with SGCE mutation have a younger age of onset than the non-carriers, while the two groups do not differ significantly in term of site of onset, disease progression or alcohol responsiveness. In none of our patients, psychiatric disorders were described. A single patient with myoclonus-dystonia carried the DYT1 mutation. In this large cohort of patients, we show that SGCE mutations are exclusively found in patients with typical myoclonus-dystonia but only in a subset of them (29%). Our data suggest that SGCE testing in other phenotypes is likely to be negative.

Assignment of a new congenital fibrosis of extraocular muscles type 3 (CFEOM3) locus, FEOM4, based on a balanced translocation t(2;13) (q37.3;q12.11) and identification of candidate genes. *P. Aubourg¹, M. Krahn², R. Bernard², K. Nguyen², O. Forzano³, V. Delague¹, M.G. Mattei¹, N. Philip², N. Lévy^{1,2}.* 1) Inserm U491, Faculté de Médecine Timone, Marseille, France; 2) Génétique Médicale, Hôpital d'enfants de la Timone, Assistance Publique, Marseille, France; 3) Service d'Ophthalmologie, Hôpital Timone, Assistance Publique, Marseille, France.

Congenital fibrosis of extra ocular muscles (CFEOM) is a rare condition characterised by congenital ptosis and external ophthalmoplegia of autosomal dominant (CFEOM1 and CFEOM3) or recessive (CFEOM2) inheritance. The manifestations are present at birth and do not progress through life. This condition is genetically and clinically heterogeneous with 3 phenotypes (CFEOM1 to 3) mapping to three loci (FEOM1-3), and the FEOM1 and FEOM2 genes have been identified as KIF21A and PHOX2A, respectively. Here, we report a three generation family in which four members present with congenital bilateral ptosis and restrictive ophthalmoplegia with limited upgaze, most consistent with the clinical diagnosis of CFEOM3. In this family, the phenotype is inherited in a dominant fashion and all affected members carry a translocation involving chromosomes 2q and 13q. In the last generation, one daughter carried the translocation in an unbalanced state and presented with CFEOM associated with mental retardation and facial dysmorphism. Molecular and FISH analyses mapped the 2q breakpoint at 2q37, within the Albright Hereditary Osteodystrophy (AHO) like syndrome critical interval; on the other side, 13q breakpoint maps in the 13q12 region, distal to the Connexin genes cluster, where, more likely, it interrupts a gene involved in the disorder. This CFEOM phenotype is likely to be associated to chromosome 13q12 region since no gene is interrupted by the breakpoint on chromosome 2, which one, moreover, lies in the AHO like syndrome critical region. We have identified several candidate transcripts, one of them, AKO54845 being interrupted by the translocation breakpoint on chromosome 13. This work defines a new CFEOM3 locus, FEOM4, and provides further evidence of the genetic heterogeneity observed in CFEOM.

The RAR-related orphan receptor A isoform 1 (*RORa1*) gene is disrupted by a balanced translocation t(4;15) (q22.3;q21.3) associated with severe obesity. J. Klar¹, B. Åsling², M. Uvsväck², A. Dellsén², C. Ström², M. Rhedin², A. Forslund³, G. Annerén¹, JF. Ludvigsson⁴, R. Nohra¹, N. Dahl¹. 1) Department of Genetics & Pathology, Uppsala University, Uppsala, Sweden; 2) AstraZeneca R&D, Mölndal, Sweden; 3) Department of Medical Sciences, Uppsala University, Sweden; 4) Department of Paediatrics, Örebro University Hospital, Örebro, Sweden.

We have characterized a family comprising a mother and two children with idiopathic and isolated obesity (BMI 41-49). The three family members carry a balanced reciprocal chromosome translocation t(4;15). A detailed characterization of the chromosomal breakpoints at chromosome 4 and 15, respectively, revealed that the translocation is almost perfectly balanced with a very short insertion/deletion. The chromosome 15 breakpoint is positioned in intron 1 of the RAR-related orphan receptor A isoform 1 (*RORa1*) gene. The chromosome 4 breakpoint is positioned 150 kb telomeric to the transcriptional start of the unc-5 homolog C (*UNC5C*) gene and 150 kb centromeric to the transcriptional start of the pyruvate dehydrogenase (lipoamide) alpha 2 (*PDHA2*) gene. A fusion gene containing the *RORa* exon 1 and *UNC5C* is created on the chromosome 4 derivative. Expression analyses reveal that the fusion gene is expressed in frame in adipocytes from the three affected individuals.

The rearrangement of the *RORa* gene predicts the loss of one isoform 1 (*RORa1*) allele. *RORa1* is implicated in the regulation of adipogenesis and lipoprotein metabolism. We hypothesize that the obesity in this family is caused by i) haploinsufficiency of *RORa1* or, ii) a gain of function mechanism mediated by the *RORa1-UNC5C* fusion gene.

Molecular Homogeneity of G6PD Deficiency In Bahrain. *N.J. Al Momen¹, S. Al Arrayed², A. Al Alawi³.* 1) Genetic laboratory , Salmaniya Medical Centre, Manama, Bahrain; 2) Genetic department, Salmaniya Medical Centre, Manama, Bahrain; 3) Pathology department, Salmaniya Medical Centre, Manama, Bahrain.

Objectives. This study aimed at investigating the molecular basis of G6PD deficiency in the Kingdom of Bahrain. Further emphasis will be presented on the genetic polymorphism at nucleotide 1311 for both normal and deficient subjects. **Methods:** DNA extraction was done for 83 G6PD-deficient subjects and 80 normal controls. A combination of PCR-RFLP and PCR-DGGE procedures were employed to uncover the sequence variations at nt 563 (C/T) (G6PD Mediterranean) and at nt 1311 (C/T) polymorphism in both subjects with deficient and normal G6PD activity. **Results:** Nearly Ninety-one percent (93/102) of the X chromosomes from G6PD deficient subjects had nt 563 (C-T) mutation (G6PD Med), whereas ~9% of the X chromosomes from G6PD deficient subjects might have other G6PD variant(s) (or normal X chromosomes in heterozygote females). Ninety-six percent (89/93) of the G6PD Med-bearing X chromosomes showed thymine (T) at nucleotide position 1311. In contrast, 70% (82/117) of the normal X chromosomes showed cytosine (C) at nucleotide position 1311, while it was thymine (T) in 30% (35/117) of the normal X chromosomes. **Conclusion.** The vast majority (91%) of X chromosomes from G6PD-deficient subjects in Bahrain are harboring nt 563 (C-T) mutation (G6PD Mediterranean). The G6PD Med variant in Bahrain is in tight linkage disequilibrium with thymine (T) at nt 1311. These data, collectively, revealed high molecular homogeneity of G6PD deficiency in Bahrain. **Recommendations.** Further studies are needed to uncover factor(s) contributing to heterogeneous phenotypic expression of the disease in Bahrain.

A novel SOD1 mutation in a patient with Brachial Amyotrophic Diplegia. *T. Sprovieri¹, P. Valentino², R. Mazzei¹, A. Patitucci¹, A. Magariello¹, R. Nisticó², D. Pirritano², A.L. Gabriele¹, C. Ungaro¹, A. Clodomiro², G. Peluso¹, M. Muglia¹, M. Zappia², F.L. Conforti¹.* 1) ISN/CNR, Mangone, Cosenza, Italy; 2) Institute of Neurology, University "Magna Graecia", Catanzaro, Italy.

Over 100 mutations have been described spreading through the entire Sod1 coding region, but also in the intronic and regulatory regions. This gene, located on chromosome 21q22, is implicated in the autosomal dominant form with late onset of the Amyotrophic Lateral Sclerosis. Until now, all the Sod1 mutations reported are associated to this pathological phenotype. In this study we describe for the first time a new Sod1 mutation in a patient with Brachial Amyotrophic Diplegia (BAD). The patient was a 77-year-old man with a 5-month history of severe, bilateral arm weakness and wasting. Family history was unremarkable for neurological disorders. Neurological examination showed a peculiar posture of the man-in-the-barrel. There was severe weakness and atrophy of both upper limb muscles, especially of shoulder girdles (MRC<3/5). Fasciculations were evident only on upper limb muscles. Nerve conduction studies showed lower amplitude compound muscle action potentials (CMAPs) in the median, ulnar and radial nerves bilaterally, normal motor and sensory nerve conduction, without significant conduction block. Needle electromyography showed denervation potentials with reduced recruitment in all upper limb muscles. A wide screening was performed to exclude other causes of man-in-the barrel syndrome. Molecular analysis of the survival motor neuron gene and X-linked spinobulbar muscular atrophy was negative. Genetic investigation of the five exons of the Sod1 gene by DHPLC and direct sequencing of the PCR products, showed a variant profile of exon 4 caused by a heterozygous CT substitution at position 1126 of the gene (Leu106Pro). This mutation was not found in more than 150 control subjects from southern Italy. In conclusion, Sod1 mutations have been actually described in a small percentage of apparently sporadic cases of ALS. Our patient is the first case of sporadic lower motoneuron disease with a mutation in the SOD1 gene. The present findings suggest that Sod1 gene should be investigated in subject with BAD.

***SALL4* deletions are a common cause of Okihiro and acro-renal-ocular syndromes and confirm**

haploinsufficiency as the pathogenetic mechanism. W. Borozdin¹, D. Boehm², M. Leipoldt¹, C. Wilhelm¹, W. Reardon³, J. Clayton-Smith⁴, K. Becker⁵, H. Muehlendyck⁶, R. Winter⁷, O. Giray⁸, F. Silan⁹, J. Kohlhase¹. 1) Inst. for Human Genetics, Univ. of Freiburg, Germany; 2) Inst. for Human Genetics, Univ. of Göttingen, Germany; 3) Natl. Centre for Medical Genetics, Dublin, Ireland; 4) Dept. of Clin. Genetics, St Marys Hospital, Manchester, UK; 5) Kennedy-Galton Centre, Harrow, UK; 6) Dept. of Neuroophthalmology, Univ. of Göttingen, Germany; 7) Inst. for Child Health, London, UK; 8) Dept. of Pediatrics, Genetics Div., Dokuz Eylul University, Izmir, Turkey; 9) Med. Biology and Genetics Dept., Abant Izzet Baysal University, Duzce, Turkey.

Okihiro (Duane Radial-Ray) syndrome is an autosomal dominantly inherited malformation syndrome characterized by radial malformations of upper limbs in combination with Duane anomaly. Previously, mutations in the putative zinc finger transcription factor gene *SALL4* were reported to cause Okihiro and acro-renal-ocular syndrome. However, in a substantial proportion of patients with such phenotypes no *SALL4* mutation was found. Segregation analysis of five intragenic SNPs was informative in four out of six families and suggested a heterozygous *SALL4* deletion of at least exon 2. To confirm these findings and establish the deletion size, quantitative real time PCR was applied. In this way, we identified two families with deletions of all four exons as well as two families with deletions of exons 1-3. In one family uninformative for the five intragenic SNPs, a heterozygous deletion of exon 4 was detected, and in a further family, a heterozygous deletion of exon 1 was found. In the latter, a deletion size of 8.9 kb was determined with one breakpoint residing within an Alu-element. In another family, the deletion size was 59.4 kb with both breakpoints in Alu-elements, suggesting that Alu-mediated recombination is responsible for at least some of the deletions. These results show that, in contrast to the likely dominant-negative action of *SALL1* mutations causing Townes-Brocks syndrome, Okihiro and acro-renal-ocular syndromes are clearly resulting from *SALL4* haploinsufficiency.

Common 5q35 microdeletions in Sotos syndrome result from DNA rearrangements between directly oriented subunits of large low copy repeats. *N. Kurotaki¹, K. Wakui², J.-F. Cheng³, S.A. Yatsenko¹, N. Matsumoto⁴, P.*

Stankiewicz¹, J.R. Lupski^{1,5,6}. 1) Dept of Molecular & Human Genetics, Baylor College Medicine, Houston, TX; 2) Dept of Medical Genetics, Shinshu University School of Medicine, Matsumoto, Japan; 3) Genome Science Dept., Lawrence Berkeley National Laboratory, CA; 4) Dept of Molecular and Human Genetics, Yokohama City University Graduate School of Medicine, Yokohama, Japan; 5) Dept of Pediatrics, Baylor College of Medicine, Houston, Texas; 6) Texas Children Hospital, Houston, Texas.

Sotos syndrome (SoS) is a well-characterized overgrowth syndrome with mental retardation, specific craniofacial features, and advanced bone age. Since NSD1 haploinsufficiency was determined to be the major cause of the syndrome, many intragenic mutations and chromosomal microdeletions involving the entire NSD1 gene have been described. In the Japanese population, approximately half of patients with SoS has a common microdeletion. We have analyzed DNA sequence of genomic segments flanking SoS common deletion. BLAST search showed 3 unique repeat sequences, termed Proximal Sos-REP (390 kb), Distal Sos-REP-A (326 kb), and Distal Sos-REP-B (50 kb). We determined the size, orientation, and extent of homology of these repeat sequences. Blast comparison of Proximal- Sos-REP and Distal Sos-REP-A revealed five subunits which were numbered from subunit 1 to 5. Each subunit was in an inverted orientation although the order of subunits was different between the two REPs. In contrast, Distal Sos-REP-B that was more than 50 kb telomeric of Distal Sos-REP-A consists of only directly oriented subunit 2. Distal Sos-REP-B and subunit 2 in other REPs are more than 98% identical. Using pulsed-field gel electrophoresis analysis, we detected a novel 0.4 Mb junction fragment in seven SoS patients with common deletion. This suggests that both Proximal- Sos-REP and Distal Sos-REP-B act as a homologous recombination substrate for the Sotos syndrome common microdeletions.

Embryonic expression and mutation analysis of the Cornelia de Lange syndrome gene, NIPBL. *E.T. Tonkin¹, T-J. Wang¹, S.N. Lisgo¹, M. Ireland¹, M. Krajewska-Walasek², T. Strachan¹.* 1) Inst Human Genetics, Univ Newcastle, Newcastle, United Kingdom; 2) Department of Medical Genetics, Children's Memorial Health Institute, Warsaw, Poland.

We recently reported identification and preliminary characterisation of NIPBL, a novel gene mapping to 5p13.1 that we showed to be mutated in Cornelia de Lange syndrome (Tonkin et al., 2004). The NIPBL gene has 46 coding exons and specifies a protein, delangin, that is significantly related to the fruitfly developmental regulator Nipped-B, and to fungal Scc2-type proteins that perform basic chromosomal functions, notably sister chromatid cohesion. We now report extended mutation analyses that survey all 46 coding exons. As well as exploring the molecular basis of phenotype discordance in sibs, our mutation analyses provide insights into the molecular basis of classical and mild CdLS. We also report extended embryonic expression analyses, including novel detailed studies of expression in the developing brain and limbs, and in craniofacial and genito-urinary systems. The pattern of embryonic expression is largely consistent with that expected from pathogenesis, but unanticipated expression patterns in some systems may provide new insights into the pathogenesis. We also present an evolutionary analysis that relates human delangin to novel vertebrate, nematode and plant counterparts as well as to known fungal and fruitfly homologues.

Fine mapping of the X-linked split-hand/split-foot malformation locus and mutation analysis of candidate genes.

*M. Ul Haque*¹, *S.H.E. Zaidi*⁵, *L.M. King*⁶, *S. Haque*², *M. Patel*¹, *M. Ahmad*², *T. Siddique*³, *W. Ahmad*², *D.H. Cohn*^{6, 7}, *L-C. Tsui*^{1, 4}. 1) Program in Genetics and Genomic Biology, Department of Genetics, Hospital for Sick Children, Toronto, Canada; 2) Department of Biological Sciences, Quaid-i-Azam University, Islamabad, Pakistan; 3) Department of Neurology, Northwestern University Medical School, Chicago, Illinois; 4) The University of Hong Kong, Pokfulam Road, Hong Kong; 5) Department of Medicine, Toronto General Hospital, Toronto, ON, Canada; 6) Ahmanson Department of Pediatrics, Steven Spielberg Pediatric Research Center, Cedars-Sinai Research Institute; 7) Departments of Human Genetics and Pediatrics, David Geffen School of Medicine at UCLA, Los Angeles, California.

Split-hand/split-foot malformation (SHFM) is a genetically heterogeneous inherited disorder, in which affected individuals display lack of median digital rays, syndactyly, and aplasia/hypoplasia of the phalanges, metacarpals and metatarsals. Four autosomal and a single X-linked locus have been reported. In the X-linked SHFM family we have previously reported linkage to a 22 Mb interval on Xq24-q26. To fine map this region and to obtain additional phenotypic details of the heterozygous carrier females, the SHFM index family was revisited. In this family, all 39 affected hemizygous males and 3 homozygous females exhibited the trait while fifteen of the obligate heterozygous females showed partial and asymmetric expression of SHFM. Analysis of DNA from 37 individuals, including 21 males and 7 females who partially or fully expressed the SHFM trait, exposed a new centromeric boundary at DXS1114 while the telomeric boundary was defined by the DXS1192. These data further refined the SHFM2 locus to a 5.1Mb region. Several candidate genes including TDU, ZIC3, FGF13 and FHL1, which are expressed in developing limb, reside within the mapped region. No mutations were identified in the coding regions of these functional and fifteen of the positional candidate genes. These data suggest that the mutation may lie in a regulatory region of one of these candidate genes or in another gene within the SHFM2 locus with unclear role in limb development.

Haplotype-specific BAC libraries for identification of dominant amyotrophic lateral sclerosis (ALS) genes on 16q12 and 18q21. *Y. Yoshinaga*¹, *T.J. Kwiatkowski, Jr*², *F. Gros-Louis*³, *C. Gros-Louis*⁴, *M. Nefedov*¹, *K. Osoegawa*¹, *J.S. de Belleruche*⁵, *G.A. Rouleau*³, *R.H. Brown, Jr*², *P.J. de Jong*¹. 1) BACPAC Resources, Children's Hospital Oakland, Oakland, CA; 2) Harvard Medical School, Charlestown, MA; 3) Montreal General Hospital Research Institute, Montreal, Qc, Canada; 4) Broad Institute, Cambridge, MA; 5) Imperial College London, London, UK.

Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disease characterized by a selective loss of motor neurons. Approximately 10% of cases are familial (FALS), mostly in an autosomal dominant form. While 25% of the familial cases are caused by mutations in the Cu/Zn superoxide dismutase gene (SOD1), the remaining familial cases are predisposed due to dominant FALS loci on a variety of other chromosomes, e.g. recently mapped ALS6 on 16q12 and ALS3 on 18q21. Our strategy to identify these ALS genes is to complete the high-quality sequencing of the affected haplotype by sequencing the haplotype-specific BAC contigs. The diploid-to-haploid conversion method was employed to create human-murine hybrid cells harboring only the haplotype linked to the human disease-allele-bearing chromosome. Three >500,000-clone libraries have been prepared from hybrid cell lines from two patients containing the 16q12 and one patient containing the 18q21 FALS loci. Each library was spotted on 28 high-density colony filters and screened using very complex probes pools (~150/pool), which are designed at regular (50 kbp) intervals along the affected 4-7 Mbp regions. All positive clones were BAC-end sequenced to prepare a BAC-contig relative to the assembled human genome containing with less than 2% of the sequence not present in the contigs. A minimum set of BAC clones for the affected regions have been processed by the shotgun sequencing. The BACs will also be used as reagents to create surrogate phenotypes as a means to narrow the choice of candidate genes. We are further optimizing haplotype-specific BAC construction protocols to test whether this approach can be applied in the search for additional dominant gene mutations. Our research is supported in part by a grant from the ALS Association.

Male-to-male transmission in X-linked Alport Syndrome. *E. Ars*¹, *B. Tazón-Vega*¹, *P. Ruiz*¹, *C. Nogués*², *O. Rajmil*³, *R. Torra*⁴. 1) Molecular Biology Laboratory, Fundació Puigvert; 2) Universitat Autònoma Barcelona; 3) Andrology Dept., Fundació Puigvert; 4) Nephrology Dept., Fundació Puigvert. Barcelona. Catalonia. Spain.

Alport Syndrome (AS) is a hereditary nephropathy affecting the glomerular basement membrane often associated with hearing loss. Genetically the disorder is heterogeneous and can be transmitted following an X-linked or an autosomal pattern of inheritance. X-linked AS is the most frequent form of the disease and is caused by mutations in the COL4A5 gene at Xq22-q23, while the autosomal form is due to mutations in the COL4A3 and COL4A4 genes, both located on chromosome 2q36-q37. Male-to-male transmission has been considered fully indicative of autosomal AS. Here we report a family with male-to-male transmission in which linkage to the COL4A3 and COL4A4 genes was excluded. Unexpectedly, linkage to chromosome X was demonstrated and it identified an extra X chromosome of paternal origin in the proband. Cytogenetically, the proband 47,XXY karyotype was confirmed and analysis of paternal sperm did not show an abnormal percentage of diploid spermatozoa. Moreover, a splicing mutation was characterized by analysis of the whole coding region of the COL4A5 gene. The outcome of this patient is unpredictable but the presence of microhematuria and proteinuria at 4 years of age reminds more of an affected boy than a female carrier. To our knowledge this is the first reported case of concurrence of Alport and Klinefelter syndromes. Bearing in mind that their incidences are 1 in 5,000 and 1 in 1,000 male births, respectively, the probability for the simultaneous occurrence of these two disorders is approximately 1 in 5,000,000 births. In spite of the unlikelihood of this phenomenon it should be considered when offering genetic counseling for AS families.

Elucidation of pathogenic genetic pathways in the hypertrophic heart using microarray technology. *H. Smeets¹, B. Van den Bosch¹, P. Lindsey¹, D. Lips², C. Van den Burg¹, P. Doevendans², R. Vlietinck¹.* 1) Dept of Genetics & Cell Biol, Univ Maastricht, Maastricht, Netherlands; 2) Dept of Cardiology of the Heart Lung Centre Utrecht (UMCU), Utrecht, Netherlands.

Introduction Gene expression differences between normal, hypertrophic and failing heart may unravel underlying pathogenic mechanisms in patients. To circumvent the complexity and scarcity of human biopsies, we used the Transverse Aortic Constricted (TAC) mouse model for cardiac hypertrophy. By gene expression profiling we aim at identifying the molecular program underlying myocardial hypertrophy, the most powerful predictor of heart failure. **Methods** Male Swiss mice (10 weeks old) were either TAC or sham-operated (n=5) and sacrificed at 48 hours, 1 week, 6 or 8 weeks after surgery. Hearts were harvested and hypertrophy was assessed by determining the ratio left ventricle weight/tibia length. Left ventricle RNA was analysed on microarrays containing 15,000 embryonic and fetal cDNA inserts (National Institute on Aging) and 4,200 controls, including RNA spikes, housekeeping genes and negative controls. **Results** At 48 hours, 1 week, 6 and 8 weeks after banding, respectively 779, 537, 1303 and 621 genes were significantly differentially expressed with fold changes ranging from 1.1 till more than 15. The differential genes included hypertrophy markers, like MHC and SERCA2, genes in known hypertrophic processes, like MAPK pathways and genes in calcium-signaling pathways. During the early hypertrophic phase, most genes were up-regulated, while at a later stage genes were mostly down-regulated. Early identified processes involved mainly signalling and transcription related genes, while energy metabolism and cell adhesion were mainly involved at a later stage. **Conclusions** Using a well-defined array design and data analysis we were able to identify significantly small changes in gene expression for large numbers of genes. Known genes and markers confirmed the hypertrophy process occurring. More extensive study of the data will be presented with new pathways and genes involved in the process of cardiac hypertrophy and may unravel targets for interventions.

Program Nr: 2516 from the 2004 ASHG Annual Meeting

***MutationView* : Development of an Intelligent Search System to Extract Disease-associated Knowledge. M.**

*Ohtsubo*¹, *S. Mitsuyama*¹, *T. Kawamura*¹, *N. Shimizu*¹, *S. Minoshima*^{1,2}. 1) Department of Molecular Biology, Keio University School of Medicine, Japan; 2) Photon Medical Research Center, Hamamatsu University School of Medicine, Japan.

In order to analyze the relation between diseases and genetic diversity, we developed an integrated database system *MutationView*, which at present mainly deals with monogenic diseases (<http://mutview.dmb.med.keio.ac.jp>).

MutationView can search, display and analyze the mutation data with graphical environment. The characteristic features of the *MutationView* include : (1) Various data display and analysis functions are available with regard to genomic/cDNA structure, functional domains of protein, the histogram of the case number of each mutation, changes in the nucleotide sequence and restriction sites, and the symptom associated with each mutation. (2) Mutation data are collected on the diseases related to eye, ear, brain, muscle, heart, autoimmunity and familial tumor.

To date, we have collected 9762 entries of mutations from 1706 literatures dealing with 251 genes involved in 235 distinct diseases. A new category systemic bone diseases including osteochondrodysplasia has been added for 31 genes. For more effective use of the *MutationView*, we have developed a new support system to automatically extract disease-associated knowledge from the literature. In addition to categorized dictionary for various fields such as clinical medicine, histology and anatomy, we have created an automatic extraction method of keywords based on the frequency of word usage. Using these, the OMIM documents are now in process of statistical language analysis. This knowledge extraction system will be implemented to *MutationView*. Computer demonstration will be performed at the meeting.

Phenotypic and Molecular Characterization of Patients with BOR Syndrome: Mutation Screening of EYA1 and SIX1 Genes and Issue of Genetic Heterogeneity. *U. Radhakrishna¹, C. Holley¹, F. Hildebrandt², C.W.R.J. Cremers³, W.J. Kimberling¹, S. Kumar¹.* 1) Dept. of Genetics, Boys Town National Res. Hosp., Omaha, NE; 2) Department of Pediatrics, University of Michigan, Ann Arbor, MI; 3) Department of Otolaryngology, University Hospital Nijmegen, The Netherlands.

Branchio-oto renal syndrome (BOR) is a human developmental disorder (autosomal dominant) which produces a wide range of clinical manifestations such as (1) branchial cleft, fistulas or cysts (2) various ear anomalies such as malformed pinnae, pre-auricular pits, structural defects of the external, middle and/or inner ear (3) hearing loss and (4) renal anomalies. It affects at least 2% of profoundly deaf children and have estimated prevalence of 1 in 40,000.

The first BOR gene has been localized to chromosome 8q13 and EYA1 gene has been implicated. We have performed mutation analysis on more than eighty BOR families by hetero-duplex followed by sequence analysis of sixteen EYA1 exons. At least 55% of our large data set of BOR families do not show mutations in the EYA1 gene. This further complicates the issue. A second genetic locus was mapped to 1q and recently, third locus was identified on chromosome 14q. Within the critical region of 14q, SIX1, SIX4 and SIX6 candidate genes have been located, which act within a genetic network of EYA and PAX genes to regulate organogenesis. Using direct sequencing, we identified mutations with SIX1 gene in BOR/BO kindreds confirming SIX1 as a new gene involved in branchiogenetic disorders. The present results, together with mutation screening and genetic linkage study, demonstrate genetic heterogeneity. A genome-wide search is being performed for the localization of fourth locus. Also, a candidate gene analysis is underway to identify genes in the critical region of second BOR locus on chromosome 1q.

These results provide the basis for a molecular-genetic testing that will help the clinical evaluation and genetic counseling of members of BOR families. Further characterization of EYA1 and SIX1 mutation and identification of other BOR genes will significantly help in defining the spectrum of defects associated with branchial and hearing anomalies.

Reduced penetrance of craniofacial anomalies as a function of deletion size and genetic background in a chromosome engineered partial mouse model for Smith-Magenis syndrome. *J. Yan*¹, *V.W. Keener*¹, *W. Bi*¹, *K. Walz*¹, *A. Bradley*³, *M.J. Justice*¹, *J.R. Lupski*^{1,2}. 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Texas Children's hospital, Houston, TX; 3) The Wellcome Trust Sanger Institute, Hinxton, UK.

Smith-Magenis syndrome (SMS) is a multiple congenital anomaly/mental retardation syndrome associated with del(17)(p11.2p11.2). The phenotype is variable even in patients with deletion of the same size. *Df(11)17/+* mice contain a heterozygous deletion in the mouse region syntenic to the SMS common deletion, and exhibit craniofacial abnormalities, seizures, and marked obesity, partially reproducing the SMS phenotype. To narrow the genomic interval responsible for the phenotype, we constructed 3 lines of mice with smaller deletions (*Df(11)17-1*, *Df(11)17-2*, and *Df(11)17-3*) using retrovirus mediated chromosome engineering to create nested deletion. Both craniofacial abnormalities and obesity have been observed, but the penetrance of the craniofacial phenotype is markedly reduced in comparison to *Df(11)17/+* mice. Overt seizures were not observed. Phenotypic variation has been observed in mice with the same deletion size in both the same and different genetic backgrounds, which may reflect the variation documented in the patients. These results indicate that the smaller deletions contain the genes for the craniofacial abnormalities and obesity. However, genes or regulatory elements in the larger deletion that are not located in the smaller deletions, as well as genes located elsewhere, also influence both the penetrance and expressivity of the phenotype. Our mouse models refined the genomic region important for a portion of the SMS phenotype and provide a basis for further molecular analysis of genes associated with SMS.

Activating mutations in *KCNJ11* cause transient as well as permanent neonatal diabetes with functional severity of activating mutation determining phenotype. A.L. Gloyn^{1,2}, F. Reimann³, C. Girard¹, E.L. Edghill², E.R. Pearson², D.J.G. Mackay⁴, I.K. Temple⁴, J.P.H. Shield⁵, K. Noyes⁶, D. Freedenberg⁷, S. Ellard², F.M. Ashcroft¹, F.M. Gribble³, A.T. Hattersley². 1) University of Oxford, UK; 2) Peninsula Medical School, Exeter, UK; 3) University of Cambridge, UK; 4) Southampton, UK; 5) Bristol, UK; 6) Edinburgh, UK; 7) Austin, Texas, USA.

The ATP-sensitive potassium (K_{ATP}) channel is a key candidate gene for diabetes, it couples metabolism to membrane electrical events and insulin secretion, with ATP closing the channel. We have shown that heterozygous activating mutations in *KCNJ11*, which encodes the Kir6.2 subunit of the β -cell K_{ATP} channel, are a common cause of permanent neonatal diabetes (PNDM) and common genetic variation in *KCNJ11* (E23K) predisposes to type 2 diabetes (T2DM). Transient neonatal diabetes (TNDM) is a rare type of diabetes that presents soon after birth and resolves by 18 months. We hypothesised that an array of naturally occurring *KCNJ11* activating mutations could exist with a range of functional severities resulting in diabetes with a spectrum of clinical presentations. Therefore we investigated the role of *KCNJ11* mutations in TNDM. *KCNJ11* was sequenced in 11 probands with TNDM. Identified mutations were expressed in *Xenopus* oocytes and functionally characterised by patch clamp analysis. Novel heterozygous mutations (G53S, G53R, I182V) which co-segregated with diabetes were identified in 3 probands. Mutations were not identified in 100 normal chromosomes. Functional analysis of the G53S and I182V mutations demonstrated that they resulted in a decrease in affinity for ATP, (K_i ; WT 8.9 2.1 vs G53S 37.8 7.6, $p = 0.0018$, I182V 28.9 3.3, $p < 0.001$, $n=10$). These defects are functionally less severe than for the R201H PNDM mutation, which had a 40 fold reduction in ATP sensitivity. Our study demonstrates a spectrum of association of *KCNJ11* with diabetes with severe mutations presenting as PNDM and milder mutations presenting as TNDM and a common polymorphism predisposing to T2DM. These results may have implications for the clinical management of these patients.

Searching for a novel MODY gene in a large Norwegian family with autosomal dominant diabetes. S.

Johansson^{1,2}, H. Ræder¹, P.I. Holm³, L. Grevle², O. Søvik¹, D.E. Undlien⁴, A. Molven⁵, P.R. Njølstad^{1,2}. 1) Section of Pediatrics; 2) Section of Med. Genetics and Molecular Med. Dep. of Clin. Med. University of Bergen; 3) Dep. of Internal Med. Haukeland University Hospital; 4) Inst. and Dep. of Med. Genetics, Ullevål University Hospital, University of Oslo; 5) Section of Pathology, The Gade Institute, University of Bergen, Norway.

Background and aims: Maturity-onset diabetes of the young (MODY) is a heterogeneous subgroup of diabetes with autosomal dominant mode of inheritance and beta cell dysfunction. Approximately 20% of families fitting MODY criteria do not have mutations in any of the six genes where mutations are known to cause MODY. We have investigated a large Norwegian family with autosomal dominant diabetes. The aim was to map a possible novel MODY locus. Subjects and methods: We studied 58 family members. Fourteen subjects had diabetes associated with a primary beta cell dysfunction and one had impaired glucose tolerance. Candidate genes were investigated either by direct sequencing in selected affected individuals or by linkage analyses using microsatellite markers flanking the locus. Results: Median age of diabetes diagnosis was 38 years (range 18-56 years) and eight of the diabetic patients were on insulin therapy. Mean BMI among diabetes patients was 24.4 kg/m² and mean fasting C-peptide was 0.30 nmol/l. Markers of autoimmunity were negative. No mutations were detected in the six known MODY genes. Furthermore, three genes encoding transcriptional factors involved in pancreas development and differentiation and five genes with a role in regulation of glucose metabolism were also excluded. The affected family members all had at least one HLA-DQB1*0602 allele known to be highly protective against autoimmune type 1 diabetes, but linkage and haplotype analyses excluded the HLA complex as the disease locus. Conclusion: We have studied a large family with monogenic diabetes fitting clinical MODY criteria. The disorder is probably caused by mutation in a novel MODY gene. Simulations of pedigree data indicate that this family may be suitable for a whole genome linkage screen. We have therefore initiated such a screen to detect the postulated novel MODY locus.

Identification of a novel mutation of the Kir6.2 gene in a Japanese family with dominantly inherited diabetes mellitus. *T. Yorifuji, K. Kurokawa, M. Mamada, M. Kawai, T. Nakahata.* Dept Pediatrics, Kyoto Univ Hosp, Kyoto, Japan.

Dominantly inherited diabetes mellitus with decreased insulin secretion is typically known as MODYs (Maturity Onset Diabetes of the Young). So far, 6 subtypes of MODYs, MODY1-6, are known with mutations in different genes. In Japan, however, MODY1-6 comprise a relatively small fraction of patients with dominantly inherited diabetes mellitus. In this study, we performed a multipoint linkage analysis of a four-generation family with dominantly inherited diabetes mellitus. The onset of diabetes varied among family members, the earliest one presented in the neonatal period and others presented later in life. Several regions of interest were identified and compared with locations of previously known genes related to insulin secretion or pancreatogenesis. By sequencing analysis of the candidate genes, we identified a novel missense mutation (C42R) in the Kir6.2 gene. Currently we are in the process of functional analysis of this mutation. If this is causing diabetes mellitus in this family, it follows that mutations in Kir6.2 could be a cause of not only neonatal diabetes but also of later onset diabetes mellitus.

A mutation in bovine keratin 5 causing epidermolysis bullosa simplex, transmitted by a mosaic sire. *H.E. Ward¹, C.A. Ford¹, A.M. Stanfield¹, A. Walden¹, M. Al-Wahb¹, E. Bohm¹, G.T. Sutherland¹, B. Smits², H. Holloway³, A.E.L. Ankersmit-Udy⁴, K. Cottier⁴, R.J. Spelman⁴, R.G. Snell¹.* 1) Bovine Genetics, ViaLactia Biosciences, Auckland, New Zealand; 2) Alpha Scientific Ltd, Hamilton, New Zealand; 3) University of Auckland, Auckland, New Zealand; 4) Livestock Improvement Corporation, Hamilton, New Zealand.

A mechanobullous skin disorder was reported in progeny of a three year-old Friesian-Jersey crossbred bull. The condition presented clinically as the loss of skin and mucosa from contact areas and resultant inflammation. Examination of skin samples from affected animals under light microscopy revealed separation of the epidermis from the underlying dermis. Electron microscopic analysis refined the site of cleavage to above the basement membrane and involving lysis of basal keratinocytes. These observations were consistent with the simplex form of epidermolysis bullosa (EB simplex) in humans. Potential candidate genes based on known human causative gene mutations were assessed, resulting in keratin 5 being identified as the most likely mutation-bearing gene. The sequence of bovine keratin 5 was established and direct sequencing led to identification of a G to A substitution common in all the affected animals. This mutation leads to an amino acid change of glutamic acid to lysine in the final E (478) of the KLLEGE motif of the protein. The sire carried a de novo mutation and was mosaic, explaining his asymptomatic status and the less than expected frequency of affected offspring. Remarkably, the same mutation has been previously described in EB simplex in humans. Semen has been collected from the bull, which could be used to generate a model for human EB simplex.

Mis-expression of the *Drosophila melanogaster* orthologue of human DMC1 disrupts the hedgehog signaling pathway in the fly wing. L. Hull¹, D.H. Cohn², L. King², L. Reiter¹, E. Bier¹. 1) Department of Biology, UC San Diego, La Jolla, CA; 2) Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, CA.

Dyggve-Melchior-Clausen dysplasia (DMC) and Smith-McCort dysplasia (SMC) are recessive allelic disorders that result from mutations in the DMC1 gene. Homozygosity or compound heterozygosity for null mutations causes DMC, a syndrome characterized by short stature and mental retardation. Compound heterozygosity for a missense mutation and an exon-skipping mutation in the gene have been found in two families with SMC, which present the same skeletal defects but lack the psychomotor dysfunction found in patients with DMC. Bioinformatic searches based on the sequence of the encoded protein, *dymeclin*, have uncovered putative transmembrane segments but no homology to any known functional protein domains. Thus function of the protein and the mechanism by which the mutations produce the phenotype are unknown. We have employed the model organism, *Drosophila melanogaster*, to uncover the function of the ubiquitously expressed protein *dymeclin*. Since *dymeclin* is highly conserved from *D. melanogaster* to humans, we used the GAL4-UAS system in *Drosophila* to overexpress human *dymeclin* as well as its unique *Drosophila* ortholog (dDMC) in a tissue specific manner. Misexpression of dDMC at high levels in the wing reduced the overall size of the wing, and at lower levels, selectively reduced the intervein space between wing veins L3 and L4. This milder phenotype was similar to the phenotypes produced by inhibition of Hh signaling found in either Hh mutants or by overexpression of the inhibitory components of the Hh signaling pathway. These data suggest that *dymeclin* overexpression disrupts hedgehog (Hh) signaling in the A/P organizer of the wing. Overexpressing dDMC in only the posterior portion of the wing did not affect L3-L4 intervein development, indicating that Hh synthesis was unaffected by increased *dymeclin*. Anterior overexpression, however, again resulted in a decrease in the distance between L3 and L4, indicating that *dymeclin* overexpression inhibits Hh signaling in cells receiving the Hh signal in the developing *Drosophila* wing.

IVS8-1G>C and T93M are the most frequent 7-dehydrocholesterol reductase mutations identified in a cohort of Smith-Lemli-Opitz syndrome patients from Brazil. *F.B. Scalco¹, L.S. Correa-Cerro¹, C.A. Wassif¹, D. Moretti-Ferreira², F.D. Porter¹.* 1) NICHD, National Institutes of Health, Bethesda, MD; 2) Servico de Aconselhamento Genetico, UNESP, Botucatu, SP, Brazil.

Smith-Lemli-Opitz syndrome (SLOS) is an autosomal recessive inborn error of cholesterol biosynthesis, caused by mutation of the 7-dehydrocholesterol reductase gene (*DHCR7*). *DHCR7* reduces 7-dehydrocholesterol (7DHC) to yield cholesterol in the final step of the cholesterol biosynthetic pathway. Biochemically, SLOS patients have elevated serum and tissue 7DHC levels and typically have low cholesterol levels. Over one hundred mutant *DHCR7* alleles have been identified. The most frequently reported *DHCR7* mutant allele is IVS8-1G>C. IVS8-1G>C is a splice acceptor mutation which causes aberrant splicing which results in the incorporation of 134 nucleotides of intronic sequence into the *DHCR7* mRNA. IVS8-1G>C is a null mutation. The second most frequently reported *DHCR7* mutant allele is T93M (278 C>T). *DHCR7*^{T93M} has been reported as being a common mutation in Italian and Cuban patients. We performed *DHCR7* mutation analysis for 14 biochemically confirmed SLOS patients and their parents from South and Southeastern Brazil. For this study, we performed mutation analyses by sequencing exons 3-9 of the *DHCR7* gene and SNP genotyping for IVS8-1G>C. The most frequent mutations found in this cohort were IVS8-1G>C (10/28 alleles) and T93M (9/28 alleles). One infant was homozygous for IVS8-1G>C. In six patients, the *DHCR7* genotype was T93M/IVS8-1G>C. Haplotype analysis was performed, and in this group of patients, the T93M mutation was found in association with haplotype L. Previously, the T93M mutation has been identified on haplotypes A, J, and K. This new and consistent association of the T93M mutation with haplotype L suggests a founder effect for this mutant allele in this Brazilian population.

Winchester Syndrome is caused by mutations in the matrix metalloproteinase 2 gene (MMP2). A. Superti-Furga¹, V. Calcaterra², M. Di Rocco³, A. Zankl¹. 1) Mol Ped Div, University of Lausanne, Lausanne, Switzerland; 2) Department of Pediatrics, University of Pavia, Pavia, Italy; 3) Pediatric Unit, Istituto Gaslini, Genoa, Italy.

The inherited osteolysis syndromes are a heterogeneous group of skeletal disorders whose classification is still uncertain. Three osteolysis syndromes show autosomal recessive inheritance and multicentric involvement predominantly of the hands and feet: Torg syndrome (OMIM 259600), Winchester syndrome (OMIM 277950), and Nodulosis-Arthropathy-Osteolysis syndrome (NAO, OMIM 605156). The latest Nosology of the International Skeletal Dysplasia Society, classifies NAO as a variant of Torg syndrome, while Winchester syndrome is considered a separate disorder. The main differences between Torg/NAO and Winchester syndrome are the presence of subcutaneous nodules in the former and more severe osteolysis and variable skin findings (but no nodules) in the latter. Recently, mutations in the matrix metalloproteinase 2 (MMP2) were reported in 2 families with prominent subcutaneous nodules, moderate osteolysis and arthropathy and a clinical diagnosis of NAO. We identified a homozygous missense mutation in MMP2 in a 19-year old girl with typical features of Winchester syndrome: severe childhood-onset generalized osteolysis, short stature, mildly coarsened facial features and hypertrichosis, but no subcutaneous nodules. Additional findings included type I diabetes mellitus and hypothyroidism. The mutation (E404K) substitutes an amino acid believed to have a key role in the catalytic activity of MMP2 and is therefore likely to cause complete loss of MMP2 function in the homozygous state. Molecular and clinical findings in this case indicate that Torg/NAO and Winchester syndrome are allelic disorders and represent a clinical spectrum that remains to be explored.

Mutations in the C-propeptide of COL2A1 cause platyspondylic lethal skeletal dysplasia, Torrance type. A.

Zankl¹, L. Neumann², J. Ignatius³, P. Nikkels⁴, C. Schrandner-Stumpel⁵, G. Mortier⁶, H. Omran⁷, M. Wright⁸, K. Hilbert⁹, J. Spranger⁹, B. Zabel⁹, A. Superti-Furga¹. 1) Molecular Pediatrics, CHUV, Lausanne, Switzerland; 2) Inst of Human Genetics, Humboldt University, Berlin, Germany; 3) Dept of Clinical Genetics, Oulu University Hospital, Oulu, Finland; 4) Dept of Pathology, University Medical Center, Utrecht, The Netherlands; 5) Dept of Clinical Genetics, Academic Hospital Maastricht, Maastricht, The Netherlands; 6) Dept of Medical Genetics, University Hospital, Ghent, Belgium; 7) Childrens Hospital, University of Freiburg, Freiburg, Germany; 8) Inst of Human Genetics, Newcastle, UK; 9) Childrens Hospital, University of Mainz, Mainz, Germany.

Platyspondylic lethal skeletal dysplasia Torrance type (PLSD-T) is a rare chondrodysplasia characterized by varying platyspondyly, brachydactyly and metaphyseal changes. Recently, mutations in the C-propeptide of type II collagen have been identified in two patients with PLSD-T, suggesting that PLSD-T may be a type II collagen-associated disorder. We present 8 additional cases with PLSD-T and mutations in the C-propeptide domain of COL2A1. The mutational spectrum includes missense, stop codon and frameshift mutations. All nonsense mutations are located in the last exon, where they could escape nonsense-mediated mRNA decay. We propose that PLSD-T is specifically caused by mutations in the COL2A1 C-propeptide domain, which lead to biosynthesis of an altered collagen chain (as opposed to a null allele). The phenotypic effects could result from a combination of diminished collagen fibril formation, toxic effects through the accumulation of mutated collagen chains inside the chondrocytes and alteration of a putative signaling function of the C-propeptide of type II collagen. We have recently suggested a similar model for spondyloperipheral dysplasia, whose clinical and radiographic features are comparable to those of long-term survivors with PLSD-T (Zankl et al., *Am J Med Genet*, in press). We propose that spondyloperipheral dysplasia and PLSD-T constitute a subfamily of the type II collagenopathies, characterized by distinctive radiological features and specific mutations in the C-propeptide domain.

The reproducibility of mRNA expression and immunoreactive levels of FSH in Chinese hamster ovary cells stably transfected with wildtype and mutant Ala43Pro human FSHB gene constructs. *L.C. Layman, A.D. Clark.* Section of Reproductive Endocrinology, Infertility, & Genetics, Dept OB/GYN, Program in Developmental Neurobiology, Institute of Molecular Medicine, & Genetics, Medical College of Georgia, Augusta, GA.

Mutations in the human follicle stimulating hormone-beta (FSHB) gene cause absent or severely impaired puberty and infertility. All mutations to date result in mRNA expression, but absent protein levels in vitro. Although controls are always used in these assays, the variability of different stably transfected cell lines is unknown, even when colonies are derived from the original plate of cells transfected. The purpose of the current study was to: 1) determine the variability of FSHB expression and immunoreactive FSH levels of individual clones derived from the original plate of transfected cells; and 2) determine if a HTZ Ala43Pro FSHB mutation identified in a female with premature ovarian failure affects transcription and protein levels in vitro. Site directed mutagenesis of pFSH constructs was performed, followed by stable transfection in Chinese hamster ovary (CHO) cells using antibiotic resistance. Either the WT alone, Ala43Pro mutant alone, or both the mutant and WT were stably transfected into CHO cells. Real-time RT-PCR and immunoassay for FSH were then performed. FSH levels were markedly elevated in the cell line expressing Ala43Pro. The initial expression results revealed no difference among the three groups (n= 4 clones each), with mean + SEM as follows: WT=12.17 + 3.89 fg/uL; Ala43Pro = 19.01 +11.90; WT/Ala43Pro = 22.62 +9.65. There was a trend toward increased expression for cell lines coexpressed with WT and Ala43Pro. Additional clones are being analyzed to determine if these preliminary findings hold true with an adequate sample size, as determined by power analysis. In contrast to all previously reported FSHB mutations, the Ala43Pro mutation results in increased immunoreactive FSH levels in vitro, which could be due to increased expression.

Spontaneous mutation over the lifespan of the mouse: Low and constant mutation frequency in the male germline and unchanged mutation types with aging. K.A. Hill^{1,2}, K. Farwell¹, J. Longmate³, W.A. Scaringe¹, J. Wang¹, S.S. Sommer¹. 1) Dept of Molecular Genetics, City of Hope Ntnl Med Ctr, Duarte, CA 91010; 2) Dept of Biology, Univ of Western Ontario, London, ON Canada N6A 5B7; 3) Division of Information Sciences, City of Hope, Ntnl Med Ctr, Duarte, CA 91010.

The frequency and pattern of spontaneous mutation was determined in individual tissues over the life cycle of Big Blue mice. A total of 95.6 million *lacI* transgene sequences were screened, 2,995 mutant transgenes harvested and 2,428 independent mutations identified. Detailed analyses included seven to nine time points during the lifespan of the mouse in adipose tissue and male germline from adolescence/young adulthood (3 months) to very old age (30 months) and in liver and neurons from pre-weaning (10 days) to very old age. The data reveal at least two tissue-specific profiles of spontaneous mutation frequency (elevation with age in adipose tissue and liver and constancy in neurons and male germ cells) and a low mutation frequency in the male germline. Despite differences in the profiles of spontaneous mutation frequency with age, mutation patterns are unchanged with age within a tissue. In middle to late adulthood, significant deviations in the mutation pattern are observed *among* the four tissues, consistent with a minor effect of tissue-specific metabolism. There are no obvious correlations between the rate of cell proliferation and mutation frequency profile with age or deviations in the mutation pattern. The absence of changes in the pattern of most mutations with age despite large numbers of mutations suggests that the qualitative nature of DNA damage and repair does not change with age. Unaltered balance of DNA damage and repair with age in the germline has evolutionary consequences and is of particular interest given the controversy over whether or not increasing germline mutation frequency with paternal age is the cause of reports associating older males with a higher incidence of some types of genetic disease. These most detailed measurements help to constrain hypotheses regarding the role of mutational mechanisms in DNA repair and aging.

Molecular relationships between Myotonic Dystrophy type 1 and 2 pathogenesis. A. Botta¹, L. Vallo¹, E. Bonifazi¹, S. Caldarola², D. Fruci³, A. Nardone¹, F. Gullotta¹, R. Massa⁴, F. Loreni², G. Novelli¹. 1) Dept Biopat, Tor Vergata Univ, Rome, Italy; 2) Dept Biology, Tor Vergata Univ, Rome, Italy; 3) Res Center, Osp Bambino Gesù', Rome, Italy; 4) Dept Neurosc, Tor Vergata Univ, Rome, Italy.

Myotonic Dystrophy (DM) is caused by two mutations: a CTG expansion in 3'UTR region of the DMPK gene (DM1; OMIM 160900) and a CCTG expansion in intron 1 of the ZNF9 gene (DM2; OMIM 602688) respectively on chromosome 19p13 and 3q21. The most accredited mechanism for DM pathogenesis is an RNA gain-of-function. Other findings suggest at least a contributory role of the of DMPK-insufficiency and, by analogy, an altered expression of ZNF9 gene and/or its neighbours may play a role in DM2. To unravel molecular parallels and divergences in the pathogenetic mechanisms leading to both disorders, we have analysed the expression profile of cells and tissues from DM2 patients of the ZNF9 gene and of a set of genes involved in the DM1 phenotypic outcome (CUGBP-1, Sp1, Sp2, Clcn1). We utilized in vitro cell cultures (EBV-transformed lymphocytes) from 5 DM2 patients and 3 unaffected controls. We observed a relative stability in the nuclear retention of ZNF9 mutated transcripts that does not alters the levels of ZNF9 in DM2 cells as verified by QRT-PCR and further corroborated by Western blot analysis, using a polyclonal antibody against the mammalian ZNF9 protein developed by our group. A significant misregulation was instead observed in the CUGBP1, Sp1 and to a lesser extent Sp2 genes expression in lymphoblasts from DM2 patients compared to controls. To determine if this transcriptional alteration could have an effect on the amount of the Clcn1 transcript, we performed QRT-PCR experiments on cDNA from muscle biopsy samples of 3 DM2 patients and 2 controls with a Clcn1-specific assay. Similarly to what already observed in DM1 tissues, DM2 muscle cells showed a marked reduction in Clcn1 mRNA levels of 2.5-3 fold (to 30%-40% of controls). Our results indicate that the DM1 and DM2 overlapping clinical phenotypes may derive, at least partially, from a common trans acting mechanism which traps and misregulates shared genes and proteins.

Mosaicism of a 313 bp deletion and premutation in the *FMR1* gene. P. Limprasert, T. Sripo, C. Charalsawadi, J. Wirojanonte. Faculty of Medicine, Prince of Songkla Univ, Songkhla 90110, Thailand.

The fragile X syndrome (FXS) is the most commonly inherited cause of mental retardation. An affected individual, full mutation, has an increased number of CGG repeats (> 200) and hypermethylation in the *FMR1* gene resulting in absence of the FMR1 protein (FMRP). Genetic diagnosis of this disease relies on the detection of CGG repeat in the *FMR1* gene. The length of the CGG correlates with the repeat instability. Instability may lead to mosaic conditions with a full mutation and premutation or rarely with normal or reduced alleles. We describe a 12-year-old boy who was referred for FXS testing because his younger brother had been diagnosed as a full mutation FXS. He had no striking FXS phenotype except his IQ was 75 (WISC). PCR analysis showed ~100 CGG repeats. Southern blot (EcoRI/EagI with StB12.3 probe) showed a hybridization signal at 3.1 kb corresponding to the unmethylated premutation allele and an additional band of 4.9 kb. We expected that this 4.9 Kb might be a deletion allele. Therefore, we used additional restriction enzymes (HindIII and PstI) that located around the CGG repeat region suggesting the deletion was in the proximal part of CGG repeats. The DNA when digested with EcoRI and NruI and hybridized with StB12.3 probe produced 3.2 kb (unmethylated permuation) and 2.6 kb bands in the patient suggesting the deletion site was distal to the NruI site. We designed primers to amplify the PCR product of 1283 bp in normal control while PCR product of the patients DNA was 1283 and ~970 bps. Direct sequencing analysis from the small PCR product demonstrated a 313 bp deletion and 26 CGG repeats. The breakpoint was located at position 13518 (Gene bank # L29074) and G(CG₂₆). The deletion included the Chi like-element (GGTGGAGG) and the EagI site. The most likely distal break point occurred within the expanded CGG repeat. The premutation allele was assumed to express the FMRP whereas the deletion of the promoter of *FMR1* gene was likely to cause the absence of FMRP. Because of the mosaic pattern, the patient had a mild FXS phenotype. To our knowledge, this is the first mosaicism of premutation and microdeletion in the *FMR1* gene.

FXTAS and SCA10 in American patients with movement disorders. A.I. Seixas^{1, 2}, M. Lin¹, A. Ahuja¹, C. Callahan¹, M. Maurer^{1, 3}, I. Silveira², R.L. Margolis¹. 1) Dpt. of Psychiatry, Johns Hopkins University School of Medicine, Baltimore, MD, USA; 2) UnIGENe, IBMC, University of Porto, Portugal; 3) Dpt. of Physiology and Pathophysiology, University of Heidelberg, Germany.

Fragile X-associated tremor/ataxia syndrome (FXTAS) was recently described in carriers of premutation expansions (55-200 CGGs) in the Fragile X mental retardation gene 1 (*FMR1*). The syndrome is characterized by cerebellar ataxia and intention tremor. The estimated prevalence of premutations in the *FMR1* gene in the general population is 1/813 males and 1/259 females. Recent studies have suggested that these premutations may account for 5% of the cases of sporadic ataxia in adult males. Spinocerebellar ataxia type 10 (SCA10) is a late onset neurodegenerative disorder caused by massive expansions of an ATTCT repeat in the *SCA10* gene. So far, SCA10 has only been described in Mexican and Brazilian pedigrees.

We examined the frequency of FXTAS and SCA10 among patients with movement disorders of unknown cause referred to Johns Hopkins for genetic testing. Genetic analysis for the two *loci* was performed by fluorescent repeat-primed PCR assay for SCA10 (Matsuura and Ashizawa, 2002; Cagnoli *et al*, 2004), and PCR optimized for amplification of GC-rich fragments for FXTAS.

All 209 patients studied for the SCA10 mutation tested negative. Of the 166 individuals (81 males, 85 females, 127 with cerebellar disease, and 60 with basal ganglia disease) tested thus far for the *FMR1* repeat length, only one has an expansion, of approximately 120 CGGs. This premutation carrier is a 51 year old man with an intention tremor and a mild gait abnormality, and a brain MRI revealing cortical and cerebellar atrophy, with an abnormal signal in the middle cerebellar peduncle. These findings are consistent with the diagnosis of FXTAS, though his deceased father was reported to have had a tremor and seizures late in life. Our results confirm that SCA10 is a very rare disease, possibly confined to specific ethnic groups. Our results also suggest that FXTAS is a rare cause of genetically unexplained movement disorders in the American adult population.

Identification and sizing of GAA trinucleotide repeat expansion of Friedreich's Ataxia in 15 Iranian patients. *M. Shafa Shariat Panahi, M. Houshmand.* Medical Genetics Department, National Institute for Genetic engineering and Biotechnology, Tehran, Iran, P.O.Box:14155-6343.

Friedreich's ataxia is a neurodegenerative disorder whose clinical diagnostic criteria for typical cases include a) early onset age, b) autosomal recessive inheritance c) progressive ataxia of limbs and gait and d) absence of lower limb tendon reflexes. It is the commonest genetic cause of ataxia and is associated with the expansion of a GAA repeat in intron 1 of the frataxin gene. Approximately 96% of patients are homozygous for this expansion mutation with 4% being compound heterozygotes for the repeat expansion and a point mutation. We studied 15 Iranian patients (9 females and 6 males) from 7 unrelated families. DNA from each patient was extracted and frequency and length of (GAA) n repeat in the first intron of the gene FRDA was analyzed using a long-Range PCR test. Also we investigated impact of GAA size on neurological findings, age of onset and disease development. Homozygous GAA expansion was found in 12 cases (80 %) all typical cases. In 3 cases (20 %), no expansion was observed, ruling out the diagnosis of Friedreich's ataxia. In cases with GAA expansions, ataxia, scoliosis and pes cavus, cardiac abnormalities and some neurological findings occurred more frequently than in our patients without GAA expansion. Molecular analysis was imperative for diagnosis of Friedreich's ataxia, not only for typical cases, but also for atypical ones. Diagnosis bases only on clinical findings is limited, however, it aids in better screening for suspected cases that should be tested.

Search for the genetic cause of ataxia in a family without living affected patients resulted in an intermediate sized SCA2 allele. *C.C. VerschuurenBemelmans¹, E.R.P. Brunt², R.P. Stulp¹, H.H. Lemmink¹.* 1) Department of Clinical Genetics, Groningen University Hospital, P.O. Box 30001, 9700 RB Groningen The Netherlands; 2) Department of Neurology, Groningen University Hospital.

Mutations in more than 10 different genes have been identified in patients with autosomal dominant cerebellar ataxia (ADCA). Spinocerebellar ataxia type 2 (SCA2) is caused by the expansion of an unstable CAG repeat of the SCA2 gene encoding a polyglutamin tract. Wildtype alleles range from 14 to 31 CAG repeats. Mutant alleles range from 34 to more than 450 CAG repeat units. 32 and 33 CAG repeats are considered to be intermediate repeats. Wildtype CAG repeats are almost always interrupted by one or two CAA triplets whereas expanded SCA2 alleles contain nearly always uninterrupted CAG repeats units. A 52 year old woman contacted us with questions concerning ataxia in her family. Her father started to show clinical features of ataxia at an age of about 30 years. Her uncle started in his mid twenties and her aunt and grandfather around 45 years of age. All patients in this family passed away. In the third generation all eleven individuals are older than 45 years of age and have no symptoms. Since affected family members were not available anymore, only presymptomatic testing was possible for the known genes. Three persons were willing to cooperate in anonymous DNA testing. An intermediate sized SCA2 allele of 33 CAG repeats was identified in one. Sequence analysis of the expanded allele showed a 33 CAG repeat without the presence of CAA interruption. Neurologic examination showed no symptoms. In the literature 2 reports describe a young asymptomatic person, one with 32 and one with 33 repeats, who inherited this allele from their symptomatic parent with 40 repeats. A mother and daughter are reported who both carried alleles with 33 CAG repeats and developed a mild ataxia phenotype later life. Although we can not rule out that our finding is a coincidence and that another unknown gene is the cause of the ataxia in this family, it is likely to suggest that patients in this family carried more than 33 CAG repeats and that during transmission to the next generation a shorter SCA2 allele was passed on.

Autosomal dominant macular degeneration in a *Cynomolgus* monkey (*Macaca fascicularis*) pedigree: Linkage and mutation analysis. R. Ayyagari¹, S. Umeda², R. Allikmets³, A.J. Karoukis¹, R. Ambasudhan¹, H. Okamoto², M.T. Suzuki⁴, K. Terao⁴, A. Mizota⁵, Y. Yoshikowa², Y. Tanaka², T. Iwata². 1) Dept Ophthalmology, Univ Michigan, Ann Arbor, MI; 2) National Institute of Sensory Organs, National Tokyo Medical Center, Tokyo, Japan; 3) Columbia University, New York, NY; 4) Tsukuba primate center for medical science, Tsukuba, Japan; 5) Chiba university graduate school of medicine, Chiba, Japan.

Purpose: To identify the gene associated with early onset macular degeneration with drusen in the macular region segregating in a large *Cynomolgus* monkey pedigree. Histopathological analysis revealed deposits between the RPE and Bruch's membrane. **Methods:** We cloned the monkey homologues of human macular degeneration genes ABCA4, VMD2, TIMP3, EFEMP1, and ELOVL4. Mutation analysis was performed by amplification of exons using DNA from 6 affected and 11 normal monkeys followed by single strand confirmation polymorphism analysis and sequencing. Microsatellite markers linked to human macular degeneration loci were amplified using DNA from 20 affected monkeys and 6 unaffected relatives. Linkage analysis was carried out using MLINK program and affecteds-only model. **Results:** Significant homology was observed between the monkey and human homologs of the five macular degeneration genes cloned. No pathogenic changes were observed in these genes. Linkage analysis did not reveal significant positive LOD scores with markers linked to human macular degeneration loci STGD1, STGD3, STGD4, ARMD1, DHRD, Sorsby's fundus dystrophy, VMD2, MCDR1, CORD5, CORD8, and CORD9. Haplotype analysis of these candidate gene regions further supported exclusion of these loci for harboring the disease-causing gene. **Conclusions:** Involvement of the ABCA4, VMD2, TIMP3, EFEMP1, and ELOVL4 loci has been excluded in the monkey pedigree by linkage, haplotype and mutation analysis. Furthermore, by linkage analysis, we have also excluded the loci for STGD1, STGD4, ARMD1, MCDR1, CORD5, CORD8 and CORD9 conditions showing phenotypic overlap with the disease observed in affected monkeys. Macular degeneration in our monkey pedigree is likely to be due to mutations in a novel gene.

A novel missense mutation in the OPA1 gene found in a large Iranian family with Autosomal Dominant Optic Atrophy (ADOA). *s. dadgar*^{1,2}, *m. garshasbi*², *e.n. haghghi*², *s. schimpf*³, *b. wissinger*³, *s. dadgar*⁴, *o.e. khorasani*⁵, *y. shafeghati*², *h. najmabadi*². 1) Best Medical Research , Charles H. Best Institute, University of Toronto, Ontario, Canada; 2) Genetics Research Center, The Social Welfare and Rehabilitation Sciences University, Tehran, Iran; 3) Molecular Genetics Laboratory at the University Eye Hospital, Tbingen, Germany; 4) George Washington University Medical Center, Washington DC, USA; 5) Clinical Skill Lab Center, Medical Science University, Firoozgar Hospital, Tehran, Iran.

Autosomal dominant optic atrophy (ADOA) is the most frequent form of hereditary optic neuropathies with an estimated disease prevalence ranging between 1:12000 and 1:50000 in different populations. We describe here a large Iranian family with 40 affected individuals (31 alive and 9 dead) showing a dominant way of inheritance of optic atrophy. For none of the patients pre-, peri- or postnatal problems have been reported. On average, at the age of 14 the visual acuity of the patients began to decrease and progressed gradually. In almost all of the patients the vision is about 10/100. Some of them have been tested by perimetry revealing central scotoma. The study of visual evoked potentials (VEPs) showed prolonged latency and decreased amplitude. These and the diagnostic findings from fundoscopy and retinal angiography support the diagnosis of optic atrophy. A major locus for optic atrophy maps to chromosome 3q28 containing the gene OPA1. Using five microsatellite markers from chromosome 3 (D3S2398, D3S2418, D3S3562, D3S1265 and D3S1311) we could confirm their cosegregation with the disease. By direct sequencing of exons 8 to 16 and 27 from OPA1 we have identified a novel heterozygous missense mutation (c.1313A>G) at the first position of exon 14 replacing the normal Aspartic acid by a Glycine (Asp438Gly). At the same position another missense mutation (1313A>T; Asp438Val) has been reported before, indicating the importance of this position in OPA1.

DENATURING HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY (DHPLC) FOR THE MUTATIONAL ANALYSIS OF THE SPAST GENE. A. Magariello¹, R. Mazzei¹, F.L. Conforti¹, A. Patitucci¹, A.L. Gabriele¹, G. Peluso¹, C. Ungaro¹, T. Sprovieri¹, M. Mancuso², S. Di Mauro², D. Branca³, U. Aguglia³, M. Muglia¹. 1) Inst Neurological Sci, National Research Council, Mangone, Cosenza, Italy; 2) Dept of Neurology, Columbia University College of Physicians and Surgeons, New York, USA; 3) Regional Epilepsy Center, A.O. Bianchi Melacrino Morelli, Reggio Calabria, Italy.

The hereditary spastic paraplegia (HSP) is characterized by progressive spasticity and hyperreflexia of the lower limbs. Clinically HSP is classified as pure or complicated form. Autosomal Dominant (AD), Autosomal Recessive (AR) and X-linked inheritance occur in both forms. Pure ADHSP is probably the most common form (40%) and up to date 10 loci have been identified. This form is caused by mutations in the SPAST gene that is located on chromosome 2p (SPG4 locus), comprising 17 exons and encodes the protein spastin, a member of the AAA family of adenosine triphosphatases. Over 100 spastin mutations include missense, nonsense and splice site point mutations, as well as little insertions and deletions. To date, the SPAST gene mutations have been revealed by SSCP analysis or by direct sequencing of cDNA. In this study we described a new method for the rapid screening of the SPAST gene by DHPLC. We performed screening mutations by DHPLC in three families with SPG4-linked HSP. In two families heteroduplex DHPLC profiles were observed in exon 5 and exon 15 respectively. Direct sequencing revealed two previously described stop codon mutations (R562Stop and T269Stop). In the last family different heteroduplex DHPLC profiles were observed in the exons 6 and 14. Direct sequencing of the exon 6 showed an already described G>A transition (P879P) and the sequence analysis of exon 14 revealed a new polymorphism in intron 13 (IVS1310). Because no additional heteroduplex patterns were observed in this family, we performed a direct sequence of the spastin, but no variations have been detected, confirming the DHPLC results. The use of DHPLC for mutation detection represents a significant advantage in the molecular diagnosis of HSP caused by mutation in the SPAST gene and it should be used for the rapid screening of a large number of patients.

Identification of genes underlying hypodontia. *P.I. Patel*¹, *P. Tarpey*², *G. Mendoza*¹, *C. Gonzales*¹, *P. Das*³, *V. Ninis*³, *D.W. Stockton*⁴, *R. Scarel-Caminaga*⁵, *L. Nino-Rosales*³, *E. Figuerido*⁶, *S. Leal*⁴, *M.R. Stratton*², *S. Line*⁵. 1) Institute for Genetic Medicine, University of Southern California, Los Angeles, CA; 2) The Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, UK; 3) Department of Neurology, Baylor College of Medicine, Houston, TX; 4) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 5) Faculty of Odontology of Piracicaba-UNICAMP, Brazil; 6) Federal University of Alagoas, Maceio, Brazil.

The congenital absence of teeth is a common developmental anomaly of human dentition that affects approximately 20% of the population. Although new genetic and molecular approaches have increased our understanding of the molecules that control tooth patterning (number, position, shape and size), the precise nature of the genes underlying congenitally missing teeth or hypodontia remains poorly understood. Hence, understanding the molecular basis for missing teeth is an important goal, that is both timely and significant to the practice of orthodontics. Our long-term goal is to elucidate factors important for tooth development in humans. We have sampled large families segregating autosomal dominant hypodontia involving a single premolar or premolars and canines. Total genome scans have been completed and fine-mapping is in progress for these families, as well as mutation analysis in candidate genes. We have also mapped the locus for an X-linked dominant form of hypodontia involving incisors to Xp11.22-Xq13.1. High-throughput sequencing is being used to identify the gene underlying this condition and these results will be presented. (Supported by NIH grant DE14102, Wellcome Trust and Center for Inherited Diseases Research).

The positional candidate genes ENO1 and RBP7 do not harbor mutations in the coding sequence for Schnyder's crystalline corneal dystrophy. *V.P. Theendakara¹, G. Tromp¹, H. Kuivaniemi^{1, 2}, P.S. White^{5, 6}, R.S. Winters⁵, J.S. Weiss^{3, 4}.* 1) CMMG, Wayne State University School of Medicine, Detroit, MI; 2) Department of Surgery, Wayne State University School of Medicine, Detroit, MI; 3) Department of Ophthalmology, Wayne State University School of Medicine, Detroit, MI; 4) Kresge Eye Institute, Wayne State University School of Medicine, Detroit, MI; 5) Division of Oncology, Children's Hospital of Philadelphia, University of Pennsylvania, PA; 6) Department of Pediatrics, University of Pennsylvania, PA.

Schnyder's crystalline corneal dystrophy (SCCD) is a rare autosomal dominant eye disease. The clinical manifestations of the disease may include bilateral corneal clouding, arcus lipoides and anterior corneal crystalline cholesterol deposition. A genome wide scan with two large Swede-Finn families mapped the SCCD locus to 1p36 (Shearman et al. *Hum Mol Genet* 5: 1667- 1672, 1996). Eleven additional families were included to narrow the critical region for SCCD. Recombination-based haplotype analysis refined the candidate interval to 2.32 Mb between markers D1S1160 and D1S1635 (Theendakara et al. *Hum Genet* 114: 594-600, 2004). Within this region there are twenty known and nine putative genes. Biologically plausible candidate genes that are expressed in the eye such as ENO1 (enolase1, LocusID 2203), encoding both a glycolytic enzyme and a lens structural protein, and RBP7 (retinol binding protein, LocusID 116362), which belongs to CRBP family that interacts with small binding proteins, were analyzed. The first phase of sequencing was performed in the coding regions and the exon-intron boundaries, to detect sequence variations and splice site mutations. Three sequence variants (IVS1G+ 61C, IVS2T+51G and IVS5C-9T) were detected in ENO1 gene. Affected individuals did not have any sequence changes in the coding regions, with respect to the reference genomic sequence (NT_021937) in either ENO1 or RBP7. These findings suggest that neither ENO1 nor RBP7 are involved in SCCD.

Evaluating a potential role for the POLK gene product in female infertility and/or ovarian failure. *L.D. McDaniel, R.A. Schultz, E.C. Friedberg.* Department of Pathology, Univ Texas SW Medical Ctr, Dallas, TX.

Female infertility and ovarian failure are significant medical concerns within the human population and represent subjects in search of candidate genes. DNA polymerase kappa (POLK), a member of the recently discovered Y family of DNA polymerases, that in vitro have demonstrated translesion synthesis past DNA damage that has stalled the normal replicative polymerases. This process has been shown to be relatively error prone. Bypass polymerases, but not POLK, have been shown to participate in the introduction of nucleotide changes in the immunoglobulin genes during the process somatic hypermutation. POLK protein has also been shown to bypass thymine glycol, Acetylaminofluorene, and benzo[a]pyrene adducts but not UV induced adducts in DNA. The human POLK gene is expressed at high levels in the seminiferous tubules of the testis, the ovaries and adrenal cortex, as well as at lower levels in most other tissues. The expression pattern of POLK makes it an interesting candidate for specific roles in germinal tissues. We have a knockout mouse model for POLK to evaluate the phenotypes. Mutant animals are viable and exhibit no overt phenotypes. Given the expression pattern, we examined the fertility of Polk mice. Crosses between Polk mutant or heterozygous males and wild type females yield an average of 8 pups per litter, equivalent to that seen in wild type crosses. In contrast, crosses between Polk females and wild type, heterozygous, or mutant males yielded equivalent results with litters of 3 to 4 pups per litter. Heterozygous females crossed to any genotype produce an intermediate litter size. Lost animals represent all genotypes equally. Thus, deficiency in Polk protein, including haploinsufficiency, yields a female-specific reduction in fertility, due to a compromise in the ability of females to initiate and/or develop fetuses to term. Quantitation of implantation rate and age of fetal demise will be presented. The possible function(s) for Polk in the adrenal cortex versus the ovary will be discussed. Additionally, approaches to role(s) for POLK mutations or polymorphisms in human infertility and/or ovarian failure and fetal demise will be discussed.

Cirhin, the protein mutant in NAIC is a transcriptional cofactor of HIVEP1 DNA binding protein. *B. Yu, G.A. Mitchell, A. Richter.* Division of Medical Genetics, Hôpital Sainte-Justine, Montréal, QC, Canada.

North American Indian childhood cirrhosis (NAIC/CIRH1A, OMIM 604901) is a severe, autosomal recessive intrahepatic cholestasis mapping to 16q22. All NAIC patients tested to date are homozygous for a mutation that changes a conserved arginine at position 565 to tryptophan (R565W) in cirhin, the 686 amino acid protein product of the locus. We determined that cirhin is a nucleolar protein. It has an active C-terminal monopartite nuclear localization signal (NLS) and a unique nucleolar localization signal. While R565W alters the predicted secondary structure of cirhin, it has no effect on subcellular localization (Yu et al, in preparation). Yeast 2 hybrid screening against human liver cDNA library revealed a single interaction partner (CIRIP, cirhin interaction protein). It is the 684 aa C-terminal fragment of HIVEP1 containing the 2nd C2H2 zinc finger domain and a domain rich in acidic residues. The R565W mutation decreased the interaction. HIVEP1 is a C2H2 zinc finger DNA binding protein that regulates transcription by binding to similar NF- κ B motifs such as those found in HIV-1 LTR, p53 and IRF-1. To validate the observed interaction between cirhin and CIRIP, they were subcloned into pcDNA3.1- and the HIV-1 LTR enhancer sequence (GGGACTTTCC) into the PGL3 promoter vector. Our results show that individually cirhin and CIRIP can significantly increase the transcriptional activity of luciferase (CIRIP: 40-70%, cirhin: 20-50%, compared to control) in HeLa cells. Thus, in contrast to claims that only full length HIVEP1 has function on the HIV-1 LTR enhancer, we find that CIRIP is also active. Co-transfection of Cirhin and CIRIP increases luciferase activity more significantly (80-150 %). Our current hypothesis is that cirhin binds to endogenous HIVEP1 or other interaction partners, and increases the transcriptional activity of the HIV1 LTR enhancer in HeLa cells. The role of R565W on this transcriptional enhancer is now under investigation. The effect of CIRIP on HIV1 enhancer supports the idea that it may be a functional alternative splice product of HIVEP1. Supported by the Canadian Institutes of Health Research.

Loss of the Shwachman-Diamond syndrome gene (*SBDS*) causes early embryonic lethality. *S. Zhang*^{1, 2}, *M. Shi*², *J.M. Rommens*^{1,2}. 1) Dept. of Molecular and Medical Genetics, University of Toronto, Toronto, ON, Canada; 2) Program in Genetics & Genomic Biology, The Hospital for Sick Children, Toronto, ON, Canada.

Shwachman-Diamond syndrome (SDS, MIM 260400) is a multi-system autosomal recessive disorder caused by mutations in the *SBDS* gene. Individuals with SDS display clinical features of exocrine pancreatic insufficiency, hematological dysfunction and skeletal abnormalities. *SBDS* is a highly conserved gene of unknown function with homologs in vertebrates, plants and archaea. Indirect evidence implicates a role in RNA metabolism. In the mouse, *SBDS* expression is broad and variable with highest levels in the early embryo. To elucidate the function of *SBDS*, we have developed an animal model using gene targeting techniques. A null allele was generated by insertion of an *IRES-lacZ-PGK-Neo* cassette in exon 1 to lead to interruption of translation. Mice, with one interrupted allele (*SBDS*^{-/+}), are phenotypically indistinguishable from their homozygous wild type littermates (*SBDS*^{+/+}) in viability, growth and fertility. No homozygous mutant mice (*SBDS*^{-/-}) were born of more than 20 *SBDS*^{-/+} intercross matings while 74 mice (65%) were heterozygous and 39 mice (35%) were homozygous for the wild type allele. Abnormal embryos were found at developmental stage 8.0-8.5dpc with the *SBDS*^{-/-} genotype, indicating that loss of *SBDS* leads to early embryonic lethality. These findings are consistent with the absence of homozygosity of common early truncation alleles in SDS patients and suggest a critical role for *SBDS* in early development.

Cellular, spatial, and temporal expression of developmentally regulated GTP-binding protein 2 (*DRG2*). V.A. Vinoverski¹, C.N. Vlangos², S.H. Elsea^{1,2,3}. 1) Dept. of Zoology, Michigan State University, East Lansing, MI; 2) Genetics Graduate Program, Michigan State University, East Lansing, MI; 3) Depts. of Human Genetics and Pediatrics, Virginia Commonwealth University, Richmond, VA.

Smith-Magenis syndrome (SMS) is a multiple congenital anomalies and mental retardation disorder with a distinct phenotype characterized by craniofacial, skeletal, neurological, and sleep abnormalities, in addition to maladaptive behaviors including self-injury and explosive temper. SMS is usually associated with an interstitial deletion of chromosome 17p11.2. We previously characterized SMS patients without a FISH detectable 17p11.2 deletion who carry dominant frame-shift mutations in the *RAI1* gene, which maps to chromosome 17p11.2. While it is likely that haploinsufficiency of *RAI1* is responsible for most of the SMS phenotype, SMS patients with *RAI1* mutations have not been found to have many of the more variable features often seen in patients with a 17p11.2 deletion. Thus, additional genes mapping to 17p11.2 may contribute to these less penetrant characteristics of SMS. *DRG2*, a member of the GTPase superfamily, maps to the SMS critical region. The mouse ortholog of human *DRG2* maps to chromosome 11 in the region syntenic to human chromosome 17p11.2. In order to understand the biochemical role of *DRG2/Drg2*, we examined the cellular localization of *Drg2* in COS-7 cells through use of a GFP-fusion construct. GFP-*Drg2* fusion protein was detected in the golgi apparatus and endoplasmic reticulum. GFP-*Drg2* was also present in small protein bundles throughout the cytoplasm and at the junctions between neighboring cells. We also studied the spatial and temporal expression of *Drg2* during development by immunohistochemistry (IHC) on sectioned mouse embryos from embryonic day eight through birth. Throughout mouse development, the IHC studies showed high levels of *Drg2* expression in the developing brain and spinal cord. Staining was also seen in numerous spinal ganglia. These data suggest a possible role in cellular communication and/or molecular trafficking between the golgi apparatus and the cell membrane especially in the developing neural tissue.

Deletions of conserved non-genic sequences (CNGs) upstream and downstream of *FOXL2* as a novel disease-causing mechanism in BPES. *D. Beysen*¹, *B.P. Leroy*¹, *A. Lucassen*², *J. Yates*³, *J. Clayton-Smith*⁴, *H. Ilyina*⁵, *S. Sklower Brooks*⁶, *S. De Jaegere*¹, *L.M. Messiaen*⁷, *A. De Paepe*¹, *E. De Baere*¹. 1) Ctr Med Genet, Ghent Univ Hosp, Ghent, Belgium; 2) Wessex Clin Genet Service, PAH, Southampton, UK; 3) Dept of Med Genet, Addenbrooke's Hosp, Cambridge, UK; 4) St Mary's Hosp, Manchester, UK; 5) Beloruss Inst for Hered Dis, Minsk, Russia; 6) NY State Inst for Basic Research, NY, USA; 7) Dept of Genet, UAB, Birmingham, AL, USA.

The expression of a gene requires not only the presence of an intact coding sequence, but also a correctly functioning regulatory control. Regulatory elements can be located at large distances from transcription units on which they exert their effect, as shown in several developmental genes. In previous studies of the developmental disorder blepharophimosis syndrome (BPES, MIM 110100), an eyelid malformation associated or not with premature ovarian failure (POF), we identified a molecular defect in 70% of BPES patients (76 intragenic *FOXL2* mutations and 8 (micro)deletions including *FOXL2*). Here, we show that BPES results from deletions located outside the transcription unit of *FOXL2*. Of the 5 deletions identified 4 were located at a minimal distance of 100 kb upstream of *FOXL2*, being telomeric to 3 known translocation breakpoints in BPES patients. These deletions were found in two sporadic BPES cases and in two BPES type II families with normal psychomotor development. Their shortest region of overlap (SRO) is 100 kb and contains several highly conserved non-genic sequences (CNGs) present in human, mouse, chicken and goat. Intriguingly, the human orthologous region of an 11.7 kb goat sequence deleted in the PIS goat, considered as an animal model for BPES, is also contained in this SRO. In addition, one 150-kb deletion was found at 13 kb downstream of *FOXL2* in a BPES family where germinal mosaicism was proven at the molecular level in the sperm of an unaffected transmitting patient, indicating this is an important counselling issue. In conclusion, we postulate that *FOXL2* transcription is altered by removal of these CNGs, acting as long-range *cis* regulatory elements of gene expression and we propose this as a novel mechanism underlying BPES.

Four Common Glomulin Mutations Cause Two-Thirds of Glomuvenous Malformations (Familial Glomangiomas): Evidence for a Founder Effect. P. Brouillard¹, M. Ghassib¹, A. Penington², L.M. Boon¹, A. DompMartin³, K. Temple⁴, M. Cordisco⁵, D. Adams⁶, F. Piette³, J. Harper⁴, S. Syed⁴, F. Boralevi³, A. Tab³, S. Danda², E. Baselga⁷, O. Enjolras⁸, J.B. Mulliken⁹, M. Vikkula¹. 1) Christian de Duve Inst & UCL, Brussels, Belgium; 2) Univ of Melbourne, St. Vincent's Hospital, Australia; 3) CHU Caen & CHU Bordeaux & CHRU Lille, France; 4) Southampton Univ & Hospital NHS Trust & Great Ormond Street Hospital for Children NHS Trust, UK; 5) Hospital Nacional de Pediatria, Argentina; 6) Children's Hospital Medical Center, Cincinnati, USA; 7) Hospital de la Santa Creu i Sant Pau, Spain; 8) Hôpital Lariboisière, France; 9) Children's Hospital, Boston, USA.

Glomuvenous malformation (GVM) is a localized cutaneous vascular lesion histologically characterised by abnormal smooth muscle-like glomus cells in the walls of distended endothelial-lined channels. We linked inheritable GVMs to chromosome 1p21-22 (Boon *et al.* 1999), and found the cause to be truncating mutations in *glomulin* (*glmn*) (Brouillard *et al.* 2002). *Glomulin* expression is restricted mainly to vascular smooth muscle cells during murine development (McIntyre *et al.* 2004). In addition, we identified a double-hit mutation in one lesion (Brouillard *et al.* 2002). This finding supports our hypothesis that GVM is due to complete localized loss of function and explains the paradominant mode of inheritance. Here, we report on the identification of a mutation in *glomulin* in 23 additional families with GVM. Three mutations are new; the others have been described previously. Among the 17 different inherited mutations in *glomulin* known to date in 43 families, the 157delAAGAA mutation is the most frequent and was present in 21 families (48.8%). One mutation was found in 5 of the families (11.8%) and two other ones were determined in two families (4.7% each). Polymorphic markers suggested a founder effect for all four mutations. Screening for these mutations should lead to a genetic diagnosis in about 70% of patients with inherited GVMs. So far, a mutation in *glomulin* has been found in all GVM families tested, thus demonstrating locus homogeneity. (vikkula@bchm.ucl.ac.be) (<http://www.icp.ucl.ac.be/vikkula>).

Haplotype structure and linkage disequilibrium across the X-linked Chronic Granulomatous Disease gene (CYBB) in human populations. *E.M. Tarazona-Santos, T. Bernig, S.J. Chanock.* Section of Genomic Variation, Pediatric Oncology Branch, National Cancer Institute/NIH, Gaithersburg, MD.

Chronic granulomatous disease (CGD) is a hereditary, primary immunodeficiency characterized by an increased susceptibility to bacteria and fungi infections due to a defect in the phagocytic respiratory burst. CGD is caused by a mutation in one of four genes in the phagocyte NADPH oxidase. Nearly seventy percent of CGD cases are X-linked and due to mutations in the CYBB gene (mapped to Xp21.1), which codes for the trans-membrane gp91 component of the phagocyte NADPH oxidase. The CYBB gene is 33kb in size and contains 13 exons. We sequenced 14 kb of the CYBB gene (including 2 kb of the 5flanking region and all 13 exons) in 102 healthy individuals from four self-described ethnic groups of the SNP500cancer program (<http://snp500cancer.nci.nih.gov>); this includes 31 European, 24 African, 23 Hispanics and 24 Pacific Rim subjects. We validated 14 SNPs in CYBB with bi-directional sequence analysis; of these, there is only one coding variant, a previously described non-synonymous C/T transition at position 23817 in exon 9. We determined the haplotype structure as well as the pattern of linkage disequilibrium in the four ethnic groups using common SNPs (i.e., frequency greater than 10%); overall, there is a substantial difference in haplotype frequencies in CYBB. Six SNPs were shared by more than one population, whereas 8 are population-specific (six in subjects of African ancestry). Further haplotype analysis demonstrates different patterns of genetic diversity and linkage disequilibrium between African and non-African groups. Knowledge of the haplotype structure should be useful to investigate the possibility that rare-family mutations in CYBB (resulting in CGD) could preferentially arise on select background haplotypes. Moreover, because the phagocyte NADPH oxidase is an integral component in host defenses against pathogens, haplotype-tagging SNPs in CYBB gene should be applied to candidate gene association studies, especially targeting infectious and auto-immune diseases.

Delineation of Cohen Syndrome following a large-scale genotype-phenotype screen. *K.E. Chandler¹, R. Wilkinson², F.D.C. Manson^{1,2,3}, J. Kolehmainen^{4,5}, J. Clayton-Smith¹, A-E. Lehesjoki^{4,5,6}, G.C.M. Black^{1,2,3}.* 1) Academic Unit of Medical Genetics and Regional Genetics Service, University of Manchester, Manchester, UK; 2) Academic Unit of Ophthalmology, University of Manchester, Manchester, UK; 3) Centre for Molecular Medicine, University of Manchester, Manchester, UK; 4) Folkhäsen Institute of Genetics, University of Helsinki, Helsinki, Finland; 5) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 6) Neuroscience Centre, University of Helsinki, Helsinki, Finland.

Cohen syndrome (CS) is a rare autosomal recessive condition characterised by developmental delay, facial dysmorphism, retinal dystrophy and neutropenia. This pleiotropic phenotype coupled with a lack of full clinical data can lead to misdiagnosis, creating confusion in the literature. We have proposed precise diagnostic criteria following detailed clinical studies in the UK and Finland and found that COH1, a novel widely expressed gene, is mutated in a number of these patients.

We have now performed a comprehensive genotype-phenotype study in 59 patients with a provisional diagnosis of CS, the largest cohort of CS patients assembled to date. We found 22 different COH1 mutations in 28 of 37 probands identified as having CS by our diagnostic criteria. An additional 3 novel mutations were identified in probable CS patients with incomplete clinical data. The majority of mutations are predicted to result in a null allele through frameshift or nonsense sequence alterations. In the 22 patients with a provisional diagnosis of CS, but who did not fulfil the diagnostic criteria, only one patient had a heterozygous sequence alteration, which was not identified in 192 control chromosomes.

This study demonstrates that predicted pathogenic sequence alterations are only associated with CS patients and that there is no apparent genotype-phenotype correlation within this group. It validates our proposed diagnostic criteria for the accurate diagnosis of CS and provides a basis for the laboratory screening of COH1.

Genomic Rearrangements in the CFTR gene: results of a worldwide survey; analysis of mutational mechanisms.

C. Ferec¹, MP. Audrezet¹, JM. Chen¹, O. Raguene¹, M. Macek², C. Bombieri³, PF. Pignatti³, T. Casals⁴, G. Cutting⁵, B. Williamson⁶, D. Barton⁷, T. McDevitt⁷, S. Fattoum⁸. 1) Lab de Biogenetique-U613, INSERM-UBO, CHU, EFS-Bretagne, Brest Cedex 2, France; 2) Charles University, Prague, Czech Republic; 3) University of Verone, Italy; 4) Institut Recerca Oncologica, Hopital Duran, Barcelona, Spain; 5) John Hopkins School of Medicine, Baltimore, USA; 6) Murdoch Children's Research Institute, Victoria, Australia; 7) National Centre for Medical Genetics, Dublin, Ireland; 8) Hopital d'Enfants, Tunis, Tunisia.

Cystic Fibrosis is caused by mutations in the Cystic Fibrosis conductance Regulator gene (CFTR/ABCC7). Over 1300 mutations have been so far identified, most of these being point mutations. We have recently reported (Audrezet et al. Human Mutation 2004) that gross genomic rearrangements could account for a part of unidentified alleles. In the present work we have set up a large collaborative study including CF chromosomes with at least one unidentified allele after an exhaustive scanning of the coding sequence of the gene (CF chromosomes were from Spain, Ireland, Scotland, Czech Republic, Italy, Belgium, France, Australia, America United States) using a QMPSF technique (Quantitative Multiplex PCR of short fragments). With the exception of Tunisia (absence of deletion), in these different populations, we have found between 10 to 20 % of deletions/insertions depending on the origin of the CF chromosomes. The breakpoint of the deletions were precisely determined and the underlying mechanisms of mutagenesis was carefully analyzed. Complex genomic rearrangements are far more frequent than previously expected and this allows us now to propose that the ideal strategy for exhaustive detection of mutations in the CFTR gene would included a screening for the 30 common mutations, a scanning of the 27 exons by D-HPLC and a finaly scanning of the coding sequence of the gene by QMPSF. This stepwise approach should maximize the mutant allele detection rate in most populations of caucasian origin.

Involvement of EIF2B genes in a large cohort of POF patients. A. FOGLI¹, F. GAUTHIER-BARICHARD¹, R. SCHIFFMANN², V. VANDERHOOF³, V. BAKALOV³, L. NELSON³, O. BOESPFLUG-TANGUY³. 1) Facult de Mdecine, INSERM U384, Clermont-Fd, France; 2) Developmental and metabolic neurology branch, NIH, Bethesda, Maryland, USA; 3) National institute of child health and human development, NIH, Bethesda, Maryland, USA.

Premature Ovarian Failure (POF) can be expressed as a primary or secondary amenorrhea lasting more than six months, associated with elevated gonadotrophins before the age 40 years. Premature OF affects 1 percent of all women and occurs in 0.1 percent before the age of 30 years. Other than karyotype abnormalities, including various X chromosome such as Turner syndrome, very few genes are known to be associated with this ovarian dysfunction. Recently, three of the five EIF2B genes (EIF2B2, 4 and 5, eight mutations) were involved in seven patients who presented with POF and white matter abnormalities on MRI (ovarioleukodystrophy). These genes encode the five subunits of the eucaryotic initiation factor 2B (eIF2B alpha to epsilon), which is involved in the first step of the protein synthesis. In ovarioleukodystrophy, a phase without neurological symptoms and an apparently isolated form of POF could be observed. Thus, to test further the involvement of EIF2B genes in classical POF, we screened a series of 93 patients with OF but without identified leukodystrophy or neurological symptoms for these eight mutations and two additional mutations found in patients with milder forms of eIF2B-related disorders. No abnormalities were identified. We concluded that eIF2B mutations already described as causing POF associated with white matter abnormalities are an uncommon cause of spontaneous premature ovarian failure (95 percent confidence limit under 3.2 percent of cases).

Program Nr: 2549 from the 2004 ASHG Annual Meeting

GJB2 mutations - passage through Iran. *K. Kahrizi¹, C. Nishimura³, Y. Riazalhosseini¹, M. Malekpour¹, A. Daneshi², M. Farhadi², M. Mohseni¹, N. Mahdieh¹, N. Bazazzadegan¹, A. Naghavi¹, M. Avenarius³, K. Javan¹, R.J.H. Smith³, H. Najmabadi¹.* 1) Genetics research center, Welfare & Rehab Univ, Tehran, Iran; 2) Rasoul Akram Hospital, Iran University of Medical Sciences, Tehran, Iran; 3) Molecular Otolaryngology Research Laboratories, Department of Otolaryngology, University of Iowa, Iowa City, IA, USA.

Hereditary hearing loss (HHL) is a very common disorder. When inherited in an autosomal recessive manner, it typically presents as an isolated finding. Interestingly and unexpectedly, in spite of extreme heterogeneity, mutations in one gene, GJB2, are the most common cause of congenital severe-to-profound deafness in many different populations. In this study of the Iranian population, we assessed the contributions made by GJB2 mutations and g.1777179_2085947del (hereafter called (GJB6-D13S1830)) to the autosomal recessive non-syndromic deafness genetic load. Probands from 664 different nuclear families were investigated. GJB2-related deafness was found in 111 families (16.7%). The carrier frequency of the 35delG mutation showed a geographic variation that is supported by studies in neighboring populations. (GJB6-D13S1830) was not found. Our prevalence data for GJB2-related deafness reveal a geographic pattern that mirrors the south-to-north European gradient and supports a founder effect in south-eastern Europe.

Program Nr: 2550 from the 2004 ASHG Annual Meeting

F508 in association with 7T - the exception that proves the rule? *D. Kennedy, T. Ashfield, J. Guo, D. Ramadeen, R. Rezaie, M. Shama, M. Skuterud, D.J. Allingham-Hawkins, H.M. Bedford.* Genetics Program, North York General Hospital, Toronto, ON, Canada.

A cord blood sample was referred for CF testing on a newborn male at 25% risk for CF. His 3.5 year old sister had been diagnosed only two weeks prior to his birth and her genotype was reported as F508/F508 by another lab. Both the baby's sample and samples from each parent were tested using the Innogenetics CFTR36 Probe Array kit which tests for 36 mutations and the 5T/7T/9T polymorphisms in intron 8. The baby was found to be neither affected nor a carrier but an unusual result was obtained with the father's sample. The father's genotype was F508/+, 7T/7T. The F508 mutation is hypothesized to have arisen in Europe 10,000 years ago (Casals *et al.*, 1992) and linkage disequilibrium has been shown with a number of polymorphisms including the 9T allele. The finding of F508 in *cis* with 7T was unusual enough to prompt a literature search, with no success, to find a similar case. The clinical significance of this finding is unknown; however, it is interesting to note that the affected child has had a relatively mild course to date. She weighed 8 lbs at birth with no meconium ileus or failure to thrive. At the time of diagnosis (approx. 3.5 years), her only overt symptom was frequent, large, oily stools. She was above the 75th percentile for weight and at the 75th percentile for height. She had not experienced more than an average number of respiratory infections nor treatment with antibiotics than expected for a child her age. There was no history of asthma. Laboratory analyses did reveal pancreatic insufficiency and vitamin E deficiency, both of which were previously undetected. Is it possible that this relatively mild clinical course is related to her genotype, specifically to having F508 in *cis* with 7T - which has a lower efficiency of appropriate exon 9 splicing than 9T - on one allele? Perhaps, but it is difficult to imagine how 7T could moderate the effect of F508 on a molecular level and this can not be determined based on a single case. Knowledge of the existence of such cases is important in the laboratory, however, especially from a quality assurance perspective.

Genotype/Phenotype correlation of 5q13 region genes in Spinal Muscular Atrophy patients from India. A.

Kesari¹, S. Phadke¹, S. Patil¹, U. Misra², G. Chandak³, B. Mittal¹. 1) Dept of Genetics, Sanjay Gandhi PostgraduateInst, Lucknow, India; 2) Dept of Neurology, Sanjay Gandhi PostgraduateInst, Lucknow, India; 3) Centre for cellular and Molecular Biology, Uppal Road, Hyderabad.

Spinal muscular atrophy is an autosomal recessive neuromuscular disorder, which leads to symmetrical muscle weakness and atrophy. SMA has been classified into four groups based on the age of onset and clinical severity of the disease. Homozygous deletion in SMN1 gene causes the disease but the clinical severity may be modified by copy number of homologous gene SMN2 as well as other genes in the flanking region. In the view of paucity of data regarding genotype/phenotype correlation, this study has been undertaken to determine the correlation in SMA patients by using the SMN and NAIP genes and two polymorphic markers. Clinically and neurophysiologically diagnosed SMA patients were included in the study. Gene deletion study was carried out in 49 SMA patients, 15 Segmental SMA (Hirayama) patients and 50 controls of same ethnic group. Both SMN1 and NAIP genes were homozygously deleted in 69 % and 31% respectively in classical SMA patients. No point mutations were found in exon 3 and intron 6 through exon 8 by sequence analysis of non deletional patients. Two to four alleles of the markers C212 and C272 were observed in normal individuals. However, majority of Type I patients showed only one allele from both markers whereas in Type II and III patients, 2-3 alleles were observed. The SMN2 copy number in our type III patients showed that patients carry 3-5 copies of SMN2 gene. Our results suggest that NAIP and H4F5 along with SMN2 copies may modify the SMA phenotype.

Novel and Recurrent Mutations in the NF1 Gene in Korean Patients with Neurofibromatosis Type 1. *C.H. Lee¹, H.W. Lee¹, E.S. Park¹, M.J. Lee¹, J.S. Lee^{1, 2}.* 1) Brain Korea 21 Project for Medical Science, Yonsei University, Seoul, Korea; 2) Dept Clinical Genetics, Yonsei Univ Col Medicine, Seoul, Korea.

Neurofibromatosis type 1 (NF1) is one of the most common autosomal dominant disorder with an incidence of 1 : 3,500 which is caused by mutations in the NF1 gene. NF1 is characterized particularly by cafe-au-lait spots and fibromatous tumors of the skin. The NF1 gene is located on the chromosome 17q11.2 and spans approximately 350 kb of genomic DNA and it consist of 60 exons and translates into neurofibromin. The neurofibromin comprises 2818 amino acids and has an estimated molecular weight of 327 kDa. The central region of neurofibromin (encoded by exons 21-27) possesses marked homology to Ras-GTPase activation proteins (GAPs). Screening of NF1 gene is complicated because of the large size of the gene, the presence of pseudogenes, the great variety of possible lesions, and the lack of significant mutational clustering. We screened for mutations in 26 patients who are clinically diagnosed as neurofibromatosis. The whole coding sequences and all splice sites were examined for mutations using DHPLC followed by direct sequencing of PCR products. Disruptive mutations were identified in 21 individuals with an overall mutation detection rate of 81%. The mutations included one indel, two insertions (nt. 4159, 1233), six deletions (nt., 953, 1017, 1541, 2679, 2816, 3525), thirteen missense / nonsense mutations (2237, 616, 2483, 1403, 2197, 2496, 2157, 2426, 2429, 1466, 192, 384, 386 codon) and one splicing error (IVS 25). Eight unclassified polymorphisms were also detected. Sixteen (69.5%) of the identified disruptive mutations are novel. Seven mutations have been previously reported.

Analysis of Duplication/Deletion of the PMP22 gene in patient with CMT1A and HNPP by DHPLC. *H.W. Lee¹, C.H. Lee¹, J.S. Lee^{1,2}*. 1) BK21 Project for Med. Science, Yonsei Univ., Seoul, Korea; 2) Dept Clinical Genetics, Yonsei Univ. Col Medicine, Seoul, Korea.

Charcot-Marie-Tooth disease (CMT) and hereditary neuropathy with liability to pressure palsies (HNPP) are the most frequent inherited disorders of the peripheral nervous system. They are clinically and genetically heterogeneous. A submicroscopic tandem duplication of 1.5 Mb in chromosome 17p11.2-12 comprising the PMP22 gene is found in 70.7% of autosomal dominant Charcot-Marie-Tooth type 1 (CMT1) patients. A reciprocal deletion is found in 87.6% of HNPP patients. For molecular diagnosis of duplication or deletion of the PMP22 gene, several approaches are available; Southern blot analysis, fluorescence in situ hybridization (FISH), real-time quantitative PCR analysis. However, there are several limitations in each method. To develop method for detection of 1.5 Mb duplication & deletion in CMT1A & HNPP patient we analyzed unrelated sixteen families diagnosed clinically with CMT1A, nine families with HNPP and thirty normal controls. Gene dosage of the region was determined by PCR with D17S122, D17S162, D17S261, followed by DHPLC analysis. Quantitative analysis by DHPLC showed that samples with duplication/deletion of PMP22 gene have different patterns. Absorbance (mV) was increased in CMT1A patient and decreased in HNPP patient. DHPLC analysis results consisted with Real-time quantitative PCR analysis and it showed correct determination of the PMP22 gene copy number. This method is fast, easy and reproducible in detecting PMP22 duplication and deletion in CMT1A and HNPP patients, respectively. This method might be very helpful for the diagnosis of patients with CMT1A/HNPP.

A synonymous *TCOF1* change in a patient with Treacher Collins syndrome causes missplicing of a constitutive exon due to disruption of a putative splicing enhancer. *D. Macaya, S. Katsanis, T. Hefferon, S. Audlin, G. Cutting.* DNA Diagnostic Lab, Inst of Genetic Med, Johns Hopkins Univ, Baltimore, MD.

Interpretation of novel sequence alterations in a disease associated gene remains a challenge in the clinical setting, especially for synonymous alterations of unknown consequence. We describe here the application of RNA transcript analysis to investigate the effect of a *de novo* synonymous transversion (S1127S or 3381A>C) 12bp downstream from the 3' splice acceptor of exon 22 of *TCOF1* in a patient with Treacher Collins syndrome (TCS). Inspection of the region surrounding this exonic mutation revealed a sequence with a higher consensus score for a 3' splice site than the reported site, leading to speculation of an alternate 3' splice site for exon 22. Because the 3381A>C mutation is in a critical position, it would disrupt splicing at this alternate site. To evaluate exon 22 splicing *in vivo*, we developed and validated protocols for RT-PCR and RNA extraction from fibroblasts, lymphoblasts, and lymphocytes. Sequencing of *TCOF1* transcripts from these three tissues from unrelated non-TCS individuals confirmed that the reported 3' site of exon 22 was used exclusively, thereby ruling out the possibility of alternate splicing of exon 22. Surprisingly, sequencing of lymphocyte RNA from the TCS patient with the 3381A>C mutation demonstrated skipping of exon 22 in entirety. Subsequent computational analysis with ESE Finder revealed two putative exonic splice enhancers, both of which are disrupted by this mutation. The loss of exon 22 is predicted to create a premature stop codon in exon 23 perhaps leading to nonsense mediated RNA decay of the mutated transcript. However, interrogation of a polymorphism in exon 2 showed approximately equal levels of transcripts from each *TCOF1* allele. Thus, on the basis of observed transcript stability we suspect that a truncated nonfunctional protein is produced from this allele. This expanded analysis of a patient with TCS identified the first putative splicing enhancer in *TCOF1* and demonstrates that complementing DNA and RNA analyses can reveal effects of sequence variations on gene function that are not predicted from genomic sequencing alone.

The Prevalence of GJB2 mutation in the baloochi population in Iran. *A. Naghavi¹, K. Kahrizi¹, J. Oveysi², M. Shakiba², H. Suraki Aliabadi³, Y. Riazalhosseini¹, N. Bazazzadegan¹, N. Mahdie¹, M. Mohseni¹, R.J.H. Smith⁴, H. Najmabadi¹.* 1) Genetics research center, Social welfare univ. , Tehran, Tehran, Iran; 2) Social Welfare & Rehabilitation Organization of Zahedan , Iran; 3) Zahedan University of Medical Sciences , Zahedan , Iran; 4) Molecular Otolaryngology Research Laboratories , Department of Otolaryngology , University of Iowa , Iowa City , IA ,USA.

Hereditary hearing impairment is a heterogeneous disability showing different pattern of inheritance and involving a multitude of different genes. Mutations in the GJB2 gene, especially the 35delG mutation, have been established as a major cause of inherited and sporadic non-syndromic deafness in various ethnic groups . The aim of our study was to determine the prevalence of GJB2 , 35delG mutation in the baloochi population in Iran . Fifty patients were examined by an extensive questionnaire to exclude syndromic forms and environmental causes of deafness. Informed consent was taken from all the patients in the study. Mutation screening of GJB2 was performed by allele-specific PCR for the detection of the 35delG mutation. The negative cases for 35delG mutation were screened by DHPLC and sequencing analysis. The 35delG mutation was not found in any of the patients. We identified 5 mutations in exon 2 (R127H, V153I, W24X, 167delT and a novel mutation, M93I) . Based on these data, the hot-spot mutations in Cx26 gene in baloochi population with non-syndromic hearing loss may be different from other ethnic groups in Iran.

A spectrum of epidermolysis bullosa phenotypes resulting from mutations in the plectin gene. *E. Pfindner, F. Rouan, J. Uitto.* Dept Dermatology & Cutaneous Biology and DebRA Molecular Diagnostics Laboratory, Thomas Jefferson Univ, Philadelphia, PA.

Epidermolysis bullosa (EB) is a group of heritable blistering diseases with extracutaneous manifestations. One subtype, EB with muscular dystrophy (EB-MD), is characterized by tissue separation within the basal keratinocytes just above the hemidesmosomes, accompanied by proximal muscle weakness that can develop during childhood (early-onset) or in the third decade of life (late-onset). Plectin is a component of the hemidesmosomal inner plaque and is also expressed in the muscle sarcolemma and the Z bands. A variety of mutations that result in premature termination codons in the plectin gene (PLEC1) have been identified in patients with EB-MD. Our laboratory has collected a cohort of 14 patients with EB-MD and identified mutations in PLEC1. In addition, two patients with EB with pyloric atresia (EB-PA) with neonatal lethality displayed epidermal tissue separation above the basement membrane and mutations in PLEC1 were identified. A comparative study of the patients examined in this laboratory and reported in the literature disclosed PLEC1 mutations in 27 patients, four of which have the lethal EB-PA phenotype and 20 with early-onset and three with late-onset EB-MD. In all 27 patients with plectin mutations skin blistering of variable severity was noted. In two of three late-onset EB-MD patients small in-frame insertions or deletions were identified on both alleles within the 4 integrin-binding domain of the protein. In the four EB-PA patients, the plectin mutations were located within the 4 integrin binding domain of the protein, resulted in STOP codons and predicted accelerated mRNA decay and absent protein. All of the mutations in the 23 early-onset EB-MD patients, without pyloric atresia, occurred outside of the 4 integrin-binding domain and resulted in STOP codons in the mRNA. The presence of mutations within the 4 integrin-binding domain attests to the functional significance of this portion of the protein and emphasizes its importance in interactions with 4 integrin in the development of the maturing fetal skin and gastrointestinal tract.

Hereditary Haemorrhagic Telangiectasia: ENG and ALK1 mutations in Dutch patients. *H.K. Ploos van Amstel¹, T.G.W. Letteboer¹, F.A.M. Hennekam¹, G. de Haas¹, E. Kamping¹, J.J. Mager², C.J.J. Westermann².* 1) Department of Medical Genetics, University Medical Center, Utrecht, The Netherlands; 2) St. Antonius Hospital, Nieuwegein, The Netherlands.

Hereditary Haemorrhagic Telangiectasia (HHT or Rendu-Osler-Weber disease (MIM 187300)) is an autosomal dominant disorder characterized by localized angiodysplasia. The resulting vascular lesions are direct arteriovenous connections without an intervening capillary bed. This can result in a range of malformations from smaller mucocutaneous telangiectases to large visceral arteriovenous malformations. The estimated prevalence in the Netherlands is 1:30,000. Mutations in at least two genes have been shown to be associated with the disease, endoglin (ENG on chromosome 9q34, HHT1) and ALK1 (ACVRL1 on chromosome 12q13, HHT2) respectively. To date, we have studied 127 probands with Rendu-Osler-Weber disease that fulfilled the Curaçoa criteria. A sequence analysis has been performed for both the ENG gene (exon 1-14) and the ALK1 gene (exon 2-10). Mutations were found in both genes: 56% of the probands had a mutation in the ENG gene, whereas 36% had a mutation in the ALK1 gene. No proband has been identified with deleterious mutations in both genes. The mutations detected were deletions, insertions, nonsense, missense and splice site mutations. Several mutations were found more frequently. For these, genealogical study showed a common ancestry that could be dated as far back as the 18th century. Currently, we are investigating the remaining 8% of the probands for gross gene abnormalities. These mutations will be missed using a sequence based approach. Organizing the clinical data, the genotype-phenotype relationship of the two patient groups with an endoglin respectively an ALK1 mutation shows that PAVM and CAVM are significantly more frequent in carriers of an ENG mutation. No significant difference for epistaxis exists between the two groups, although in HHT1 patients epistaxis starts earlier. The identification of carriers enables appropriate medical attention and the prevention of unnecessary clinical screening of non-carrier children in the family.

Evaluation of the GJB6 large deletion in the Iranian patients with autosomal recessive non-syndromic hearing

loss. *Y. Riazalhosseini*^{1, 2}, *C. Nishimura*³, *K. Kahrizi*¹, *A. Daneshi*⁴, *S. Arzhangi*¹, *M. Mohseni*¹, *N. Mahdieh*¹, *M. Avenarius*³, *RJH. Smith*³, *H. Najmabadi*¹. 1) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Tehran, Iran; 2) Khatam University, Tehran, Iran; 3) Molecular Otolaryngology Research Laboratories, Department of Otolaryngology, University of Iowa, Iowa City, IA, USA; 4) Rasoul Akram Hospital, Iran University of Medical Sciences, Tehran, Iran.

Hearing impairment affects 1 in 1000 newborns and about half of these babies, the loss has a genetic basis. Autosomal recessive non-syndromic sensorineural deafness (ARNSD) is the most common form of severe inherited hearing impairment. To date, at least 40 loci for ARNSD have been identified, indicating it as an extremely heterogeneous disorder. These loci are referred to as *DFNB* loci. Mutations in the gene that encodes the gap-junction protein connexin 26 (*GJB2*) at the *DFNB1* locus on chromosome 13q12 are the most common cause of ARNSD in many different populations. A second gap-junction gene, *GJB6*, also localizes to the *DFNB1* interval. Interestingly, the encoded protein connexin 30 is expressed in the same inner-ear structures as connexin 26 and both connexins are functionally related. The importance of *GJB6* to normal hearing has been confirmed by the identification of a large deletion involving the first two exons and a part of third exon of *GJB6* and a large region of the upstream sequence ((*GJB6*-D13S1830)) in persons with ARNSD. Homozygotes for this deletion and compound heterozygotes carrying (*GJB6*-D13S1830) and a deafness-causing allele variant of *GJB2* have severe-to-profound congenital deafness. To evaluate the importance of (*GJB6*-D13S1830) in the Iranian population, we screened 116 Iranian deaf probands with normal *GJB2* alleles in addition to 16 Iranian probands heterozygote for only one *GJB2* mutation for this deletion. Screening for (*GJB6*-D13S1830) was completed using PCR primers that amplify the breakpoint junction of this deletion. (*GJB6*-D13S1830) was not detected in our subjects, indicating that this mutation is not a common cause of deafness in Iran. Our finding suggests that (*GJB6*-D13S1830) is not wide-spread in the world.

Identification of Four Novel Pathogenic Mutations in Patients from Southern Italy with CADASIL. *C. Ungaro, T. Sprovieri, F.L. Conforti, A. Magariello, G. Di Palma, A. Patitucci, O. Gallo, A.L. Gabriele, G. Peluso, M. Muglia, R. Mazzei.* Institute of Neurological Sciences-CNR, Mangone, Cosenza, Italy.

Cerebral Autosomal Dominant Arteriopathy with Subcortical Infarcts and Leukoencephalopathy (CADASIL; MIM#125310) is a late-onset syndrome characterized by subcortical ischemic strokes, attacks of migraine with aura, and vascular dementia. Subcortical dementia, in all cases associated with pseudobulbar palsy, is the second commonest clinical manifestation of CADASIL. All individuals, both symptomatic and asymptomatic, have prominent signal abnormalities on brain Magnetic Resonance Imaging (MRI). CADASIL is caused by mutations in the Notch3 gene encoding a transmembrane receptor. The contribution of Notch3 mutations to the Italian population incidence of CADASIL was unknown. In the present study, twenty-five patients from 10 families of South Italy have been clinically examined and submitted to neuroimaging studies. Molecular investigation has been performed on 22 of 33 exons of the Notch3 gene encoding for the extracellular domain, containing the 34 Epidermal Growth Factor (EGF)-like repeats, by DHPLC and following direct sequence. Ten pathogenic mutations have been detected: two in the exon 3 (2x R90C), two in the exon 6 (2x R322C), four in the exon 8 (C428T, C428R, C440S, R449C), one in the exon 10 (G528C), and one in the exon 22 (R1231C). Three mutations in the exon 8 and one in the exon 10 are new. All these missense mutations involve gain or loss of a cysteine residue. Furthermore, we detect 14 different polymorphisms, 7 out of 14 were nonsense substitutions, 5 were amino acid changes, 2 intronic variations.

A Novel Allele of the β -Globin Gene Cluster Containing Both the $\beta^{3.7}$ and $\beta^{\text{anti4.2}}$ Crossover Junctions - Implications for Thalassemia Genotyping. W. Wang¹, A.Y.Y. Chan², E.S.K. Ma², S.S. Chong^{1,3}. 1) Pediatrics, Ob/Gyn, Lab Medicine, National Univ Singapore & Hospital, SINGAPORE; 2) Pathology, Univ Hong Kong & Queen Mary Hospital, Hong Kong, PRC; 3) Pediatrics, Gyn/Ob, Institute of Genetic Medicine, Johns Hopkins Medicine, USA.

Misalignment and unequal crossover between the homologous XYZ boxes of the β -globin gene cluster results in single β -globin gene deletions (-) and reciprocal β -globin gene triplications (). During screening of patients for β -globin gene deletions by Southern analysis, an anomalous ~20 kb *Bgl*III - / -globin fragment was detected in a β -thalassemia major patient (Cd 41/42 / Cd 41/42) and an unrelated β -thalassemia carrier (-28 /). Subsequent β -globin multiplex-PCR analysis indicated the presence of both the $\beta^{3.7}$ and $\beta^{\text{anti4.2}}$ alleles in both patients. A *bona fide* compound heterozygous $\beta^{3.7} / \beta^{\text{anti4.2}}$ sample showed the same PCR results but not the anomalous ~20kb fragment. Parental DNAs were available for the thalassemia major patient. Southern and PCR analyses revealed a normal paternal β -globin genotype, but a maternal result identical to the patient, thus showing that the patient cannot be compound heterozygous for $\beta^{3.7}$ and $\beta^{\text{anti4.2}}$. We hypothesized that the patient, her carrier mother, and the unrelated carrier are heterozygous for a novel rearranged β -globin cluster arising from two sequential unequal crossover events. This dual recombinant allele contains both the $\beta^{3.7}$ and $\beta^{\text{anti4.2}}$ unequal crossover junctions, resulting in no net gain/loss of β -globin genes. We devised a large fragment nested PCR strategy to test this hypothesis. Predicted fragments of the expected sizes were observed only in the three individuals, thus confirming the presence of the novel allele in them. The existence of this dual recombinant allele dictates caution in the interpretation of PCR-based β -globin genotyping results. DNA samples positive for both the $\beta^{3.7}$ and $\beta^{\text{anti4.2}}$ junction fragments by PCR analysis should be confirmed by Southern or large fragment nested PCR analysis in order to discriminate between the compound heterozygous $\beta^{3.7} / \beta^{\text{anti4.2}}$ state and heterozygosity for the novel " $\beta^{3.7+\text{anti4.2}}$ " allele.

Increasing the Jagged1 Mutation Detection Rate in Alagille Syndrome. *D.M. Warthen, E.C. Moore, B.M. Kamath, S. Yehuda, J.J.D. Morrissette, N.B. Spinner.* Div of Human Genetics, Dept of Pediatrics, The Children's Hospital of Philadelphia and The University of Penn School of Medicine.

Alagille syndrome (AGS) is caused by mutations of Jagged1 (JAG1). Studies from multiple laboratories have demonstrated JAG1 mutations in 60-70% of patients with AGS. Screening has been performed using single strand conformation polymorphism (SSCP) or denaturing high-pressure liquid chromatography (DHPLC). The inability to detect mutations in the remaining patients has been thought to be due to technical limitations in screening this 26-exon gene, though it raises the possibility that there is another locus for AGS. To rule out the presence of a second locus, we developed an aggressive screening protocol. We studied 233 patients with AGS. Initial screening was done by SSCP (190 patients) or conformation sensitive gel electrophoresis (CSGE) (43 patients). If no mutation was identified, sequencing of cDNA or genomic DNA was carried out. Of the 190 patients screened using SSCP, JAG1 mutations were identified in 123 (65%) individuals. Twenty-six of the 67 patients in whom no mutations were identified have had further investigations (CSGE, sequencing) and mutations were identified in 17/26. Therefore, of the patients completely studied, 140/149 had mutations detected. Of 43 patients initially screened using CSGE, mutations were identified in 29(67%). Nine of the 14 patients unshifted on CSGE underwent sequencing and 6 mutations were found (35/38). In total, 187/233 patients completed a sequential approach to mutation identification, with mutations found in 174/187 (93%) patients. To further study the patients in whom no mutation has been identified, we developed an RNA based test to look for instability of a mutant RNA, which would suggest nonsense-mediated decay. cDNA is analyzed for the presence of known polymorphisms when cells are grown in the presence and absence of cycloheximide (which stabilizes mutant RNA). To date, we have studied 4 patients and found evidence for one unstable JAG1 allele in 2/4, further increasing our suspected mutation rate. This higher rate of mutation identification in AGS (93%) reduces the likelihood that another locus for this condition exists.

Duplications within the DMD gene. *S.J. White¹, A. Aartsma-Rus¹, T. Lalic², K. Flanigan³, I. Ginjaar¹, G.J.B. van Ommen¹, M.H. Breuning¹, J.T. den Dunnen¹.* 1) Center for Human & Clinical Genetics, Leiden University Medical Center, The Netherlands; 2) Laboratory for Medical Genetics, Mother and Child Health Institute of Serbia, Serbia and Montenegro; 3) Departments of Neurology and Human Genetics, University of Utah, Salt Lake City, Utah, USA.

The Duchenne Muscular Dystrophy (DMD) gene is the largest known, spanning ~2.4 Mb of genomic sequence on Xp21. Mutations in the gene cause DMD and BMD, with deletions and duplications of one or more exons being found in ~70% of cases. Deletions in males can be easily detected, whereas duplications require a quantitative method of analysis. Using Multiplex Amplifiable Probe Hybridisation (MAPH) and Multiplex Ligation-dependent Probe Amplification (MLPA) we rescreened a cohort of patients with hitherto undetected mutations and found over 40 duplications. The majority of cases contain a simple contiguous duplication, however we also detected several non-contiguous duplications, with one including a triplication as well. In such instances the 3' end of the gene is often affected, which is a region not usually screened by multiplex PCR. These mutations would therefore go undetected, whilst potentially disturbing the reading frame of the mRNA. This emphasizes the importance of screening the entire gene for rearrangements. Overall, there is a significant difference in the distribution of deletions and duplications. Whilst the major deletion hot spot is localised around exons 45-55, more than 50% of the duplications are at the 5' end of the gene. A more detailed comparison of the regions affected showed that a duplication of exon 2 only was the single most common duplication found, whereas the reciprocal deletion has never been described. This could be due to structural or mechanistic restraints, or it may be that a deletion within this region is not compatible with life. Initial mapping and sequencing of duplication junctions shows that all exon 2 duplications were of a different size, suggesting that there is no specific hotspot for recombination within either intron 1 or intron 2. A better characterization of these rearrangements should increase our understanding of the molecular mechanisms behind these events.

Hemizyosity for *NPHS1* (nephrin) mutations associated with congenital nephrosis, (Finnish type). C.A.

*Friedrich*¹, *H.G. Bock*¹, *G.L. Barnett*¹, *R. Baliga*². 1) Dept Prev Med, Div Medical Gen, Univ Mississippi Medical Ctr, Jackson, MS; 2) Pediatric Nephrology, UMMC, Jackson, MS.

Congenital nephrosis (Finnish type, OMIM 256300) is an autosomal recessive condition caused by mutations in the *NPHS1* gene that codes for nephrin. A 4-month-old African-American female with edema and proteinuria had renal biopsy findings consistent with congenital nephrosis, Finnish type. Both parents are healthy. Consanguinity and non-paternity were denied. DNA testing of the patient revealed apparent homozygosity for eight single nucleotide transitions or transversions: T1110C, A1926G, GIVS7 + 6A, AIVS7 + 26T, C2289T, T2728C, T2971G, and CIVS24 + 36T. T2728C should produce a Ser910Pro amino acid sequence change, and T2971G should produce a Val991Leu change. Her mother was heterozygous for the T1110C, A1926G, GIVS7 + 6A, AIVS7 + 26T, C2289T, T2728C and T2971G mutations, and homozygous for the CIVS24 + 36T mutation. The patient's father was homozygous for five single nucleotide transitions or transversions: CIVS1-5G, AIVS3 + 61, C1320T, C2289T, and CIVS24 + 36. The patient was apparently homozygous for two mutations that would result in amino acid sequence changes although neither of these mutations was present in her father. She was also apparently homozygous for four other silent mutations that were not present in her father. Neither of the missense mutations has been reported previously, and their significance is unknown.

The simplest explanation for these findings is the father has a deletion that spans from at least nt1110 to nt2971. Inheritance of the deleted chromosome from the father would allow the detection of apparent homozygosity in the daughter of alleles that are heterozygous in her mother. If the only intact gene produces a protein with two amino acid changes this may affect the function of nephrin and cause disease. This mechanism of disease has not been reported previously in this disease. Mutations associated with this disease have not been reported previously in this ethnic group. Molecular studies to confirm the mechanism are being pursued.

Screening of the Sperm Nuclear Protein Genes in a Population of Infertile Males. *V.W. Aoki, G.L. Christensen, D.T. Carrell.* IVF and Andrology Laboratories, University of Utah, SLC, UT.

Introduction: During spermatogenesis, spermatid chromatin undergoes substantial compaction. This process occurs by the replacement of the somatic histones with the transition nuclear proteins and, subsequently, the protamine proteins. These sperm nuclear proteins are often abnormally expressed in cases of severe male-factor infertility. The objective of this study was to evaluate the sperm nuclear protein genes for clinically relevant mutations in a population of infertile males.

Methods: A total of 96 males presenting with severe male factor infertility, and 48 fertile controls were enrolled in the study after informed consent. Genomic DNA was isolated and PCR primers were developed to amplify the promoter region and exons of transition protein 1, transition protein 2, protamine 1 and protamine 2. Internal primers were designed to allow sequencing in both the forward and reverse directions. Sequence trace files were assembled and evaluated using Phrap, Phred, and Consed software.

Results: A total of six different heterozygous polymorphisms were identified in the four genes studied. Three were found in intronic regions and three in the exons. Two resulted in amino acid changes. The first change, identified in two infertile patients and one fertile control, converted an arginine residue to lysine in exon one of protamine 1. The second, identified in a single infertile patient, resulted in a conversion of lysine to glutamate in exon one of transition protein 1.

Conclusions: At least one of the identified polymorphisms resulting in an amino acid change may contribute to the infertility of the affected individual. The data also suggest that mutations within the nuclear proteins are rare and not a common cause of male factor infertility. Our findings suggest that other factors are responsible for the abnormal nuclear protein expression observed in many infertile males.

Mutation screening of COH1 and BAFME on 8q22-q24.1. *S. Asakawa¹, K. Miyamoto², A. Shimizu¹, S. Yamazaki¹, S.K. Ishikawa¹, T. Sasaki¹, J. Kudoh¹, H. Yamagata², Y. Tabara², S. Minoshima³, I. Kondo², N. Shimizu¹.* 1) Department of Molecular Biology, Keio University School of Medicine, Tokyo, Japan; 2) Department of Hygiene, Ehime University School of Medicine, Ehime, Japan; 3) Photon Medical Research Center, Hamamatsu University School of Medicine, Hamamatsu, Japan.

We have sequenced the 20Mb-genomic region of 8q22-24.1. We also made detailed annotation on the 51.6 Mb-region covering 8q22-qter, where we found 260 protein coding genes and 179 putative non-coding RNA genes or pseudogenes. Several genetic diseases including Cohen syndrome and benign adult familial myoclonus epilepsy (BAFME) are mapped in this region. The Cohen syndrome is an autosomal recessive disorder characterized by psychomotor retardation and microcephaly, distinct facial appearance, childhood hypotonia and joint hyperextensibility etinocholoidal dystrophy and myopia, and periods of isolated leucopenia. In addition to the authentic Cohen syndrome (Finnish Type), a Cohen-like syndrome (Israeli type) was also reported. Recently, a causative gene of Cohen syndrome, COH1, was identified, so we searched COH1 mutation in two Japanese Cohen syndrome families with Finish type and Israeli type. We found a mutation in the Finish type patient. BAFME is inherited in an autosomal dominant manner and is characterized by adult-onset tremulous finger movement, myoclonus, epileptic seizures, and a non-progressive course. BAFME is recognized mainly in Japanese families and the causative locus was mapped on 8q24.1. We have performed mutation screening against the coding regions of all genes in the causative region, but we found no mutations in 53 genes. Therefore, we started to mutation search in the regulatory regions of these genes and the non-coding RNA genes found in the region. We will present the results of our comprehensive mutation screening.

Identification and characterization of the breakpoint region in a Japanese Sotos syndrome patient with a common microdeletion. *R. Visser*^{1,2,3,4,5}, *N. Niikawa*^{1,4}, *N. Matsumoto*^{3,4}. 1) Department of Human Genetics, Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan; 2) Department of Pediatrics, Leiden University Medical Center, Leiden, The Netherlands; 3) Department of Human Genetics, Yokohama City University Graduate School of Medicine, Yokohama, Japan; 4) CREST, Japan Science and Technology Corporation, Kawaguchi, Japan; 5) International Consortium for Medical Care of Hibakusha and Radiation Life Science, The 21st Century COE (Center of Excellence), Nagasaki, Japan.

Sotos syndrome (SoS) (OMIM #117550) is a childhood overgrowth syndrome characterized by pre- and postnatal overgrowth, distinctive craniofacial features, and various degrees of developmental delay. Aberrations of the *NSDI* gene, which include intragenic mutations or microdeletions of *NSDI* and adjacent genes, account for approximately 60-70% of the SoS patients. A striking difference in microdeletion and mutation prevalence is reported between Japanese and non-Japanese SoS patients, with microdeletions being far more prevalent in the Japanese SoS patient population. Low copy repeats have been identified harboring the deletion breakpoints in SoS. Abnormal genomic rearrangements between these areas of high homology, so called Non Allelic Homologous Recombination (NAHR), are hypothesized to be underlying mechanism causing the microdeletions in SoS. PFGE and hybrid cell lines are the techniques commonly used for characterization of the junction fragments in genomic disorders. We here report the construction of a BAC library of the genome of a Japanese SoS patient with a common microdeletion. PCR based library screening enabled us to identify the clone containing the breakpoint region as well as other clones of the flanking low copy repeats. Currently we are developing a screening system for the identification of a similar breakpoint region in other Japanese SoS patients. The identification and characterization of the breakpoint region will give more insight in the underlying mechanism of microdeletions in SoS.

New mutations in KIAA1985 gene implicated in a demyelinating form of autosomal recessive Charcot Marie Tooth (CMT4C) disease. *H. Azzedine¹, N. Ravise¹, A. Gabrels-Festen², M. Tazir³, N. Birouk⁴, D. Grid⁵, A. Brice^{1, 6}, J. Senderek⁷, E. LeGuern^{1, 6}, the GIS-orphan diseases institute network on autosomal recessive form of Charcot-Marie-Tooth disease⁸.* 1) INSERM U289-NEB, Hpital de la Salpatriere, Paris, France; 2) Institute of Neurology, University Medical Centre Nijmegen, Nijmegen, the Netherlands; 3) Service de Neurologie, CHU Mustapha, Algiers, Algeria; 4) Service de Neurologie, Hpital des Spcialits, Rabat, Morocco; 5) AFM-BTR, Gnthon, Paris, France; 6) Neurogenetics laboratory, Pitié-Salpêtrière Hospital, AP-HP, Paris, FRA; 7) Departments of Human Genetics and Neuropathology, Aachen University of Technology, Aachen, Germany; 8) the GIS-orphan diseases institute network on autosomal recessive form of Charcot-Marie-Tooth disease.

The CMT is a pathologically and genetically heterogeneous group of hereditary motor and sensory neuropathies characterized by slowly progressive weakness and atrophy, primarily in peroneal and distal leg muscles. Two major types have been distinguished: demyelinating or axonal form. Several loci (30) and various modes of inheritance were described: autosomal dominant, X linked and autosomal recessive (ARCMT). The demyelinating form of CMT is characterized by reduced nerve-conduction velocities in the medium nerve (MNCVs <38 m/s), segmental demyelination and remyelination, and onion bulb formation in nerve biopsy. The ARCMT type 4C (CMT4C) is a childhood-onset demyelinating form of hereditary motor and sensory neuropathy often associated with an early-onset scoliosis. twelve families from different geographical and ethnical origins with linkage to 5q23-q33 locus where screened for the KIAA1985 gene (Senderek et al 2003) in order to identify the responsible mutations. Direct sequencing on affected individuals identified 9 new mutations localised in different portions of the gene. One among them was recurrent in these families, with haplotype reconstructions suggesting a founder effect. This series of 31 patients allow to define the phenotype associated with mutation in KIAA1985. SnapShot experiments (Applied Biosystems) are in progress to confirm these data.

A novel LIM2 mutation associated with autosomal recessive non-congenital cataract. *G.D. Billingsley¹, A.V. Levin^{2, 3}, S. Herd¹, R. Sidhu¹, E. Héon^{1, 2, 3}.* 1) Genetics and Genomic Biology, The Hospital for Sick Children Research Institute, Toronto, ON, Canada; 2) Dept of Ophthalmology and Vision Sciences, Hospital for Sick Children, Toronto, ON, Canada; 3) University of Toronto, Department of Ophthalmology and Vision Sciences, Toronto, Ontario, Canada.

Cataracts constitute a leading cause of blindness worldwide and the mechanisms of lens opacification remain unclear. Approximately one-third of all congenital cataracts are familial and recent studies suggest that ~50 % of age-related cataracts could be accounted for by Mendelian inheritance. In contrast to the large number of genes and loci (at least 20) identified in human autosomal dominant cataract, only three genes, CRYAA, LIM2, GCNT2 and two loci with as yet unidentified genes have been implicated in AR cataract. We have studied a consanguineous Lebanese family in which two sibs had early onset bilateral cataract. STRP markers for the previously published AR loci (3p21.1 - p21.3, 9q13-q22, 19q13.4, 21q22.3) were chosen for genotyping. Markers in a 2 cM region flanking the LIM2 locus (19q13.4) were homozygous in the two affected sibs. All other AR loci were excluded by haplotype analysis. Sequence of the LIM2 coding exons (exon 2-5) was normal. A novel homozygous sequence change (tg) was observed 33 base pairs 3' of the stop codon. This nucleotide is part of a 6 base pair segment highly conserved in mouse, rat, bovine and human. The sequence change removes a MseI restriction enzyme site and was shown to cosegregate with the affected status in the family. This change was not seen in one hundred control chromosomes which were screened by means of the restriction enzyme digestion, but only the wild-type variant was found. The molecular characterization of AR cataract may contribute to the better understanding of the complex cascade of events modulating lens opacification in the more common age-related cataract. Grant Support: Canadian Institute for Health Research.

Haplotypes of the TAS2R38 Bitter Taste Receptor Link PTC and PROP Psychophysical Functions With *in vitro* Expression Sensitivity. P.A.S Breslin¹, D.R. Reed¹, C.D. Tharp¹, U.K. Kim², D. Drayna², B. Bufe³, W. Meyerhof³, C.

Kuhn³, J. Slack⁴. 1) Monell Chemical Senses Ctr, Philadelphia, PA; 2) National Institute of Deafness and Other Communicative Disorders, NIH, 5 Research Ct., Rockville MD 20850; 3) Dept. Mol. Genet. German Inst. Human Nutrition, Potsdam-Rehbruecke, Arthur-Scheunert-Allee 114-116, 14558 Nuthetal, Germany; 4) Givaudan Roure Flavors, 1199 Edison Drive, Cincinnati, OH 45216.

Most human populations may be subdivided according to whether they are sensitive to bitterness from PTC. Recently a gene, TAS2R38 on Chr 7 was associated with PTC recognition thresholds in humans (Kim et al., Science 2003). Presently, we screened Kim et al's sample population (and others) for recognition thresholds and suprathreshold concentration-intensity functions for PTC & PROP. We simultaneously tested three individuals with specific TAS2R38 haplotypes at amino acid positions 49, 262, 296 who are homozygous for the AVI (non-taster), PAV (taster), and the rarer recombinant AAI haplotype. For each of these three, we measured recognition thresholds and psychometric functions with the method of constant stimuli to determine their detection thresholds to PTC & PROP. These functions enabled direct comparison between the humans perceptual thresholds and the *in vitro* thresholds of their haplotypes as determined by an HEK293 cellular expression system in which their TAS2R38 genes were cloned and tested. We found that homozygous AVI and PAV subjects' PTC psychophysical measures were highly correlated with haplotype and had virtually no overlap between these two groups. Both the heterozygous subjects and the AAI subject had intermediate sensitivity. PROP intensity ratings were correlated with haplotype at perithreshold and low intensity concentrations but not at high concentrations. PTC sensitivities based upon psychometric functions were very similar to *in vitro* measures with the subjects expressed TAS2R38 proteins. Thus, a bottom-up approach to understanding genetic contributions to perception can successfully explain individual differences in bitter taste. This research was funded in part by NIH DC02995 and DC004698 (breslin@monell.org).

Polymorphisms at PRX gene causing Charcot-Marie-Tooth Phenotype. *A. Cornier¹, J. Acevedo², S. Carlo¹, E. Suarez¹, N. Arciniegas³, I. Flores⁴.* 1) Genetic Division, Ponce School Medicine, Ponce, PR; 2) Department of Nursing, Univ of Puerto Rico at Arecibo, Arecibo, PR; 3) Department of Pediatrics, Ponce School of Medicine, Ponce, PR; 4) Department of Microbiology, Ponce School of Medicine, Ponce, PR.

Charcot-Marie-Tooth (CMT) (MIM# 118220) is a polyneuropathy syndrome that presents a heterogeneous group of peripheral nerve disorders. Clinical manifestations vary and can be classified in two large groups: CMT1 which represents a symmetrical demyelinating disease that presents earlier in life, usually of autosomal dominant inheritance whereas CMT2, autosomal dominant as well, manifests later in life. We are presenting a case of a 14 years old female (KG) who presents with clinical manifestations consistent with CMT1 including hammer toes, gait disturbances, distal muscle weakness, cold intolerance and diminished deep tendon reflexes. DNA mutation analysis for CMT showed an *ERG2* sequence alteration consisting of an A C transversion at position 1086 that do not codified for an amino acid change. *PRX* allele one had a sequence alteration consisting of a C A transversion at position 619 that codified for a leucine to methionine change in her other allele. Interestingly, she presents additional polymorphisms at her other *PRX* allele consisting of an Ala882Val, and Pro885Pro. Although when the clinical meaning of these polymorphisms are not determined the DNA sequence in this patient is predicted to change the amino acid sequence of the protein and thus may altered the protein function. Nerve conduction studies confirm clinical findings showing mild prolonged median and ulnar DMLs with reduced median, ulnar and tibial motor amplitudes with an absent peroneal motor response. Sensory amplitudes were reduced for the radial, median and ulnar nerves with an absent serial sensory response. We believe that these polymorphisms do translate to clinical manifestations in our patient consisting of a CMT1 mild to moderate presentation. Genetic analysis of *PMP-22*, *Cx32*, *MPZ*, and *NF-L* genes was performed and no sequence alteration detected.

Search for modifier genes of cystic fibrosis: candidate gene approach. R. Dorfman¹, A. Sandford², D. Markiewicz¹, A. Master¹, G. Deng¹, M. Corey¹, X.-W. Yuan¹, M. Tan¹, F. Lin¹, D. Frangolias², P.D. Paré², L.-C. Tsui^{3,1}, P. Durie¹, J. Zielenski¹, *Canadian CF Clinics*. 1) Genetics and Genomic Biology, Hospital for Sick Children, Toronto, ON, Canada; 2) University of British Columbia, Vancouver, BC, Canada; 3) University of Hong Kong, Hong Kong.

Clinical severity of cystic fibrosis (CF) is determined both by mutations in cystic fibrosis transmembrane conductance regulator (CFTR) as well as variations in other genes (CF modifiers). One of the approaches to identifying CF modifiers is analysis of candidate genes selected on the basis of their relevance to various aspects of CF disease. This approach is used in the Canadian CF Modifier Gene Project recently launched to map and identify genes influencing severity of CF. We report the preliminary results of association analyses of genes tested in the study as potential CF modifiers. In total 57 genes were selected for the study. The criteria of selection were based on their functional relevance to the pathophysiology of CF including antibacterial defense, innate and adaptive immune response, mucociliary clearance, tissue repair, protein folding and lung morphogenesis. We selected 89 intragenic polymorphisms (mainly SNPs) for genotyping a Canadian cohort of CF patients (N=513) and families (N=330). Association between polymorphic markers and clinical variables was evaluated either by ANOVA for CF patients or Family-Based Association Tests (FBAT) for CF families. Partial results were obtained for 48 intragenic markers in CF patients and/or CF families. Our preliminary analysis of the genotypic and clinical data identified 10 markers corresponding to 9 genes with statistical significance for specific clinical variables. Four of them correspond to genes that have been previously implicated as CF modifiers. They are genes encoding surfactant proteins (SP-A and D), transforming growth factor beta (TGF) and defensin beta (DEF). As we ascertain additional CF families, we continue association analysis of these candidate genes in order to verify our findings in the larger study population. (Supported by Genome Canada and Canadian CF Foundation).

Implication of a novel sequence change in *BBS6* resulting in a mild BBS phenotype. *W. Ferrini*^{1,3}, *N. Noordeh*^{1,2}, *S. Herd*¹, *A. Levin*³, *E. Héon*^{1,2,3}. 1) The Genetics and Genomic Biology Program, The Hospital for Sick Children Research Institute, Toronto, Ontario, Canada; 2) The Institute of Medical Sciences, University of Toronto, Ontario, Canada; 3) Department of Ophthalmology and Vision Sciences, The Hospital for Sick Children, Toronto, Ontario, Canada.

Purpose: Bardet-Biedl syndrome (BBS) is an autosomal recessive multi-systemic disorder. BBS ultimately leads to blindness due to severe retinitis pigmentosa. BBS is genetically heterogeneous with 8 loci identified. Mutations in *BBS6* are proposed to account for a minority of cases (4-5%) (Katsanis et al., 2001). We investigated the role of *BBS6* (MIM 604896) in an ethnically diverse patient population affected with BBS.

Methods: Twenty-eight patients diagnosed with BBS were recruited through The Hospital for Sick Children, Canada. All 4 coding exons and the flanking introns of *BBS6* were screened for sequence changes using direct cycle sequencing.

Results: A novel homozygous missense sequence change was identified at amino acid position 99 (C99R) in an 11 year old boy. The phenotype of this patient included good school performance in grade 6, body weight in the 95th percentile, post axial polydactyly of 4 limbs, and mild kidney abnormalities with normal function. Visual acuity was measured at 20/30 in both eyes. Electroretinography showed non-recordable rod responses but recordable rod-cone and cone function. His peripheral field was of 90 degrees horizontally. No other systemic features were documented.

Conclusion: Here we report a novel sequence change in *BBS6* resulting in a mild phenotype of BBS. The cysteine residue and the surrounding area are conserved between human, mouse and rat orthologues.

Alpha-synuclein gene multiplications are responsible for familial Parkinson disease. P. Ibanez¹, E. Lohmann^{1, 3}, B. Debarges¹, F. Durif⁴, A. Destee⁵, AM. Bonnet³, S. Laine¹, Y. Agid^{1,3}, A. Durr^{1,2}, A. Brice^{1,2,3}, French Parkinson's Disease Genetics Study Group. 1) INSERM U289, Hopital de la Salpetriere, Paris, France; 2) Departement de genetique, cytogenetique et embryologie, Hopital de la Salpetriere, Paris, France; 3) Federation de Neurologie, Hopital de la Salpetriere, Paris, France; 4) Service de Neurologie, CHU de Clermont-Ferrand, France; 5) Service de Neurologie, CHU de Lille, France.

A growing number of responsible loci/genes have been identified in familial forms of Parkinson disease (PD). The alpha-synuclein gene (PARK1) has been implicated in rare autosomal dominant forms caused by missense mutations or gene triplications and duplications. The aim of this study was to determine whether multiplications of the alpha-synuclein gene are responsible for a subset of familial forms of PD. For this purpose we screened 222 individuals from families with dominant PD, mostly from French Caucasian origin, for alpha-synuclein gene multiplications by semi-quantitative multiplex PCR. Cases with a duplication or triplication were further validated using newly developed microsatellite markers spanning the alpha-synuclein gene and flanking regions. We found 4 patients with a heterozygous duplication and one with a triplication. In the remaining 217 patients normal peak height ratios were detected. The phenotype in duplicated patients was indistinguishable from idiopathic PD but, as reported in recently reported cases, the patient with triplication of the synuclein gene presented atypical features and a more severe course of the disease. In addition to a dopa-responsive Parkinson syndrome with onset at age 52, the patient was demented after a disease duration of 6 years (MMS 6/30). He had swallowing difficulties and died at age 65. Taken together with previously reported results, this data strongly suggest that the severity of the phenotype increases with the number of copies of the gene. The identification of alpha-synuclein gene duplication in 4 independent families and triplication in one out of 222 with dominant PD indicates that mutations in the alpha-synuclein gene are more frequent than previously thought.

Spectrum of UGT1A1 mutations in Crigler-Najjar (CN) syndrome patients: identification of thirteen novel alleles and genotype-phenotype correlation. A. Iolascon¹, V. Servedio², M. d'Apolito², N. Maiorano², B. Minuti³, L. Boschetto¹, S. Ronchi⁴, F. Torricelli³. 1) CEINGE, Napoli, Napoli, Italy; 2) Molecular Medicine, University of Foggia; 3) U.O. Citogenetica, Az. Osp. Careggi, Firenze; 4) Ospedali Infermi, Rimini.

Crigler-Najjar syndrome types 1 and 2 (CN1,CN2) are inherited as autosomal recessive conditions and are characterized by severe non-haemolytic unconjugated hyperbilirubinaemia. CN1 is the most severe form, associated to the absence of UGT1A1 activity. A milder variant of this disorder CN2 presents incomplete deficiency of hepatic UGT1A1 activity. The causative gene, UGT1A1, on chromosome 2q37, encode for UGT isoenzyme 1A1. The analysis allows us to identify in 31 unrelated Crigler-Najjar (CN) syndrome patients 22 mutations, 13 of which were novel, including one nonsense mutation, two altered typical splice sites, one single amino acid deletion and none missense mutations. We report the first case of de novo mutation in a boy with CN2. We also tried to discern any possible correlation of structure-function of UGT1A1. Several novel missense mutations localize in critical domain of UGT1A1 enzyme. In addition, the evaluation of Gilbert-type promoter of UGT1A1 in Crigler-Najjar syndrome patients was performed. UGT1A1 mutations produced different phenotype resulting from the association with the polymorphism of the promoter region. The presence of at least of one TA7 allele in association with structural mutations of the UGT1A1 produces a more severe phenotype. For the 3 patients which have unique heterozygous missense mutations and a TATA-box insertion we detected the simultaneous presence of trans A(TA)₇TAA. This study represents the molecular characterization of the largest cohort of Italian Crigler-Najjar Gilbert syndromes patients studied so far; increase the mutational spectrum of UGT1A1 allelic variants worldwide; provide a new insight useful for clinical diagnosis and genetic counselling. Present study suggests that initial screening of any new Italian seeking Crigler-Najjar Gilbert syndromes type I should start by seeking for the common c.877T>A 878-890del that seems to be the most prevalent in Italian population.

Mutation analysis and regulating region characterization of CACNA1A gene coding for P/Q voltage-gated calcium channel 1A subunit. *C. Jodice¹, S. Albertosi¹, E. Mantuano², L. Veneziano², S. Guida², S. Lagnese¹, D. Pesce¹, M. Frontali².* 1) Department of Biology, "Tor Vergata" University, Rome, Italy; 2) Institute of Neurobiology and Molecular Medicine CNR, Rome, Italy.

The CACNA1A gene, coding for the 1A-subunit (Cav2.1) of voltage-gated calcium channel type P/Q is responsible for Episodic Ataxia type 2 (EA2), Familial Hemiplegic Migraine (FHM) and Spinocerebellar Ataxia type 6 (SCA6). Several mutations causing these diseases have been described. In addition, families segregating for the disease with the CACNA1A, but not showing any mutations in the coding region, have also been found. Thirty-four patients with typical EA2, and 8 with cerebellar ataxia of unknown genetic type, are screened for CACNA1A gene mutations. Four new Cav2.1 missense or non-truncating mutations and 1 truncating mutation have been detected. From an analysis of the localization of the non-truncating mutations together with those reported in literature it is further confirmed that: 1) they tend to be preferentially located in specific protein regions, namely S5-S6 linkers and their borders; 2) their associated clinical phenotype suggests a higher age at onset and a lower frequency of mental retardation. Families segregating for the disease with the CACNA1A markers, but not showing mutations of the coding region, suggest a further characterization of the gene. A new 3terminal exon, namely 48B, has been characterized. An alternative splice site about 300 bp upstream from 5end of exon 48 creates a so far unknown isoform similar to BI-1(V2.V3) but with a longer exon 48. Results from bioinformatic analysis show that the two isoforms with the alternatively spliced exon 48 have at least two different polyadenylation signal candidates. Since preliminary results suggest that mRNAs of this gene have dendritic localization and mRNA transport studies show a clear implication of the 3 tail in subcellular localization, these exons are being characterized both for the alternative polyadenylation signal usage and transport and for mutations causing disease in EA2 and cerebellar ataxia patients. Supported by grants MIUR cofin 2003 to CJ and FIRB2001, RBNE01XMP4-008, FISR2000 to MF.

Identification of a novel LAMB3 mutation causing Junctional Epidermolysis bullosa type Herlitz (JEB-H). *F.MK. Jonsson¹, T. Gedde-Dahl Jr^{2,3}, E-L. Stattin¹, G. Holmgren¹, J. Jonasson¹.* 1) Clinical Genetics, University Hospital of Ume, Ume, Sweden; 2) Institute of Forensic Medicine, University of Oslo, Oslo, Norway; 3) Dermatological DNA Laboratory, Department of Dermatology, Rikshospitalet University Hospital, Oslo, Norway.

Junctional Epidermolysis bullosa type Herlitz (JEB-H) is an autosomal recessive disorder causing severe blistering of skin and mucosa. The carrier frequency in Northern Sweden is estimated to 1/50. In Scandinavia, along with a R635X founder mutation in the laminin 5 gene LAMB3, families with apparent compound heterozygosity have also been identified.

Aiming to identify this unknown mutation(s), haplotype analysis of the LAMB3 gene region on chromosome 1q32 was undertaken in six North-Scandinavian JEB-H families. Haplotype analysis using 9 microsatellite markers covering approximately 32 cM region revealed identical 1q32 haplotypes for all six families, including one Norwegian family where the index patient was homozygous. Subsequent mutation screening of the LAMB3 gene identified a 1 bp deletion in exon 19, 3024 delT, resulting in a downstream premature termination codon. All alleles with the identified 1q32 haplotype could also be confirmed to carry the 3024delT mutation.

This mutation has previously been reported in a large Philadelphia kindred of unknown origin. Interestingly, this patient exhibited a non-lethal form of JEB and was reported to be a compound heterozygote with the genotype 3024delT/unknown mutation.

In conclusion, we here demonstrate that the 3024delT LAMB3 mutation results in the lethal type Herlitz form of JEB, when present either in combination with the R635X mutation, or in its homozygous state. Therefore, molecular testing for the 3024delT LAMB3 mutation is of significant value for prenatal diagnostics and genetic counseling in JEB-H families, especially in kindreds of Scandinavian origin.

Analysis of most common mutations H1069Q, R778G and R778L in Wilson disease patients from North West

India. *G. Kaur*¹, *S. Kumar*², *B.R. Thapa*³, *R. Prasad*⁴. 1) Gurjit Kaur, Dept Physiology, Chandigarh Medical Col, Chandigarh, India; 2) Sandeep Kumar, Department of Biochemistry, PGIMER, Chandigarh, India; 3) Baburam Thapa, Department of Pediatric Gastroenterology, PGIMER, Chandigarh,; 4) Rajendra Prasad, Department of Biochemistry, PGIMER, Chandigarh,.

Wilson Disease (WD) is an autosomal recessive disorder of copper metabolism with a worldwide prevalence. The disorder manifests itself chronic liver disease and/or neurological impairment. The H1069Q point mutation in exon-14 of ATP7B is the most common mutation in Northern, Eastern, or Central European patients of WD. The other most common mutations R778L and R778G are present in population of Asian countries like Japan, Korea, china and Taiwan. The prime aim of this study was to investigate the frequency of most common mutations for assiduity of genetic testing in our population. A total of 57 patients with WD from 55 families residing in the North West states of India were examined. A seminested Polymerase Chain Reaction (PCR) based restriction fragment length polymorphism (RFLP) technique was used to detect the H1069Q mutation, while characterization of R778L and R778G mutations in exon-8 of ATP7B were carried out by using single strand conformational polymorphism (SSCP) and direct DNA sequencing. The data of our study are compatible with the hypothesis of the absence of H1069Q in Asian population, while exceptionally, the R778L and & R778G mutations were also absent in WD patients of North West India. Our data have also proved that the mutation in ATP7B tends to occur in a population- specific manner.

***NIPBL* Mutational Analysis in 120 Individuals with Cornelia de Lange Syndrome and Evaluation of Genotype-Phenotype Correlations.** I.D. Krantz¹, L.A. Gillis^{1, 2}, J. McCallum¹, M. Kaur¹, C. DeScipio¹, D. Yaeger¹, A. Mariani¹, A. Kline³, H. Li⁴, M. Devoto^{4, 5}, L.G. Jackson^{1, 6}. 1) Division of Human Genetics and Molecular Biology, The Childrens Hospital of Philadelphia and The University of Pennsylvania School of Medicine, Philadelphia, PA; 2) Divisions of Gastroenterology and Genetics, The Vanderbilt University Medical Center, Nashville, TN; 3) The Harvey Institute of Human Genetics, Baltimore, MD; 4) Nemours Childrens Clinic, Wilmington, DE; 5) Department of Biology, Oncology, and Genetics, University of Genoa, Italy; 6) The Division of Obstetrics and Gynecology, Drexel University School of Medicine, Philadelphia, Pennsylvania.

The Cornelia de Lange syndrome (CdLS [MIM #122470]) is a multisystem developmental disorder characterized by facial dysmorphism, upper extremity malformations, hirsutism, cardiac defects, growth and cognitive retardation, and gastrointestinal abnormalities. Both missense and protein truncating mutations in *NIPBL*, the human homolog of the *Drosophila Nipped-B* gene, have recently been reported to cause CdLS. The function of *NIPBL* in mammals is unknown. The *Drosophila* Nipped-B protein facilitates long-range enhancer-promoter interactions and plays a role in Notch signaling and other developmental pathways as well as being involved in mitotic sister chromatid cohesion. We report the spectrum and distribution of *NIPBL* mutations in a large, well-characterized cohort of individuals with CdLS. Mutations were found in 56 of 120 (47%) unrelated individuals with sporadic or familial CdLS. Statistically significant phenotypic differences between mutation-positive and mutation-negative individuals were identified. Analysis also suggested a trend towards a milder phenotype in individuals with missense mutations as compared to other types of mutations.

The phenotypic spectrum of exon skipping mutations in the COL1A2 gene. *F.L. Malfait, S. Symoens, P. Coucke, A. De Paepe.* Center for Medical Genetics , Ghent University Hospital, De Pintelaan 185, B-9000 Ghent, Belgium.

Mutations in the genes encoding collagen type I, COL1A1 and COL1A2, are commonly found in Osteogenesis Imperfecta (OI), but they occasionally result in an Ehlers-Danlos Syndrome (EDS). In EDS arthrochalasis type (EDS VIIA/B), skipping of exon 6 of COL1A1 or COL1A2 leads to loss of the cleavage site for procollagen I N-proteinase. Skipping of adjacent exons in COL1A2 have rarely been reported to result in an OI/EDS overlap phenotype. We present 2 new patients and compare clinical, electron-microscopic, biochemical and molecular findings. Patient 1 was diagnosed with EDS VIIA/B because of bilateral dislocation of the hip, hypotonia, joint hyperlaxity and recurrent luxations. She has a history of several fractures, but normal bone density. SDS-PAGE of procollagens and pepsin-digested collagens secreted in the medium and retained in the cell layer showed accumulation of pN1(I) and pN2(I) on the procollagen level, as well as presence of pN2(I) in the medium and the cell layer. Pulse chase experiments showed inefficient conversion of procollagen to collagen. Electron microscopy (EM) showed that the dermal collagen fibrils are round with mild surface irregularities in transverse sections. Molecular screening of COL1A2 revealed a heterozygous deletion of exon 6. Patient 2, a 36-year-old female, presents a phenotype overlapping OI and EDS with hyperextensible skin, moderate joint hypermobility, repetitive luxations, short stature, blue sclerae, osteoporosis and recurrent fractures. SDS-PAGE revealed no abnormalities, but pulse chase experiments showed inefficient conversion of procollagen to collagen. EM of dermal collagen fibrils is being performed. Molecular screening of COL1A2 revealed a heterozygous deletion of exon 7. Whereas skipping of COL1A2-exon 6 results in a characteristic EDS VIIB phenotype, due to loss of the procollagen I N proteinase cleavage site, skipping of adjacent exons, at the start of the triple helix, results in an OI/EDS overlap phenotype. The ligamentous laxity can probably be explained by incomplete processing of the N-propeptide, whereas the bone fragility is probably related to the structural alteration of the 2(I)-triple helix.

Program Nr: 2580 from the 2004 ASHG Annual Meeting

Mendelian disorders: connecting genotype to phenotype in the Mouse Genome Informatics (MGI) system. *L.J. Maltais, C.M. Lutz, C.W. Goldsmith, C. Smith, D.L. Burkart, L.L. Washburn, P. Vanden Borre, H. Dene, M. Lennon-Pierce, I. Lu, J.T. Eppig, MGI Staff.* Bioinformatics, The Jackson Laboratory, Bar Harbor, ME.

Understanding the genetic contribution to disease is integral to effective treatment and prevention strategies. However, navigating and integrating the vast array of genetic and phenotypic information available is, like disease itself, complex. The Mouse Genome Informatics Database (www.informatics.jax.org/) provides integrated access to the genetics, genomics, and biology of the laboratory mouse, including phenotypic information on the many mouse models used for the study of human disease. MGI contains phenotypic information on approximately 10,000 spontaneous, induced, and genetically engineered mutant alleles representing nearly 4400 Mendelian genes. To better capture genotype to phenotype relationships, the Mammalian Phenotype Ontology (MPO), a structured vocabulary for describing phenotypes, has been developed. MPO contains over 3200 terms and facilitates consistent annotation and comparative analysis of phenotypic data. In addition to data on single gene mutations, MGI will utilize the MPO for integrating phenotypic descriptions of QTLs, complex traits, and strains (whole animal genotypes). To further enhance the genotype to phenotype to disease link, MGI provides associations between mouse phenotypes and Online Mendelian Inheritance in Man (OMIM), thus allowing comparisons with functionally or phenotypically similar human diseases and syndromes. Contextual information relating genotypes, expression, gene function, and comparative mapping augment the understanding of phenotypes within MGI. Phenotype representation integrated with other biological data will contribute to model building, the delineation and understanding of pathways, and the determination of the underlying mechanisms of genetic disease. Supported by NIH grant HG00330.

MOLECULAR STUDY OF OSTEOGENESIS IMPERFECTA IN BRAZILIAN PATIENTS. *F. Reis¹, C. Oliveira¹, F. Alexandrino¹, D. Cavalcanti², E. Sartorato¹*. 1) Lab de Genética Humana/CBMEG, UNICAMP, Campinas, São Paulo, Brasil; 2) Depto. Genética Médica/FCM - UNICAMP, Campinas - São Paulo, Brasil.

Osteogenesis imperfecta (OI) is a genetic disorder of increased bone fragility and low bone mass. Severity varies widely, ranging from intrauterine fractures and perinatal lethality to very mild forms without fractures. Most patients with a clinical diagnosis of OI have a mutation in one of the two genes that encode the α chains of collagen type I. The mild forms are usually caused by mutations which inactivate one allele of COL1A1 gene and result in a reduced amount of normal type I collagen, while the severe and lethal forms result from dominant negative mutations in COL1A1 or COL1A2 genes which produce structural defects in the collagen molecule. The aim of the present study was to identify OI-causing mutations in OI patients/families using direct sequencing of PCR products amplified from COL1A1 gene. This gene, located on chromosome 17, encodes the pro α 1 chain of type I procollagen and is composed of 52 exons scattered over 18 Kb of chromosomal material. Detection of mutations in type I collagen genes is complicated and difficult because of their large size and highly repetitive GC-rich coding regions. Here we report six mutations in COL1A1 gene in six unrelated Brazilian patients with OI types I-IV. Of them, four mutations appeared to be novel (c.1885delG, Pro239Arg, Gly592Ser and Gly649Asp) and the other two (Arg237Stop and Gly382Ser) were already described. The variety of mutations described in the COL1A1 gene giving rise to an OI phenotype is in accordance with the clinical heterogeneity of the disease.

FOXC2 Mutations are not associated with the Meige Disease (Lymphedema without Distichiasis). *T. Rezaie¹, R. Ghoroghchian¹, R. Bell², S. Jeffery², G. Brice², K. Burnand², J. Beninson², P. Mortimer², A. Child², M. Sarfarazi¹.* 1) University of Connecticut Health Center, Farmington, CT; 2) St Georges Hospital Medical School, London, UK.

Lymphedema-Distichiasis is an autosomal dominant disorder with clinical presentation of limbs edema and double row of eyelashes. This condition maps to 16q24.1 and mutations in FOXC2 gene have been reported in families with this disorder. We screened 16 Lymphedema families with a total of 81 living affected and additional 13 sporadic cases for mutations in FOXC2. The single coding exon of FOXC2 gene was PCR amplified and sequenced in 3 overlapping fragments. A 22-bp deletion was identified only in a single 3-generation family consisting of 8 affected members with Lymphedema-Distichiasis and 3 normal subjects. This deletion covers nucleotides at position 563-584 (ATG considered as base 1 in Y08223). Subcloning of PCR products into a TA cloning vector from both mutant and wild type alleles verified the nature of this deletion. This deletion located 17 amino acids after the Forkhead domain (nucleotides 211-510) and leads to truncation of the mature protein by 38%. This truncation eliminates a region at the carboxyterminal of FOXC2 Forkhead domain that is essential for interaction of FOXC2 with the transcriptional complex. This novel mutation segregates with the disease phenotype in all of the 8 affected but not with the 3 normal individuals of this family. Furthermore, this deletion was absent in a total of 202 normal control chromosomes. Therefore, co-segregation of this 22-bp deletion with the Lymphedema-Distichiasis phenotype in this family, its absence in unaffected individuals, and its truncating effect on the normal FOXC2 protein support the causative nature of this mutation. All the other 28 probands with Lymphedema but without Distichiasis (15 familial and 13 sporadic cases) did not show any mutations in the FOXC2 gene. Therefore, our study clearly shows that mutations in FOXC2 are limited to the Lymphedema families with Distichiasis but not with Meige Disease (Lymphedema without Distichiasis). Supported By: NIH-HL66150.

SMN2 copy number predicts acute or chronic SMA but does not account for intrafamilial variability in siblings.

E. Tizzano¹, I. Cusco¹, M.J. Barcelo¹, S. Alcover¹, L. Caselles¹, I. Illa², R. Rojas², C. Cervera³, J. Gamez³, A. Pou⁴, G. Izquierdo⁵, M. Baiget¹. 1) Dept Genetics, Hosp Sant Pau, Barcelona; 2) Dept Neurology, Hosp Sant Pau, Barcelona; 3) Dept Neurology, Hosp Vall de Hebron, Barcelona; 4) Dept Neurology Hosp del Mar, Barcelona; 5) Dept Neurology, Hosp V. Macarena, Sevilla, Spain.

Spinal muscular atrophy (SMA) is an autosomal recessive disorder that affects motor neurons. It is caused by mutations in the survival motor neuron gene 1 (SMN1). The SMN2 gene, which is the highly homologous SMN1 copy that is present in all the patients, can be regarded as a naturally occurring hypofunctional allele of SMN1 and is unable to prevent the disease. We applied a quantitative SMN dosage method to assess the influence of the SMN2 copy number in patients with different SMA types (n=96) and in siblings of SMA patients with homozygous deletions or mutations in the SMN1 gene (n=6 pairs), whose disease outcome was notably different. Subsequent analysis and comparison were performed in these siblings to detect large-scale deletions or rearrangements in the SMA locus. Our results confirmed that the SMN2 copy number plays a key role in predicting acute or chronic SMA. However, siblings with discordant SMA phenotypes showed an identical SMN2 copy number and identical markers, indicating that the genetic background around the SMA locus is insufficient to account for the intrafamilial variability. Given that SMN2 is regarded as a target for potential pharmacological therapies in SMA, the identification of genetic factors other than the SMN genes is necessary to better understand the pathogenesis of the disease in order to implement additional therapeutic approaches. Supported by FIS 02-1275 and Red INERGEN C03-05.

Genotype-phenotype correlation in a large cohort of IP patients and identification of novel NEMO mutations interfering with NF- κ B activation. *M.V. Ursini¹, F. Fusco¹, G. Fimiani¹, A. Di Pardo¹, V. Mercadante², M.G. Miano¹, M. D'Urso¹.* 1) Institute of Genetics and Biophysics, Adriano Buzzati Traverso, CNR, Naples, Italy; 2) BioGeM, Ariano Irpino, Italy.

Incontinentia Pigmenti (IP) is an X-linked genodermatosis, lethal for males and presents in females with abnormal skin pigmentation and high variable clinical signs. NEMO gene, responsible for IP, encodes the regulatory subunit of the IKK complex for NF- κ B activation. We analyzed NEMO in 122 IP patients from EC and identified mutations in 83 (36 familiar and 47 sporadic cases). However, NEMO mutations isolated in this study account for the majority but not all clinical cases. The recurrent NEMO 4-10 deletion that is the major cause of the disease was present in 73 females. In addition 10 point alterations were identified. A phenotype scoring system was used for correlation between the mutation type and the clinical IP presentation. To assess genotype-phenotype correlation in IP patients we listed features that are typical for IP but not consistent in all patients and could therefore reflect the severity of the syndrome. For calculating the score we included only defects relative to nervous system, eyes, teeth, hair and nail, that are most frequently, but not always, observed in IP patients. If a genotype-phenotype correlation does exist, females who carry loss-of-function mutations would be expected to have the most severe phenotype. In our study, however, this is not the case: 50 patients with the same exon 4-10 NEMO deletion have severity score ranging from 1 to 8. In addition, we found that mutations preserving some activity (i.e. same point mutations) show an atypical phenotype characterized by involvement of much more tissues than classical IP phenotype. Thus, the detected mutation spectrum do not allow genotypephenotype correlation, leading to the hypothesis that other factors may modulate the IP pathogenesis. Such a factor is likely to be X-inactivation. Indeed, 64% of our patients have extremely skewed X-inactivation pattern (80:20). Overall IP pathogenesis thus depends on a combination of X-inactivation and protein domain that recruit upstream factors and activate NF- κ B.

Analysis of the behavioral phenotypic consequences of gene dosage imbalance utilizing the mouse models for $\text{del}(17)(\text{p}11.2\text{p}11.2)$ and $\text{dup}(17)(\text{p}11.2\text{p}11.2)$ contiguous gene syndromes. *K. Walz, R. Paylor, J.R. Lupski.*
Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

Contiguous gene syndromes (CGS) refer to a group of disorders associated with chromosomal rearrangements in which the phenotype is thought to result from altered copy number of physically linked dosage sensitive genes. Smith-Magenis syndrome (SMS) is a CGS associated with a deletion within band p11.2 of chromosome 17. Patients harboring the predicted reciprocal duplication product [$\text{dup}(17)(\text{p}11.2\text{p}11.2)$] have also been described. We have previously described the construction of mouse models for these two independent CGS. Taking advantage of the availability of animals harboring different gene dosage in this specific interval (0, 1, 2, 3 and 4n) we wanted to study the phenotypic consequences of this imbalance. We analyzed here the viability of the different groups of animals. Pathological and histological studies were performed for most of these genotypes. In addition a battery of tests was utilized to study the behavior. While homozygous deletion animals are lethal, homozygous duplication animals present a severe compromise in their viability, only a few survive the neonatal period. All the others genotypes are present at the normal mendelian ratios. Preliminary behavior analysis indicate that the homozygous duplication ($\text{Dp}(11)17/\text{Dp}(11)/17$) animals have a more profound phenotype when compared with the heterozygous duplication ($\text{Dp}(11)17/+$) and heterozygous deletion ($\text{Df}(11)17/+$) animals, and also presented a learning and memory deficiency in the pavlovian conditioned fear, not only to the context (as the duplication heterozygous), but also to the acoustic cue. Our murine models clearly demonstrate that there are specific genes in this interval that are dosage sensitive genes, and that behavior is influenced by having either too few (0-1n) or too much (3-4n) of at least one of these genes products.

CFTR Gene Haplotype Determines the Phenotype Associated with the 5T Variant. *B. Anderson, W. Sun, J. Redman, A. Buller, M. McGinniss, F. Quan, C. Strom.* Dept Molecular Genetics, Quest Diagnostics Nichols Institute, San Juan Capistrano, CA.

Mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene are responsible for the disease in almost all CF patients. Mild CFTR mutations and variants have been associated with atypical clinical presentations including congenital bilateral absence of the vas deferens (CBAVD), chronic pancreatitis, and chronic rhinosinusitis. A tract of 5 thymidines in intron 8 of the CFTR gene, the 5T variant, is a common CF variant, with an allelic frequency of 0.04 in our test population. It disrupts processing of CFTR mRNA and thus results in less gene product being made. When found on the opposite chromosome from a severe CF mutation, the 5T variant has been associated with a normal phenotype or with male infertility stemming from CBAVD or atypical CF. To better understand the molecular basis for these different clinical phenotypes, we analyzed the polymorphic TG dinucleotide repeat adjacent to the 5T variant in intron 8 as well as codon 470 in exon 10. All patients selected for this study were positive for both the 5T variant and the major CF mutation, Delta F508, as our study showed that the CFTR gene containing the Delta F508 mutation appeared to have the 10TG-9T-470M haplotype. Out of the 65 samples analyzed by direct sequence analysis, 39 (60%) were 11TG-5T-470M, while 24 (37%) were 12TG-5T-470V, and 2 (3%) were 13TG-5T-470M. Of the 44 cases for which we had clinical information, 33 (75%) were normal (23 with 11TG, 8 with 12TG and 2 with 13TG) and 11 (25%) had some atypical CFTR-related symptoms (7 with 12TG and 4 with 11TG). Thus, 7 of the 15 cases having a 12TG haplotype had an abnormal phenotype versus only 4 of the 27 cases having 11TG haplotype, suggesting that a 12TG-5T-470V haplotype is more likely to cause atypical CF than an 11TG-5T-470M haplotype. In view of these results (low penetrance and 12TG association with abnormal phenotype), haplotype determination may be useful for clinical interpretation of a 5T variant. Additional studies are needed to verify our results.

HAPLOTYPIC CLASSIFICATION OF THE DYSTROPHIC EPIDERMOLYSIS BULLOSA IN TUNISIAN FAMILIES. *H. OURAGINI*¹, *W. DAOUD*², *F. CHERIF*², *A. BEN OSMAN*², *K. DELLAGI*¹, *S. ABDELHAK*¹. 1) Laboratory of Immunology, Vaccinology and Molecular genetics, Institut Pasteur de Tunis, Tunis, Tunisia; 2) Departement of Dermatology, Hospital of La Rabta, Tunis, Tunisia.

Dystrophic Epidermolysis Bullosa (DEB) is a rare skin disorder that is characterized by tissue separation under the dermal-epidermal basement membrane zone, because of an alteration of the anchoring fibrils (AF). COL7A1 gene encodes for type VII collagen, the major component of the AF. Mutations within this gene have been shown to be responsible for DEB. The COL7A1 gene is composed of 118 exons and localised at 3p21.3. DEB is transmitted either in a dominant or a recessive mode. More than 200 mutations have been identified. These mutations consist of nonsense mutation, small insertion or deletion. Our aim is to classify the DEB Tunisian patients on the basis of their haplotype. Sixteen families have been typed with three markers overlapping the COL7A1 gene region. At least two haplotypes (222-252-276 and 226-246-290) have been identified. In a family, a pseudo-dominant mode of inheritance have been suspected. A neomutation in one of the tested markers, has been also identified within this family. This preliminary study is essential for mutation screening.

Exclusion of candidate genes in a french-canadian cohort with a milder form of UCMD. *M. Tetreault*^{1,2}, *A. Duquette*¹, *I. Gosselin*¹, *A. Klein*^{1,2}, *M. Vanasse*³, *Y. Robitaille*³, *G. Karpati*⁴, *B. Brais*^{1,2}. 1) Neurogenetic, CHUM-Hopital Notre-Dame, Montral, Quebec, Canada; 2) Molecular Biology Departement, University of Montreal, Quebec, Canada; 3) Hopital Ste-Justine, Montreal, Quebec, Canada; 4) Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada.

Ullrich congenital muscular dystrophy (UCMD) is a heterogeneous autosomal recessive dystrophy associated with proximal contractures and distal hyperlaxity. UCMD has been associated with complete or partial loss of collagen VI due to mutations in genes coding for its three subunits. This rare hereditary disorder account for 60% of all CMDs in Quebec. Most UCMD French-Canadian cases have a mild phenotype. Objective: Establish if the higher prevalence of UCMD in the French-Canadian population is due to mutations in one of the subunits of collagen VI and if not screen genes loci coding for proteins interacting with collagen VI. Methods: We have recruited 14 affected patients from 11 UCMD families in Quebec for the clinical and genetic characterization of UCMD in French Canadians. DNA and muscle biopsies from affected patients and DNA samples from relatives were obtained following informed consent. We have completed haplotype analyses in all families with polymorphic markers at the *COL6A1-A2* and *COL6A3* loci. Linkage analysis were also performed at the *HSPG2*, *COL4A3-COL4A4*, *DAG1*, *ITGA2*, *DCN*, *COL2A1*, *COL4A1-COL4A2* loci. Using RT-PCR, the mRNA for *COL6A3* was completely sequenced in three cases. Immunofluorescent microscopy was performed on available muscle and culture fibroblasts using the anti-collagen VI antibody. Results: Haplotype analyses excluded that a founder mutation in the *COL6A1* and *COL6A2* genes is responsible for UCMD in our cohort. Similar analysis at the *COL6A3* locus was not conclusive. The sequencing of *COL6A3* gene by RT-PCR in three cases did not uncover any mutations. Immunofluorescence microscopy demonstrated the presence of collagen VI in the four studied cases. The haplotype analysis performed at the other loci excluded them as candidate genes in our cohort. Together our results indicates that the milder form of UCMD in French Canadians is a distinct disease genetically.

A Novel Mutation In The Uroporphyrinogen III Synthase (UROS) Gene Causes Congenital Erythropoietic Porphyria In A Pakistani Family. *A. Abid, M. Ismail, S. Khaliq, S.Q. Mehdi.* Biomedical and Genetic Engineering Laboratories, Islamabad, Pakistan.

Porphyrias are inherited disorders of heme biosynthesis. Congenital erythropoietic porphyria (CEP) or Gunther disease is a rare autosomal recessive disease caused due the deficient activity of uroporphyrinogen III synthase (URO3S) enzyme. CEP is typically expressed at birth or in early childhood. However, a few cases of adult-onset CEP have also been reported. It is characterized by the accumulation of porphyrins in erythrocytes and bone marrow and excreted in the urine and feces at later stages. In this study a consanguineous Pakistani family, with 4 affected members, in which CEP phenotype segregated as an autosomal recessive trait were investigated. The affected members show signs of hemolytic anemia and scarring of the skin. The nails, hairs and teeth of the patients were pink or dark brown due to the accumulation of large amount of porphyrins. High levels of porphyrins were also excreted in the urine and feces. Progressive degeneration of digits, ears, nose and vision was also observed in one severely affected patient aged 28y. Linkage analysis of this family mapped the disease locus on chromosome 10q25.2-q26.3, a region harboring the Uroporphyrinogen III synthase gene (UROS) gene. Mutation screening of the UROS gene revealed a novel T to C homozygous substitution in exon 10 in all the patients of 1CEP family. The parents were heterozygous (carriers) for the mutation. This mutation alters the codon 237 for leucine to proline (CTT to CCT) that abolishes the N-myristoylation site in the mutated protein product resulting in the dysfunction of the biochemical pathway. These results indicate that this novel mutation may be the cause of CEP in this family.

Towards the identification of the gene(s) causing Dup(17)(p11.2p11.2) by BAC transgenesis. *P. Fonseca, K. Walz, R. Paylor, J. Lupski.* Dept Human Molecular Genetics, Baylor Col Medicine, Houston, TX.

Smith-Magenis Syndrome and the reciprocal Dup(17)(p11.2p11.2) Syndrome are independent genomic disorders associated with a deletion/duplication within band p11.2 of chromosome 17. Engineered mouse models for both syndromes suggest the presence of dosage-sensitive gene(s) in the region. Although mutations in *RAI1* were associated with Smith-Magenis Syndrome, it is still an open question whether the same gene is responsible for the clinical features observed in patients harboring a duplication of this chromosomal region. We generated three different lines of transgenic mice containing 3 candidate dosage-sensitive genes to generate an overexpression model that recapitulates the phenotype of the Dup(17)(p11.2p11.2) Syndrome mouse model, to rescue the phenotype of the SMS mouse model and to identify dosage sensitive genes in the SMS critical region. These animals were subjected to several tests that evaluate different domains of CNS that were abnormal for mice harboring the duplication. Preliminary data for *DEXRAS/RASD1* transgenic mice showed no significant differences between transgenic animals (N=8) and wild-type littermates (N=3) in the open-field exploratory (average total distance: 290994.20 cm (wt), 2437170.0 (transgenic), $p=0.14$; average movement time: 32224.5 sec (wt), 27719.0 (transgenic), $p=0.22$) and light-dark tests (average number of transitions: 268.8 (wt), 203.1 (transgenic), $p=0.4$). There were also no significant differences in any parameter of the prepulse inhibition of the acoustic startle response or the conditioned fear tests (percentage freezing to the context: 719.5 wt, 577.1 transgenic, p value=0.31; percentage freezing to the sound: 723.2 wt, 588.3 transgenic, p value=0.6). These data suggest that *RASD1* is not the dosage sensitive gene causing the behavioral abnormalities seen in the Dp(17)(11) mouse. *DRG2* transgenic mice do not present any obvious abnormality and behavioral tests are in progress. Transgenic mice carrying the human *RAI1* gene, as well as the murine cDNA, are currently being analyzed for the behavioral features and weight phenotype observed in the Dup(17)(p11.2p11.2) mouse model.

RAI1DEXRAS/RASD1RASD1DRG2.

Brachydactyly Type A1 (BDA1): Identification and Characterization of the Genes Involved. *A. Grimsey*^{1,3}, *E. McCready*^{1,3}, *C. Armour*¹, *S. Nikkel*², *A. Hunter*², *D. Bulman*^{1,3,4}. 1) Ottawa Health Research Institute; 2) Division of Genetics, CHEO; 3) Department of Biochemistry, Microbiology and Immunology, University of Ottawa, Ottawa and Neuromuscular Research Group; 4) Department of Medicine, Division of Neurology, University of Ottawa, Ottawa.

Brachydactyly Type A1 (BDA1) belongs to a group of rare, congenital disorders whereby normal bone development and patterning is adversely affected, leading to shortened and malformed digits. BDA1 has the unique feature of being the first human trait described in terms of autosomal dominant Mendelian inheritance. A missense mutation within the Indian hedgehog (IHH) gene at codons 95, 100 or 131 are known to cause this disorder. IHH is essential for bone development as it regulates proliferation and differentiation of chondrocytes. We recently identified linkage of BDA1 to a second locus on chromosome 5p13.3 in a large Canadian kindred indicating BDA1 is a genetically heterogeneous disease. The critical region on chromosome 5p has been refined to 7cM (3.5-4Mb) by genotype and haplotype analysis of family members, and the detection of a common haplotype that cosegregates with BDA1. Our main objective is to identify the BDA1 gene on chromosome 5 and characterize its involvement in skeletal development. Future directions include acquiring other BDA1 family members and new BDA1 families to aid in refining the position of the BDA1 locus on chromosome 5p, eventually leading to its identification and characterization.

New loci for Fraser Syndrome and mouse blebbing mutants. *S. Jadeja*¹, *I. Smyth*¹, *J. Pitera*^{1,2}, *M. van Haelst*¹, *C. Roberts*¹, *S. Darling*¹, *A.S. Woolf*², *P.J. Scambler*¹. 1) Molecular Medicine Unit, Institute of Child Health, London, United Kingdom; 2) Nephrourology Unit, Institute of Child Health, London, United Kingdom.

Fraser syndrome is a multisystem malformation usually comprising cryptophthalmos, syndactyly and renal defects; other defects occur more rarely. The condition is genetically heterogeneous with the first disease locus (*FRAS1*) having been identified. The mouse blebbed mutants are a group of five mouse strains with cryptophthalmos, syndactyly and renal defects that provide a model for Fraser syndrome. One of these mutants blebbed (*bl*) has been shown to carry a mutation in *Fras1*. The FRAS1 protein shares homology with the sea urchin extracellular matrix (ECM) blastocoelar protein ECM3. The domain structure of these proteins suggests a structural role in the extracellular matrix as well as in cell signalling. The blebbed mutants have a separation of the dermis from the epidermis, below the basement membrane.

Linkage analysis and homology searching has identified a second disease locus *FREM2* (FRAS1-like Extracellular Matrix gene/ protein), in which a missense mutation (E2041K) has been found. The murine orthologue of *FREM2* is closely linked to the *my* (myelencephalic) blebs locus. Expression analysis of *my* has revealed epithelial and renal localization. In the *bl* mutants, collagen IV and VI expression is lost, however; collagen IV is present in *my* mice. Mutation screening of *Fras2* has yet to identify a mutation, although a gene trap mutant is available and tests for allelism are underway.

To investigate the affect the different blebbed strains would have on each other, compound mutants were created by crossing the *bl* and *my* strains. Double homozygote mice (*blbl/mymy*) are viable but present with a severe renal, limb and eye phenotype.

These mouse models for Fraser syndrome should provide important insights into the development of epithelial structures, as well as eye and kidney development.

X-linked cone-rod dystrophy (COD4) in a Finnish family is caused by mutation in *CACNA1F*. R. Jalkanen¹, M. Mäntyjärvi², R. Tobias³, T. Alitalo¹, N.T. Bech-Hansen³. 1) Biomedicum Helsinki, Department of Obstetrics and Gynecology, Helsinki University Central Hospital, Helsinki, Finland; 2) Department of Ophthalmology, University of Kuopio, Kuopio, Finland; 3) Department of Medical Genetics, University of Calgary, Calgary, Alberta, Canada.

X-linked cone-rod dystrophy (COD) is a progressive retinal disease primarily affecting the cone photoreceptors. Affected males show reduced visual acuity, moderate to high myopia, photophobia, defects in color vision, central scotomas, and affected cone or cone-rod ERG responses. The disease is genetically heterogeneous and at least three genes are known to be behind the disorder. COD1 is caused by mutations in the *RPGR* gene (Xp21.1). Mutations of the *RPGR* gene are also responsible for RP3 type retinitis pigmentosa. COD2 has been localized to the long arm of the X-chromosome (Xq27.2-28). We have recently localized the third X-linked COD locus, *COD4*, on Xp11.4-q13.1 (*J Med Genet* 40:418-423).

The aim of our study was to identify the disease gene behind the COD4 phenotype. We sequenced a number of genes in the candidate region to find a disease causing mutation. Using direct PCR sequencing we screened all 48 exons of the *CACNA1F* gene (Xp11.23). A novel mutation in the splice acceptor site of intron 28 co-segregated with the disease in the Finnish X-linked COD family, and was not observed in 100 control chromosomes. This sequence change may lead to skipping of exon 29 or an alternative acceptor site upstream of exon 29.

Mutations of *CACNA1F* are known to cause two other retinal diseases: incomplete form of X-linked congenital stationary night blindness (CSNB2), including an Åland Island eye disease -like phenotype, and retinal and optic disc atrophy. Our results indicate that yet another phenotype, COD4, is caused by a mutation in the *CACNA1F* gene.

Supported in part by the Helsinki University Hospital Grant TYH1338 (Finland), and Foundation Fighting Blindness (Canada). NTBH is the Roy and Joan Allen Professor in Sight Research.

Polymorphisms of Wnt1 inducible signalling pathway protein 3 (WISP3) and susceptibility to Juvenile Idiopathic Arthritis. *R.M. Lamb¹, W. Thomson¹, E. Ogilvie³, R. Donn^{1,2}, The British Society of Paediatric and Adolescent Rheumatology.* 1) ARC/EU, University of Manchester, Manchester, England, UK; 2) Centre for Molecular Medicine, University of Manchester, UK; 3) UCL, London, UK.

Background: Juvenile Idiopathic Arthritis (JIA) is the most common chronic rheumatic disease of childhood. Progressive Pseudorheumatoid Dysplasia (PPD) is a rare skeletal disorder, which clinically mimics JIA. Mutations of the WISP3 gene are causal of PPD. WISP3 SNPs are therefore important candidates for investigation in JIA. **Aims:** To identify WISP3 SNPs and determine their role in JIA. **Methods:** Exonic mutation screening by dHPLC was performed in 86 UK Caucasian JIA cases and 20 controls. Genotyping for the identified SNPs, together with publicly available WISP3 promoter and 3UTR SNPs, was by allelic discrimination. In total seven SNPs were studied in 612 unrelated controls and, initially, 372 UK Caucasian JIA cases (Cohort 1). For replication a separate cohort of 372 UK Caucasian JIA cases (Cohort 2) were used. Comparison of genotype and allele frequencies was by the χ^2 test. Haplotype frequencies, inferred by the EM algorithm, were compared using HelixTree (GoldenHelix Inc). **Results:** Two WISP3 SNPs were associated in both JIA cohorts. Specifically, homozygosity (TT) of rs2280153 (Cohort 1 OR 1.92 95%CI 1.143.24, p=0.008; Cohort 2 OR 1.7 95%CI 12.9, p=0.036) and possession of the mutant allele rs971531A (Cohort 1 OR 1.2 95%CI 11.5, p=0.05; Cohort 2 OR 1.2 95%CI 11.5, p=0.04) is associated with increased risk of JIA susceptibility. Comparison between JIA subgroups showed no significant differences. Although strong LD exists between the associated SNPs in both JIA cases and controls ($r^2=0.9$, $D=0.9$) no significant haplotypic association of the WISP3 SNPs and JIA susceptibility was found. **Discussion:** Replication of association of the two SNPs, rs2280153 within intron 1 of the WISP3 gene and the 3UTR SNP rs971531 with JIA susceptibility was seen. Further analysis is underway in TDT families to identify linkage and association. Functional studies of linked and associated SNPs will then follow.

ANALYSIS OF INTRON 1 AND 22 INVERSIONS IN FACTOR VIII GENE IN SEVERE HEMOPHILIA A MEXICAN PATIENTS. *J. Mantilla¹, A.R. Jaloma-Cruz¹, C.P. Beltran-Miranda¹, A. Esparza², B. Lopez-Guido², L. Aguilar-Lopez².* 1) Division de Genetica, Centro de Investigacion Biomedica de Occidente. IMSS. Guadalajara, Mexico; 2) Division de Hematologia. Centro Medico Nacional de Occidente, IMSS. Guadalajara, Mexico.

Hemophilia A (HA) is caused by mutations in factor VIII gene (FVIII), it is the most common sex-linked inherited bleeding disorder. The severe disease is caused by FVIII gene intron 22 inversion (inv22) in approximately 50% of patients and by intron 1 inversion (inv1) in 5%. Both inversions result from an intra-chromosomal recombination between homologous regions, at intron 1 or 22, and their extragenic copies telomerically located from FVIII gene. The goal of the present study is to analyze the presence of large structural changes in the FVIII gene in Mexican severe HA patients. **METHODS:** We studied 102 severe HA patients from 69 families. We based our protocol on the modification to the subcycling-long distance PCR (by individual reactions) for detection of inv22 and rapid PCR for detection of inv1, both procedures for the simultaneous detection of rearrangements in patients and carriers. **RESULTS:** Until the moment we found the inv22 in 47% (14/30) of severe HA patients. After the screening of inv1 in all our severe HA population we identified only wild type individuals. **DISCUSSION:** We support the observation that intron 22 represents a hot spot of mutations in FVIII gene in severe HA patients of Mexico in similar way to other populations. In contrast, in Mexico inv1 frequency it is significant lower than in diverse European populations. **CONCLUSIONS:** The frequency of inv22 is similar to other populations, while intron 1 inversion seems to be not common in Mexicans.

Toward the identification of a new gene responsible of anhidrotic ectodermal dysplasia. *A. Munnich, A. Morlon, L. Faivre, S. Hadj-Rabia, A. Smahi.* Dept Ped Genetics, Inserm U393, Hosp Enfants Malades, Paris, paris, France.

Ectodermal dysplasia (ED) is a clinically heterogeneous condition characterized by the abnormal development of ectoderm-derived structures including teeth, hair, nails and eccrine sweat glands. The anhidrotic form (EDA) is characterized by the association of sparse hair (atrachosis or hypotrichosis), abnormal or missing teeth (anodontia or hypodontia) and the inability to sweat (anhidrosis) which is responsible for life-threatening brain-damaging episodes due to hyperthermia. The most common type of EDA (MIM 305100) is a X-linked recessive disorder caused by mutations in the ectodysplasin gene (ED1), a member of TNF (Tumor Necrosis Factor) cytokine superfamily. Autosomal dominant and recessive forms of EDA have been also reported (MIM 224900) and are allelic at the ED3 locus that encodes EDAR a protein belonging to the TNF receptor superfamily. Mutations in the EDARADD gene are also responsible of autosomal recessive EDA. During skin appendages morphogenesis, EDAR is activated by Ectodysplasin and uses EDARADD as an adapter to build a signal-transducing complex leading to NF- κ B activation. We present a three-generation family with an autosomal dominant EDA. Among the 55 members of this family, 17 individuals were affected and presented the classical phenotype of EDA with marked dental abnormalities. By linkage analysis, we excluded the ED3 (2q13) and EDARADD (1q42) loci. We also excluded XEDAR (Xq12), Troy (13q12.12) and TRAF6 (11p12) genes which are candidate genes for anhidrotic ectodermal dysplasia. We performed a genome wide search and are currently investigating the candidate regions.

Identification of the gene mutated in Amish Brittle Hair (Hair Brain) syndrome. *K. Nakabayashi¹, D. Amann², N. Avidan², Y. Ren¹, U. Kere³, S. Gentles¹, J. MacDonald¹, E.G. Puffenberger⁴, A. Martinez-Mir⁵, J. Salas⁵, A. Christiano⁵, C. Les⁶, E. Seboun⁷, J. Beckmann², C.E. Jackson⁸, S.W. Scherer¹.* 1) Dept. of Genet., The Hosp. for Sick Children, Toronto; 2) Dept. of Mol. Genet., Weizmann Inst. of Science, Rehovot, Israel; 3) Dept. of Dermatol., Univ. of Helsinki, Finland; 4) The Clinic for Special Children, Strasburg, PA; 5) Dept. of Dermatol., Columbia Univ., New York, NY; 6) Henry Ford Hosp., Detroit, MI; 7) Div. of Genet. and Microbiol., Univ. Pierre et Marie Curie, Paris, France; 8) Dept. of Med., Scott & White Memorial Hosp., Temple, TX.

Amish Brittle Hair syndrome (OMIM:234050) is an autosomal recessive disorder characterized by short stature, intellectual impairment, brittle hair, and decreased male fertility. The patients hair shows low sulfur content, an irregular and grooved surface on scanning electron microscopy and distinct changes on polarization microscopy. Sabinas syndrome, trichorrhexis nodosa with mental defect, and Pollitt syndrome have been suggested to be the same disease with Brittle Hair syndrome. Homozygosity mapping on a subset of affected members from a large Amish consanguineous kindred identified a 2 Mb candidate locus on chromosome 7p. Mutation screening of 7 candidate genes within the interval identified a homozygous sequence variation that causes an amino acid change (methionine to valine) in one of the genes. Further mutational analysis revealed that all 13 affected members are homozygous for the sequence variation, and 28 unaffected members are either heterozygous for the variation or homozygous for the normal allele (150 controls including 48 Amish individuals were found to be homozygous for the normal allele). These data strongly suggest that this sequence variation is causal for the disease phenotypes in the kindred. Involvement of this gene with Sabinas syndrome has been excluded by the lack of linkage to the 7p locus. The gene is predicted to encode a 180 amino-acid (aa) protein, which does not contain any known motifs. The mutated aa residue is located in a fifteen aa sequence that is highly conserved from fly to mammals. Characterizations of gene expression patterns and protein functions are underway.

Characterisation of a de novo translocation in a patient with isolated respiratory complex I deficiency. *L. Parry¹, E. Haquet¹, D.R. Thorburn^{1,2,3}, H. Dahl^{1,2}.* 1) Murdoch Children Research Institute, Royal Childrens Hospital, Flemington Rd, Parkville, Melbourne, VIC 3052, Australia; 2) Genetic Health Services Victoria, Royal Childrens Hospital, Parkville, Melbourne, VIC 3052, Australia; 3) Department of Paediatrics, University of Melbourne, Melbourne, Australia.

With a minimum birth prevalence of 1/5,000, primary respiratory chain disorders are one of the most common forms of neuromuscular disease. Respiratory complex I (CoI) deficiency, the most prevalent respiratory chain disorder, is a genetically heterogeneous condition. Although mutations have been identified in eight nuclear subunits and seven mitochondrial DNA genes, the etiology of most CoI cases remain unknown. In the majority of cases the families are not suitable for linkage analysis. Furthermore, little is known about the factors needed for assembling and modifying the CoI complex. As a consequence it has been difficult to identify novel genes responsible for CoI deficiency and alternative approaches are needed. We have identified a unique patient with a de novo chromosome 11:18 translocation [t(11:18)(p12;q21.3)]. FISH analysis identified BACs, which spanned the breakpoints on the derivative chromosomes. Currently for chromosome 11 southern analysis has reduced the 199kb region identified by BAC RP11-768P16 to ~70kb. For chromosome 18 the 146kb region identified by BAC R145-D03A has been reduced to 35kb, with a ~0.5Mb inversion identified adjacent to this. Neither of the regions disrupted by the rearrangements disrupts any known genes. Analysis of ESTs within the region has identified a single EST which was expressed in control cDNA but absent in patient cDNA. Here we present data on the refinement of the complex genomic rearrangement, analysis of EST sequences expressed in the region and microarray analysis of global gene expression in patient cells.

Familial tumoral calcinosis is an O-glycosylation disorder due to loss of function mutations of GALNT3 and is genetically heterogeneous. G. Richard¹, O. Topaz^{2, 3}, R. Bergman^{2, 3}, D.L. Shurman¹, M. Indelman², R. Ratajczak¹, M. Mizrachi^{2, 3}, Z. Khamaysi², D. Behar³, D. Petronius², V. Friedman³, I. Zelikovic^{2, 3}, S. Raimer⁴, A. Metzker⁵, E. Sprecher^{2, 3}. 1) Thomas Jefferson University, Philadelphia, PA; 2) Rambam Medical Center, Haifa, Israel; 3) Technion-Israel Institute of Technology, Haifa, Israel; 4) University Texas Medical Branch, Galveston, TX; 5) Tel Aviv-Sourasky Medical Center, Israel.

Familial tumoral calcinosis (FTC) is an autosomal recessive metabolic disorder with normal or elevated serum phosphate levels characterized by massive, painful calcium deposits in the skin and subcutaneous tissues resulting in profound disability and mutilation. We mapped hyperphosphatemic FTC in 2 large kindreds of different origins to a 3 Mb region in 2q24-q31 while 4 families with normophosphatemic FTC showed no linkage, suggesting that normo- and hyperphosphatemic FTC are not allelic. The 2q region harbors the *GALNT3* gene encoding a member of the GalNAc-transferases family (ppGalNAc-T3) responsible for initiating mucin-type O-glycosylation. RT-PCR analysis demonstrated expression of *GALNT3* in the skin, kidney, bone marrow, lung and other epithelial organs. DNA sequencing revealed 3 pathogenic *GALNT3* mutations, a nonsense mutation in exon1 and 2 distinct nucleotide transitions altering the donor splice site in intron 7, segregating in the hyperphosphatemic FTC families. The mutations in both families were shown to abolish full-length *GALNT3* transcripts and, in one family, resulted in low production of an aberrant splice variant lacking 44 residues due to skipping of exon 7. Nevertheless, immunostaining of ppGalNAc-T3 in affected epidermis was completely absent. ELISA tests demonstrated that serum levels of FGF23, a key regulator of circulating phosphate levels, were significantly elevated in FTC patients, suggesting a compensatory upregulation of FGF23 or decreased FGF23 clearance. Our results demonstrate for the first time the pathological consequences of a genetic defect in a mucin-type O-glycosylation pathway and implicate ppGalNAc-T3 in the regulation of phosphate homeostasis and basic calcium crystal formation.

Recovery, additional characterization and further mapping of mouse coralliform cataract (Coc) locus. D.

Sidjanin¹, J. Favor², L. Jackson^{1,3}, K. Schneck¹, E. Talamas¹. 1) Department of Ophthalmology, Medical College of Wisconsin, Milwaukee, WI; 2) GSF-National Research Center for Environment and Health, Institute of Mammalian Genetics, D-85764 Neuherberg, Germany; 3) Wiley College, Marshall, TX.

Cataracts, or lens opacities, are the leading cause of blindness worldwide. The coralliform cataract (Coc) is a murine autosomal dominant locus recovered in the offspring of a 5.1 + 5.1 Gy X-irradiated male. Both Coc/Coc and Coc/+ were shown to exhibit small spherical opacities in the central part of the lens. The Coc locus was mapped to 28 cM of chr. 16 in the region with synteny with HSA3p12-q21 and cryopreserved. In this study we recovered the Coc mice from Coc/+ sperm, further clinically described the affected mice and generated additional backcross progeny. Utilizing a standard IVF techniques 6 mice (5 males and 1 female) were generated. On a slit lamp examination two recovered males showed no signs of lens opacities. The remaining four littermates (three males and a female) all showed microphthalmia, squinting of the eyes, coralliform nuclear cataracts and were presumed to be Coc/+. The recovered Coc/+ mice were outcrossed to C57BL/6 and mice (C3H Coc/+ x C57BL/6) that showed cataracts (Coc/+) were then backcrossed to C57BL/6 to generate a backcross panel for further mapping. The cataract phenotype of affected backcross animals was similar to the parental phenotype. Further mapping of the Coc locus is currently in progress. In addition to generating a backcross panel we set up a cross of heterozygotes (Coc/+ x Coc/+). A litter of six mice was generated and at weaning no ocular abnormalities were detected in 4 littermates. The two remaining littermates appeared to be affected: one showed microphthalmia, squinting of the eyes and coralliform nuclear cataract similar to the parental phenotype; the other mouse had unopened sinking eyelids suggesting absence of both eyes. Both affected mice were smaller in size relative to the wild type littermates. Further matings have been set up to generate additional Coc animals for histological analysis.

Program Nr: 2601 from the 2004 ASHG Annual Meeting

A new mutation of *EFHC1* associating with juvenile myoclonic epilepsy. T. Suzuki¹, A.V. Delgado-Escueta², K. Aguan¹, M.E. Alonso³, J. Shi¹, M.T. Medina⁴, T. Takeuchi¹, D. Bai², J.N. Bailey², A. Ochoa³, A. Jara-Prado³, A. Rasmussen³, F. Rubio-Donnadieu³, K. Yamakawa¹. 1) Lab. for Neurogenetics, RIKEN BSI, Saitama, Japan; 2) Epilepsy Genetics/Genomics Laboratories, Comprehensive Epilepsy Program, UCLA School of Medicine and VA GLAHS-West Los Angeles, Los Angeles, CA; 3) National Institute of Neurology and Neurosurgery, Mexico City, Mexico; 4) National Autonomous University, Tegucigalpa, Honduras.

Among idiopathic generalized epilepsies, juvenile myoclonic epilepsy (JME) is the most common, accounting for 10-20 % of all epilepsies. Previously we mapped one of the candidate regions on chromosome 6p12-p11 (*EJMI*), and narrowed it to the 3.5cM region (Bai *et al.* Am J Med Genet 113:268-274, 2002). Recently we reported JME mutations of a new gene *EFHC1* in the *EJMI* region and functional copromises of EFHC1 protein by the JME mutations (Suzuki *et al.*, 2004 in press). We then further recruited new JME families, performed mutation analyses on these families, and identified an additional novel missense mutation of *EFHC1* in the mutation hot spot region further suggesting the functional significance of the region. We also show the functional effects of EFHC1 with the mutation on apoptosis.

Canadian Cystic Fibrosis Modifier Gene Project. *J. Zielenski¹, A. Sandford², M. Corey¹, R. Dorfman¹, D. Markiewicz¹, X-W. Yuan¹, A. Master¹, I. Evtoushenko¹, G. Deng¹, M. Patel¹, I. Aznarez¹, M. Tan¹, F. Lin¹, P.D. Paré², L-C. Tsui^{3,1}, P. Durie¹, and Canadian CF Clinics.* 1) Hospital for Sick Children, Toronto, Canada; 2) iCAPTURE/UBC, Vancouver, Canada; 3) University of Hong Kong, Hong Kong.

Cystic fibrosis (CF) is a monogenic disease caused by mutations in the cystic fibrosis transmembrane regulator (CFTR) gene. The phenotypic variability of CF is influenced by CFTR mutations as well as variations in other genes (modifiers). Due to the complex nature of these influences, genetic analyses of large populations are recommended. To this end, the Canadian CF Modifier Gene Project has been launched, aiming at the mapping and isolation of genes influencing severity of disease in CF. The Project involves: (1) blood collection from Canadian CF families; (2) clinical data collection from CF patients; (3) re-structuring and updating Canadian CF Patient Data Registry; (4) CF modifier candidate gene analysis and (5) genome linkage analysis to detect CF modifier loci. To date, 30 Canadian CF Clinics have obtained consents from 1128 CF families (target: ~2300 families). Genomic DNA was extracted from 4858 blood samples collected from patients and parents. In addition, 923 lymphoblast cell lines have been established. Extensive cross-sectional and longitudinal clinical data is being collected from medical charts of CF patients. Approximately 80% of the data have been securely submitted to the database from charts of participating patients. Testing of genes and loci as potential CF modifiers is performed using two approaches: candidate gene analyses and genomic scans. Currently, 57 genes with relevance to CF have been selected as potential modifiers. Genotyping of 89 intragenic markers is in various stages of completion. Also, a chromosome 6qter locus is being tested in CF families as a putative modifier of pulmonary function. The progress in these areas of the project is presented in separate abstracts. In order to oversee, regulate and govern resources created in the current Project, the Canadian Consortium for CF Modifier Studies is being established (Supported by Genome Canada and Canadian CF Foundation).

Imprinting and acid sphingomyelinase deficient Niemann-Pick disease. C. Simonaro, J. Park, E. Schuchman. Dept Human Genetics, Mount Sinai Sch Medicine, New York, NY.

An inherited deficiency of acid sphingomyelinase (ASM) activity results in the lysosomal storage disorder, Niemann-Pick disease (NPD). Historically, two clinically distinct forms of NPD have been associated with this enzyme deficiency: the infantile, neuronopathic Type A, and the non-neuronopathic Type B. However, recent research has revealed a wide spectrum of disease among patients with ASM deficiency, including the identification of some patients with later onset and less severe neurological involvement. In addition, at least one manifestation of ASM deficiency, very low HDL-cholesterol, is often found in carrier (heterozygous) individuals. It has been suggested previously that the ASM gene locus (*SMPD-1*), located on the short arm of chromosome 11 (11p15.1-15.4), may be imprinted based on the observation that an individual with Beckwith-Weidemann syndrome who inherited two paternal chromosome 11's also had low ASM activity and hepatosplenomegaly (Rethy *et al.*, Path. Oncol. Res., 2000). We therefore examined the expression of *SMPD-1* mutant alleles in several patients and carriers with ASM deficient NPD. We observed preferential expression of the maternal allele, and found that in some families the disease phenotype could be correlated with the severity of the mutation carried on the maternal chromosome. We also observed in some carrier individuals that low HDL-cholesterol could be correlated with maternal inheritance of the mutant allele. Thus, we propose that the variation in clinical findings among ASM deficient NPD patients and carriers may be partially explained by genomic imprinting at the *SMPD-1* locus.

Mutation analysis in *ABCC6* reveals no evidence for dominant inheritance of Pseudoxanthoma Elasticum (PXE).

In 1972 British families were reported to show dominant inheritance of PXE. Mutations in the *ABCC6* gene cause PXE. During our mutation screen of *ABCC6* in 170 PXE chromosomes from 81 families we also analyzed a subset of 9 families with the occurrence of PXE in more than 1 generation or in first degree cousins suggesting an apparent dominant mode of inheritance of the disease. Familial haplotype analysis did not identify affected sib pairs as heterozygotes at the gene locus. This was confirmed by mutation analysis that showed all affecteds to carry two allelic *ABCC6* mutations in accordance with a recessive molecular inheritance mechanism. The transmission of the disease from an affected parent to the next generation always required two parental mutant allelic variants independent of the clinical disease status of each parent. This proves pseudo-dominance as the relevant inheritance mechanism. Moreover, affecteds of 93 % (67 out of 72) of the families with PXE in a single generation are either homozygous for the same, or compound heterozygous for 2 mutations. The remaining 5 families with only one uncovered mutation show allelic compound heterozygosity for the cosegregating PXE haplotype. Despite other previous clinical and molecular claims our results show only evidence for recessively inherited PXE. This has profound consequences for the genetic counseling of families with PXE.

Refinement of the Cerulean Cataract Type 1 Locus on 17q25.3 to a 0.5 Mb Critical Region. *M.B. Gorin^{1,3}, B.W. Rigatti¹, F.Y. Demirci¹, S.R. Clarke¹, T.S. Mah¹, D.E. Weeks^{2,3}, R.E. Ferrell³*. 1) Dept Ophthal, Univ Pittsburgh, Pittsburgh, PA; 2) Dept Biostatistics, Univ Pittsburgh, Pittsburgh, PA; 3) Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA.

Cerulean cataracts (CCA) are autosomal dominant, juvenile-onset hereditary cataracts that are noteworthy for tiny blue or white opacities, predominantly in the lens cortex. The CCA1 locus was originally mapped in a single large family between microsatellite markers D17S802 and D17S836 based on 6 recombinations. We have redefined that interval by identifying additional family members (now totaling 137 members) and evaluating new polymorphic markers. These new markers (microsatellites and SNPs) were evaluated by using a combination of ABI genotyping, DHPLC (Transgenomic Wave), RFLP, and direct PCR sequencing techniques.

At this time, we have established a narrower critical interval of 0.5 Mb. In addition to 7 known microsatellite markers, 10 of the 18 novel microsatellite markers and 16 of the 22 SNPs have been found to be informative in this family. Selection of potential candidate genes within the critical interval has been based on their expression in lens by using the NEIBank lens cDNA database, NCBI UniGene expression information and confirmation by PCR in human lens cDNA library. Thirty-four candidate genes interspersed within the original 4.7 Mbp region of 17q25.3 were evaluated for expression in human lens and for mutation analysis. All exons and splice junctions were screened for mutations by direct PCR sequencing that revealed no evidence of disease-causing variations. Within our new critical region, there are only 15 known or putative genes that have not yet been screened. Of these, 9 show evidence of lens expression. Testing of these genes is currently underway as well as the evaluation of additional SNPs to further refine the critical region and the testing of the remaining 6 genes for expression in the lens cDNA library. Elucidation of the causative gene for CCA1 is likely to identify a novel gene whose role in lens biology has not been previously recognized and which may yield new insights into the pathogenesis of hereditary cataracts.

Four Additional Missense Mutations in *VEGFR3* Underlying Primary Congenital Lymphedema (Milroy disease).

A. Ghalamkarpour¹, A. Irrthum¹, L.M. Boon^{1, 2}, S. Morlot³, A. Raas-Rothschild⁴, R. Spiegel⁵, S.A. Shalev⁵, J.B. Mulliken⁶, M. Vikkula¹. 1) Laboratory of Human Molecular Genetics, Christian de Duve Institute and Université catholique de Louvain, Brussels, Belgium; 2) Center for Vascular Anomalies, Université catholique de Louvain, Brussels, Belgium; 3) Praxis für Humangenetik, Hannover, Germany; 4) Department of Human Genetics, Hadassah Ein-Kerem Hospital, Jerusalem, Israel; 5) Genetics Institute, Ha'Emek Medical Center, Afula, Israel; 6) Vascular Anomalies Center, Children's Hospital, Harvard Medical School, Boston, USA.

Primary lymphedema is an excessive fluid accumulation in subcutaneous tissues due to idiopathic failure of lymphatics. Genetic studies have identified specific genetic mutations causing primary lymphedema and lymphedema-associated disorders. Mutations in vascular endothelial growth factor receptor 3 (*VEGFR3*), a transmembrane tyrosine kinase receptor, cause primary congenital lymphedema (PCL) or Milroy disease (MIM 153100) (Irrthum et al., 2000; Karkkainen et al., 2000). Lymphedema-distichiasis syndrome (LD; MIM 153400) has been shown to be caused by mutations in the *FOXC2* gene, a member of the forkhead/winged-helix family of transcription factors (Fang et al., 2000). The most recent studies have identified mutations in the *Sry*-related HMG box containing transcription factor gene *SOX18*, to cause lymphedema associated with hypotrichosis and telangiectasia (HLT; MIM 607823) (Irrthum et al., 2003). To date, thirteen mutations in *VEGFR3* have been identified causing PCL (Irrthum et al., 2000; Karkkainen et al., 2000; Evans et al. 2003). In this study, we present four novel mutations in the *VEGFR3* gene underlying PCL. The mutations were found to co-segregate with lymphedema in the families. All of the mutations were missense mutations causing amino acid substitutions in the kinase domain I or II of the receptor. None of the mutations were present in control individuals. We predict that these mutations result in a defective receptor due to the role of the kinase domain of *VEGFR3* for its catalytic activity. (<http://www.icp.ucl.ac.be/vikkula>) (vikkula@bchm.ucl.ac.be).

Novel Tunisian mutations in mucopolysaccharidoses IH and IVA. *S. Laradi*^{1,2,3}, *M. Erazo*¹, *A. Haj Khelil*², *J. Shabber*¹, *S. Ferchichi*^{2,3}, *A. Kassab*³, *S. Ben Mdalla*³, *M. Chaabouni*⁴, *T. Jraad*⁵, *H. Soua*⁶, *L. Chkioua*³, *H. Bouzidi*^{2,3}, *R. Taalouche*^{2,3}, *H. Zaglaoui*^{2,3}, *B. Tabarki*³, *A. Miled*^{2,3}, *T. Tukul*¹, *R.J. Desnick*¹. 1) Mount Sinai School of Medicine, New York, NY; 2) Faculty of Pharmacy, Monastir, Tunisia; 3) F Hached Hospital, Sousse, Tunisia; 4) H Chaker Hospital, Sfax, Tunisia; 5) Msaken Hospital, Tunisia; 6) T Sfar Hospital, Mahdia, Tunisia.

Mucopolysaccharidoses (MPS) types IH (Hurler syndrome) and IVA (Morquio A) result from the defective activity of -L-iduronidase (IDUA) and N-acetylgalactosamine-6-sulfatase (GALNS), respectively. Both diseases have severe and milder phenotypic subtypes. Three unrelated severe MPS IH patients and four severe MPS IVA patients from Central and Southern Tunisia were screened for DNA mutations. Each of the exons and intron-exon junctions of IDUA or GALNS were sequenced after PCR-amplification from genomic DNAs. In the MPS IH patients, two novel (3904delTinsGAACA in exon 13 and I270S in exon 7) and two previously reported (P533R and R628X) IDUA mutations were detected. The novel missense mutation I270S was found in a patient who also had the nonsense mutation R628X on the other allele. In MPS IVA, three patients were homozygous for a novel G to A transition in the conserved donor splice site in intron 1 (GACgtGACat; designated IVS1^{+1G-A}). The fourth patient was homozygous for a G to C transversion in exon 1 predicting a glycine to arginine missense mutation (G66R). Thus, identification of these mutations should facilitate prenatal diagnosis and counseling for MPS IH and MPS IVA in Tunisia where a very high rate of consanguinity still exists.

Characterization of New *SDHD* Mutations in Sporadic and Familial Head and Neck Paraganglioma from Belgium. A. Persu¹, V. Grégoire², J.-F. De Plaen¹, P. Garin⁴, M. Hamoir³, M. Vikkula⁵. 1) Nephrology Dept and; 2) Radiotherapy Dept and; 3) Otolaryngology Dept, Clin Univ St-Luc, Brussels; 4) Otolaryngology Dept, Clin Univ de Mont-Godinne (UCL), Yvoir; 5) Lab of Human Molecular Genetics, Christian de Duve Institute & Université catholique de Louvain, Brussels, Belgium.

Head and neck paraganglioma (PG) are hypervascular tumors derived from the neural crest. Mutations of the *SDHD* gene, which encode a subunit of complex II of the mitochondrial respiratory chain are at the origin of most familial cases of PG and a minority of apparently sporadic pheochromocytoma. We recruited all patients with PG seen in the main Academic Centers in Belgium from May 2003 to May 2004. Written informed consent, standardized clinical information and blood samples for DNA extraction were obtained. Screening of the coding parts of *SDHD* was performed by SCCP and heteroduplex analysis, followed by sequencing whenever a shift was observed. *SDHD* screening was performed in 31 index patients including 26 patients without familial history of PG and 5 patients with at least one other affected family member. In the latter, recruitment was further extended to available family members. Familial and sporadic cases differed by mean age at diagnosis (30.09.6 vs. 53.515.7 years), proportion of bilateral (78% vs. 12%), multiple (67% vs. 0) relapsing (56% vs. 15%) or ectopic tumours (44% vs. 0%) and prevalence of *SDHD* mutations (80.0% vs. 7.7%). Five different mutations (3 frameshift mutations leading to premature stop codon, one splice site mutation and one substitution) were found in 6 different patients including 4 familial cases and 2 apparently sporadic cases. Four of them were not described previously. Interestingly, the single family for which no *SDHD* mutations was found was characterized by a particularly severe phenotype with rare manifestations including hepatic, vertebral and mediastinal localizations. In this pedigree, screening for mutations in the coding parts of the 2 other genes at the origin of familial PG, *SDHC* and *SDHB*, also proved negative, which suggests further genetic heterogeneity in hereditary PG. (alexandre.persu@nefr.ucl.ac.be) (<http://www.icp.ucl.ac.be/vikkula>).

Preliminary analysis of human chromosome 6q27 locus as modulator of pulmonary disease in cystic fibrosis. I. Evtoushenko¹, D. Markiewicz¹, G. Deng¹, M. Patel¹, R. Dorfman¹, M. Corey¹, M. Tan¹, F. Li¹, A. Sandford³, P. Paré³, P. Durie¹, L-C. Tsui^{2,1}, J. Zielenski¹, and Canadian CF Clinics. 1) Hospital for Sick Children, Toronto, Canada; 2) University of Hong Kong, Hong Kong; 3) iCAPTURE/UBC, Vancouver, Canada.

Several independent studies have demonstrated genetic contribution to pulmonary function (PF). The presence of a major gene locus influencing PF has been recently reported on human chromosome 6q27 (Framingham Heart Study). The strongest linkage and association was documented for the Forced Expiratory Volume in 1 sec (FEV1) using short tandem repeat (STR) markers located in the region. To test for the potential modulating effect of the 6q27 locus on the severity of pulmonary disease in cystic fibrosis (CF) patients we have initiated an association study for selected STR markers in this region. Up to 381 CF families ascertained in the Canadian CF Modifier Gene Project were genotyped for three STR markers from the 6q27 region: D6S281, D6S1027 and D6S1693. The most recent patient PF measurements were adjusted for age, height and gender (percent predicted values; FEV1PP). Standard deviation scores of FEV1PP values were calculated based on a reference population of patients homozygous for deltaF508. Association was tested using the Family Based Association Tests (FBAT) software. Parametric FBAT analysis of association between the spirometric measurements and STR markers was performed using different models (additive, recessive and dominant). The genotype data obtained for these markers demonstrated allelic frequencies similar to those previously published. At present, our preliminary FBAT analysis shows a significant association only for D6S281 with FEV1PP ($p=0.01$) in the dominant model. The same marker was associated in the Framingham Heart Study. We continue the testing in a larger study population to verify the 6q27 region as a potential modifier locus of the pulmonary phenotype in CF. In addition, candidate genes in the region of the associated marker are also being investigated. (Supported by the Genome Canada and Canadian CF Foundation).

Program Nr: 2610 from the 2004 ASHG Annual Meeting

preliminary analysis of human chromosome 6q27 region as a potential modifier locus for pulmonary disease in cystic fibrosis. *I. Tevtoushenko¹, D. Markiewicz¹, G. Deng¹, M. Patel¹, R. Dorfman¹, M. Corey¹, M. Tan¹, F. Li¹, L. Sun³, A. Sandford⁴, P. Pare⁴, P. Durie¹, L.C. Tsui^{2,1}, J. Zielenski¹, participating Canadian CF Clinics Directors.* 1) Genetics and Genomic Biology, Hospital for Sick Children, Toronto, Canada; 2) University of Hong Kong, Hong Kong; 3) University of Toronto, Toronto, Canada; 4) iCAPTURE/UBC, Vancouver, Canada.

Background: The contribution of genetic factors to pulmonary function has been investigated in several independent studies. Heritability of these measures has been estimated at around 40%. Evidence for a major gene locus influencing pulmonary function has been recently reported on human chromosome 6q27 by the Framingham Heart Study. Both linkage and association to FEV1 and FVC were documented for short tandem repeat (STR) markers in the region. We have initiated an association study for selected STR markers in the 6q27 region to test for a potential modifying effect on pulmonary function in CF. Methods: Available trios (CF patient + parents) ascertained by the Canadian CF Modifier Gene Study were genotyped for 3 STR markers selected from the 6q27 region: D6S281 (N=381), D6S1027 (N=180), and D6S1693 (N=149). The most recent spirometric measurements (FEV1 and FVC) submitted by participating Canadian CF Clinics were adjusted for age, height and gender using standard equations (percent predicted FEV1 and FVC).

Golabi-Ito-Hall syndrome results from a missense mutation in the WW domain of the PQBP-1 gene. *F.E. Abidi¹, L. Holloway¹, H. Lubs¹, A. Meindl², R.E. Stevenson¹, C.E. Schwartz¹.* 1) JC Self Research Institute, Greenwood Genetic Center, Greenwood, South Carolina, USA; 2) Department of Medical Genetics, Ludwig-Maximilians-University, Munich, Germany.

Golabi-Ito-Hall syndrome is characterized by X-linked mental retardation (XLMR), microcephaly, short stature and ectodermal manifestations (brittle scalp hair, nail hypoplasia, cutis marmorata, and large maxillary central incisors). The clinical features of microcephaly and short stature are associated with other XLMR syndromes such as the Renpenning syndrome and the Sutherland-Haan syndrome. Recently, mutations in the PQBP-1 gene have been reported in both these syndromes. Based on this observation, analysis of the PQBP-1 gene in a member of the original family with Golabi-Ito-Hall syndrome was undertaken. A missense mutation was identified which changes the conserved tyrosine residue in the WW domain at position 65 to a cysteine (p.Y65C). This finding is unique as it is both the first report of a missense mutation in PQBP-1 and the first mutation identified in the WW domain of the gene.

The WW domain has been shown to play an important role in the regulation of transcription by interacting with the PPxY motif found in transcription factors. The p.Y65C mutation may affect the proper functioning of the PQBP-1 protein as a transcriptional co-activator. The five mutations previously reported cause premature truncation of the PQBP-1 protein. Three of them result in a protein lacking part of the DR/ER repeat in the PRD domain as well as the entire NLS (nuclear localization signal) and the C2 domains. The DR/ER stretch is involved in transcriptional control by binding to the poly Q region of BRN2 which inhibits transcription. The other two mutations affect neither the PRD domain nor the NLS domain. Instead, they give rise to a truncated protein which partially or completely lacks the C2 domain, which maybe involved in signal transduction or membrane trafficking. It is interesting that the ectodermal manifestations observed in the Golabi-Ito-Hall syndrome have not been reported in the families with truncating mutations.

ATRX syndrome : Novel mutations in the helicase domain. *C. Badens¹, F. Giuliano², A. Verloes³, C. Mouradian¹, P. Malzac¹, N. Philip¹, N. Levy¹.* 1) Department of Genetics, Hopital de la Timone, Marseille, France; 2) Departments of Genetics, Hopital l'Archet 2, Nice , France; 3) Department of Genetics, Hopital Robert Debre, Paris, France.

The main features of the ATR-X syndrome are profound mental retardation, characteristic facial dysmorphism and -thalassemia. Although this latter feature is not constant, it led to the initial identification and description of this syndrome. The gene involved in this syndrome, designated ATRX, maps to Xq13.3 and codes for a zinc finger helicase . Since its identification, more than 70 mutations have been described in 150 families. Correlation between phenotype and genotype is not straight forward but so far, the Zn finger domain, one of the functional domain, has been much often investigated than the other regions, especially the helicase domain. As a result, 80% of the mutations described are localised in the Zn Finger domain. In order to determine if mutations in other parts of the gene have been under-investigated, we planned to perform systematic sequencing of the ATRX gene in a group of 30 patients selected as follow : 1-Characteristic facies, 2- unbalanced X inactivation in the patients mother, 3-no mutation in the Zn Finger domain. So far, we investigated the region from exons 16 to 35 which includes the helicase domain. Three (10%) new missense mutations were found in exons 19, 26 and 30 (respectively G1676A, L2022F and R2178W), all situated in highly conserved regions. Although 20% of the targeted region remains to be analysed, mutations in the 3part of the gene seem to be less frequent than mutations in the Zn finger domain, representing 20% of all ATRX mutations identified in our laboratory. Beside the molecular study, exhaustive clinical data are collected, including IQ determination, in the patients currently investigated and in patients previously characterised with mutation in the Zn finger domain. This will permit to determine if a specific phenotype (especially mild mental retardation) is associated with mutations in the 3 part of the gene.

Kainic acid seizures in the fragile X knock out mouse and reduced GABA-A receptor expression. *C. Dobkin¹, A. El Idrissi³, X-H. Ding¹, E. Trenkner², R. Bauchwitz⁴*. 1) Dept Human Genetics, NYS Inst Basic Research, Staten Island, NY; 2) Developmental Cell Biology, NYS Inst Basic Research, Staten Island, NY; 3) Department of Biology, College of Staten Island/CUNY, Staten Island, NY; 4) St. Luke's-Roosevelt Institute of Health Sciences, Columbia University, NY, NY.

One feature of the fragile X mental retardation syndrome is an increased prevalence of childhood seizures. The fragile X mouse model for this disorder has been shown to have an increased susceptibility to audiogenic seizures. We found that the fragile X mouse also has increased susceptibility to limbic seizures induced pharmacologically by peripheral injection of kainic acid (KA). Congenic FVB/N as well as congenic C57BL/6 fragile X mice both show increased susceptibility to KA seizures quantified by seizure duration and by excitotoxic cell death in the CA3 region of the hippocampus. We also found that introduction of the human fragile X gene, FMR1, into the FVB/N fragile X mice essentially reversed the increased seizure susceptibility induced by the knock out of the endogenous Fmr1 gene. To investigate the neuropathogenesis of increased seizure susceptibility, we examined GABA-A receptor expression in the FVB/N fragile X mouse. Western blot analysis indicated that expression of the GABA-A receptor beta subunit (GABAR β) was reduced in the cortex, hippocampus, diencephalon and brainstem in adult male fragile X mice. Immunohistochemical analysis of brain sections suggested a reduction in GABAR β immunoreactivity. These results imply that the absence of Fmrp leads to significant alterations of the GABAergic system that could account for the increased seizure susceptibility of the fragile X mouse and may be relevant to the seizures and the abnormal behaviors in the fragile X syndrome.

A novel candidate gene for X-linked non syndromic mental retardation. A. Dubos¹, H. Dollfus², F. Abidi³, N.L. Tang⁴, S. du Manoir¹, S. Pannetier¹, C.E. Schwartz³, A. Hanauer¹. 1) Institut de Genetique et de Biologie Moleculaire et Cellulaire, CNRS/INSERM/ULP, BP10142, 67404 Illkirch Cedex, France; 2) Service de Genetique Medicale, Hopitaux Universitaires de Strasbourg, Avenue Moliere, 67098 Strasbourg Cedex, France; 3) J C Self Research Institute, Greenwood Genetic Center, Greenwood, SC, USA; 4) Department of Chemical Pathology, Faculty of Medicine, The Chinese University of Hong Kong, Kong Kong.

Non syndromic X-linked mental retardation (MRX) is defined by an X-linked inheritance of low IQ (<70) and adaptive skills limitations without other clinical features. Eighteen MRX genes have been identified so far, while more than 50 are expected. To identify novel MRX genes, we have studied female patients presenting mental retardation and balanced X:autosome translocations. After detection of the X breakpoint spanning clone by fluorescence *in situ* hybridization (FISH), we searched *in silico* for genes in the breakpoint region. In one patient with mild mental retardation and a (X:19) translocation, we identified a gene, KIAA1202 disrupted by the X breakpoint. Furthermore, a serine to leucine amino acid change (S1089L) was found in a Brazilian family after KIAA1202 mutation screening in a panel of 18 X-linked mental retardation families from South and North America. S1089L change segregated with the disease in the family and was not found in 300 control individuals. Northern-blot analysis in human revealed a predominant transcript in all tissues and brain regions tested with high expression in medulla, putamen and occipital, frontal and temporal lobes. RT-PCR experiments in mouse showed KIAA1202 mouse homolog expression during development (E7,5 to E16,5) and in all brain regions tested with highest expression in brain stem, striatum and cerebellum. KIAA1202 belongs to the Apx/APXL/Shroom protein family. Apx is associated in a macromolecular complex to the epithelial sodium channel (ENaC) and Shroom regulates cytoarchitecture during neurulation. Moreover, KIAA1202 contains a PDZ domain, a motif also present in DLG3, recently identified as an important contributor gene in MRX. Our results suggested that KIAA1202 is a good candidate gene for mental retardation.

A novel in-frame deletion in ARX is associated with lissencephaly with absent corpus callosum and hypoplastic genitalia. *R.C. Rogers, S. Bhat, K.R. Holden, A.K. Srivastava.* J. C. Self Research Institute of Human Genetics, Greenwood Genetic Center, Greenwood, SC.

Aristaless-related homeobox (ARX) gene mutations cause several X-linked neurodevelopmental disorders that include lissencephaly with abnormal genitalia (XLAG), syndromic and nonsyndromic mental retardation, dystonia, and epilepsy. We identified an infant who had multiple neonatal tonic-clonic seizures. Initial exam showed unusual cranial shape with posterior sloping and flattening of the frontal skull and hypoplasia of the external genitalia, with a small penis and undescended testes. The anterior fontanel was soft and measured 4 cm x 4 cm. There was mild splitting of the sutures. The brain magnetic resonance imaging scan demonstrated lissencephaly with pachygyria and agenesis of corpus callosum (ACC). His karyotype was determined to be 46, XY. Mutations of the DCX gene in this infant were ruled out. We analyzed the ARX gene and identified a novel 9-bp deletion at nucleotide 996-1001 (c.996/1001_1001/1009 del9) in exon 2. The alteration is predicted to result in an in-frame deletion of 3 amino acids (p.T333/T334_T335/F336 del.) in the ARX homeodomain. The change was found to be absent in 368 control male individuals. Whether this novel alteration is a rare polymorphism can not be completely excluded. However, our findings are consistent with a previous report in which nonconservative missense mutations in the homeodomain of the ARX were found in XLAG patients with a milder phenotype (lissencephaly with hypoplastic male genitalia rather than ambiguous genitalia). Our results suggest that the novel in-frame deletion in the ARX homeodomain is likely to have a pathogenic role as an etiology for lissencephaly with ACC and hypoplastic genitalia.

Mutation screening of *MECP2* gene causing Rett syndrome. D. Zahorakova¹, R. Rosipal¹, J. Hadac², M. Misovicova³, A. Zumrova⁴, L. Pospisilova¹, V. Bzduch⁵, J. Zeman¹, P. Martasek¹. 1) Department of Pediatrics, 1st Faculty of Medicine, Charles University, Prague, Czech Republic; 2) Department of Child Neurology, Thomayer University Hospital, Prague, Czech Republic; 3) Department of Clinical Genetics, Martin University Hospital, Martin, Slovakia; 4) Department of Child Neurology, University Hospital Motol, Charles University, Prague, Czech Republic; 5) 1st Department of Pediatrics, Comenius University, Bratislava, Slovakia.

Rett syndrome (RTT) is a severe X-linked neurodevelopmental disorder, affecting almost exclusively females. It is caused by mainly de novo mutations in ubiquitously expressed methyl-CpG-binding protein 2 gene (*MECP2*). Methyl-CpG-binding protein 2 (MeCP2) binds specifically to methylated DNA and plays an important role in gene silencing. Mutations in *MECP2* lead to decrease/loss of MeCP2 function. More than 200 mutations have been identified in *MECP2*, including missense, nonsense, deletions and insertions. We report mutation analysis of 67 girls with clinical diagnosis of classic RTT from Czech and Slovak Republics and prenatal diagnosis in three families with RTT patient. Genomic DNA was used to amplify the coding sequence and exon/intron borders of *MECP2*. Products were examined by RFLP and sequencing. The analysis revealed 20 different mutations in 50 patients. 27 patients had missense mutations (R106W, R133C, S134C, K135E, T158M, P302S, R306C), 15 patients carried nonsense mutations (Y141X, R168X, S204X, R255X, R270X, R294X), 7 had frameshift mutations (K286fs, G269fs, S355fs, H372fs, P385fs, P388fs) and one had in-frame deletion S357. 3 mutations have not been previously published: a missense mutation P302S and deletions S355fs and S357. The frequency of mutation T158M compared to other databases (e.g. RettBASE 9.25%) has been much more higher in our patients (22%). Prenatal diagnoses were performed in 3 families with patients carrying mutations R168X, S204X and P388fs. No mutations in fetal DNA were found. Our results show molecular heterogeneity in Czech and Slovak patients with RTT, facilitate the RTT diagnosis at the molecular level, and provide insight into the molecular pathology of RTT. Supported by grant GAUK8/04.

ETHE1 mutations are a prevalent cause of Ethylmalonic Encephalopathy. *M. Zeviani¹, E. Briem¹, E. Lamantea¹, P. Rinaldo², E. Christensen⁸, P. Dickinson³, F. Ezgu⁴, M. Owaidha⁵, L. Heberle⁶, B. Abu-libdeh⁷, V. Tiranti¹.* 1) Dept Molecular Neurogen, Inst Nazionale Neurologico, Milano, Italy; 2) Mayo Clinic, Rochester, MN; 3) Harbor-UCLA Medical Center, Torrance, CA; 4) Gazi University Hospital, Ankara, Turkey; 5) Al-Jahara Hospital, Kuwait; 6) Al-Sabah Hospital, Kuwait; 7) Al-Quds University, Jerusalem; 8) Dept. of Clinical Genetics, Juliane Marie Centre, Rigshospitalet, Copenhagen, Denmark.

The identification of nuclear disease genes is a hot issue in mitochondrial medicine, but is hampered by the clinical and genetic heterogeneity of mitochondrial syndromes and the scarcity of informative families. The development of new bioinformatics tools and the completion of the human genome project, together with traditional strategies, can help progress in this area. An example is the recent discovery of the gene responsible for Ethylmalonic Encephalopathy (EE). EE is an infantile, fatal metabolic disorder, characterized by symmetrical lesions in the basal ganglia and brainstem, diffuse microvasculopathy, hyperlactic acidemia and high levels of ethylmalonic acid (EMA) in the body fluids. The 625G>A SNP in the short-chain acylCoA dehydrogenase (SCAD) gene was proposed as a co-factor in the etiology of EE, but this hypothesis has remained controversial for many years. Using an integration of physical and functional genomic data sets, we identified ETHE1 as a new gene, on chromosome 19, which is responsible for this disease. To investigate the prevalence of ETHE1 mutations and the 625G>A SNP in EE, we analyzed 28 patients with typical EE and 9 patients with non-EE EMA aciduria. Sequence analysis revealed 14 loss-of-function mutation and 7 missense mutations in 27 out of 28 typical EE cases. No ETHE1 mutations were identified in non-EE EMA aciduria cases. No difference in the frequency of the 625G vs. the 625A SCAD alleles was found in the ETHE1 mutants and in 53 control individuals. The 625A allele was significantly over-represented in non-EE EMA aciduria. Our data indicate that mutations of ETHE1 are the only responsible for the high level of excretion of ethylmalonic acid in this condition.

Rapid and reliable multiplex-PCR assay for deletions causing hereditary persistence of fetal hemoglobin

(HPFH). *U. Bhardwaj*^{1,2}, *L.L. McCabe*^{1,2}, *E.R.B. McCabe*^{1,2}. 1) Depts of Pediatrics and Human Genetics, David Geffen School of Medicine at UCLA, LA, CA; 2) Mattel Children's Hospital at UCLA, LA, CA.

The human γ -globin gene locus consists of five developmentally regulated genes 5-GA-3, regulated by two switches: embryonic (ϵ) to fetal (γ) and fetal (γ) to adult (β and δ) globin gene. Occasionally failure of normal hemoglobin switching from fetal to adult genes leads to persistent production of fetal hemoglobin (Hb F) into adulthood, resulting in HPFH. Clinically HPFH is a benign condition; however, it can reduce the phenotypic consequences for individuals homozygous for α -thalassemia or sickle cell disease. In addition, for newborn screening, neonates co-inheriting an HPFH deletion on one chromosome with the S allele on the other can be misinterpreted as homozygous for sickle cell disease when polymerase chain reaction (PCR) amplification is used. So far, eight deletions of variable size and position are known to be associated with HPFH in certain populations. Therefore, our purpose was to develop multiplex-PCR assay to detect these deletions in a single tube to facilitate rapid and accurate molecular diagnosis. Multiplex-PCR was performed using a gap-PCR strategy. Primers were designed across the deletion breakpoints of HPFH-1 (Black), HPFH-2 (Ghanaian), HPFH-3 (Indian), HPFH-4 (Italian), HPFH-5 (Italian), HPFH-6 (Vietnam), HPFH-7 (Kenya) and SEA-HPFH (Southeast Asia). The technique was standardized on DNA samples with known deletions (NIGMS Human Mutant Cell Repository) or cloned breakpoints. For two deletions, HPFH-3 and HPFH-7, we generated positive controls by cloning ligated telomeric and centomeric breakpoint regions. The breakpoint region of these controls was confirmed by sequencing. The multiplex-gap-PCR approach was tested on samples with known deletions by using eight pairs of primers bridging each breakpoint in a single tube. We were able to amplify a distinct deletion-specific product for all eight deletions without any false positive or negative amplification. We conclude that this multiplex-PCR strategy provides the most rapid and accurate diagnosis for the deletions of the γ -globin cluster causing HPFH.

Factor IX germline mutations in early embryo: Preferential occurrence of G:C>A:T non-CpG transitions. *W.A. Scaringe¹, J. Drost^{1,2}, X. Li¹, A. Halangoda¹, K. Hill^{1,3}, R. Ketterling⁴, C. Kasper⁵, S.S. Sommer¹.* 1) Departments of Molecular Genetics and Molecular Diagnosis, City of Hope National Medical Center, Duarte, CA, USA; 2) Department of Biological Sciences, Louisiana State University, Baton Rouge, LA, USA; 3) Department of Biology, The University of Western Ontario, London, ON, Canada; 4) Department of Pathology, Mayo Clinic/Foundation, Rochester, MN, USA; 5) Orthopaedic Hospital, Los Angeles, CA, USA.

Hemophilia B is a model for analyzing recent germline mutations in humans. For 91 individuals identified as the mutation origin, leukocyte DNA sequences of *F9* were analyzed directly by genomic sequencing. Somatic mosaicism for the causative mutation was identified in six females and three males with 5% to 70% of the leukocytes detected as mutant. One additional origin female transmitted the mutation to two offspring although the mutation was not detected in her leukocytes. Six of these ten defined mosaics had G:C>A:T transitions at non-CpG dinucleotides. Three of these six were at the G of CTG sites and another was adjacent to CTG. The preferentially embryonic occurrence of this *F9* mutation type over all other types is significant ($p=0.002$). This suggests that non-CpG G:C>A:T transitions occur preferentially in early embryogenesis, an intriguing observation given the recent report of a high frequency of non-CpG methylation in embryonic stem cells.

OPA3 gene mutations are responsible for autosomal dominant optic atrophy and cataract (ADOAC). D.

Bonneau¹, P. Amati-Bonneau², A. Guichet¹, P. Belenguer³, H. Dollfus⁴, C. Verny⁵, Y. Malthièry², P. Reynier². 1) Service de Génétique Médicale, CHU Angers, France; 2) Service de Biochimie et Biologie Moléculaire, CHU Angers, France; 3) Laboratoire de Biologie Cellulaire UMR CNRS 5088, Toulouse, France; 4) Service de Génétique Médicale, CHU Strasbourg, France; 5) Département de Neurologie, CHU Angers, France.

Hereditary optic atrophy is a heterogeneous group of genetic disorders in which several modes of inheritance have been described. The most common forms are autosomal dominant optic atrophies (ADOA, OMIM 165500) and Leber's hereditary optic neuropathy (LHON, OMIM 53500). OPA1, encoding for a mitochondrial protein, is currently the only gene identified in ADOA and is involved in 60-80% of the cases. Here we report that OPA3, a gene until now implicated in type III methylglutaconic aciduria, an autosomal recessive syndromic optic atrophy (OMIM 258501) is also responsible for ADOA with cataract (ADOAC). OPA3 was directly sequenced as a candidate gene in two unrelated families affected with ADOAC of whom 11 affected individuals and 10 healthy relatives participated in the study. Two different mutations in exon 2 of OPA3 were found in patients with ADOAC. The 277G-A (G93S) mutation was present in one family, and the 313C-G (Q105E) mutation in the other. Both mutations segregated with the disease in each family and were absent in healthy relatives and in 400 control chromosomes. Since OPA3 encodes a mitochondrial protein of unknown function, the possible mitochondrial dysfunction in skin fibroblasts from a patient affected with ADOAC was investigated. The respiratory chain, the mitochondrial membrane potential and the organisation of the mitochondrial network showed no abnormalities. However, the fibroblasts were highly susceptible to sautosporine-induced apoptosis. The results indicate that OPA3 is responsible for autosomal dominant OA as well as autosomal recessive OA. Thus, along with autosomal dominant optic atrophy (mutations in OPA1) and Lebers hereditary optic neuropathy (mutations in mtDNA), ADOAC (mutations in OPA3) is yet another form of hereditary optic atrophy involving a mitochondrial inner membrane protein.

Cellular models for Friedreich Ataxia uncover unexpected consequences of frataxin deficiency. *H. Seznec¹, N. Carelle¹, D. Simon¹, L. Reutenauer¹, P. Rustin², M. Koenig¹, H. Puccio¹.* 1) Molecular Pathology, IGBMC, Illkirch, France; 2) INSERM U393, Hopital Necker-EM, Paris, France.

Friedreich ataxia (FRDA), the most common autosomal recessive ataxia, is defined by a progressive sensory ataxia and cardiomyopathy. The disease is due to a severely reduced level of frataxin (fxn), a mitochondrial protein involved in Fe/S cluster and heme synthesis. The mechanisms leading to Fe/S enzyme deficiency, mitochondrial iron deposits, and impaired oxidative stress defense are still controversial. Deciphering the molecular mechanisms and finding therapeutics for FRDA would be facilitated by the availability of cellular models. Until now, cellular models for FRDA rely on an exogenous oxidative stress to produce a phenotype. Therefore, although these models reproduce part of the pathophysiology due to oxidative insult, none present the FRDA features observed in patient tissues. In addition, the nature of these models make them unsuitable for pharmacological screening procedures. We therefore urgently need to generate cell models that faithfully and spontaneously reproduce the FRDA features. We generated fxn knock-out and knock-down immortalized cell lines. Total fxn deficiency leads to cell death in proliferating cells, however in vitro myogenic differentiation is not altered. These data indicate that the absence of fxn is more deleterious in dividing cells than in post-mitotic cells, even rich in mitochondria. To circumvent this lethality, we generated a fxn knock-down cell lines by using a ribozyme targeted against fxn. Several clones show a significant decrease in fxn expression (9,6% residual level), a growth retardation, and a decrease in aconitases activity (Fe/S enzyme). Surprisingly, the ribozyme cellular models show decreased sod2 expression (-30%), without oxidative stress, and no iron metabolism alteration. These unexpected observations, also found in the mouse models, underlined that these knock-down cellular models reproduce alterations closely linked to fxn deficiency. Therefore, these novel models are the first good tool to decipher the molecular consequences of frataxin deficiency and for large scale drug screening for finding therapeutics for FRDA.

Program Nr: 2622 from the 2004 ASHG Annual Meeting

Development of an ALSIN Knockout mouse model. *H.X. Deng, R. Fu, H. Zhai, E. Soriano, T. Siddique.* Neurology Dept, Northwestern Univ, Chicago, IL.

Amyotrophic lateral sclerosis (ALS) is a progressive paralytic disorder caused by degeneration of the upper motor neurons in the motor cortex and lower motor neurons in the brainstem and the spinal cord. We previously linked the recessive form of juvenile ALS type 3 (ALS2) to chromosome 2q3335, and subsequently we reported that a differentially spliced gene encoding short and long forms of a protein, which we named alsin, is mutated in both juvenile ALS and juvenile primary lateral sclerosis (JPLS). This gene has two transcriptional forms with two distinct poly(A) signals. The short form has 4 exons and the long form has 34 exons, respectively, with the first 4 exons shared by both forms. The gene products, which we called alsin, are two distinct proteins with the short one being 396 amino acids and long one being 1657 amino acids in size, and the short form shares 371 amino acids with the long form at the N-terminus (Yang et al, 2001). To investigate the physiological function of alsin and the pathogenic mechanism by which loss of alsin leads to ALS or PLS, we constructed a targeting vector that was designed to replace exon 4 and a part of exon 3 with neo- cassette. We identified two positive ES cells with right targeting events and alsin gene-targeted mice were developed from these ES cells. The homozygous mice develop motor deficit from around 1 year old. Progression of the disease is very slow, as that seen in humans. Axonal degeneration is present in cortex, cerebellum and spinal cord.

Chromatin remodeling and transcriptional alterations in polyglutamine expansion diseases. *D. Devys¹, D. Helmlinger¹, S. Hardy², G. Abou-Sleymane¹, Y. Trottier¹, L. Tora², J.L. Mandel¹.* 1) Dept Molecular Pathology, IGBMC, Illkirch, France; 2) Dept of Transcription IGBMC, Illkirch, France.

Spinocerebellar ataxia type 7 (SCA7) belongs to a group of progressive neurodegenerative diseases, caused by an expansion of a polyglutamine tract in the respective disease-causing proteins. Genetic and biochemical studies have shown that polyglutamine pathogenesis arises from a gain of function. We demonstrated that ataxin-7, the protein mutated in SCA7, is the human orthologue of yeast SGF73, recently identified as a new subunit of the Spt/Ada/Gcn5 histone acetylase (SAGA) complex, which is a coactivator required for transcription of a subset of RNA polymerase II-dependent genes. Ataxin-7 is a bona fide subunit of human TBP-free GCN5 histone acetyltransferase-containing complexes (TFTC/STAGA), which are mammalian SAGA-like complexes. Using SCA7 patient cells and our SCA7 transgenic mouse model, we observed that normal and mutant ataxin-7 can equally incorporate into TFTC/STAGA complexes. In parallel, we investigated whether transcriptional dysregulation underlies the retinal dysfunction that we recently described in SCA7 mice. Using Affymetrix chips and quantitative RT-PCR, we observed an early and strong downregulation of numerous genes that are highly and specifically expressed in rod photoreceptors. Finally, these transcriptional alterations were strikingly correlated with a dramatic chromatin remodeling in photoreceptors nuclei, suggesting that downregulation of photoreceptor-specific genes is caused by dysregulation of chromatin-modifying factors. We are thus currently assessing whether the presence of mutant ataxin-7 within the TFTC/STAGA complexes modifies their histone acetyltransferase activity and/or their recruitment at specific promoters. A non-regulated transcriptional activity would result in a gain of TFTC/STAGA function that might provide a specific mechanism for SCA7 retinal pathogenesis.

A mouse model for oculodentodigital dysplasia generated by random mutagenesis. *A.M. Flenniken¹, I. Vukobradovic¹, I. Voronina¹, D. Qu¹, Y. Zhu², G.A. Wood¹, K. Peterson¹, R. Zirngibl¹, N. Anderson¹, J.G. Sled², J. Henderson⁴, C. McKerlie¹, J.E. Aubin¹, W.L. Stanford¹, B.G. Bruneau², G.M. Kidder³, S.L. Adamson¹, L.R. Osborne¹, J. Rossant¹.* 1) Centre for Modeling Human Disease, Toronto, Canada; 2) Hospital for Sick Children, Toronto, Canada; 3) Physiology and Pharmacology, University of Western Ontario, London, Canada; 4) Centre for Bone and Periodontal Research, McGill University, Montreal, Canada.

Oculodentodigital dysplasia (ODDD) is a dominant, multisystem disorder characterized by Type III syndactyly, plus numerous other clinical symptoms with variable penetrance, such as neurodegeneration, craniofacial abnormalities and conductive deafness. More than 30 families with ODDD have been shown to harbour missense mutations of GJA1 (connexin 43) that are predicted to disrupt the proper formation of gap junctions in many tissues. Gja1 gene targeted mouse mutants exhibit a recessive phenotype and die at birth from cardiac malformations making them poor models for the human disease.

We have identified a mouse model for ODDD from a dominant, random chemical mutagenesis screen in mice. The mutant mouse harbors a G60S amino acid substitution and exhibits many of the clinical symptoms of humans with the disorder. These symptoms include syndactyly, absence of the middle phalanx of the fifth digit of the hind limbs, enamel hypoplasia, and abnormalities in cardiovascular function resulting in mild first degree atrioventricular block with some instances of complete heart block as assessed by conscious ECG telemetry.

In addition, we have discovered other phenotypes that have not been reported in humans, such as a reduced bone density and bone mineral composition, and severe bone marrow atrophy of the long bones, which is evident at 25 weeks of age and becomes progressively worse. Immunostaining of tissue sections from the mutant and wildtype mice revealed very few identifiable gap junction plaques containing connexin 43 in heart or ovary. This mouse represents a true model of the human disorder ODDD, and will be invaluable in determining the functional nature of mutations in GJA1.

Osteopontin and kidney stone disease in a mouse model. *H. Tinkel-Vernon, C. Osborne, J. Chen, J. Tischfield, A. Sahota.* Dept Genetics, Rutgers Univ, Piscataway, NJ.

Cell culture studies and animal models of acute renal injury have shown that osteopontin (OPN) inhibits the aggregation of calcium oxalate monohydrate crystals and promotes inflammation at sites of tissue injury. However, the role of OPN in chronic inflammatory kidney stone disease is not well defined. The adenine phosphoribosyltransferase (*Aprt*) knockout mouse, with 2,8-dihydroxyadenine nephrolithiasis, is a well-characterized model for the study of this disease. To better delineate the role of OPN, we generated *Aprt/Opn* double knockout (DKO) mice and examined the kidneys from these and *Aprt* knockout mice using histochemical morphometric, and gene expression techniques. Twelve week old DKO male mice had more kidney stones, increased fibrosis and more markers of inflammation than their *Aprt^{-/-}Opn^{+/+}* counterparts. We attribute this to the stone inhibiting properties of OPN, leading to more stones and more pathological changes in DKO mice. *Aprt* knockout female mice had less pathology than their male counterparts regardless of the *Opn* genotype. However, kidneys from DKO female mice had more pathology than *Aprt* knockout female mice. Interestingly, the DHA stone burden in the two female groups was comparable. We hypothesized that some of the phenotypic differences may be due to OPN causing the up-regulation of inflammation-related genes which are differentially expressed between genotypes and sexes. cDNA array and RT-PCR analyses identified several such genes, including interleukin 15 receptor, interleukin 10 receptor, interleukin 6 signal transducer, MCP-3, and interleukin 2. The expression patterns of these genes and their functions reflect the phenotypic differences seen. Increased expression of IL-15 receptor and interleukin 6 signal transducer in wild type female compared with male mice may explain the severity of disease in males regardless of *Opn* genotype. MCP-3 was most highly expressed in male DKO mice; OPN potentially down regulates this gene and this may explain the severe phenotype seen in DKO male mice. Increased inflammation in OPN deficiency is likely due to the increased stone burden and an up-regulation of pro-inflammatory genes.

Mutation analysis of MECP2A and MECP2B in patients referred for Rett Syndrome. *S.L. Bleoo, P.J. Bridge, A.M. Innes, J.S. Parboosingh.* Medical Genetics, University of Calgary, Calgary, Alberta, Canada.

Rett syndrome is a neurological disorder characterized in females by a period of normal development (6-18 mos.) followed by developmental stagnation and then regression of fine motor and language skills. Patients develop stereotypical hand movements with loss of purposeful hand movements. Although females with Rett syndrome survive into adulthood, the developmental regression results in profound mental retardation. Rett syndrome is caused by mutations in the MECP2 gene, found in Xq28. This gene encodes a transcriptional repressor which, when bound to methylated CpG dinucleotides, affects chromatin remodelling. Originally it was thought that MECP2 involved a single isoform whose translational start site begins in exon 2. This transcript is now referred to as MECP2A. A second isoform, MECP2B was recently identified as a transcript whose initiation codon is in exon 1 but, due to alternative splicing, does not include exon 2. Although most mutations have been identified within exons 3 and 4, two reports have described frameshift mutations in classic Rett patients that affect exon 1. We have investigated 40 patients, 7 male and 33 female, referred through our medical genetics clinic for Rett syndrome for mutations in MECP2A and MECP2B by direct sequencing. We identified 10 mutations in the 33 females and no mutations in the males. All 10 mutations were in exon 4. One was a novel mutation, P388T (MECP2A) or P400T (MECP2B), identified in a two-year old girl. This patient does not appear to have classic Rett syndrome: it is unclear whether she ever had a period of normal development, and she developed no speech or purposeful hand movements. However, our patient does have Rett syndrome features including progressive microcephaly, hand stereotypies, bruxism, growth retardation, and lack of verbal communication. Our laboratory has not confirmed the involvement of MECP2B in Rett syndrome. However, given the documented cases of MECP2B mutations in affected individuals, clinical testing will continue to involve sequencing of exons 1 - 4 as well as multiplex ligation-dependent probe amplification (MLPA) to detect deletions missed by sequencing.

Y-Position Cysteine Substitution in Type I Collagen (1(I) R888C) Is Associated with Type IV Osteogenesis

Imperfecta. W.A. Cabral¹, A. Ashok¹, E. Makareeva², A.D. Letocha¹, N. Scribanu³, S. Leikin², J.C. Marini¹. 1) Bone & Extracellular Matrix Branch, NICHD/NIH, Bethesda, MD; 2) Sect. on Physical Biochemistry, NICHD/NIH, Bethesda, MD; 3) Dept. of Pediatrics, Georgetown Med. Ctr., Washington, D.C.

The most common mutations in type I collagen causing types II-IV OI result in substitution of a glycine in a Gly-X-Y triplet by another amino acid residue. Only one non-glycine substitution in type I collagen has been described; it is an X-position change, 1(I) arg134cys, which causes Ehlers-Danlos syndrome. We have delineated a Y-position substitution in a father and son with mild type IV OI. The 12 yr old proband sustained 4 fractures and has moderate joint laxity. He is osteopenic with L1-L4 DEXA z-score of -1.3. His father had 2 fractures and large-joint hyperextensibility. They have an 1(I) arg888cys substitution in one COL1A1 allele. The CT nt change eliminates an MboI restriction site and heterozygosity was confirmed in gDNA. SDS-urea-PAGE of [³H]-proline labelled steady-state collagen reveals only slight overmodification of the 1(I) monomer band, less than expected for a glycine substitution at this position, and a faint 1(I) dimer. [³⁵S]-cysteine labelling of collagen demonstrated dimers in about 10% of trimers in media and cell layer of fibroblasts. Since a maximum of 25% dimers can occur, dimer formation is inefficient, probably due to decreased proximity of the cysteines in adjacent chains. Immunofluorescence detected no accumulation of mutant procollagen in the ER on ascorbate stimulation, confirming efficient secretion of mutant procollagens from fibroblasts. Differential scanning calorimetry revealed only local helix destabilization. In matrix deposited by cultured fibroblasts, [³H]-proline labelled dimers were seen in immaturely and maturely cross-linked fractions. *In vivo*, proband dermal fibril diameters have a wider range than controls. This Y-position argcys substitution may cause matrix abnormalities by (a) loss of an arginine residue important for staggered helix conformation and interaction with adjacent helices during fibril growth, and/or (b) gain of a reactive SH moiety in this position.

Genetic factors modifying clinical features of dominant retinal diseases: role of polymorphic protein haplotypes

in trans. S.P. Daiger¹, S.P. Shankar¹, A.B. Schindler¹, L.S. Sullivan¹, S.J. Bowne¹, T.M. King², E.W. Daw³, J.R. Heckenlively⁴, E.M. Stone⁵, D.K.H. Wheaton⁶, D.G. Birch⁶. 1) Human Genetics Ctr, Sch Public Health, and Dept Ophthalmol, Univ Texas HSC, Houston, TX; 2) Med Sch, Univ Texas HSC, Houston, TX; 3) MD Anderson Cancer Ctr, Univ Texas, Houston, TX; 4) Kellogg Eye Ctr, Univ Michigan, Ann Arbor, MI; 5) Dept Ophthalmol, Univ Iowa Hosp Clinics, Iowa City, IA; 6) Retina Found SW, Dallas, TX.

Clinical features of dominantly-inherited diseases often differ considerably among affected individuals, even individuals within the same family. To evaluate the role of genetic factors in modifying autosomal dominant retinitis pigmentosa (adRP), we are studying two model systems: adRP caused by an Arg677ter mutation in the RP1 gene, and retinal disease caused by an IVS2+3 AT mutation in the peripherin/RDS gene. The RP1 mutation is found in over 90 members of an extended family with classic symptoms of adRP. Individuals with the RP1 mutation vary in severity, including two non-penetrant individuals. The RDS mutation is present in over 40 individuals from 8 independently-ascertained families with dominant retinopathies. Individuals with the RDS mutation vary in phenotype, with diagnoses of retinitis pigmentosa, pattern dystrophy or central RPE atrophy.

For both mutations, haplotype analysis confirms that the mutation descends from a common ancestor, thus excluding variation in *cis* to the mutation as a factor. Both genes, though, harbor multiple, polymorphic amino acid substitutions, with 3 to 5 distinct, polymorphic protein haplotypes in each case. The haplotypes in *trans* are plausible modifying factors.

In a retrospective study we tested for association between severity (RP1) or phenotype (RDS) and haplotypes in *trans*. Association was evaluated using analysis of variance, a TDT test, and Loki, a Monte Carlo Markov chain approach. For RP1, analysis suggests that a portion of the genetic component of variability maps to the disease locus. Further analysis suggests that RP1 haplotype 3 may play a role in modifying severity. For RDS, preliminary analysis does not support involvement of the RDS haplotypes.

Further molecular characterization of an Alagille Like Syndrome with Autosomal Recessive Inheritance not linked to JAG1 locus. *S. Dyack*^{1, 3}, *M. Cameron*³, *A. Otley*^{1,3}, *W. Greer*^{2,3}. 1) Dept of Pediatrics, IWK Health Centre; 2) Dept of Pathology, QEII Health Sciences Centre; 3) Dalhousie University, Halifax, Nova Scotia, Canada.

Alagille syndrome is an autosomal dominantly inherited syndrome characterized by intrahepatic bile duct paucity and other associated features including cardiac anomalies, vertebral anomalies, a recognizable facial gestalt, and ocular findings. The development of this condition is associated with mutations in the JAG1 gene, located on chromosome 20p. We have identified a consanguineous Native American kindred with five affected individuals with a paucity of the intrahepatic bile ducts and several other features of Alagille syndrome that is inherited in an autosomal recessive fashion. We first initiated linkage analysis for the JAG1 locus, and the disease was neither associated with homozygosity by descent or with a consistent haplotype at the JAG1 locus. Further investigation was initiated for linkage to other known genes in the notch signalling pathway, and no linkage was detected. A genome scan to determine areas of homozygosity by descent is underway. In conclusion we here illustrate a unique family where where an Alagille like syndrome with intrahepatic paucity of bile ducts is inherited in an autosomal recessive fashion and is not linked to the JAG1 locus. Previously only JAG1 has been implicated in the development of Alagille syndrome. Further investigation of this family may confirm genetic heterogeneity in the development of Alagille syndrome.

Program Nr: 2630 from the 2004 ASHG Annual Meeting

Deficient mucus production causes chronic enteritis in the MONTEZUMA mouse model for IBD. *J. Grosse, L. Zeitlmann, B. Schneider, W. Jagla, P. Wabnitz, A. Marquardt, J. Laufs, A. Popp, K. Dembowski, M. Nehls.* Ingenium Pharmaceuticals, Martinsried, Germany.

Ingenium uses random mutagenesis of the entire mouse genome to locate novel therapeutic entry points for drug development. In combination with the information provided by the mouse model itself, Ingenium rapidly locates the gene responsible for the phenotype by positional cloning and gathers extensive knowledge of the gene's function and how the alteration influences the biological mechanisms that result in disease (1). The aim of this work was to identify novel genes involved in inflammatory bowel disease (IBD), to characterize their molecular functions and evaluate their therapeutic potential. A variant mouse line, MONTEZUMA, was identified which suffers from chronic diarrhea and impaired growth. Histologic analysis demonstrated morphological goblet cell abnormalities and inflammatory infiltration of intestinal epithelia. Deficient mucus production precedes inflammatory responses, suggesting that a primary defect in mucosal barrier function can lead to IBD-like symptoms in mice. The causative mutation was identified by positional cloning and found to affect a previously uncharacterized gene expressed in mucosal tissues. Detailed analysis of the phenotype and molecular characterization of the mutated gene will be presented. We identified a mutation in a novel gene leading to IBD-like symptoms in mice. The pathomechanism involves deficient mucus production by the intestinal epithelium, which precedes mucosal inflammation. We are currently investigating the therapeutic use of the protein in inflammatory bowel disease and the diagnostic value for prediction of disease predisposition in humans. References: (1) Russ A, Stumm G, Augustin M, Sedlmeier R, Wattler S, Nehls M. Random mutagenesis in the mouse as a tool in drug discovery. *Drug Discov Today*. 2002 Dec 1;7(23):1175-83. Review.

TGF- receptor mutations in early-onset pulmonary arterial hypertension. *R.E. Harrison¹, R.M.F. Berger², S.G. Haworth³, R.M. Tulloh⁴, C.J. Mache⁵, N.W. Morrell⁶, R.C. Trembath¹.* 1) Division of Medical Genetics, University of Leicester, Leicester, United Kingdom; 2) University Hospital Groningen, Netherlands; 3) Institute of Child Health, UCL, London, UK; 4) Guys and St Thomas Hospital, London, UK; 5) Medical University Graz, Austria; 6) Addenbrookes Hospital, University of Cambridge, UK.

Pulmonary arterial hypertension (PAH) may develop in association with systemic or cardio-pulmonary disease but many cases appear idiopathic (IPAH). Low penetrance mutations of *BMPR2* and *ALK-1*, encoding receptors in the TGF- signalling pathway, underlie the development of IPAH in adult life. PAH may also present in childhood, when it can be related to congenital heart defects (CHD) but is frequently idiopathic. We investigated the role of TGF- signalling in the aetiology of early-onset PAH.

Eighteen children presenting with PAH before the age of 6 years were identified; 14 with a diagnosis of IPAH and 4 with PAH and congenital heart defects. Mutation analysis of genes encoding receptors of the TGF- family revealed heterozygous mutations in 22% (4/18) patients.

A novel missense mutation in the NANDOR box region of *ALK-1* (1/18, 5.5%), and a novel branch site mutation of *endoglin* (1/18, 5.5%) were identified in children presenting with IPAH, highlighting the potential for hereditary haemorrhagic telangiectasia to present with early onset PAH.

Partial gene deletion of *BMPR2* was seen in two patients (2/18, 11%); one diagnosed with IPAH, and one child with PAH and a ventricular septal defect. Similar cardiac defects are seen in animal models of defective BMP signalling raising the possibility that *BMPR2* mutations may lead to congenital heart defects in humans as well as a predisposition to PAH.

Although the aetiology of early onset PAH is heterogeneous, disruption of TGF- signalling plays a vital role, with diverse genetic defects identified in this cohort.

PITX2 gain-of-function in Axenfeld-Rieger eye model. *T. Hjalt*¹, *J. Holmberg*¹, *C.-Y. Liu*². 1) Dept Cell & Molecular Biology, Lund University, Lund, Sweden; 2) Bascom Palmer Eye Institute Miami, FL.

The Axenfeld-Rieger syndrome is autosomal dominant and affects the development of eyes, teeth, and gut. The eye manifestations include cloudy corneas, tearing, glaucoma, iris hypoplasia, irido-corneal adhesion, and occasionally megalocornea. Mutations have been found in the genes for transcription factors PITX2 and FOXC1. Mice homozygous for disruption of PITX2 are embryonic lethal from heart malformation. These mice also have hypertrophic corneas. Most mutations found in humans are defective in either DNA binding or reporter gene transactivation in cell culture. One mutation previously studied exhibited increased transactivation. Another has been shown to be dominant negative. Here we have made a transgenic mouse model, overexpressing normal human PITX2A in the cornea. These mice present with cloudy corneas, tearing, irido-corneal adhesions, mild to severe corneal hypertrophy and severe progressive retinal degradation. The corneal collagen superstructure is disrupted. Proposed PITX2 target gene procollagen lysyl hydroxylase 2 (Plod2) is down-regulated by whole eye RTPCR. The proposed cardiac PITX2 target gene cyclin D2 is not affected. This model provides in vivo evidence for a gain-of-function pathology for PITX2 causing Axenfeld-Rieger-like eye symptoms. In addition to the eye phenotypes, there is a random left-right forelimb malformation. The radius is curved over the ulna, locking the elbow in a pronation-extension position.

Isolation and characterization of immortalized renal cells from Pkd2 knockout mice. *J. Horst, M.P. Manitz, M. Polkehn, B. Dworniczak, P. Pennekamp.* Institut fuer Humangenetik, Universitaetsklinikum Muenster, Muenster, Germany.

Autosomal dominant polycystic kidney disease (ADPKD) is a frequent hereditary disorder, mainly characterized by the formation of multiple renal tubular cysts, leading to endstage renal failure. ADPKD is caused by mutations in the PKD1 and PKD2 genes, encoding the transmembrane proteins polycystin-1 (PC1) and polycystin-2 (PC2), respectively. In mouse knock-out models, homozygous impairment of the Pkd2 gene results in prenatal lethality. Because the death of these animals at the embryonic stage prevents a detailed functional analysis of PC2, we have isolated renal epithelial cells from Pkd2-deficient embryos. To establish immortalized Pkd2^{-/-} renal epithelial cell lines, heterozygous Pkd2^{+/-} mice were crossed with ImmortoMouse which is transgenic for the temperature sensitive SV40 large T antigen (H-2Kb-tsA58). We obtained Pkd2^{+/-} Immorto⁺ animals which were intercrossed to generate embryos with the various genotypes. To establish epithelial cell lines, embryonic kidneys (E16.5) were minced and digested with collagenase and epithelial cells were enriched with DBA-coated Dynabeads. Cells were seeded on VPM coated culture dishes and cultured under standard conditions described for kidney epithelial cells. Immunohistochemistry staining, FACS analysis and real-time RT-PCR were employed to study the expression of epithelial marker molecules. Cells isolated from control and PC2-deficient embryonic kidneys in culture displayed an epithelial phenotype. When seeded on collagen and cultured under non-permissive conditions (39°C, no Interferon), T-Antigen expression declined after 2 days of culture. All cells expressed lectins Dolichos biflorus agglutinin (DBA) and Phaseolus vulgaris (PHA-E). The adherens junction protein E-cadherin and its associated catenins, acetylated tubulin, and other marker molecules such as aquaporin-1 (AQP1), Ca²⁺-dependent Cl-channel 1 (ClCa-1), zonula occludens protein-1 (ZO-1) and epidermal growth factor receptor (EGF-R) have been detected in Pkd2^{-/-} Immorto⁺ and control cells. These immortalized renal epithelial cells from Pkd2 knock-out mouse embryos will allow the study of the role of polycystin-2 in signalling transduction pathways.

Bi-allelic inheritance and absence of somatic mutation in PPH provide evidence against a tumour suppressor role for BMPR2. *V. James¹, R.D. Machado¹, M.A. Aldred¹, M. Southwood², N.W. Morrell², R.C. Trembath¹.* 1) Division of Medical Genetics, University of Leicester, Leicester, Leicestershire, United Kingdom; 2) Department of Medicine, University of Cambridge, UK.

Idiopathic pulmonary arterial hypertension (IPAH) is a lethal disorder of the pulmonary vasculature typified by dysregulated endothelial cell proliferation and the formation of characteristic plexiform vascular lesions. Inheritance of familial PAH is complex, being autosomal dominant with incomplete penetrance and a significant female sex bias. Heterozygous germline mutations have been identified in bone morphogenetic receptor type II (BMPR2), a member of the transforming growth factor-beta (TGF-) signaling superfamily. When complexed with a type I receptor, BMPR-II relays intracellular signals by phosphorylating a series of cytoplasmic mediators, of which the Smad proteins are the most extensively characterized. Somatic mutations in genes encoding TGF- signaling molecules have been implicated in cancer progression (e.g. SMAD4 in juvenile polyposis, and TGFRII in gastrointestinal lesions). We describe a patient with biallelic pathogenic mutations of BMPR2. Biochemical studies revealed each variant to have distinct effects on downstream signaling yet cumulatively are permissive of residual Smad activity. The patient developed PAH at a stage (age 20 yrs) comparable to heterozygous carriers of mutant BMPR2 alleles. We next questioned if somatic mutations were evident in progressive pulmonary arterial disease. We used laser capture microdissection to collect plexiform lesions from lung explant tissue of 7 familial (three with identified germline mutations) and 2 sporadic patients, to investigate loss of heterozygosity (LOH) of BMPR2 and genomic instability, through analysis of 5 microsatellite markers, of key cell growth or apoptotic genes. We observed neither LOH nor microsatellite instability in any of the nine patient samples. Taken together these studies provide no support for multiple mutational events at the BMPR2 locus or acquired genome instability as significant factors in the progression of familial PPH.

Malcavernin, the cerebral cavernous malformations 2 protein, is preferentially expressed in neurons: Implications for CCM pathogenesis. *C.L. Liquori, T.L. Squire, N.W. Plummer, J.S. Zawistowski, H. Matsunami, D.A. Marchuk.* Dept Mol Genet and Microbiol, Duke University, Durham, NC.

Cerebral cavernous malformations (CCMs) are vascular abnormalities of the brain that can result in a variety of neurological disabilities, including stroke and seizures. Three known loci CCM1, CCM2, and CCM3 - are responsible for familial CCM. The CCM1 protein is KRIT1. The CCM2 protein is malcavernin. The CCM3 protein remains unknown. Conflicting data on the expression pattern of KRIT1-in situ analysis shows neuronal expression while immunostaining shows endothelial expression-has raised a fundamental question. Is the dysregulation of vascular morphogenesis leading to CCM formation a result of an intrinsic defect within the vasculature itself or a response to a defect in the surrounding brain tissue? Our identification of the CCM2 protein and preliminary evidence that malcavernin binds KRIT1 provide an independent means to better understand CCM pathogenesis and to resolve the discrepancy in the KRIT1 expression pattern. We examined expression of CCM2 using -gal histochemistry on CCM2 knockout (+/-) mice as well as in situ analysis and immunostaining of wildtype mice. LacZ staining revealed that CCM2 was present in both the cerebral cortex and cerebellum of adult brain. The in situ analysis also showed widespread expression in adult brain, with the strongest expression in Purkinje cells, hippocampus, caudate putamen, olfactory tubercle, and third and fourth ventricles. Very similar patterns were observed with in situ analysis of Krit1 and Icap1, a binding partner of KRIT1. The CCM2 in situ expression pattern closely resembled the pattern of the neuronal cell marker NSE. Immunostaining with a CCM2 antibody showed the strongest expression within the Purkinje cells. Again, the CCM2 pattern resembled that of another neuronal marker NF200, but it did not resemble the pattern of either the glial cell marker GFAP or the endothelial marker VWF. The CCM2 protein is expressed in neurons and not in the brain vasculature. Taken together, our data indicate that CCM lesions develop within the brain vasculature in response to altered signalling from the surrounding neuronal tissue.

Novel heterozygous compound of the CYP1B1 gene in primary congenital glaucoma. *O. Messina*¹, *C. Chima*², *L. Gonzalez*², *S. Kofman*², *M. Rivera*², *I. Babayan*¹, *S. Cuevas*². 1) Oftalmologia, Hospital General de Mexico, Mexico D.F., Mexico; 2) Genetica, Hospital General de Mexico, Mexico D.F., Mexico.

Primary congenital glaucoma (PCG) is a disease with an incidence that ranges from 1 in 1,1250 to 1 in 22,000 births in several populations. PCG seems to have an autosomal recessive mode of inheritance. PCG has been linked to homozygous mutations in the CYP1B1 gene that is located on chromosome 2p22-p21. The CYP1B1 gene contains 3 exons with an ORF of 1,629 bp starting in the second exon, and harbors nine TCDD-responsive (dioxin-responsive) enhancer core binding motifs. The CYP1B1 gene codifies for cytochrome P4501B1, a member of a subfamily of cytochrome P450. In the present study, we describe a family with PCG due to defective heterozygous compound of the CYP1B1 gene. This family also harbored a variant of the cytochrome P4501B1 previously reported in other population causing PCG. This mutation corresponded to a 13 bp deletion in exon 3 and a 1 bp deletion in exon 2 in both alleles of the CYP1B1 gene. More than a non-equal recombination event, we consider that this heterozygous compound was due to consanguinity of the region.

Kinetic alterations due to a missense mutation in the Na,K-ATPase alpha 2 subunit cause Familial Hemiplegic Migraine type 2. L. Segall¹, R. Scanzano¹, M.A. Kaunisto², M. Wessman², A. Palotie³, J.J. Gargus⁴, R. Blostein¹. 1) Biochemistry and Medicine, McGill University, Montreal, Quebec, Canada; 2) Biomedicum Helsinki and Clinical Chemistry, University of Helsinki, Finland; 3) Finnish Genome Center, University of Helsinki, Finland and Pathology and Human Genetics, University of California, Los Angeles, CA; 4) Human Genetics, Pediatrics, Physiology & Biophysics, University of California, Irvine, CA.

Several missense mutations in the Na,K-ATPase alpha 2 subunit gene (*ATP1A2*), have been identified in familial hemiplegic migraine with aura (FHM2). Loss-of-function and haploinsufficiency were the suggested mechanism of disease based on 2 mutants functionally unable to support *in vitro* cell growth. However a myriad of critical physiological processes rely upon normal pump function. This paper reports that the growth-failure phenotype is not shared by several other FHM2 alleles, and describes a kinetic analysis of mutant T345A, identified in a detailed genetic analysis of a large Finnish family (Kaunisto et al., *Neurogenetics*, 5: 141-46, 2004), that reveals a mutant-specific alteration in pump function. Introduction of T345A into the conserved rat alpha 2 enzyme does not alter cell growth or catalytic turnover but causes a decrease in apparent K⁺ affinity. In view of the location of T345 in the cytoplasmic stalk domain adjacent to transmembrane segment 4, the increase (2-fold) in K_{0.5(K)} is probably due to T345A replacement altering K⁺ binding/occlusion. Faster K⁺ deocclusion of the mutant via the E2(K) + ATP → E1ATP + K⁺ partial reaction is evidenced in (i) marked (300%) increase in K⁺-stimulation of Na-ATPase at micromolar ATP together with (ii) a 4-fold decrease in K_{ATP} and (iii) modest (3-fold) increase in I₅₀ for vanadate. We suggest that the decreased apparent K⁺ affinity is the basis for a reduced rate of extracellular K⁺ removal, delaying the recovery phase of nerve impulse transmission in the CNS, and thereby, the clinical picture of FHM2. This is the first demonstration of a mutation which leads to a disease resulting from a kinetically altered but fully functional Na,K-ATPase, refining the molecular mechanism of pathogenesis in FHM.

The incidence of small deletions of the HFE gene causing iron overload in the population of Ontario. *S.A.M. Taylor, M. Wing, L. Weiler, S. Windsor, A. Lyng, H.E. Feilotter, D.P. Lillicrap.* Pathology and Molecular Medicine, Queen's University and Kingston General Hospital, Kingston, ON, Canada.

There are two common mutations of the HFE gene, C282Y and H63D associated with hemochromatosis and iron overload. Rarely, other point mutations of the HFE gene causing amino acid substitutions and splicing abnormalities have been observed. The incidence of deletions of the HFE gene is unknown. At our centre the two common mutations are screened for in individuals with a clinical or family history of hemochromatosis or iron overload using PCR and diagnostic restriction enzyme digestion of exons 2 and 4 of the HFE gene. In 3 of 9800 cases analyzed we have observed additional (heteroduplex) bands after electrophoresis. Sequencing of the relevant exon revealed the presence of a small deletion in each case. The first is a novel 2 bp deletion of exon 4 (c.del640_641) observed in a male diagnosed with hemochromatosis and who is also a compound heterozygote for the C282Y mutation. The deletion is a frameshift mutation and is expected to result in a truncated form of the HFE protein. The second case occurred in a male of Japanese descent who presented with increased ferritin levels. He was found to have a novel 3 bp deletion of exon 4 (c.del691_693), which removes residue Y231. The effect of this mutation on the function of the HFE protein is unclear, however it is located in the alpha3 domain which is involved in beta2 microglobulin binding and it is conserved amongst other human and mammalian HFE and MHC Class I proteins. Iron overload in the Japanese population that is due to mutations of the HFE gene is rare and mutations other than the two common mutations have not been reported. From the sequence of the HFE gene both deletions are likely to have been the result of DNA strand slippage. These two unreported cases in addition to a 22 bp deletion of the HFE gene that was previously reported by us (Clinical Genetics 63: 163) would put the incidence of small deletions of the HFE gene in our population at 1 in 3270. This is a conservative estimate as only a portion of the HFE gene has been analyzed in each individual tested and the finding of heteroduplex bands was incidental.

Fibrinogen gene mutations: from rare bleeding disorders to common quality control pathways of protein secretion. *D. Vu, M. Neerman-Arbez.* Genetic Medicine & Development, University Medical Centre, Geneva, Switzerland.

Congenital afibrinogenemia is a rare bleeding disorder characterized by the complete absence of fibrinogen in circulation. Fibrinogen, synthesized in hepatocytes, is a hexamer composed of 2 sets of 3 homologous polypeptides i.e. A-, B-, and γ -chains, each chain encoded by a distinct gene, FGA, FGB, and FGG on chromosome 4q28-31. All afibrinogenemia mutations described so far are localized in the fibrinogen locus, the great majority in FGA. All are null apart from four missense mutations in FGB: L383R, G430D, G444S and W467G. The missense mutations lie in the C-terminal portion of the B-chain, which is highly conserved amongst vertebrates. In addition, two nonsense mutations in this same region were recently described: W467X and W470X. Expression studies in transfected cells performed for four of these FGB mutations suggested that an intact B C-terminal domain was necessary for hexamer secretion into the media but not intracellular hexamer assembly. Interestingly, this property of the fibrinogen B-chain differs from that of the γ -chain C-terminus which has been shown to be necessary for fibrinogen assembly. In this study, expression of serial deletions demonstrated that in the B C-terminal region, only the 6 last residues are dispensable for secretion, suggesting that an intact last beta strand is necessary for maintaining the tri-dimensional structure of the B D domain which in turn seems to be critical for fibrinogen secretion. Immunofluorescence co-localisation data demonstrated that a secretion-impaired fibrinogen FGB mutant (R485X deleted of only seven residues) is retained in the endoplasmic reticulum and is not transported to the Golgi apparatus. Co-immunoprecipitation experiments are ongoing in order to determine if other proteins e.g. molecular chaperones are involved in this quality control of fibrinogen secretion. The data should also allow us to gain insight into retention and degradation mechanisms of other mutant secreted proteins.

A third locus of Limb Girdle Muscular Dystrophy (LGMD) among Arabs in the north of Israel: LGMD2C in a large consanguineous Bedouin family. *Y. Goldberg*¹, *T. Harel*², *E. Chervinsky*¹, *R. Ofir*², *O.S. Birk*², *S. Shalev*^{1,3}. 1) Genetic Institute, HaEmek Medical Center, Afula; 2) Genetics Institute, Soroka Medical Center, Ben-Gurion University, Beer Sheva, Israel; 3) Rappaport School of Medicine, Technion, Haifa.

LGMDs represent a heterogeneous group of diseases characterized mainly by muscle wasting of the lower and upper limbs, with a wide range of clinical severity. To date, 10 genes associated with the autosomal recessive forms of LGMD have been identified.

We describe five members of a large consanguineous Bedouin tribe in the north of Israel, affected with a Duchene like form of LGMD, inherited in an autosomal recessive pattern. A genome-wide screen followed by fine-mapping revealed linkage to a region on chromosome 13 harboring the gamma-sarcoglycan gene (SGCG), associated with LGMD2C. A 525delT mutation was found in a homozygous state in all affected individuals. This mutation is common mainly in north Africa. Interestingly, our patients carry the mutation on a different haplotype background than the one associated with the mutation in the north African population. LGMD2C is the third type of LGMD detected among the Arab population in Israel. Two other forms have been previously described in Arab families: LGMD2I and LGMD2B. It is noteworthy that the 3 affected families belong to the same ethnic group and reside in great proximity in the north of the country. We searched for co-existence of a compound genotype, of mutations in both the SGC and FKRP genes (triallelic inheritance), as a possible explanation for the intra-familial phenotypic variability of LGMD2I; however, none of our patients inherited mutations in both genes.

As the clinical features of these three pathologies are different, diagnosis can be guided by the origin of the family, and established by clinical assessment followed by molecular testing. Besides the scientific significance of these findings, they might assist in the diagnosis of LGMD in middle-eastern populations in general, and in affected patients of Bedouin origin in particular.

Overexpression of Pitx1 gene activates muscle atrophy pathways: a pathological model of FSHD. *L. Li¹, Y.-W. Chen^{1, 2}*. 1) Center for Genetic Medicine Research, Children's National Medical Center, Washington, DC; 2) Department of Pediatrics, George Washington University, Washington, DC.

Muscle atrophy and weakness are the most common presenting manifestations of facioscapulohumeral muscular dystrophy (FSHD). We previously showed that paired-like homeodomain transcription factor 1 (Pitx1) was specifically up-regulated in FSHD patients and hypothesized that up-regulation of Pitx1 contributed to the pathological changes in FSHD. To identify the molecular targets of Pitx1, we expression profiled mouse triceps over-expressing Pitx1 gene using Affymetrix Mouse Genome 430A 2.0 microarrays. In addition, we investigated the effect of Pitx1 on myocyte proliferation and differentiation using C2C12 cells transfected with Pitx1 gene. The control samples were transfected with insertless vector. At day 3 after gene delivery by electroporation, immunofluorescence staining showed that the overexpressed Pitx1 protein was localized in the myonuclei. By comparing the profiles of Pitx1 overexpressing samples to controls collected at day 3 after gene delivery, we identified 22 and 15 known genes significantly up- and down-regulated in Pitx1 overexpressing samples, respectively (p<0.01). Five of the 22 genes were members of ubiquitin-proteasome pathways, including atrogin-1/MAFbx which has been reported strongly induced in skeletal muscle atrophy. The up-regulation of atrogin-1 was confirmed by quantitative RT-PCR (4.6 fold) (p<0.05, n=5). In addition, 4 enzymes responded to oxidative stress, including glutathione peroxidase 3, were significantly increased. At 7 days after gene delivery, we identified NADH staining-positive atrophic myofibers in the Pitx1 overexpressing muscles. Overexpression of Pitx1 in the C2C12 cells showed that the protein inhibited cell proliferation and induced early cell differentiation. In conclusion, our in vivo and in vitro data suggested that up-regulation of Pitx1 activated molecular pathways involved in muscle atrophy and disturbed cell proliferation and differentiation of myocytes, which might contribute to the pathophysiology of FSHD.

A novel mutation in the EDAR gene is responsible for anhidrotic ectodermal dysplasia in two Moroccan families.

L. Baala Jr^{1,2}, F. EL-Kerch², A. Smahi¹, A. Munnich¹, S. Lyonnet¹, A. Sefiani². 1) Genetique INSERM U393, Hsop Necker, Paris 15, France; 2) Departement de Genetique Medicale, Institut National d Hygiene, Rabat, Maroc.

Hypohidrotic (HED) and anhidrotic ectodermal dysplasia in human (AED) and their mouse analogues tabby, downless, and crinkled (Ta/dl/cr) cause ectodermal defects of teeth, hair and sweat glands. The mutated genes, which produce a similar phenotype encode proteins of the tumor necrosis factor (TNF) signaling pathway: ectodysplasin (EDA-A1), a TNF ligand, its receptor (EDAR) and the intracellular adapter protein (EDARADD). The ectodysplasin-EDAR signaling pathway is involved in skin appendage morphogenesis. EDAR activates the NF-kB pathway, the activity of which is defective both in severe forms of anhidrotic ectodermal dysplasia and in downless mice. Hitherto few mutations in the autosomal genes EDAR and EDARADD have been reported. Here, we report the identification of a novel missense homozygous mutation (T59G) in the EDAR gene changing a Leucine into Proline at codon 20. This mutation was found in two unrelated Moroccan families with autosomal recessive ectodermal dysplasia, suggesting a founder effect. The mutation was not found in a series of 100 chromosomes matched for the ethnic origin. This mutation occurred in the signal peptide of EDAR and possibly affects the downstream signaling-transduction complex. Our study support the view that EDAR gene is both genetically and fonctionnaly heterogeneous with autosomal dominant and recessive modes of inheritance. Ongoing studies in additional Moroccan families, aimed to the goal of understanding how this mutation alters NF-kB activation, are currently in process.+ This work is supported by "Accord INSERM-CNCPRST".

Program Nr: 2643 from the 2004 ASHG Annual Meeting

Congenital glaucoma: *CYP1B1* mutations in Israeli Bedouin Kindreds. *U. Bar Yosef, J. Levy, O. Agamy, K. Elbedour, R. Ofir, R. Carmi, O.S. Birk.* Laboratory of Human Molecular Genetics and the Genetics Institute, Soroka University Medical Center, Ben-Gurion University, Beer-Sheva, Israel.

Primary congenital glaucoma is an autosomal recessive disorder presenting from birth to 3 years of age. In the absence of treatment, the high intra-ocular pressure leads to ocular enlargement (buphthalmos), corneal edema and progressive optic nerve cupping culminating in progressive loss of vision and ultimate blindness. Often, clinical diagnosis is made only after irreversible damage to the optic nerve has already occurred hence the importance of early diagnosis. Most cases of congenital glaucoma result from mutations in the *CYP1B1* gene, a member of the cytochrome p450 family. We now show that in 9 of 11 non-related affected consanguineous Israeli Bedouin families, the congenital glaucoma was associated with homozygosity of *CYP1B1* mutations. As in Saudi Arabian families, the 3987G>A *CYP1B1* mutation accounted for ~50% of cases. A novel *CYP1B1* mutation, 8405G>A, was found in two unrelated families. In two consanguineous families there was no evidence of homozygosity or mutations in either *CYP1B1* or in two other candidate genes, *ARNT* and *AhR*. Thus, our data suggest that other, yet unraveled gene(s) take part in the causation of the phenotype.

Screening for mutations of the CDCrel-1 and Pael-receptor genes in Parkinsons disease patients. *P. Bauer¹, A. Bob¹, I.S. Mäcke-Jentsch¹, D. Berg^{1,4}, D. Voitalla², T. Müller², K. Berger³, R. Krüger⁴, O. Riess¹.* 1) Department of Medical Genetics, University of Tübingen, Tübingen, Germany; 2) Department of Neurology, Ruhr-University Bochum, Bochum, Germany; 3) Institute of Epidemiology and Social Medicine, University of Münster, Münster, Germany; 4) Hertie Institute of Clinical Brain Research, University of Tübingen, Tübingen, Germany.

Mutations in Parkin have been implicated in autosomal recessive juvenile Parkinsonism (AR-JP). CDCrel-1, a synaptic vesicle-associated protein, is ubiquitinated by Parkin, which promotes degradation of CDCrel-1. Likewise a putative G protein-coupled transmembrane polypeptide, named Parkin-associated endothelin receptor-like (Pael-R), has been characterized as interactor with Parkin. This receptor accumulates in AR-JP brains. In order to analyze whether both genes are involved in familial Parkinsons disease, we performed a screening for mutations by means of denaturing High Pressure Liquid Chromatography (dHPLC). For both genes the complete open reading frame has been analyzed for heteroduplicates in pooled PCR amplicons, indicating heterozygous sequence variants. Overall, we analyzed 293 Parkinsons disease (PD) samples for both genes. For CDCrel-1 one aberrant elution profile could be detected in exon 7. Sequencing revealed a heterozygous silent nucleotide exchange (c.552C>T; p.I148I) in one PD patient. The latter has not been observed in more than 250 control alleles. For Pael-R only three common exonic non-synonymous sequence variants (c.48T>C, p.L16L; c.1047C>T, p.T349T; c.1329G>C, p.L443L) have been detected. Frequencies of these polymorphisms did not differ significantly between the PD patient group and a control group (242 control samples). In conclusion we did not find potential disease causing mutations neither in the CDCrel-1-gene nor in the Pael-R-gene in PD patients. Moreover, the comparison of allele frequencies for three common polymorphisms in these genes between PD patients and controls did not argue for an involvement of these functionally relevant genes in familial parkinsonism.

Lipoid proteinosis: Clinical heterogeneity in an extended Bedouin family with a novel splice-site mutation in the ECM1 gene. *R. Birnbaum, A. Zvulunov, L. Fuchs, R. Ofir, A.D. Cohen, K. Elbedour, O. Agami, O.S. Birk.* human genetics laboratory, Ben Gurion University of the Negev, Beer Sheva, Israel.

Lipoid Proteinosis (Urbach-Wiethe disease, MIM #247100) is an autosomal recessive disease that invariably affects the skin and mucous membranes and, occasionally, the central nervous system. The disease is caused by loss of function mutations in the extracellular matrix protein (ECM1) gene, coding for a secreted glycoprotein with 3 isoforms (ECM1a,b,c). So far, 18 different mutations in the ECM1 gene have been identified, mostly in exons 6 and 7, and all within the coding sequence. We describe a consanguineous extended Israeli Bedouin family with 5 individuals affected with the disease; all 5 were homozygous for a novel splice-site mutation in the intron 3' flank of exon 8 (truncating the C termini of the ECM1a, ECM1b and ECM1c isoforms). Although all the affected individuals shared the same mutation, there were pronounced differences in their clinical manifestations, proving clear phenotypic variability in lipoid proteinosis. Based on the findings to date, we suggest that the lipoid proteinosis phenotype might be at least in part the consequence of accumulation of mutant ECM1 protein, and not necessarily caused by ECM1 malfunction. Furthermore, it is unlikely that defects in the ECM1b isoform, known to be associated with keratinocyte differentiation, is essential in the disease process.

Screening of CFTR gene rearrangements in Italian CF patients. *C. Bombieri*¹, *O. Raguénès*², *M.P. Audrézet*², *A. Bonizzato*³, *C. Castellani*³, *C. Férec*², *P.F. Pignatti*¹. 1) Sec Biol & Genetics, Dpt. Moth. Child & Biol-Genet, Univ Verona, Verona, Italy; 2) Inserm Unit 613, University Hospital, Brest, France; 3) Veneto Rgional CF Center, Verona, Italy.

Despite the extensive efforts over the past years, a significant percentage of CF alleles still remain to be identified in most populations. Only a few large deletions have been found so far in the CFTR gene. For this reason, it has been suggested that genomic rearrangements could account for a significant percentage of the unidentified disease alleles. These mutations, if present at the heterozygous state, elude the conventional PCR-based screening methodologies commonly used, including direct sequencing, and denaturing high performance liquid chromatography (DHPLC), leading to the underestimation of large genomic rearrangements involving the CFTR gene. The first systematic screening for large rearrangements of the 27 exons of the CFTR gene was recently performed, using quantitative multiplex PCR amplification of short fluorescent fragments (QMPSF), in French CF patients (Hum Mut 23:343,2004). We used this method to analyse a well characterised cohort of 25 Italian CF patients: all had classical CF and carried at least one unidentified allele after complete CFTR gene screening by DGGE or DHPLC analysis. Three rearrangements were identified in 6/26 of the previously unidentified Italian alleles (21%): an ins/del mutation involving exon 1 (c.4-IVS1+69del119bpins299bp), previously described in French CF patients, was found in 2 alleles; a deletion spanning exons 17a to 18 (3120+1Kbdel8.6Kb), previously described in Palestinian CF patients, was found in 3 alleles. Moreover, a deletion of exon 11 was found in 1 allele: at present the characterization of this mutation is going on. These results are in agreement with the data obtained in the French cohort (Hum Mut 23:343,2004).

Germline mosaicism for *de novo* mutations of the calcium-sensing receptor (*CASR*) gene: implications for genetic diagnosis of hypoparathyroidism. R.A. Booth^{1,2}, B.Y.L. Wong¹, G.N. Hendy³, D.E.C. Cole^{1,2,4,5}. 1) Dept of Clinical Pathology, Sunnybrook & Women's College Health Sciences Centre, Toronto ON; 2) Dept of Laboratory Medicine & Pathobiology, Univ of Toronto, Toronto ON; 3) Depts of Medicine, Physiology & Human Genetics, McGill Univ, Montreal QC; 4) Dept of Medicine, Univ of Toronto, Toronto ON; 5) Dept of Genetics, Hosp for Sick Children, Toronto ON, Canada.

Patients with unexplained isolated hypoparathyroidism may carry *de novo* activating mutations of the *CASR* gene, associated with autosomal dominant hypocalcemia (ADH) and hypercalciuria. Using routine PCR and restriction digestion of genomic DNA from peripheral blood, we identified one copy of a novel F788L mutation in two affected siblings, but none in either parent. The mother was subsequently found to be a mosaic for the mutation, based on (1) denaturing HPLC (dHPLC) screening, and (2) sequence analysis of multiple clones derived from the involved PCR amplicon (*J Clin Endocrinol Metab* 2003;**88**:3674).

We therefore undertook screening of five additional families, each with a single affected offspring bearing a mutation considered *de novo* by conventional testing. In three families, inactivating mutations (F42S, R185Q, C582Y) were associated with familial hypocalciuric hypercalcemia (FHH), while the other two carried activating mutations (E228K, N802I) responsible for ADH. Screening by dHPLC was negative in 4 families but a small shift in the profile of the E4-1 amplicon (the 5' end of exon 4) was noted in the mother of the child with an E228K mutation. Maternal mosaicism was confirmed by allele-specific oligonucleotide (ASO)-based amplification capable of detecting 2% heterozygosity. Peak heights of the sequencing profile (nt682GA) and dilution studies using ASO amplification suggested 10-20% heterozygosity in maternal blood. In summary, we have detected maternal mosaicism in 2 out of 6 families for whom clinical assessment and routine testing indicated a mutation arising *de novo* in the proband. Caution should be exercised in counseling such families for recurrence risks until a careful search for parental mosaicism is undertaken.

NIPBL mutations and genetic heterogeneity in Cornelia de Lange syndrome. *G. Borck¹, R. Redon², D. Sanlaville¹, M. Rio¹, M. Prieur¹, M. Vekemans¹, N.P. Carter², A. Munnich¹, L. Colleaux¹, V. Cormier-Daire¹.* 1) INSERM U393, Hopital Necker-Enfants Malades, Paris, France; 2) Wellcome Trust Sanger Institute, Genome Campus, Hinxton, UK.

Cornelia de Lange syndrome (CdLS) is characterized by facial dysmorphism, microcephaly, growth and mental retardation, and congenital anomalies including limb defects. Recently, mutations in the human NIPBL gene have been found in approximately 20% of CdLS cases.

We present a comprehensive clinical, cytogenetic, and molecular genetic study of 14 children with CdLS. The series included seven boys and seven girls ranging in age from 14 months to 17 years. All had typical dysmorphic features, pre- and postnatal growth retardation, mental retardation, and microcephaly. None had limb reduction defects. The study included a high-resolution chromosome analysis, a search for small chromosome imbalances using array-CGH at ~1 Mb resolution, and direct sequencing of the 46 NIPBL coding exons.

Cytogenetic or molecular genetic anomalies likely to underlie CdLS were found in 6/14 cases, including two chromosome imbalances and four NIPBL mutations. Chromosome analysis detected an isochromosome 18p in a girl with a mild CdLS phenotype. By array-CGH, a girl with severe manifestations of CdLS was found to have a submicroscopic de novo deletion of chromosome 1q. We detected four heterozygous de novo NIPBL mutations including one splice-site (IVS2+1 G>A), one frameshift (95delT), and one missense (N2236I) mutation and a deletion of three nucleotides (leading to N2218del). No mutations were found in the two children with a chromosome imbalance. We could exclude deletions encompassing the NIPBL locus by array-CGH as BAC clone RP11-7M4 gave a normal hybridisation signal in all cases.

We conclude that NIPBL mutations account for ~30% of CdLS cases in our series. There is allelic heterogeneity at the NIPBL locus in CdLS, as there is no recurrent mutation reported to date. The absence of NIPBL mutation in 70% of CdLS cases and the observation of two distinct cytogenetic anomalies is highly suggestive of genetic heterogeneity.

Mutation screening of *LRP5* in familial exudative vitreoretinopathy (FEVR) patients. *H.M. Bottomley¹, L.M. Downey¹, D.A. Mackey², J.E. Craig³, C.F. Inglehearn¹, C. Toomes¹.* 1) Molecular Medicine Unit, University of Leeds, Leeds, United Kingdom; 2) Centre for Eye Research Australia, Royal Victorian Eye and Ear Hospital, Melbourne, Australia; 3) Department of Ophthalmology, Flinders Medical Centre, Adelaide, Australia.

Familial exudative vitreoretinopathy (FEVR) is an autosomal dominant disorder which affects the development of the retinal vasculature. Using a positional candidate approach we recently identified mutations within the low-density-lipoprotein receptor-related protein 5 gene (*LRP5*) in FEVR families. In this study we screened *LRP5* in a panel of 60 FEVR patients to ascertain the type, frequency and location of mutations within this gene. We used intronic primers to amplify the 23 *LRP5* exons from genomic DNA and screened these using a combination of single strand conformational polymorphism/heteroduplex analysis (SSCP-HA) and direct sequencing. This work is still ongoing but to date we have identified more than ten mutations within *LRP5* including a splice site mutation (c4488+2tg), truncating mutations (K1374fsX1549, R1270fsX1438) and missense mutations (T173M, V667M, Y1168H and C1361G). None of these mutations were present in 200 control individuals. Molecular modeling of the missense changes within *LRP5* indicates that they are likely to either disrupt the correct folding of the protein or affect a proposed protein interacting domain. These results suggest that FEVR is the result of loss-of-function mutations in *LRP5* and that *LRP5* mutations are only responsible for 20% of FEVR.

Currarino Syndrome: Clinical and Genetic analysis of 25 cases. C. *CRETOLLE*¹, D. *SANLAVILLE*¹, J. *MARTINOVIC*², M. *ZERAH*³, C. *FEKETE*⁴. 1) GENETICS, Necker-Enfants Malades Hospital, PARIS, France, U393; 2) Foetopathology department; 3) Neurosurgery department; 4) Pediatric surgery department.

The Currarino triad is a variant of the caudal regression syndrome with typical sickle-shaped sacrum, anorectal malformation and presacral mass. It often displays a broad inter- and intrafamilial phenotypic variability. Some patients may have no symptoms. Mutations of the HLXB9 homeobox-gene, involved in sacral and anorectal development, have been recently identified as disease causing in the Currarino triad, with an autosomal dominant mode of inheritance. It has been mapped to the terminal end of human chromosome 7 (7q36). HLXB9 encodes the HB9 protein, a 403 amino acid transcription factor, that interacts with DNA through a specific homeodomain region of the protein. Here, we report the clinical and genetic retrospective and prospective study of 25 cases of Currarino syndrome (13 males and 12 females) including seven familial cases. All patients had a sacral malformation. An anorectal malformation was found in 23/25 cases. The presacral mass was an anterior meningocele in 5/25 cases, a teratoma in 4/25 cases, a neuroenteric cyst in 3/25 cases and a lipoma in 2/25 cases. There was no presacral mass in the remaining cases. All the 25 patients also had a tethered spinal cord. All these patients had a karyotype with FISH analysis at the HLXB9 locus and DNA sequencing of the HLXB9 coding sequence was performed. Five patients belonging to familial cases and two sporadic cases harboured a heterozygous point mutation of the coding sequence, that would predict a deleterious change in the protein (Ins C/nt53, Del A/nt587, Del G/nt711, Del GC/nt 732, Ins A/nt 783, L279F, S276X). All mutations involved the homeodomain, suggesting that amino acid changes in that region are relevant to the normal function of the protein. No mutation was found in other cases, and particularly in sporadic cases. Our data further support the involvement of HLXB9 in the Currarino triad, and its role in the development of the embryological tail bud development. Other genes probably account for cases with no mutation of the HLXB9 gene.

High heterogeneity of CFTR mutations in Iranian CF patients. *E. Elahi*^{1, 2}, *A. Khodadad*³, *M. Ronaghi*⁴, *Y. Thorstenson*⁴. 1) Dept Biological Sci, Tehran Univ, Tehran, Iran; 2) National Institute of Genetic Engineering and Biotechnology, Tehran, Iran; 3) Children's Hospital Medical Center, Tehran Univ, Tehran Iran; 4) Stanford Genome Technology Center, Stanford University, Palo Alto, CA.

All exons of the CFTR gene were sequenced in 60 Iranian CF patients to ascertain the mutation spectrum in the population. Twenty six putative disease causing mutations were identified, representing a very large mutation heterogeneity spectrum. Four of the mutations were novel: N185+1insA, N1821CA, N3713AC, N3811TG. F508 was the most frequent mutation, representing an expectedly low relative frequency of 15.8%. The six most common mutations together represented 43.3% of the mutated alleles. A haplotype analysis using ten intragenic polymorphisms identified 11 haplotypes and revealed that at least five mutations, including F508, were associated with more than one haplotype, indicating that these are rather old mutations in the population. A carrier frequency of 2.5 in 100 for CFTR mutations was estimated, suggesting that cystic fibrosis is a fairly common under-diagnosed disease in Iran. Eighteen putative non-disease causing polymorphisms were also identified, three of which are novel.

MECP2 gene deletions account for ~10% of Rett syndrome cases. *P. Fang*¹, *W. Jin*¹, *D.G. Glaze*³, *A. Percy*⁴, *H.Y. Zoghbi*^{2, 3}, *B.B. Roa*¹. 1) Baylor DNA diagnostic laboratory, Dept Molec Human Genetics, Baylor Col Medicine, Houston, TX; 2) Dept Molec Human Genetics, Baylor Col Medicine, Houston, TX; 3) Dept Pediatrics, Baylor Col Medicine, Houston, TX; 4) Dept Pediatrics, Univ.of Alabama, Birmingham, AL.

Rett syndrome is an X-linked neurodevelopmental disorder that affects ~1 in 10,000 females. Rett syndrome is caused by mutations in the MECP2 gene encoding the transcriptional repressor methyl CpG-binding protein 2. Diagnostic testing has mostly involved sequencing of exons 2 through 4 of the MECP2 coding region, which can identify mutations in approximately 80% of patients. MECP2 gene deletions have also been reported, although the overall frequency has not been well-defined. We developed a quantitative Southern analysis for large rearrangements in MECP2. Heterozygous deletions are detected by dosage differences of bands for exons 1 through 4. We performed Southern analysis on 153 patients who previously tested negative on MECP2 sequencing. This group included 36 patients with a thoroughly documented diagnosis of Rett syndrome, and 117 patients with varying amounts of clinical information provided by various referral sources. A total of 33 patients tested positive for MECP2 deletions which mostly involve exons 3 and 4; one patient had an insertion of ~100 bases in exon 4. Representative Southern data correlated with other quantitative methods like multiplex ligation probe amplification (MLPA) or real-time PCR. Analysis of our subset of well-characterized Rett patients indicate that MECP2 mutations identified by sequencing account for ~85% of cases, and MECP2 gene rearrangements comprised mostly of deletions account for ~10%. Thus, MECP2 deletions account for a substantial fraction of Rett syndrome patients. A combined strategy of sequencing and deletion analysis of a single gene, MECP2, can therefore provide a detection rate approaching 95% for Rett syndrome molecular genetic testing.

Sequencing of *IRF6* exons detects 67% and 90% of mutations in Van der Woude and Popliteal pterygium syndromes. R. Ferreira de Lima^{1,2}, S.A. Hoper¹, M. Johnson¹, S. Kondo¹, M. Fang¹, T.M. Zucchero¹, S. Daack-Hirsch¹, A.M. Mach¹, J.C. Murray¹, B.C. Schutte¹. 1) Pediatrics, The University of Iowa, Iowa City, IA; 2) Aconselhamento Genético, UNESP, Botucatu, Brazil.

Mutations in Interferon Regulatory Factor 6 (*IRF6*) cause Van der Woude (VWS) and Popliteal Pterygium syndromes (PPS). We completed sequencing on all exons in 129 unrelated VWS samples and 20 unrelated PPS samples and identified the following missense (M), protein truncation (PT), and splice site (S) mutations in our VWS and PPS (in parentheses) samples.

Exon	1	2	3	4	5	6	7	8	9	Total
M	0 (0)	0 (0)	9 (0)	13 (14)	0 (0)	1 (0)	17 (0)	5 (0)	1 (1)	46 (15)
PT	1 (0)	1 (0)	6 (0)	5 (0)	2 (0)	7 (1)	5 (0)	3 (1)	9 (1)	39 (3)
S	0 (0)	0 (0)	0 (0)	1 (0)	0 (0)	0 (0)	0 (0)	0 (0)	0 (0)	1 (0)
Total	1 (0)	1 (0)	15 (0)	19 (14)	2 (0)	8 (1)	22 (0)	8 (1)	10 (2)	86 (18)

The 46 new VWS and 5 new PPS mutations place the detection rate for exon sequencing at 67% and 90%, respectively. The over-representation of missense mutations in the DNA binding (exons 3 and 4) and protein binding (exons 7 and 8) domains, indicate their functional importance. Previously we reported 2 large and 9 probable deletions in VWS cases. No mutations or deletions were detected in 32 VWS pedigrees. Analysis of the largest pedigree suggests linkage to *IRF6*. Although small, 8 pedigrees are consistent with autosomal dominant inheritance. Since little evidence exists to suggest genetic heterogeneity, we conclude that a significant number of VWS-causing mutations are located outside the exons of *IRF6*. We used comparative genomic analysis to identify potential regulatory elements and are sequencing them for mutations.

Twenty novel mutations revealed by DHPLC analysis of the neurofibromatosis type 1 (NF1) gene in unselected southern Italian NF1 patients. *A. Gabriele¹, M. Ruggieri^{2,3}, G. Peluso¹, T. Sprovieri¹, A. Patitucci¹, A. Magariello¹, M. Muglia¹, R. Mazzei¹, F. Conforti¹, S. Genovese², E. Ciancio², A. Quattrone⁴.* 1) ISN, CNR, Cosenza, Italy; 2) ISN, CNR, Catania, Italy; 3) Department of Paediatrics, University of Catania; 4) Institute of Neurology, University of Magna Graecia, Catanzaro.

The identification of mutations in the neurofibromatosis type 1 (NF1) gene has presented a considerable challenge because of the large size of the gene, the lack of significant mutational clustering, the diversity of the underlying pathological lesions and the presence of NF1 pseudogenes. Recently, denaturing high performance liquid chromatography (DHPLC) has been successfully applied to the mutational screening of NF1 yielding mutation detection rates of between 68% and 72.5%. To further testing its suitability in a routine diagnostic setting we evaluated prospectively, by means of DHPLC and DNA sequencing, the full coding region (60 exons) and splice junction of the NF1 gene in a panel of 85 consecutive, genetically uncharacterized, NF1 patients (43 familial and 42 sporadic cases) from Sicily and Calabria (southern Italy). Germ-line mutations were identified in 68 subjects (80%): 20 of these alterations were novel including two stop codons: c.3574G>T (E1192X) and c.4078C>T (Q1360X); five nucleotide substitutions: c.3327A>C (L1109F), c.3577T>A (F1193I), c.4180A>G (N1394D), c.4193T>A (V1398D), c.6364G>C (E2122Q); five small insertions: c.310_1insTAGCATAAACGATGCTGGTCCAGCA, c.1074_5insGAACCTGCTTTTT, c.4511_2insA, c.6488_9insA, c.6792_3insC ; six small deletions: c.4508delG, c.4625delA, c.5524delA, c.7017delT, c.7084_9delAACTCT, c.7365delT and two splice site mutations c.4269+1G>A, c.7806+1G>A. None of the novel mutations was detected in 100 control chromosomes from a group of healthy individuals from the same southern Italian regions. These novel mutations further contribute to the definition of the germ-line mutational spectrum of NF1. DHPLC confirms to be a rapid, efficient and accurate tool for NF1 mutational analysis. The mutation detection rate of 80% in the present study is the highest so far reported by means of DHPLC analysis.

Additional mutations in *SMAD4* in the combined Juvenile Polyposis-Hereditary Hemorrhagic Telangiectasia syndrome. C.J. Gallione¹, T. Leedom¹, M. Faughnan², T. Berk³, K.J. Henderson⁴, J. Beis⁵, M.D. Ludman⁵, R.I. White⁴, D.A. Marchuk¹. 1) Dept. of Molecular Genetics and Microbiology, Duke University Medical Center, Durham, NC; 2) Dept. of Medicine, University of Toronto, Toronto, Canada; 3) Mount Sinai Hospital, Toronto, Canada; 4) Dept. of Diagnostic Radiology, Yale University School of Medicine, New Haven, CT; 5) Dept. of Pediatrics, Dalhousie University Faculty of Medicine, IWK Health Centre, Halifax, Canada.

Juvenile Polyposis (JP) and Hereditary Hemorrhagic Telangiectasia (HHT) are two uncommon autosomal dominant disorders characterized by distinct and essentially non-overlapping clinical features. JP, an inherited gastrointestinal malignancy predisposition, is caused by mutations in either *SMAD4* or *BMPRIA*. HHT is a vascular malformation disorder caused by mutations in either *Endoglin* or *ALK1*. All four of these genes encode proteins involved in the TGF-signaling pathway. We previously reported 7 families segregating both JP and HHT phenotypes that were all found to have mutations in the carboxy terminus of *SMAD4*. None of these had mutations in either *Endoglin* or *ALK1*. We have continued to collect samples from unrelated patients and families with this combined JP/HHT syndromic phenotype in order to validate these initial findings. We have performed sequence analysis of *Endoglin*, *ALK1*, *SMAD4*, and *BMPRIA* and have found three more cases where the affected patients have mutations in *SMAD4*. These three represent *de novo* cases bringing the total of documented *de novo* cases of this syndrome to 6 out of our total of 10 instances. This high incidence of *de novo* cases could have important implications for genetic screening and counseling of both patients and families.

Molecular analysis of the CRYG-D gene in a family with congenital lamellar cataract. *L. Gonzalez¹, O. Messina², S. Kofman¹, O. Sanchez¹, S. Cuevas¹.* 1) Genetica, Hospital General de Mexico, Mexico D.F., Mexico; 2) Oftalmologia, Hospital General de Mexico, Mexico D.F., Mexico.

Congenital or infantile cataract is one of the most common cause of blindness in childhood. It occurs in 1-6 cases per 10, 000 births and has multiple causes. Cataract may be present as the only ocular affliction or as a part of an inherited disorder. Most inherited cataracts, in which solely the lens is involved, harbor an autosomal dominant pattern. Lamellar cataract have also been called zonular, perinuclear or polymorphic. The degree of opacification is variable and visual acuity may be preserved or reduced. It occurs at the anterior and posterior Y sutures. CRYG genes encode the beta and gamma crystallins, the major lens proteins. The family of CRYG genes is a cluster of six closely related genes located on human chromosome 2q33-35. Previous studies in families with congenital lamellar cataract report mutations in the CRYG-D gene. In the present study, we analyzed the CRYG-D gene in a family that included 21 affected individuals in four generations with congenital lamellar cataract. The patients showed a different evolution of the symptoms and some of them harbored a high degree of myopia. DNA sequencing analysis of the peripheral blood showed no molecular defects, only polymorphic changes were found to be present. This result excludes the participation of the CRYG-D gene in congenital lamellar cataract in our family indicating the genetic heterogeneity of this type of cataract.

A Novel Mutation in SPG4 Gene Causes Autosomal Dominant Hereditary Spastic Paraplegia. *S.M. Grzeschik, A. Lewis, C.H. Wang.* Neurology, Stanford University, Stanford, CA.

Hereditary spastic paraplegia (HSP) is a heterogeneous group of neurodegenerative disorders with clinical features of progressive and bilateral spasticity of the lower limbs. The inheritance of HSP includes autosomal dominant (AD-HSP), autosomal recessive (AR-HSP) and X-linked (X-HSP) transmissions. Mutations leading to AD-HSP have been localized to chromosomes 14q, 2p, 15q, 8q and 12q. About 40 % of AD-HSP patients show mutations in the SPG4 gene on locus 2p. We report a novel mutation in the SPG4 gene that causes AD-HSP in a family with multiple affected individuals. Three affected individuals (the propositus - a three year old girl, her mother, and her 2 year old half-brother from the same mother but a different father) and two unaffected family members (the step-father of the patient, and her other half-brother) were evaluated in the clinic by two pediatric neurologists. All affected patients exhibited typical clinical features of HSP. We screened for mutations in SPG3, SPG4, and NIPA1 genes by complete sequencing of the coding regions in the index case. We discovered a missense mutation at nucleotide position 1289 (T-> C) in exon 8 of SPG4 that resulted in an amino acid change from lysine to asparagine. This mutation was found in all three symptomatic family members but in none of the two asymptomatic members. We also screened 56 unrelated control chromosomes and none of these contained this sequence variation. This novel mutation on the SPG4 gene is, therefore, considered disease-causing in this family. A previously reported mutation localized to the same codon at position 1288 (A->G) resulting in a change of amino acid from lysine to arginine also proved to be disease causing. The current finding supports the notion that the lysine residue at this position plays a crucial role in the SPG4 function.

Detection of CFTR Gene Mutations in Iranian Cystic Fibrosis Population. *M. H Darvishi¹, T. Hamzehloei¹, F. Bayat¹, M. Karimi¹, A. Khatami².* 1) Biotechnology Department, Pasteur institute of Iran, Tehran, Iran; 2) Emam khomini Hospital-Tehran-Iran.

Cystic Fibrosis is an autosomal disorder caused by mutations in the Cystic Fibrosis Transmembrane Conductance Regulator (CFTR) gene, which may cause a common lethal disease. Since isolation of the gene more than 1000 mutations have been reported to the Cystic Fibrosis Analysis Consortium. The frequency of these mutations varies in different populations. Identification of mutations causing Cystic Fibrosis in the Iranian populations is essential for assessment of the molecular basis of CF in Iran and development of strategies for prenatal diagnosis and genetic counseling. In the present study, we report the mutations found in 33 Iranian CF families by heteroduplex analysis on MDE gel matrix. We found the following six mutations: F508, 2183AAG, 574delA, D110H, R334W, 2043delG, and the frequency of the mutations were 25.75%, 4.54%, 3.03%, 1.51%, 1.51% and 1.51% respectively. The frequency of major CF mutation (F508) was less in Iranian population than the worldwide spectrum and almost same as the Turkish population. This study could only detect 36% of disease-causing mutations in this population, that reflecting the high molecular heterogeneity of the Iranian population.

CTDP1 mutations in consanguineous families with typical or partial CCFDN. *T. Hamadouche*^{1,2}, *C. Lagier-Tourenne*³, *R. Bernard*⁴, *I. Boccaccio*², *H. Dolfuss*⁵, *N. Philip*⁴, *N. Levy*^{2,4}. 1) Laboratoire de Biologie Moleculaire, Institut Pasteur, Alger, Algeria; 2) INSERM U491, Faculte de Medecine, Marseille, France; 3) IGBMC, Strasbourg, France; 4) Genetique Medicale, Hopital d'Enfants, Marseille, France; 5) Federation de Genetique, CHU Strasbourg, France.

Congenital cataracts facial dysmorphism neuropathy (CCFDN) syndrome is a complex autosomal recessive disorder involving multiple systems and organs. Initially reported from the Roma Gypsy group originating from Bulgaria, CCFDN is characterized by developmental impairments affecting eyes and face, peripheral and central nervous system, growth and intellect. Recently, the disease causing gene was identified, CTDP1, encoding an essential component of the eucaryotic transcription machinery. So far, a unique founder homozygous mutation, g.IVS6+389CT, has been identified in CCFDN patients, resulting in a mechanism leading to aberrant splicing and causing partial loss of expression. In this study, we report molecular analysis of three consanguineous Gypsy families with either typical or partial CCFDN. The homozygous mutation was identified in families G and B. Indeed, although typical CCFDN phenotype was observed in patients from family G, in family B, a 5 years old girl mainly presented a demyelinating neuropathy with congenital cataract although developmental delay and facial dysmorphism were slight. In family L, initially diagnosed as non syndromic CMT4, the same mutation was found to be heterozygous in one patient. We are investigating other loci already known to segregate in Gypsies (NDRG1, HMSN-R) and transcriptional studies are in progress from cultured lymphocytes from CCFDN individuals of these families. However, despite the homozygous presence of the mutation in one affected patient (family B), the clinical phenotype is somewhat different, either suggesting that modifying factors are involved in the disease course or, more likely, that typical CCFDN, due to the severe evolution of this syndrome, might be misdiagnosed at lower ages. We thus propose CTDP1 as a candidate gene in patients affected with a combination of peripheral neuropathy and congenital cataract, even in absence of others developmental features.

Frequent Occurrence of DNA Rearrangements in the Cystic Fibrosis Transmembrane Conductance Regulator Gene. *F.M. Hantash, J.B. Redman, B. Anderson, C. Tubman, K. Starn, A. Buller, M. McGinniss, F. Quan, W. Sun, C.M. Strom.* Department of Molecular Genetics, Nichols Institute, Quest Diagnostics Inc., San Juan Capistrano, CA.

Of the >1000 CF mutations described thus far, almost all are point mutations or small base pair insertions or deletions. The frequency of the few single or multiple exonic rearrangements described may represent gross underestimation because DNA sequencing, the primary method of mutation detection, will not detect most single or multiple exon deletions or duplications. To detect such mutations, we developed a single tube Semi Quantitative Fluorescent PCR assay that amplifies fragments representing the promoter and all 27 CFTR exons and 3 internal controls from different chromosomes for signal normalization. Using this method, we analyzed DNA samples submitted for extensive CFTR sequencing and several samples with rearrangements were identified. A deletion encompassing the CFTR promoter, and exons 1 and 2 was detected in one sample, and the same mutation was detected in the maternal DNA. In another family, a deletion of the promoter and exon 1 was detected in three siblings. It is interesting to note that in both of these cases, the families were African-American, and a 3120+1G>A splice site mutation was identified on the other chromosome. These deletions have not been described before. In a third case, a Caucasian patient, a deletion of exons 17a, 17b and 18 was identified and the same mutation was detected in the paternal DNA. In four other cases, we identified the following deletions: exons 2 and 3; exons 4, 5 and 6a; exons 17a and 17b; and exons 22, 23 and 24. These mutations would remove parts of transmembrane domain 1, transmembrane domain 2, or the second nucleotide binding domain. In patients diagnosed with classic CF submitted for sequencing analysis, 22.6% (7/31) harbored rearrangements, accounting for 11% of CF chromosomes. The frequency of occurrence of rearrangements in classic CF patients when only one mutation is identified by DNA sequencing is 50% (7/14). It is possible that complex abnormalities may account for a significant proportion of CF chromosomes in the general population.

Connexin 26 (GJB2) gene mutations in different populations of Iran. *M. Hashemzadeh^{1,2}, D.D. Farhud¹, H. Hoghooghi Rad³, M. Dolati³, R. Sasanfar⁴, A. Hoseinipour⁴, A. Tolooi⁴, M. Ghadami⁴, M. Montazer Zohour¹, L. Andonian¹, H.R. Pourjafari⁵, M.A. Patton⁶.* 1) Dept. of Human Genetics, School of Public Health, Tehran University of Medical Sciences, Iran; 2) Dept. of Biochemistry and Genetics, Medical School, Shahrekord University of Medical Sciences, Iran; 3) Department of Genetics, School of Biology, Azad University, Tehran, Iran; 4) Dept. of Exceptional Children, Ministry of Education and Training, IR Iran; 5) Genetic Div., Medical School, Hamadan University of Medical Sciences, Iran; 6) Medical Genetics Unit, St Georges Hospital, Medical School, University of London, UK.

Autosomal recessive and sporadic non syndromic hearing loss (ARSNSHL) is the major form of hearing deafness. Mutations in the GJB2 gene encoding Connexin 26 (Cx26) protein are the main cause for ARSNSHL in many populations. To determine the role of the GJB2 mutations as a cause of deafness in different populations of Iran, 952 hearing impaired students and their deaf siblings from 781 families in 9 provinces of Iran (Tehran, Azarbayjan sharqi, Gilan, Khorasan, Sistan & Baluchestan, Hormozgan, Kordestan, Khuzestan and Golestan) were studied. The prevalence and type of the GJB2 gene mutations were investigated using nested PCR pre screening strategy and direct sequencing of the coding exon of the gene. Altogether 32 different genetic variants were detected. Cx26 mutations were found in 18% of the deaf families including T8M, 35delG, W24X, V27I+E114G, R32H, V37I, E47X, 167delT, W77X, 235delC, L90P, delE120, R127H, Y136X, R143W and R184P. We found Cx26 mutations in both alleles in 11.5% of deaf families. However, 35delG mutation was the most common GJB2 mutation accounting for 72.3% of the Cx26 mutations in populations studied. This study identified 9 novel variants H16R, E101E, K102Q, 327delG, 327delG+G109G, G130A, 431insC, R159H and G200R. Our data indicated a high rate of Cx26 mutations types and frequencies exists in different populations of Iran. The presented significance of Cx26 mutations in development of hearing loss advocates their usage as a basis of further prenatal genetic counseling and clinical guidelines.

Molecular analysis in Gitelman Syndrome: 43 novel mutations in a cohort of 93 patients. *L.H. Hoefsloot¹, H.G. IJntema¹, J. Schoots¹, H. Scheffer¹, N.V.A.M. Knoers².* 1) DNA Diagnostics, Dept Human Genetics, University Medical Centre, Nijmegen, Netherlands; 2) Clinical Genetics, Dept Human Genetics, University Medical Centre, Nijmegen, Netherlands.

Gitelman Syndrome is an autosomal recessive renal transport disorder, characterized by hypomagnesemia, hypokalemia, metabolic alkalosis, and hypocalciuria. Most patients suffer from carpopedal spasms, paresthesias, and fatigue. Although the disease is considered to be relatively mild, the quality of life of most patients is considerably lower than in control persons. The causative gene is the *SLC12A3* gene, which encodes the thiazide-sensitive sodium-chloride co-transporter (NCC) in the distal tubule of the renal nephron. In the past few years we have analyzed DNA samples of 93 Gitelman syndrome patients by direct sequencing of all 26 exons of the *SLC12A3* gene. In 50 (54%) patients two mutations were found. In another 16 patients one mutation was detected. This means that in 66 patients (71%) the diagnosis Gitelman syndrome was supported, and that 116/132 (88%) of the alleles have been identified. In total 43 novel mutations were identified. Of these, the majority (30) were missense mutations, the other mutations were splice site mutations (9), nonsense mutations (2), one insertion and one deletion. Furthermore, we were able to prove that a few amino acid changes which have been described before as possible mutations, are in fact polymorphisms. We conclude from these analysis that scanning the whole coding sequence of the *SLC12A3* gene is the best option to identify mutations in Gitelman Syndrome, as opposed to assaying only the known mutations.

Mutation Analysis of COL8A2 Gene in Patients with Posterior Polymorphous Corneal Dystrophy. S.M.

Hosseini^{1,3}, *G. Billingsley*¹, *A.V. Levin*², *S. Kmoch*⁴, *M. Fillipek*⁴, *E.M. Stone*⁵, *E. Héon*^{1,2,3}. 1) Program in Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Ophthalmology and Vision Sciences, The Hospital for Sick Children, Toronto, Canada; 3) Institute of Medical Science, University of Toronto, Toronto, Canada; 4) Institute of Inherited Metabolic Diseases and Department of Ophthalmology, Faculty of Medicine, Charles University, Prague, Czech Republic; 5) Department of Ophthalmology, University of Iowa Hospitals and Clinics, Iowa City, USA.

Purpose: Posterior Polymorphous Corneal Dystrophy (PPCD) (MIM#122000) is an autosomal dominantly inherited endothelial dystrophy. PPCD has significant phenotypic variability and genetic heterogeneity. Mutations in *VSX1* and *COL8A2* genes have been associated with PPCD. We screened a cohort of PPCD patients for mutations in the *COL8A2* gene.

Methods: A cohort of 30 PPCD patients with diverse ethnic origin were screened for mutations in *COL8A2* by single strand conformational polymorphism analysis (SSCP). As a preliminary screen, only amplicons with previously documented mutations were analyzed. These patients were already screened for mutations in the *VSX1* gene by direct sequencing and did not have any disease causing mutation documented. Any change detected was confirmed by direct sequencing and was assessed in controls by restriction enzyme digestion.

Results: A novel missense mutation (L450W) was found in the sample of a patient with PPCD. The change occurs in a conserved amino acid residue in the important tri-helical region of the protein. The change was not present in any of 154 control chromosomes screened by restriction enzyme digestion (Bsr1).

Conclusion: We found a novel mutation in the *COL8A2* gene in our patients which confirms the former observation of *COL8A2*'s role in PPCD. The fact that no change was found in *VSX1* or *COL8A2* genes in other patients could further expand the genetic heterogeneity of PPCD.

Types and frequencies of mutations in *ABCC6* that characterize the molecular genetics of Pseudoxanthoma Elasticum. *S. Ibbá*^{1,8}, *A. Lumsden*², *U.P. Guenther*¹, *D. Foernzler*⁷, *S. Christen-Züch*³, *R. Ramesar*⁴, *M. Lebwohl*⁵, *D. Hohl*³, *K.H. Neldner*⁶, *K. Lindpaintner*⁷, *R.I. Richards*², *B. Struk*^{1,8}. 1) Max-Delbrueck Centrum, Berlin, Germany; 2) Department of Molecular Bioscience, The University of Adelaide, Australia; 3) Department of Dermatology, University of Lausanne, Switzerland; 4) Department of Human Genetics, Medical School, University of Cape Town, South Africa; 5) Department of Dermatology, Mount Sinai School of Medicine, New York, NY; 6) Department of Dermatology, Texas Tech University Health Sciences Center, Lubbock, TX; 7) F. Hoffmann-La Roche Ltd, Roche Genetics, Pharmaceuticals Division, Basel, Switzerland; 8) Charité, Franz-Volhard Clinic, HELIOS-Klinikum, Humboldt-University Berlin, Germany.

Mutations in the *ABCC6* gene have recently been found to cause pseudoxanthoma elasticum (PXE). We performed a mutation screen in *ABCC6* through direct sequencing of 170 PXE chromosomes from 81 families. We identified a total of 59 distinct mutations, of which 43 are novel variants. Considering 68 known mutations so far, this increases the total number of PXE mutations identified to 111. From 59 mutations 32 are missense, 8 are nonsense, 6 are likely splice site point mutations, 1 is a small insertion, 7 are small deletions, 5 are large deletions. Potentially disease causing mutations were uncovered in 97% (165/170) of chromosomes. This is the highest mutation detection rate for this gene. While most mutations are single variants, the mutations *R1141X*, *R1164X*, *Q378X*, the splice donor site mutation c.2787+1G>T and the large deletion comprising exons 23-29 are the most frequent PXE mutations at 26%, 5%, 3,5% 3% and 11% respectively. Phase of the PXE haplotype was established from segregation analysis of two proximal and two distal *ABCC6* flanking polymorphic markers. Most chromosomes carrying *R1141X*, *R1339C*, the IVS21 splice donor site mutation and e23-29 deletion have related haplotypes suggesting their origin from single founder mutations. The types of mutations found support loss-of-function as the molecular mechanism for the PXE phenotype, compatible with a recessive mode of inheritance.

Detection of four novel mutations in Hermansky-Pudlak syndrome type1 gene(*HPS1*). *S. Ito, T. Suzuki, K. Inagaki, N. Suzuki, Y. Tomita.* Dermatology, Nagoya University, Nagoya, Aichi, Japan.

Hermansky-Pudlak syndrome(HPS) is an autosomal recessive disorder characterized by oculocutaneous albinism(OCA), bleeding tendency due to a lack of platelet-dense granules, and lysosomal storage of ceroid-like material. The albinism results in various degrees of pigment dilution, congenital nystagmus, amblyopia, and marked iris transillumination. Life-threatening manifestations are frequent, and death typically results from restrictive lung disease in patients aged 30-50 years. So far seven subtypes of HPS, which are associated with seven genes(*HPS1*, *ADTB3A*, *HPS3*, *HPS4*, *HPS5*, *HPS6*, and *DTNBPI*), have been described. The most common type is HPS-1, and more than 18 pathological mutations in the *HPS1* gene have been reported. We screened the *HPS1* gene of 29 unclassified OCA patients with the PCR-SSCP/heteroduplex method. PCR products showing aberrant patterns were reamplified and sequenced directly. We detected nine different mutations including four novel mutations (W583X, L668P, 532insC, and del1691A), and identified eleven individuals with HPS-1. Two of the four novel mutations were frameshift mutations and one of them was nonsense mutation. These three mutations were definitely pathogenic. In case of amino acid substitution, L668P, we examined the frequency in normal Japanese. We screened 112 normally pigmented Japanese for the L668P mutant allele, and failed to detect this mutation. This indicates that the L668P missense mutation might be very rare in general Japanese population and could be defined statistically as a pathological mutation. Clinically, some HPS-1 patients had not noticed their own bleeding tendency because of the mild symptoms, and were hardly distinguished from other types of OCA by clinical feature, especially in childhood. Therefore the diagnosis of HPS-1, which enable to prognose implications and early treatment, should be made by genetic analyses.

Genetic characterization of familial hypercholesterolemia in four large Swedish pedigrees. *H. Jiao*², *S. Lind*^{1,3}, *C.M. Lindgren*², *M. Eriksson*³, *V. Mkel*², *I. Fransson*², *G. Eggertsen*¹, *J. Kere*², *B. Angelin*³. 1) Division of Clinical Chemistry, Department of Laboratory Medicine, Karolinska Institutet, Stockholm, Sweden; 2) Department of Bioscience at Novum, Karolinska Institutet, Stockholm, Sweden; 3) Center for Metabolism and Endocrinology, Department of Medicine and Center for Nutrition and Toxicology, Karolinska Institutet, Stockholm, Sweden.

The most common form of autosomal dominant familial hypercholesterolemia (FH) is caused by mutations in the low density lipoprotein receptor gene (LDLR). Other similar forms of this disorder are caused by mutations in the genes for apolipoprotein B-100 or the PCSK9 gene. In order to understand the genetic basis of the disease in Swedish FH families, twenty microsatellite markers representing 5 known FH-related genes, LDLR, apoB100, CYP7A1, PCSK9 and ARH, were selected for an exclusion study in 4 FH pedigrees in which no mutations in the LDLR and apoB100 genes were detected in probands by SSCP and sequence analysis. Out of the 5 genes, four were excluded by linkage analysis, but the LDLR gene showed linkage in three pedigrees with a maximum NPL score 3.6. Six patients from the 4 pedigrees were chosen for sequence analysis of the LDLR gene (the promoter region and all 18 exons). Sequence results revealed 4 pedigree-specific sequence variants in the 3 pedigrees showing linkage to the gene. One novel missense mutation Q639R showed segregation with the disease in one of the families. The mutation was not detected in 51 healthy controls. The missense mutation (D200G), previously reported, was detected in another pedigree. In the third pedigree, two affected individuals were found to carry two intronic variants (IVS6+37G>A; IVS1+56C>T). In the fourth family there was no evidence for linkage to the investigated loci. Thus, mutations in yet unidentified gene(s) may be a cause for the FH phenotype.

Mutations of NOTCH3 in Korean patients with cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy. *Y. Kim*^{1, 2, 3}, *K. Min*², *J.Y. Park*², *G. Kim*², *J.H. Choi*^{2, 3}, *H.W. Yoo*^{2, 3}. 1) Asan Inst for Life Sciences, Univ Ulsan College of Medicine, Seoul, Korea; 2) Genome Research Center for Birth Defects and Genetic Diseases, Asan Medical Center, Seoul, Korea; 3) Department of Pediatrics, Asan Medical Center, Seoul, Korea.

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is a small vessel disease of the brain, which is characterized by recurrent subcortical ischemic attacks, stepwise or progressive cognitive decline, and white-matter abnormalities on brain magnetic resonance images. Mutations in the human Notch homologue 3 gene (*NOTCH3*) were identified as the underlying cause of CADASIL in different ethnics. The human *NOTCH3* protein contains EGF-like repeats, three Notch/Lin-12 domains, and three cdc10 ankyrin-like repeats. The EGF-like repeats reside in the extracellular domain of *NOTCH3*, and upon binding of a ligand to the EGF-like repeats, the intracellular domain of *NOTCH3* is released from the membrane to the nucleus by proteolytic cleavage and functions as a transcription regulator. So far, 56 missense mutations of *NOTCH3* have been identified, and all of them are either loss or gain of a cysteine residue in the EGF-like repeats, possibly resulting in an unpaired cysteine residue within a given EGF-like repeat in the extracellular domain. Using PCR-directed DNA sequencing analysis, we identified five heterozygous missense mutations of *NOTCH3* in 10 of 36 Korean CADASIL patients, including a novel mutation, R587C, and four reported mutations, R110C, R133C, C174R and R544C. To further confirm the association of R587C with CADASIL, we tested 140 alleles of non-patients for the presence of R587C, verifying that R587C is not present in the healthy controls. All the identified mutations were located within the EGF-like repeats. The incidence of *NOTCH3* mutations was 27.8 % in the Korean CADASIL patients, approximately similar to the incidence reported in other Asian groups. Our findings further confirm that *NOTCH3* is the defective gene in CADASIL throughout different ethnic backgrounds and that defective disulfide bridging of *NOTCH3* may be a primary cause in the pathogenesis of CADASIL.

Screening of point mutations causing α -thalassaemia using denaturing high-performance liquid chromatography (dHPLC). *H.Y. Law¹, M. Chee², E. Tan², G.P. Tan², I. Ng^{1,2}*. 1) Dept Pediatrics, KK Women's & Children's Hosp, Singapore, Singapore; 2) National Thalassaemia Registry, Ministry of Health, Singapore.

α -thalassaemia is a common genetic disorder in South East Asia. The most severe form of α -thalassaemia, Barts hydrops foetalis is not only fatal but causes complication during pregnancy. Barts are usually caused by homozygous 2-gene deletions which account for >70% of α -thalassaemia alleles in Singapore. Mutations in Cd30(GAG) and Cd59(GGC/GAC), both found in local population, have been reported to cause HbH Barts. Our mutation screening strategy thus includes a reverse dot blot (RDB) method for detection of these and 3 other point mutations (Hb Constant Spring, Hb Quong Sze, and Hb Pakse). As heterozygous carriers of these 5 mutations have borderline or normal MCV values, RDB analysis often yields negative results. To improve the efficiency of screening, we have developed a dHPLC protocol to pre-screen samples before confirmation with RDB. DHPLC screening includes specific amplification of the α globin gene followed by 3 nested PCR reactions. The 3 amplicons cover the CAAT box to middle of IVSI, Cd53 to Cd120 in exon 3, and 3 of IVSII to 30bp 3 to poly A. DHPLC analysis carried out at 65.7C, 65.4C and 64.5C for the respective amplicons detected heteroduplexes of Cd30(-GAG), Cd59(GGC/GAC), HbQS, HbCS, and HbPk. These conditions were thus used to 1) screen for 70 samples for point mutations and 2) test for sensitivity in identifying 6 other mutations in the same regions. DHPLC screening of 70 samples found 2 suspected to be carriers of HbQS and 3 of Cd59 and were confirmed by RDB. Two unusual heteroduplexes were observed. They were found to be a SNP in 3' UTR region (nt50 G/C) and IVSII sequence of 1 gene respectively by sequencing. Analysis of 6 other mutations (StCd(-T); IVSI donor site(-5nt), poly A(AATAAA/AATGAA), and 3 variant chains, HbG Waimanalo, Hb Manitoba and HbJ Singapore) found heteroduplexes readily detected in all. In conclusion, a dHPLC protocol is established to efficiently screen for mutations causing α -thalassaemia in our population. Pre-screening using dHPLC reduces the number of samples for confirmatory RDB or sequencing analyses.

Program Nr: 2669 from the 2004 ASHG Annual Meeting

Two de novo mutations of TCOF1 gene in Taiwanese of Treacher Collins syndrome. *J. Lin.* Genetic Div, Pediatric Dept, Chang Gung Children's Hosp, Taipei, Taiwan.

Treacher Collins syndrome is a disorder of craniofacial development. The features include antimongoloid slant of the eyes, coloboma of the lid, micrognathia, microtia and other deformity of the ears, hypoplastic zygomatic arches, and macrostomia. Conductive hearing loss and cleft palate are often present (Dixon, 1996). We design 27 pairs of primers for PCR and analyzed the 25 exons of TCOF1 gene by direct sequencing in fifteen patients of craniofacial disorder. Two de novo mutations were found in two typical patients of Treacher Collins syndrome. Nt1483 del (AG) was found in exon 10 in one patient. Nt2606 del(C) located in exon 16 was detected in other patient. No mutations were found in several atypical patients. But high rate of SNP was confirmed again in TCOF1 gene and discussed.

VHL gene mutations in young individuals with polycythemia and high serum erythropoietin. *M. Martella¹, M.L. Randi², A. Casarin¹, M.C. Putti¹, G. Opocher², A. Murgia¹.* 1) Pediatrics, Univ Padua, Padua, Italy; 2) Medical And Surgical Sciences, University of Padua, Italy.

The Chuvash polycythemia is a familial congenital polycythemia with increased erythropoietin (Epo) level, which has been found to be associated with homozygosity or compound heterozygosity for mutations of the von Hippel-Lindau (VHL) gene, with the p.Arg200Thrp variant being the most frequent alteration. We have studied the VHL gene in seven young individuals, 5 unrelated and 2 siblings, with congenital sporadic polycythemia and inappropriately high Epo levels, all from north-eastern Italy. In only one patient a heterozygous VHL gene variant, never previously reported in polycythemic or in von Hippel-Lindau subjects, was identified (c. 430G>A; p.Gly144Arg). No other VHL point mutations or deletions have been detected. The 48 year-old mother of this subject, carrier of the same VHL variant, does not have erythrocytosis, and no signs of VHL disease have been detected in either individual after a thorough clinical and radiological investigation. No other siblings of the proband available for the study have been found to carry the VHL variant; the family history is negative for VHL-related manifestations or polycythemia. The causative role of this new VHL missense mutation in determining the erythrocytosis of this patient is questionable. As for other heterozygote cases reported in literature, it is possible to hypothesize that some other unknown factors, maybe a second unidentified mutation in another oxygen-sensing pathway gene, might contribute to determining the polycythemia phenotype, according to a digenic mode of inheritance. This report underscores the fact that VHL mutations may not be the only defect responsible for polycythemia due to disturbed hypoxia-sensing mechanisms.

Mechanisms of *COL5A1* Null Alleles in Classical Ehlers-Danlos Syndrome. *A.L. Mitchell, U. Schwarze, J.F. Jennings, P.H. Byers.* Univ of WA, Seattle, WA.

Classical EDS is an autosomal dominant connective tissue disorder, characterized by soft, doughy skin, hyperextensible joints, and atrophic, widened scars. The majority of cases result from abnormalities in type V collagen, a heterotrimer of two 1(V) and one 2(V) chains, which are encoded by the *COL5A1* and *COL5A2* genes, respectively. About 25% of patients are haploinsufficient for *COL5A1* expression at the RNA level (termed null alleles), as a result of mutations that lead to premature stop codons (PTCs) and subject the message to nonsense-mediated decay (NMD). We identified the genomic mutations in 9 patients with null alleles. Five affected splicing (4 were intronic and 1 was exonic), 2 were nonsense codons, and 2 were insertion/deletions. We then studied nuclear RNA from these patients to assess the effect(s) of the mutations on RNA expression. For the nonsense and frameshift mutations, as well as for 2 of the splice site mutations, there was only 1 outcome- a product with an altered reading frame that was degraded in the NMD pathway. We term these "total nulls" since all of the message from the disease allele is unstable and degraded. The other 3 splice site mutations resulted in 2 RNA products. For 2 cases, one of the products had an altered reading frame and was subject to decay, while the second maintained an intact reading frame through exon skipping and was stable. We call these "partial nulls" since only some of the product from the abnormal allele is degraded. We identified +1 donor site mutations (g>a) in 2 different introns- 19 and 35- and the outcomes differed. The IVS19 alteration resulted in use of a cryptic intronic splice site, partial intron inclusion (4 bp), and a frameshift. The IVS35 change resulted in 2 outcomes- an out-of-frame partial intron inclusion, which was degraded, and an in-frame exon skip, which was stable. From this we conclude that splice site mutations can have solely qualitative effects on mRNA (total nulls) or both qualitative and quantitative effects (partial nulls), that the outcome of a splice site mutation cannot be predicted by the genomic alteration alone, and that the phenotype may depend primarily on loss of type V collagen rather than the presence of abnormal molecules.

CFTR gene mutations and Haplotypes in Cystic Fibrosis and Chronic Rhinosinusitis Chilean patients. G.

Molina¹, M. González¹, J. Manríquez¹, A. Vera¹, A. Milinarsky², V. Lezana², F. Krause³, F.J. González¹. 1) Laboratorio de Biología y Genética Molecular. Escuela de Medicina. Universidad de Valparaíso, Valparaíso, Chile; 2) Departamento de Pediatría, Escuela de Medicina. Universidad de Valparaíso, Valparaíso, Chile; 3) Cátedra de Otorrinolaringología. Escuela de Medicina. Universidad de Valparaíso, Valparaíso, Chile.

Cystic Fibrosis (CF) is the most prevalent lethal autosomal recessive disease in the Caucasian population (1/2500 newborns). Its prevalence in Chile is calculated to range 1/4000 to 1/2000 newborns in different regions. CF is caused by mutations in the cystic fibrosis transmembrane regulator (CFTR) gene, which encodes a protein that functions as a chloride channel. This protein regulates electrolyte and water transport through secretory cells. Failure of this protein increases viscosity of mucus and other secretions. Chronic Rhinosinusitis (CR) is a CFTR related disease, since greater viscosity of mucus is one of its causes. More than 1000 CFTR gene mutations have been described. Mutation frequency varies among different ethnic groups and clinical presentations. Twenty CFTR mutations were evaluated in 28 CF patients. Fifteen mutations were evaluated in 10 CR patients. Haplotypes using three intragenic genetic markers (M470V, T854T and IVS8T) were determined in both groups of patients. Four mutations in CF patients were found. Delta F508 was found in 18 chromosomes, G542X in 3 chromosomes, R334W in 2 chromosomes and R117H in one chromosome. Using SSCA and sequencing, we found two variants (T351S, G528G) in three chromosomes. The latest last one modifies the last base of exon 10. The most usual haplotype present in chromosomes bearing mutations was M470,T854(-),T7. In CR patients we did not find any mutation, including T5 variant in IVS8T. The percentage of detection in CF patients was 44%, less than it has been reported for the same panel of mutations in other Caucasian or Hispano-Americans populations. The absence of mutations in CR patients is also different from what has been reported in Caucasian population. Both observations may be due to Chilean population ethnic admixture. DIPUV 28/2001.

Absence of homozygosity of the common *SBDS* truncation mutation in Shwachman-Diamond syndrome. *J.A. Morrison¹, N. Richards¹, G.R.B. Boocock^{1,2}, X. Bai¹, Y. Liu¹, L. Ellis^{3,4}, P.R. Durie^{3,4,5}, J.M. Rommens^{1,2}.* 1) Program in Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Molecular and Medical Genetics, University of Toronto, Toronto, Ontario, Canada; 3) Program in Integrative Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 4) Division of Gastroenterology and Nutrition, The Hospital for Sick Children, Toronto, Ontario, Canada; 5) Department of Paediatrics, University of Toronto, Toronto, Ontario, Canada.

Shwachman-Diamond syndrome (SDS; OMIM260400) is an autosomal recessive disorder, characterized by exocrine pancreatic insufficiency, hematological dysfunction, and skeletal abnormalities. Mutations in the *SBDS* gene have been determined to be causative of SDS. *SBDS* is located at 7q11, and is comprised of 5 exons spanning 7.9 kb of genomic sequence. An unprocessed pseudogene (*SBDSP*) shares >97% identity, and occurs in a paralogous duplicon located 5.8 Mb distally. Gene conversion, leading to the incorporation of pseudogene sequences into *SBDS*, has been found to be the primary cause of SDS-related mutations. Mutation screening by restriction analysis or direct sequencing of PCR-amplified exons has been performed on patients from 171 families meeting inclusion criteria (occurrence of neutropenia and exocrine pancreatic insufficiency). Three common gene conversions have been identified in SDS patients, including a nonsense mutation (183_184TA>CT), a splice site mutation (258+2T>C) and an extended conversion encompassing both sites. Mutations have been identified in 149 families, with 90% having at least one converted allele, and 67% having two converted alleles. Twenty-six less common mutations have been found, including two exon 3 gene conversions. Despite accounting for two-thirds of disease-causing alleles, no SDS patients were homozygous for 183_184TA>CT. This mutation is predicted to cause early protein truncation; the absence of homozygosity in SDS patients indicates that *SBDS* is an essential gene, and that complete loss of function is incompatible with life.

Molecular Characterization of BBS2 in an Ethnically Diverse Canadian Population with Bardet-Biedl Syndrome.

N. Noordeh^{1,2}, *S. Herd*¹, *W. Ferrini*¹, *A. Levin*³, *E. Héon*^{1,2,3}. 1) Department of Genetics & Genomic Biology, The Hospital Sick Children, Toronto, Ontario, Canada; 2) The Institute of Medical Science, University of Toronto, Toronto, Ontario, Canada; 3) Department of Ophthalmology and Vision Sciences, The Hospital for Sick Children, Toronto, Ontario, Canada.

Purpose: Bardet-Biedl syndrome (BBS) is an autosomal recessive multi-systemic disorder. BBS ultimately leads to blindness as a result of severe retinitis pigmentosa. BBS is genetically heterogeneous with 8 loci documented. Mutations in *BBS2* are proposed to account for a minority of cases (8-16%) (Katsanis et al., 2001). We investigated the role of *BBS2* (OMIM; 606151) in an ethnically diverse Canadian population with Bardet-Biedl syndrome.

Methods: Patients diagnosed with BBS were recruited through the Hospital for Sick Children and from the Northwest Territories. Patients were screened for sequence changes in all 17 coding exons of *BBS2* using a combination of single strand conformational polymorphism (SSCP) analysis and direct cycle sequencing. Sequence changes were confirmed with restriction enzyme digestion.

Results: We have identified a combination of novel and previously described *BBS2* sequence changes in our patient cohort. Sequence changes identified include a homozygous L125R in a First Nations family, heterozygous D104A and Y24X previously described sequence changes and a novel heterozygous R703X.

Conclusion: We report novel changes in *BBS2* in patients with a BBS phenotype. The role of *BBS2* in our diverse patient cohort appears to be minor, consistent with previous reports.

Support: Foundation Fighting Blindness - Canada, Vision Science Research Program, University of Toronto.

Mutation Analysis of the Spastin Gene (SPG4) and the Atlastin Gene (SPG3A) in Korean Patients with Hereditary Spastic Paraplegia. *S.Y. Park¹, C.S. Ki¹, H.J. Kim¹, D.H. Sung², B.J. Kim³, W.Y. Lee³, S.G. Lee¹, E.H. Cho¹, J.W. Kim¹.* 1) Department of Laboratory Medicine, Sungkyunkwan University School of Medicine, Samsung Medical Center, Seoul, Korea; 2) Department of Physical Medicine and Rehabilitation, Sungkyunkwan University School of Medicine, Samsung Medical Center, Seoul, Korea; 3) Department of Neurology, Sungkyunkwan University School of Medicine, Samsung Medical Center, Seoul, Korea.

Hereditary spastic paraplegia (HSP), a genetically and clinically heterogeneous group of neurodegenerative disorders, is characterized by progressive lower limb weakness and spasticity. Among the 8 loci associated with the autosomal dominant uncomplicated HSP (AD-HSP), mutations in the SPG4 gene on the chromosome band 2p22 are most common, accounting for about 40% of all cases and the SPG3A locus on chromosome 14q11-21 comprises approximately 10% of patients. In this study, 18 Korean patients clinically diagnosed with uncomplicated HSP (11 AD and 7 sporadic) were screened for mutations in the SPG4 gene by full sequencing of all coding exons and the flanking intronic sequences. Those negative for SPG4 mutation were analyzed for mutations in the SPG3A gene. We identified 8 SPG4 mutations, seven of which have not been reported elsewhere. Among the detected mutations were 3 missense mutations (I344K, R499H, and D584V), 2 in-frame deletions (1210_1212delTTT and 1137_1142delACTCTT), 2 frameshift mutations (1650_1651delAG and 1276_1277delCT), and one splice mutation (1413+3delAAGT). Additional testing with the SPG3A gene in the SPG4-negative patients did not show any mutations. This is the first comprehensive report on SPG4 mutations in Korean patients with uncomplicated AD-HSP, showing a higher mutation detection rate (7/11; 64%) than those in previous studies. On the other hand, there was only one patient with sporadic HSP carrying the SPG4 mutation (1/7; 14%), showing a good concordance to previous reports.

Truncation of HERG proteins cause Long QT Syndrome in two Dutch families. A.D.C. Paulussen¹, A. Raes², R.J. Jongbloed¹, R.A.H.J. Gilissen³, A.A. Wilde⁴, D.J. Snyders², H.J. Smeets¹, J. Aerssens³. 1) Dept Genetics & Cell Biology, Univ Maastricht, Maastricht, The Netherlands; 2) Laboratory of Molecular Biophysics, Physiology and Pharmacology, University of Antwerp, Antwerp, Belgium; 3) Dept Drug Discovery, Jonhson & Johnson Research and Development, Beerse, Belgium; 4) Experimental and Molecular Cardiology Group, Academic Medical Centre, Amsterdam, The Netherlands.

Background Long QT Syndrome (LQTS) is a ventricular arrhythmia, recognized by a prolongation on the ECG and which causes symptoms such as synopes and sudden death. Six genes have been identified for this syndrome. Mutations in one of these genes, the *KCNH2* (HERG) ion channel gene, are responsible for LQTS by causing a reduction of the delayed rectifier current I_{Kr}. This reduction delays repolarisation of cardiac cells and renders patients vulnerable to ventricular arrhythmias. *Methods and Results* We identified and characterized two heterozygous mutations (E698X and P872fs877) in the C-terminus of the *KCNH2* gene in two Dutch LQTS families. Both mutations lead to premature truncations of the C-terminus of the HERG protein. Biochemical, confocal microscopy and electrophysiological techniques were used to investigate protein expression, trafficking and function. The E698X protein, lacking 461 amino acids, was expressed with reduced quantities en produced no currents *in vitro*. The P872fs877 protein, lacking 282 amino acids was expressed and functional. P872fs877 mutant channels produced currents with biophysical properties similar to WT channels. Heterologous co-expression of WT and P872fs877 subunits showed a complex functionality; during action potential clamp experiments the capacity of hERG current was increased from ~30 percent (homologous WT or mutant expression) to 70 percent. However, this positive effect was completely abolished by a high increase in ER-retention of heterotetramers. *Conclusions* LQTS in the first family is caused by haplo-insufficiency due to absence of E698X HERG proteins. LQTS in the second family is caused by ER retention due to heterotetramerization, which has a greater impact than the apparent gain in function of mutated channels.

A novel point mutation in the KCNQ1 gene changes the channel gating kinetics and causing Long QT Syndrome.

M. Qi^{1,2}, *A. Moss*³, *L. Ning*^{1,2}, *S. Song*¹, *J. Shuttleworth*⁴, *W. Zareba*³, *J. Robinson*³, *Y. Xu*^{1,2}, *B. Yates*^{1,2}, *R. Porter*¹, *D. Ryan*¹, *T. Begelesich*⁴. 1) Dept Pathol/Lab Med, Univ Rochester Medical Ctr, Rochester, NY; 2) Center for Cardiovascular Research; 3) Dept. of Medicine; 4) Dept. of Pharmacology.

Long QT syndrome (LQTS) is a hereditary cardiac disorder characterized by syncope, seizures, and sudden death from ventricular arrhythmias, specifically torsade de pointes. Several ion channel genes (KCNQ1, KCNH2, SCN5A, KCNE1, and, KCNE2) are associated with LQTS, and multiple mutations have been identified. The KCNQ1 gene on chromosome 11 encodes the alpha-subunit of slowly repolarizing cardiac potassium channel, and defects in this protein cause the most common form of LQTS referred to as LQT1. Over 80 mutations have been identified in KCNQ1 to be associated with autosomal dominant LQTS. The effects of some of these mutations can be studied by cellular expression assay since the characteristics of the expressed gene define a cellular phenotype. Loss of function or defective subcellular trafficking have been revealed as the molecular pathologic mechanisms. In this study, one family with clinical evidence of LQTS was analyzed for mutations by use of dHPLC and DNA sequencing analyses for mutation screening in the KCNQ1 gene coding region. The affected members were found to have a previously unidentified, point mutation K393N in the C-terminal. This mutation changes the channel gating kinetics. Moreover, it shows a smaller instead of larger current magnitude when co-expressed with wild-type beta-subunit minK. These data suggest that this mutant may act through a different molecular pathogenic mechanism.

Detection of large deletions in the *MECP2* gene by Real-Time Quantitative PCR. *G. Raca, A. Alkhateeb, S. Das.*
Human Genetics, University of Chicago, Chicago, IL.

The molecular basis of Rett syndrome has been well established and numerous mutations in the *MECP2* gene have been reported. Approximately a quarter of patients with classic Rett syndrome however, do not have a detectable mutation within the coding region of the *MECP2* gene. Recently, large deletions in the *MECP2* gene have been identified in a proportion of patients in whom current PCR-mediated assays failed to identify molecular abnormalities. We investigated the presence of large deletions in the *MECP2* gene in a group of 180 patients with suspected Rett syndrome whose samples were sent to our DNA diagnostic laboratory for testing, and in whom no mutations were identified in the *MECP2* gene by full gene sequencing. We used a real-time quantitative PCR based assay to test for heterozygous deletions. The assay consists of simultaneous amplification of a fragment from the test gene (*MECP2*) together with a fragment from a reference gene (albumin), and the *MECP2* copy-number derived by comparing calculated concentrations of the test and the control gene. All patients were tested for two regions within the *MECP2* gene, exons 3 and 4, which lie in the region of the gene, found to be deleted, in previous reports. Deletions were excluded in 165 patients. So far deletions of exons 3 and 4 have been identified in at least 3 patients (1.6%). One patient shows results that strongly suggest the presence of a duplication within the gene. The deletion/duplication status of the remaining 11 patients is currently being investigated. We are also in the process of confirming our results by using alternative methods. Our results support the finding that deletions, and perhaps duplications, in the *MECP2* gene play an important role in patients with Rett syndrome. Deletion analysis of the *MECP2* gene should be considered in addition to mutation analysis for clinical testing purposes in patients with suspected Rett syndrome.

A Novel point mutation in NKX2.5 gene in a moroccan family with Atrioventricular conduction disturbance (AV block) and secundum atrial septal defect (ASD). *L. Rifai*¹, *A. Laamri*¹, *A. Maazouzi*², *A. Sefiani*¹. 1) Genetique medicale, Insitut National d Hygiene, Rabat, Morocco; 2) Service de Chirurgie CardioVasculaire, Hopital Ibn Sina, Maroc.

Atrial septal defect (ASD), which is found in 6 to 10 percent of all people born with congenital heart disease, usually occurs as an isolated malformation but it shows an autosomal dominant pedigree pattern in familial cases. Several mutations in NKX2.5 gene have been described and co-segregate with varied cardiac anomalies, including ASD and AtrioVentricular conduction defects, what suggests that this transcription factor contributes to various cardiac developmental pathways, and particularly to regulation of septation and maturation and maintenance of atrioventricular node function. Here we report the identification of a novel missense heterozygous mutation: a A to C transversion, resulting in a Glutamine to Proline substitution at codon 160 (Q160P) occurring in a moroccan family. This mutation co-segregates with all affected individuals screened by sequence analysis, but not with unaffected members. This mutation creates a new restriction site for Mlu113I, and was not found in 100 controle DNA samples from unrelated individuals. This mutation occurs in the Homeodomain which is a highly conserved region, and therefore its predicted to alter the DNA binding affinity, and to reduce transcription activity. This data reinforces the hypothesis according to which the NKX2.5 haplo-insufficiency causes ASD and atrioventricular node dysfunction.

Screening of the XLMR genes *ARX*, *MECP2* and *FMR2* in 200 mentally retarded males from Italy. *M. Rosati*^{1,2}, *M.G. Pomponi*¹, *G.M.E. Marino*¹, *A. Terracciano*¹, *A. Pampanos*¹, *P. Chiurazzi*¹, *G. Neri*¹. 1) Istituto di Genetica Medica, Universit Cattolica, Rome, Rome, Italy; 2) Ospedale San Giacomo, ASL RM/A, Rome, Italy.

X-Linked Mental Retardation (XLMR) is a genetically heterogeneous condition which can present in either syndromic (MRXS) a nonspecific (MRX) form. The *ARX* and the *MECP2* genes were found mutated in both MRXS and MRX cases, while expansions in the *FMR2* gene are usually associated with MRX. We screened 200 male patients with mild to severe MR for mutations in the *ARX*, *MECP2* and *FMR2* genes. All patients were negative for the amplification in the *FMR1* gene, thus excluding fragile X syndrome, and none of them had dysmorphic features. Only few (7%) had a history of seizures or infantile spasms. *ARX* mutations were screened by SSCP, using 8 primer pairs designed by us (available upon request). We found 4 cases with a silent point mutation in exon 4 (G1347T), one with a G>T transversion in intron 3 (position +81) and one *de novo* case with the 24-bp duplication, previously described by Strømme et al. [Nature Genet. (2002) 30:441-445]. This latter patient was a 4-year old child with dystonic movements of the hands, typical of Partington syndrome. The *MECP2* gene was analyzed by direct sequencing of the entire coding sequence. We found 5 silent point mutations in exon 3, one G>C transversion in intron 3 (+30) and a C1024T transition causing the previously unreported aminoacidic change P342S, which may account for the MR phenotype. Finally, no expansion was detected in the CGG repeat of the *FMR2* gene. Our results suggest a minor role for the *ARX*, *MECP2* and *FMR2* genes in causing nonspecific XLMR and suggest that other yet unidentified genes wait to be characterized.

Novel ENPP1 mutations in patients with generalized arterial calcification of infancy. *N. Ruff¹, B. Uhlenberg^{1, 2}, R. Terkeltaub³, P. Nürnberg^{1, 4}, F. Rutsch⁵.* 1) Gene Mapping Center, Max-Delbrueck-Centrum, Berlin, Germany; 2) Department of Neuropediatrics, Charite, University Medical School Berlin, Germany; 3) Department of Medicine, VAMC, UCSD, San Diego, USA; 4) Institute of Medical Genetics, Charite, University Medical School Berlin; 5) University Childrens Hospital, Muenster, Germany.

Generalized arterial calcification of infancy (GACI) is characterized by calcification of the internal elastic lamina of large and medium-sized muscular arteries and stenosis due to myointimal proliferation. Sometimes peri-articular calcification is also observed. Although survival to adulthood has been reported, most patients die within the first six months of life. Recently, we identified mutations of ENPP1 as the cause of this recessive genetic defect (OMIM 208000). ENPP1 encodes ecto-nucleotide pyrophosphatase/phosphodiesterase 1. This cell surface enzyme generates inorganic pyrophosphate, a solute that regulates cell differentiation and serves as an essential physiologic inhibitor of calcification. Mutations were shown to dramatically reduce enzyme activity. In this study, all 25 exons including their flanking splice sites and the promoter region of ENPP1 were amplified by PCR and sequenced bi-directionally from genomic DNA from patients of 12 unrelated families with GACI. We identified 11 novel homozygous or compound heterozygous mutations in 10 out of 12 unrelated patients. Thus, combined with the data of our first study, we identified a total of 24 different homozygous or compound heterozygous mutations in 18 of 23 unrelated patients. The mutations, 3 nonsense, 15 missense, 1 single amino acid deletion, and 5 frame shift mutations were scattered over the whole coding region. We identified 3 recurrent mutations, 7 x P305T, 2 x R774C, and 2 x R888W. Haplotype analysis suggests a founder effect of British extraction for mutation P305T. In contrast, mutations R774C and R888W were CpG-to-TpG mutations presumably caused by spontaneous desamination of 5-methyl cytosine. This study confirms the role of ENPP1 mutations as the main cause of GACI and reveals a broad spectrum of different mutations in GACI patients.

Novel mutations in the *POMGnT1* gene in Muscle-Eye-Brain disease. A. Saarinen¹, C. Diesen¹, H. Pihko², W.B. Dobyns³, T. Joensuu¹, A.-E. Lehesjoki¹. 1) Folkhälsan Institute of Genetics, Department of Medical Genetics and Neuroscience Center, Biomedicum Helsinki, University of Helsinki, Finland; 2) Department of Pediatric Neurology, University of Helsinki, Finland; 3) Departments of Human Genetics, Neurology and Pediatrics, University of Chicago, IL, USA.

Muscle-Eye-Brain disease (MEB) is an autosomal recessive disorder characterized by brain malformation, congenital muscular dystrophy and ocular abnormalities. It occurs worldwide but is enriched in the Finnish population due to a founder effect. Mutations in the *POMGnT1* gene encoding protein *O*-linked mannose 1,2-*N*-acetylglucosaminyltransferase 1 (POMGnT1) underlie MEB. POMGnT1 catalyzes glycosylation of proteins by transferring GlcNAc to *O*-mannose. The *POMGnT1* gene was analyzed for mutations by sequencing in a panel of 19 Finnish and 14 non-Finnish patients. We identified nine novel *POMGnT1* mutations, adding the number of reported MEB-associated mutations to 22. Three of the mutations found in this study predict protein truncation, and four altered splice products, while two are missense mutations. In addition, we found that a mutation reported previously in three patients, c.1539+1G>A that results in an inframe deletion of 42 amino acids, is the prevalent mutation in the Finnish MEB patients. Compatible with the haplotype data in Finnish MEB patients, the founder mutation accounts for 99% of the disease chromosomes in Finland. The clinical phenotypes of the non-Finnish patients in this study and published previously fall within the variation observed in the Finnish patients that are homozygous for the founder mutation. This indicates that, in addition to mutations in the *POMGnT1* gene, other genetic and environmental factors influence the MEB phenotype.

Homozygosity mapping in Turkish variant late infantile neuronal ceroid lipofuscinosis. *E. Siintola*¹, *M. Topcu*², *T. Salonen*¹, *T. Joensuu*¹, *A. Kohlschütter*³, *A.-K. Anttonen*¹, *A.-E. Lehesjoki*¹. 1) Folkhälsan Institute of Genetics, Department of Medical Genetics and Neuroscience Center, Biomedicum Helsinki, University of Helsinki, Finland; 2) Department of Pediatrics, Hacettepe University Faculty of Medicine, Ankara, Turkey; 3) Children's Hospital, University of Hamburg, Germany.

The neuronal ceroid lipofuscinoses (NCLs) are a group of autosomal recessive neurodegenerative lysosomal storage diseases characterized by the accumulation of autofluorescent storage material in several cell types, especially in neurons. Clinical features include epileptic seizures, progressive psychomotor deterioration, visual failure, variable age of onset and usually premature death. At least seven subtypes of childhood-onset NCLs have been identified. The NCLs with late infantile onset (LINCL) are genetically heterogeneous with three underlying genes identified (*CLN2*, *CLN5* and *CLN6*). A variant form of LINCL present in Turkish patients has been considered a distinct clinical and genetic entity (*CLN7*). However, we recently showed that mutations in the *CLN8* gene account for a subset of Turkish variant LINCL. Our aim is to identify the *CLN7* gene in a group of ten inbred Turkish variant LINCL families by using homozygosity mapping.

As a first step, we have screened all the currently known human and animal NCL loci, *CLN1*, *CLN2*, *CLN3*, *CLN5*, *CLN6*, *CLN8*, *Cathepsin D* and *CLCN3*, for homozygosity using fluorescently labelled microsatellite markers flanking each locus in the Turkish variant LINCL family panel. Homozygosity was observed for *CLN3* and *CLN6* in patients from two families each. The *CLN3* and *CLN6* genes were sequenced in respective patients. No mutations were identified in *CLN3*. Two putative mutations were identified in *CLN6* indicating that Turkish variant LINCL may be caused by mutations in the *CLN6* gene in addition to *CLN8*. A genome-wide scan to identify the true *CLN7* locus and gene will be initiated in the remaining eight families.

Genetic analysis of the progressive familial intrahepatic cholestases. *S.S. Strautnieks¹, J.A. Byrne¹, G.M. Mieli-Vergani¹, A.S. Knisely¹, L.N. Bull², R.J. Thompson¹.* 1) Institute of Liver studies, King's College Hospital, London, UK; 2) UCSF Liver Center Laboratory, San Francisco General Hospital, San Francisco, USA.

The progressive familial intrahepatic cholestases (PFIC) are a heterogeneous group of conditions characterised by defects in the various proteins, which collectively produce bile. They are amongst the main indications for paediatric liver transplantation worldwide. The common features are presentation in childhood of a subsequently progressive cholestasis leading to fibrosis and end stage liver disease by the second decade. The incidence is 1/70,000 UK births and 2 main types of low / normal gamma GT PFIC are recognised: bile salt export pump (BSEP) deficiency and familial intrahepatic cholestasis 1 (FIC1) deficiency. Both show autosomal recessive inheritance and are caused by mutations in the *ABCB11* and *ATP8B1* genes on chromosomes 2q24-31 and 18q21 respectively. Over 500 patients have been accepted for genetic analysis at KCH / UCSF in the last 5 years. Haplotype analyses in several populations indicate that BSEP deficiency is prevalent, comprising some 40% of cases, FIC1 deficiency some 20%. A significant proportion (up to 20%) of families are unlinked suggesting further PFIC loci. Mutation analysis of *ABCB11* shows that the majority of patients are compound heterozygotes and to date 52 different mutations have been identified, on 139 mutant alleles, in 95 BSEP deficient patients. These include a panel of fifteen common or recurring mutations: the missense changes E297G, D482G, and A588V which have been found on 72 mutant alleles in 52 European patients, and twelve changes associated with hypermutable CpG sites which recur in all populations. The remaining mutations comprise: 21 missense / termination changes, 4 splice site changes, and 13 insertions and deletions which include 2 whole gene deletions. Genetic screening allows both definitive diagnosis and the provision of genetic counselling. Genotype is also a major prognostic indicator for therapeutic interventions such as biliary diversion and ileal exclusion that may delay or even prevent the need for transplantation in these conditions.

Mutation screening of *FZD4* in familial exudative vitreoretinopathy (FEVR) patients. *C. Toomes¹, H.M. Bottomley¹, S. Scott¹, D.A. Mackey², J.E. Craig³, L.M. Downey¹, C.F. Inglehearn¹.* 1) Molecular Medicine Unit, University of Leeds, Leeds, United Kingdom; 2) Centre for Eye Research Australia, Royal Victorian Eye and Ear Hospital, Melbourne, Australia; 3) Department of Ophthalmology, Flinders Medical Centre, Adelaide, Australia.

Familial exudative vitreoretinopathy (FEVR) is an autosomal dominant disorder which affects the development of the retinal vasculature. Autosomal dominant FEVR is genetically heterogeneous with at least four different genes responsible for the disorder. Two of these genes have been identified, *FZD4* which encodes Frizzled-4 and *LRP5* which encodes low-density-lipoprotein receptor related-protein 5. In this study we screened *FZD4* in a panel of 60 FEVR patients to ascertain the type, frequency and location of mutations within this gene. We used primers to amplify the two *FZD4* exons and flanking intronic sequences from genomic DNA and screened these by direct sequencing. This work is still ongoing but to date we have identified over twelve mutations within *FZD4*. These include deletions (957delG, 1498delA, 1501delCT), nonsense mutations (Q505X) and missense mutations (G36D, M105T, M157V and S497F). None of these mutations were present in 200 control individuals. These results indicate that mutations within *FZD4* are responsible for only 20% of FEVR and suggest that other autosomal dominant FEVR loci may make a larger contribution to this condition than previously thought.

Mutations of the PTPN11 gene among Finnish Noonan syndrome patients. *M. Vaisanen¹, S. Ylönen¹, A. Mannermaa^{1, 2}, M. Somer³, S. Kivirikko³, E. Kajantie⁴, J. Körkkö¹, J. Ignatius¹.* 1) Dept. of Clinical Genetics, Oulu University Hospital and University of Oulu, Oulu, Finland; 2) Dept. of Clinical Pathology and Forensic Medicine, Kuopio University Hospital and University of Kuopio, Kuopio, Finland; 3) Family Federation of Finland, Helsinki, Finland; 4) Hospital for Children and Adolescents, Helsinki University Central Hospital, Helsinki, Finland.

Noonan syndrome (NS) (MIM 163950) is a developmental disorder characterized by typical facial dysmorphism, short stature, cardiac defects and skeletal malformations. Mutations in PTPN11, the gene encoding the non-receptor-type protein tyrosine phosphatase SHP-2, have been reported to cause NS. This study aimed to screen for mutations in the PTPN11 in Finnish NS patients. We screened for sequence alterations in exons (2-15) and splice regions of the PTPN11 gene by using PCR-CSGE and direct sequencing in 20 unrelated Finnish patients with typical Noonan symptoms and some of their family members. We identified missense mutations from four patients. The mutation Asn308Asp, the most common mutation described in Noonan patients, was found from two patients. The other two mutations were Asn308Thr and Thr73Ile. This study further emphasizes the importance of codon 308 mutations in Noonan syndrome, as three out of four of the found mutations affected it. Although Asn308Thr has not been described in other studies, our study shows that a PTPN11 mutation spectrum in Finnish NS patients does not differ from those in other populations. Interestingly, mutations were found from only 20% of the NS patients compared to estimates of ~50%, which suggests an important role for mutations in other genes in Finnish NS patients.

Mutations in the newly discovered coding exon 1 of *MECP2* are a rare cause of classic Rett syndrome. I. Van den Veyver^{1,2}, R. Amir¹, P. Fang², Z. Yu¹, D. Glaze³, A. Percy⁴, H. Zoghbi^{2,3,5}, B. Roa². 1) Dept Ob/Gyn; 2) Dept Molec Hum Genet; 3) and Dept Pediatr, Baylor Coll Med, Houston, TX; 4) Dept Pediatr, Univ Alabama, Birmingham, AL; 5) HHMI, Baylor Coll Med, Houston, TX.

About 85% of individuals with Rett syndrome (RTT) have a mutation in the coding sequence of exons 3 or 4 of *MECP2* and some have large genomic deletions. However, the mutations in the remainder are still unknown. An alternative *MECP2* splice variant (*MECP2B/MECP2*) has been discovered which encodes a MeCP2 isoform that excludes exon 2 but contains a novel N-terminus encoded by exon 1. We searched for mutations in exon 1 in genomic DNA of 63 patients, 38 of whom have classic RTT and 25 have atypical RTT. Mutations of coding exons 2, 3 and 4 were previously excluded. The 38 classic RTT patients were from a total cohort of 321 previously analyzed patients. We identified a *de novo* 2-base pair (bp) deletion at the splice donor site of intron 1 (c.62+1delGT, numbered according to the ATG of *MECP2B*). This patient has classic RTT but with still some preservation of eye contact. X-chromosome inactivation (XCI) studies on leukocyte-derived DNA revealed 68%:32% skewing with the maternal X chromosome being preferentially active, possibly explaining her slightly milder phenotype. We did not detect aberrantly spliced transcripts by RT-PCR analysis on leukocyte-derived RNA, although their presence can not be excluded given the pattern of XCI. The second identified mutation in a patient with atypical Rett syndrome is an 11 bp deletion (c.47_57del) which creates a frameshift and premature stop codon (p.Gly16GlufsX36). We also discovered a 3 bp in-frame insertion (c.47_48insAGG) in a girl with classic Rett syndrome. The significance of this sequence variant is currently unclear. We conclude that exon 1 mutations are present in 0.3% (1/321) of all classic Rett syndrome cases. In samples from RTT patients (classic and variant forms combined) who were negative by prior mutation analysis, we found mutations in exon 1 in 3.1% (2/63). Although mutations in exon 1 of *MECP2* comprise a small percentage of RTT cases, analysis of this exon should be incorporated for a complete DNA diagnostic testing strategy for Rett syndrome.

Large deletions/rearrangements of the *MECP2* gene were found in clinical diagnosed Rett syndrome patients using Multiplex-Ligation-PCR-analysis (MLPA). *M. Van Ghelue*¹, *A. Steinkjer*², *T. Rath Olsen*³, *C. Jonsrud*¹, *O. Skjeldal*². 1) Department of Medical Genetics, University Hospital, UNN, Tromsø, Norway; 2) Department of Pediatric Neurology, University Hospital, Oslo, Norway; 3) Child Habilitation Centre, University Hospital, UNN, Tromsø, Norway.

Rett syndrome (MIM# 312750) is an X-linked dominant neuro-developmental disorder and a leading cause of mental retardation in females. In the large majority of females that have Rett syndrome the gene encoding methyl-CpG binding protein 2 (*MECP2*) is mutated. However, despite routine sequence based screening of the coding exons and adjacent intronic sequences, mutations are not been identified in about 10-15 % of the patients. One possible reason could be that a second gene/locus might be involved in Rett syndrome. Another possibility is that mutations may occur within regulatory regions of *MECP2*, which are not routinely screened. Yet another explanation may be the occurrence of larger deletions that may be missed by routine PCR-based screening.

In the present study we investigated clinical diagnosed Rett syndrome patients, which did not have mutations within the *MECP2* coding region as determined by a sequence based screening method. However using multiplex-ligation PCR analysis (MLPA), we were able to identify the molecular cause of several individuals within this patient group. Results of the MLPA investigations and the characterization of the deletions/rearrangements will be presented.

Two novel de novo mutations in the Na⁺, K⁺-ATPase pump gene ATP1A2 associated with Familial Hemiplegic Migraine type 2. *K.R.J. Vanmolkot¹, V. Barone², U. Turk³, E.E. Kors⁴, D. Turkdogan⁵, S. Kheradmand Kia¹, D.F. Black⁶, J. Haan^{4, 7}, R.R. Frants¹, M.D. Ferrari⁴, G. Casari², A.M.J.M. van den Maagdenberg^{1, 4}.* 1) Dpt Human Genetics, Leiden University Medical Centre, Leiden, The Netherlands; 2) Human Molecular Genetics Unit, Dibit-Dan Raffaele Scientific Institute, Milan, Italy; 3) Dpt Neurology, Dr. Ltfi Kirdar State Hospital, Maltepe, Istanbul, Turkey; 4) Dpt Neurology, Leiden University Medical Centre, Leiden, The Netherlands; 5) Dpt Pediatric Neurology, Institute of Neurological Sciences, Maltepe, Istanbul, Turkey; 6) Dpt Neurology, The Mayo Clinic, Rochester, MD, US; 7) Dpt Neurology, Rijnland Hospital, Leiderdorp, The Netherlands.

Migraine is a common neurovascular disorder characterised by attacks of severe headache and autonomic and neurological symptoms, affecting up to 12% of males and 24% of females in the general population. Familial hemiplegic migraine (FHM) is a rare autosomal dominant subtype of migraine with aura, associated with hemiparesis. The first gene identified in families with familial hemiplegic migraine (FHM1), namely CACNA1A, encodes a P/Q-type calcium channel subunit. Recently, missense mutations in the ATP1A2 gene, encoding an α -subunit of the Na⁺,K⁺-ATPase were reported for the second FHM locus (FHM2) on chromosome 1q23. Here we describe two novel de novo missense mutations, V628M and R593W, in the ATP1A2 gene in a Turkish family and a Dutch family with pure FHM. Functional analysis showed a loss-of-function effect for both mutations. Furthermore, two monozygotic twin brothers that were V628M carriers showed variation of clinical symptoms, illustrating environmental influence on the FHM2 phenotype.

Identification of deletions in patients with spinal muscular atrophy (SMA) type I, II and III and determination of gene copy numbers using MLPA analysis. *Y.J. Vos¹, H.H. Lemmink¹, A.H. v.d. Hout¹, J. Dijkhuis¹, C. Lummen¹, J.P. Schouten², C.H.C.M. Buys¹.* 1) Department of Clinical Genetics, Groningen University Hospital, Groningen, The Netherlands; 2) MRC Holland, Amsterdam, The Netherlands.

In about 95% of patients with spinal muscular atrophy (SMA) mutations have been identified in the SMN1 gene localized at chromosome 5q12-13. SMA patients are clinically distinct and classified into three different types. The clinical phenotype varies between the lethal SMA type I to the intermediate type II and the milder type III. Almost 95% of patients of all three clinical types have a homozygous deletion of at least exon 7 of the SMN1 gene. A very similar gene, SMN2, centromeric to SMN1, has been proposed as a modifying gene, since patients with the milder forms of SMA appear to have more SMN2 gene copies. Additionally, there is a clear preponderance of homozygous NAIP (neuronal apoptosis inhibitor protein) gene deletions in SMA type I patients. A novel multiplex ligation-dependent probe (MLPA) assay has been adapted by us to detect SMN1, SMN2, and NAIP gene deletions and to quantify gene copy numbers. A total of 19 SMA type I, 30 type II and 27 type III patients were tested and in all these cases at least exon 7 of SMN1 was absent. The determination of SMN1, SMN2 and NAIP gene copy numbers using MLPA has been validated by comparison with results from controls and patients obtained by dosimetric exon 7 SMN analysis and Pulsed Field Gel Electrophoresis. Upon MLPA analysis around 84% of type I, 93% of type II and 81% of SMA type III patients carried a total of 2, 3 and 4 SMN2 gene copies, respectively, and 74% of type I, 70% of type II and 55% of type III patients carried a total of 0, 1 and 2 NAIP gene copies, respectively. We conclude from our study that the numbers of SMN2 and NAIP gene copies are associated with the SMA phenotype.

Somatic and gonadal mosaicism in Hutchinson-Gilford progeria. *W. Wuyts¹, M. Biervliet¹, E. Reyniers¹, G. Novelli², K. Storm¹.* 1) Dept of Medical Genetics, University and University Hospital of Antwerp, Antwerp, Belgium; 2) Dept of Biopathology, Tor Vergata University of Rome, Rome, Italy.

Hutchinson-Gilford progeria syndrome (HGPS) is a very rare disorder characterized by acceleration of the aging process. All molecular characterized HGPS cases described so far result from de novo LMNA mutations, mostly originating on the paternal allele. In almost all patients, HGPS is caused by a 1824 C>T (G608G) mutation, leading to the activation of a cryptic splice donor site, resulting in the deletion of 150 bp at the mRNA level and the formation of a truncated LMNA protein. We describe a young boy with typical HGPS phenotype including failure to thrive, alopecia, skeletal abnormalities and sclerodermatous skin changes. Molecular analysis of the LMNA gene showed the presence of the 1824 C>T (G608G) mutation. Screening of both parents showed a wild type sequence in the father but surprisingly a weak signal corresponding to the mutant sequence was observed in the mother's leukocyte DNA, suggesting somatic mosaicism. Molecular characterization and segregation analysis of a 3' UTR G/A SNP located 566 bp after the stop codon further confirmed that the mutation in the proband resides on the maternal allele. Further studies also showed mosaicism for the 1824 C>T mutation in buccal cells of the mother with a similar ratio of mutant versus wild type of 1/10. No mutated allele could be detected in DNA from cultured fibroblasts and hair roots. Clinical examination of the mother did not reveal any clinical abnormalities. This is the first reported case of somatic and germline mosaicism for HGPS and it demonstrates the necessity for screening of both parents of HGPS patients as the presence of germline mosaicism has great implications towards the recurrence risk.

Mutational analyses in Japanese patients with *FGD-1*-linked Aarskog-Scott syndrome. *K. Yanagi*¹, *T. Kaname*¹, *Y. Chinen*², *K. Naritomi*¹. 1) Medical Genetics , University of the Ryukyus , Nishihara, Okinawa, Japan; 2) Paediatrics, University of the Ryukyus , Nishihara, Okinawa, Japan.

Faciogenital dysplasia 1 (*FGD-1*) gene has been identified as a responsible gene for Aarskog-Scott syndrome (AAS). A mutational analysis of the *FGD-1* gene was performed in six Japanese patients with AAS (four familial and two sporadic cases). We found three point mutations; i.e. two missense mutations in the exon 11 (1906C>T) and exon 15 (2221G>T), and a mutation at first position of 5 splice donor site of the intron 14 (IVS14+1, G>A), reducing *FGD-1* gene expression. As indicated previously, no genotype/phenotype correlations were further confirmed by this study. This is the first report of a mutation analysis in non-Caucasian *FGD-1* - linked AAS patients.

MUTATIONS IN THE *IRF6* GENE IN TWO PATIENTS WITH POPLITEAL PTERYGIUM SYNDROME.

*R.M. Zechi-Ceide*¹, *M.L. Guion-Almeida*¹, *N.M. Kokitsu-Nakata*¹, *M.R.S. Passos-Bueno*^{2,3}. 1) Setor de Genética Clínica, HRAC-USP, Bauru, Brazil; 2) Laboratório de Genética Molecular-IB, USP, Brazil; 3) CEGH-IB, USP, Brazil.

Popliteal pterygium syndrome (PPS) is a rare autosomal dominant disorder, characterized by popliteal webbing, cleft lip and/or cleft palate, lower lip pits, syndactyly, genital anomalies and pyramidal skin folds in halluces nails. Families with PPS have been linked to chromosome 1q32-q41, the critical region for the van der Woude syndrome (VWS1), suggesting that these two disorders are allelic. Mutations in *IRF6* gene have been identified in families affected with PPS and families affected with VWS. In this study, we describe two unrelated cases with clinical signs suggestive of the PPS with mutation in *IRF6* gene. Case 1: sporadic, cleft lip and palate, popliteal webs, syndactyly of toes, pyramidal wedge of soft tissue overlying the first toenails, ectopic testes, and misplaced anus. Case 2: familial, cleft lip and palate, lower lip pits, syndactyly of toes, pyramidal wedge of soft tissue overlying the second toenails. Mother of the case 2: cleft lip and palate and lower lip pits. Sequencing analysis of *IRF6* gene: mutations c250G>T and IVS3-5C>G in case 1; mutation c182C>A in case 2 and in his mother. The mutation IVS3-5C>G represents a SNP, with a frequency of 19% in our population, while the mutation c250G>T, leading to the substitution of the residue Arginine to Cysteine, at position 84, was described in other 5 patients with SPP. Except by absence of lower lip pits, the case 1 presented typical PPS. The mutation c182C>A, detected in case 2 and in his mother, leads to a predicted amino acid residue change from Alanine to Aspartic Acid at position 61. The substitution of this same amino acid was observed, previously, in one individual with VWS1. Interestingly, case 2 presents phenotypic features of both PPS and VWS1, while his mother presents typical VWS1. These data favors that the mutation in the amino acid 84 is highly correlated with the PPS phenotype while the change in the amino acid 61 might cause both diseases, even within the same family. It will be important to elucidate the molecular mechanisms leading to these clinical differences. FAPESP/CEPID.

Pathogenetic studies of the Hutchinson-Gilford progeria syndrome (HGPS). *W. Brown, W. Ju, A. Potempska, J. Shen, S. Li, P. Mehta, D. Miller, G. Merz, G. Wen, N. Zhong.* NYS Inst Basic Research, Staten Island, NY.

HGPS is a very rare premature aging syndrome with autosomal dominant inheritance. Recently, HGPS has been found to result from genetic defects of the LMNA gene, which encodes nuclear envelope proteins lamin A/C. A silent mutation, c2063CT that results in G608G, generates a cryptic splicing site in exon 11 of LMNA, and consequently truncates 50 amino acids near the C-terminus of lamin A, has been identified in ~80% of HGPS alleles. This has led us to explore the pathogenic mechanism driving the development of the HGPS as well as the molecular basis of other laminopathies. Our studies demonstrate dominant negative effects of the mutant protein progerin. It produces irregular nuclear structures, thickened abnormalities of the inner nuclear membrane, reduced nuclear pore complexes, and increased ribosome numbers. Ultrastructural analysis showed large vacuous structures within mitochondria within progeria but not control cells. Analysis of mitochondrial membrane function using an apoptotic marker of membrane potential showed significant differences between progeria cells (40%) and normal controls (73%). We have generated a progerin-specific polyclonal antibody, which detects only progerin from progeria cells and nothing from control. By comparison an anti-lamin A/C monoclonal antibody detects both progerin and the normal lamin A/C in progeria cells. Using this antibody, we are now able to localize the mutant protein within progeria cells. This approach will be useful to help understand the pathogenesis of HGPS.

Homozygous SMN1 deletions in unaffected family members and modification of the phenotype by SMN2. *T.W. Prior¹, K. Swoboda², H.D. Scott³, A.Q. Hejmanowski¹*. 1) Pathology, Ohio State University, Columbus, OH; 2) Neurology, University of Utah, Salt Lake City, UT; 3) Medicine, Brown Medical School, Providence, RI.

Spinal muscular atrophy is a common autosomal recessive neuromuscular disorder caused by the homozygous loss of the SMN1 gene. The absence of the SMN1 gene has been shown to occur in all types of SMA, childhood and adult forms. In rare cases, asymptomatic family members have also been found with homozygous mutations in the SMN1 gene, suggesting a role for phenotypic modifiers. We describe three unrelated asymptomatic individuals, with family histories of SMA, who were shown to have the homozygous SMN1 deletion. Quantitative studies indicated that the three individuals all had increased SMN2 copy numbers. In one of the cases we describe sibs with homozygous deletions with different SMN2 levels and discordant phenotypes. These cases not only support the role of SMN2 in modifying the phenotype, but our data also demonstrate that expression levels consistent with 5 copies of the SMN2 genes maybe enough to compensate for the absence of the SMN1 gene. It is also important to correctly distinguish the asymptomatic homozygous from the standard heterozygous carriers, since there is an increased recurrence risk of affected offspring and all of their offspring will be carriers. Lastly, in cases similarly to the ones described, the measurement of the SMN2 gene copy number may provide valuable prognostic information.

Studies on Cultured Myoblasts from Patients with Limb Girdle Muscular Dystrophy type 2H (LGMD2H): TRIM32 and Vesicular Aggregation. *K. Wrogemann¹, G.L. Stelmak¹, A.J. Halayko¹, E. Shoubridge², J.D. Berry¹, C.R. Greenberg¹, S. Pind¹, P. Hazelton¹, P. Frosk¹.* 1) University of Manitoba, Winnipeg, MB, Canada; 2) Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada.

Limb girdle muscular dystrophy type 2H (LGMD2H) is an autosomal recessive myopathy with a high prevalence in the North American Hutterite population. Our laboratory has mapped the gene for LGMD2H to chromosome region 9q31-33 and identified the causative mutation as D487N in the TRIM32 gene (AJHG 70:663-672). The TRIM32 protein belongs to a family of proteins believed to be ubiquitin ligases. In an effort to delineate the pathogenesis of LGMD2H we have produced semi-transformed myoblast cell lines from both normal and affected individuals. We have found that compared to the normal myoblasts there is a consistent vesicular aggregation in myoblasts from two separate LGMD2H patients. Cells probed with our anti-TRIM32 antibody by fluorescence microscopy show the association of TRIM32 with large cytoplasmic bodies, but no difference is apparent between normal and affected cell lines. The same pattern is also found in mouse skeletal muscle myoblasts, dog smooth muscle myoblasts, human skin fibroblasts, and baby hamster kidney cells. Preliminary results using immunogold electron microscopy on partially purified TRIM32 suggest that these bodies are approximately 40-50 nm in size. Immunoblot indicates that TRIM32 may be ubiquitinated, a characteristic feature of many ubiquitin ligases, often due to auto-ubiquitination. Interestingly, we have also discovered an apparent absence of these cytoplasmic bodies containing TRIM32 in myoblasts that have been induced to form myotubes. This coincides with a relatively weak immunohistochemical staining for TRIM32 in mature skeletal muscle sections. The data suggest that TRIM32 is involved in the ubiquitin proteasome system and is more important in muscle precursor cells rather than in mature muscle, indicative of a role in development / regeneration. At this time it is unclear whether the vesicular phenotype that we have identified in the LGMD2H myoblasts is directly related to this role or is a further downstream effect of the TRIM32 mutation.

Molecular basis of a temperature-sensitive PEX13 mutation of peroxisomal biogenesis disorder (2): 3D-structure and folding of the protein.

Z. Kato¹, K. Hashimoto¹, T. Nagase¹, N. Shimozawa¹, K. Kuwata², K. Omoya¹, A. Li¹, E. Matsukuma¹, Y. Yamamoto¹, H. Ohnishi³, H. Tochio³, M. Shirakawa³, Y. Suzuki⁴, R. Wanders⁵, N. Kondo¹. 1) Department of Pediatrics, Graduate School of Medicine, Gifu University; 2) Department of Biochemistry and Biophysics, Graduate School of Medicine, Gifu University; 3) Graduate School of Integrated Science, Yokohama City University; 4) Medical Education Development Center, Graduate School of Medicine, Gifu University; 5) Department of Clinical Chemistry and Pediatrics, Academic Medical Centre, University of AmsterdamG.

We have revealed that a patient with NALD phenotype carried a missense mutation of PEX13 (I326T within a SH3 domain). He showed normal development just before a sudden deterioration with a high fever due to a respiratory infection and fibroblasts of the patient showed a temperature-sensitive (TS) phenotype in peroxisome assembly. As a first step to study its mechanism, we have analyzed the protein phenotype of the human (Hs) Pex13p-SH3 domain using immunohistochemical and biochemical analyses suggesting the fragility of the mutant protein (See Hashimoto et al. ASHG 2004). However, the precise molecular basis of the TS phenotype at a high temperature still remains unknown. To elucidate the mechanism, we have analyzed the 3D-structure and folding of the protein using fluorescence, circular dichroism (CD), multi-dimensional nuclear magnetic resonance (NMR), and bioinformatics. Three kinds of recombinant proteins, wild, natural mutant (I326T), and artificial mutants (I326F, I326L, I326V, I326A), were prepared. The structural analyses revealed that the recombinant HsPex13p-SH3 domain had a beta-barrel structure, which is typical for SH3 domain. Fluorescence and CD of the proteins indicate the different sub-structures of the domain. The melting temperature and folding-unfolding balances of the mutants were significantly lower than those of the wild. From these analyses, the temperature-sensitive nature of the mutation I326T in HsPex13p should be recognized, not only as simple fragility, such as susceptibility to the proteases of the native protein, but also as an imbalance of folding and unfolding kinetics, which results in an increase of unfolded proteins even at a lower temperature. Mutation effects of non-catalytic residues in genetic diseases have been implicated simply as protein degradation by structural instability. However, as shown in this study, which has directly revealed the folding state of protein in the TS-phenotype mutation, more precise investigations utilizing structural analyses could reveal the true nature of the mutations; giving a better understanding of genotype-phenotype correlation and assisting the development of new therapeutic approaches including the use of chemical chaperones.

Common TagSNPs Haplotypes of Genes Association with Fluvastatin Treatment in Familial

Hypercholesterolemic Patients. *D. Bercovich¹, S. Korem¹, Y. Friedlander², A. Houminer², A. Hoffman³, L. Kleinberg³, C. Shochat¹, E. Leitersdorf⁴, V. Meiner⁵.* 1) HMG & Pharm, MIGAL-Galille Bio-Technology Ctr, Israel; 2) Dept of Social Medicine, Heb Univ; 3) School of Pharmacy; 4) Dept of Medicine B; 5) Dept of HG, Hadassah-University Hospital, Jerusalem, Israel.

Familial hypercholesterolemia (FH) patients are commonly treated with HMG CoA reductase inhibitors. Yet, therapeutic response is frequently variable also among patients with identical LDL receptor mutations. This heterogeneity can result from differences in pharmacodynamic (PD) and pharmacokinetic (PK) parameters, which may be genetically determined. We analyzed SNPs in the CETP and the MDR1, representing PD and PK determinants respectively, and their association with variable response to fluvastatin in 77 molecularly characterized FH patients. Lipid levels were determined in a compliance-monitored clinical study at baseline and following 16 weeks of treatment with escalating doses of fluvastatin. CETP and MDR1 SNP genotyping was performed using DHPLC and sequence analysis. Linear regression was used to examine the associations between common SNPs and haplotypes (based on tagSNPs) and lipids response. Treatment with Fluvastatin resulted in mean LDL-C reduction of 21.48%; mean triglyceride (TG) reduction of 8.33%; and a mean HDL-C increase of 13.42%. Five tagSNPs in both genes were used to reconstruct 5 and 6 haplotypes accounting for 71.4% and 90.2% of the observed haplotypes in the CETP and MDR1 genes, respectively. An increase in LDL response was associated with CETP-H13 (-29.38% p=0.026) and with MDR1-h4 (-26.56% p=0.025). Similarly, CETP-H5 was shown to be significantly associated with decreased TG and HDL-C response, while MDR1-h10 was associated with a decrease in TG response. A multivariate regression model indicated an independent additive effect of CETP-H5 and MDR1-h10 on the level of TG response. SNP-haplotypes in CETP and MDR1 have significant independent effects on lipid changes following a Fluvastatin treatment in FH patients. Further studies on genetic determinants correlated with adverse-effects to Statin treatment of FH patients are underway.

A new polymorphism in chloride channel gene 2. *K.W. Kimberley¹, F.C. Britton², J.R. Hume³, H.H. Hobart¹, C.A. Morris¹.* 1) Dept. of Pediatrics/Division of Genetics, U. of Nevada School of Medicine, Las Vegas, NV; 2) Dept. of Physiology and Cell Biology, U. of Nevada School of Medicine, Reno, NV; 3) Dept. of Pharmacology, U. of Nevada School of Medicine, Reno, NV.

Cardiac arrhythmias, disturbances in the electrical conduction of the heart, are responsible for most of the 250,000 cases of sudden cardiac deaths that occur each year. Ion channels are responsible for the initiation and conduction of the electrical activity in the heart. Presently, 9 cation channel genes and 1 non-ion channel gene have been identified as causes of cardiac arrhythmias. Anion channels have also been shown to play a role in cardiac electrical conductance. Chloride channel gene 2 (CLCN2) encodes outward rectifying, volume-sensitive chloride channels when expressed in mammalian cells. To date, 25 polymorphisms have been identified in this gene: 5 in exons, 20 in introns. We screened CLCN2 to look for mutations that may be associated with cardiac arrhythmias.

We studied 100 DNA samples from individuals with LQT and other forms of arrhythmia with no mutations in the known LQT genes. Each exon of CLCN2 was amplified using PCR and analyzed by SSCP. Anomalous bands were cut out and the DNA extracted. The extracted DNA and corresponding patient sample were re-amplified and sequenced.

A new polymorphism was identified in 4 of the samples tested (2 with sick sinus syndrome, 1 with 2 syncopal episodes, QTc=0.42, and 1 normal control with 1 syncopal episode during exercise). Sequencing revealed a C to T base pair substitution at position 119 of exon 15. This mutation occurs in the third position of the codon but does not change the amino acid. However, this exon is in the splice region and the base change could affect splicing even though the amino acid is unchanged. Functional studies will be required to determine what effect, if any, this base pair substitution has on splicing and subsequent chloride channel function.

Genomic Structure and Organization of the High Grade Myopia-2 Locus (MYP2) Critical Region: Mutation Screening of 9 Positional Candidate Genes. *G.S. Scavello Jr¹, P.C. Paluru¹, J. Zhou¹, P.S. White^{2,3}, R.S. Spielman⁴, W.R. Ganter¹, T.L. Young¹.* 1) Divisions Ophthalmology and Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Division of Oncology, The Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Pediatrics, University of Pennsylvania, Philadelphia, PA; 4) Department of Genetics, University of Pennsylvania, Philadelphia, PA.

Autosomal dominant high myopia is a common complex eye disorder, with implications for blindness due to increased risk of retinal detachment, chorioretinal degeneration, premature cataracts, and glaucoma. An interval of 2.2 cM was defined on chromosome 18p11.31 using 7 families with AD high myopia and was designated the MYP2 locus. We sought to characterize the causative gene(s) by direct sequencing of 9 known positional candidate genes in the region. The BLAST algorithm was used to query BAC clones against the nt and EST databases to search for evidence of expression of candidate genes from the MYP2 interval. Exon/intron boundaries were also determined from known gene structures described in the NCBI Map Viewer. Reverse-transcription polymerase chain reactions (RT-PCR) and queries of the UniGene database were performed to substantiate gene expression in ocular tissues. Coding regions, intron/exon boundaries and untranslated exons of all known genes were sequenced using genomic DNA samples from 12 affected and 8 unaffected MYP2 pedigree members, and from 4 unaffected and 1 highly myopic external controls. Polymorphic sites were compared to known variants from the dbSNP database. 116 polymorphisms were found by direct sequencing; 12 were missense, 17 were silent, 34 were not translated, 51 were intronic, and 2 were homozygous deletions. Forty-six polymorphisms were novel. Novel SNPs were submitted to dbSNP; observed frequencies were submitted for known SNPs. No identified sequence alterations were associated with the disease phenotype. Further studies of MYP2 candidate genes, including analysis of putative genes predicted in silico, are underway to ascertain the determinant(s).

A mutation creating an upstream initiation codon in the SOX9 5 UTR causes campomelic dysplasia. *G. Scherer*¹, *R. Pop*¹, *D. Johnson*², *J. Tolmie*², *D. Morris-Rosendahl*¹. 1) Institute of Human Genetics, Freiburg, Germany; 2) Institute of Medical Genetics, Yorkhill NHS Trust, Glasgow, UK.

Campomelic dysplasia (CD) is a semilethal skeletal malformation syndrome that results from de novo heterozygous mutations in SOX9. These mutations are distributed over the entire coding region and cause loss-of-function of the protein, resulting in haploinsufficiency. We report on a 2 year-old girl with a 46,XX karyotype who has clinical and radiological features of surviving CD, including micrognathia, tracheomalacia, small scapulae, 11 pairs of ribs and short ischia. Sequence analysis of the SOX9 coding region failed to reveal a mutation. However, a heterozygous mutation G>A at position 188 in the 5 UTR was found. The patients mother, father and healthy brother were homozygous G/G at this position, as were 100 control chromosomes. Paternity was confirmed by microsatellite marker analysis. The G>A mutation creates an upstream translation start codon (GTG>ATG) with a much better fit of its flanking sequence to the Kozak consensus than that at the wildtype ATG start codon (4/6 vs. 1/6). If used, the upstream ATG would lead to translation of a short peptide of 62 amino acids from a reading frame that terminates just after the wildtype ATG start codon. Such an upstream open reading frame could reduce or prevent translation of the wildtype protein. Reduced amounts of SOX9 protein from the mutant mRNA would be compatible with the milder phenotype of the patient. Although described only rarely in human genetic disease and for the first time here for CD, mutations creating upstream ATG codons may be more common than generally assumed.

Canine X-linked ectodermal dysplasia as a model for the human disease: mutational analysis and further characterization of disease. *M.L. Casal¹, E.A. Mauldin², O. Gaide³, J.L. Scheidt¹, J.L. Rhodes¹*. 1) Medical Genetics, Veterinary Hospital, Univ Pennsylvania, Philadelphia, PA; 2) Dept Pathobiology, Univ Pennsylvania, Philadelphia, PA; 3) Dept Dermatology, Univ Hospital of Geneva, Switzerland.

A breeding colony of dogs with X-linked ectodermal dysplasia (XHED) is maintained at the University of Pennsylvania for the study of both mechanisms of disease and similarities to human XHED. We sequenced the canine ED1 gene and determined the disease to be caused by a nucleotide substitution (G to A) in the splice acceptor site of intron 8. A cryptic acceptor site is subsequently used within exon 9, resulting in a truncated message and, thus, the loss of the TNF homology domain, the receptor-binding site of ectodysplasin. As in human patients with XHED, affected dogs are at risk for pulmonary disease characterized by frequent infections and unexpected deaths due to opportunistic respiratory infections. Previous experiments aimed at examining the XHED dogs immune system showed no differences between affected and normal dogs. Recently, we examined morphological differences in respiratory organs from XHED dogs and normal age-matched controls to understand the basis of respiratory disease. Histopathologic changes consisted of complete loss of branched tubuloalveolar mucous glands from nasal turbinates, trachea, and bronchi resulting in reduced respiratory ciliary motility. In humans, several reports point to a total absence of mucous glands in pharynx, larynx, trachea, and large and small bronchi, sometimes associated with complete tracheal obstruction by mucous debris. This finding was thought to be the basis for the observed abnormal tracheobronchial secretions and increase in susceptibility to respiratory infections. Other canine organs with glandular components were examined; there was complete absence of eccrine glands from the gastrointestinal tract and from footpads, which is the only site of sweat glands in normal dogs. In humans, mucous glands are absent in the upper esophagus and hypoplastic in the colon. This is thought to predispose affected children to intussusceptions that may also have a fatal outcome.

***DNALI* and *NME5*: two candidate genes for Kartagener syndrome with ultrastructurally normal cilia.** M.L. Lacombe¹, A. Moore^{2,3}, A. Munier¹, A. Coste^{2,4}, N. Desmazes-Dufeu⁴, B. Duriez³, S. Amselem^{3,4}, E. Escudier^{2,4}. 1) INSERM U402, Paris; 2) INSERM U492, Creteil; 3) INSERM U468, Creteil; 4) AP-HP, Paris; France.

Primary Ciliary Dyskinesia (PCD) is a rare disease characterized by airway infections (bronchiectasis and rhinosinusitis) due to abnormal ciliary structure and function mainly due to defects of dynein arms. In half cases, respiratory symptoms are associated with *situs inversus* therefore defining Kartagener syndrome (KS). In our population, 19% of patients with KS display cilia with normal axonemal ultrastructure. In these cases, diagnosis of PCD is based on typical clinical features and immotile cilia. As no structural defect could be identified by electronic microscopy, we postulated that genes responsible for the disease could encode small structural or enzymatic proteins important for ciliary beating. We selected two genes: *DNALI*, a gene orthologous to *lc1* identified in *Chlamydomonas reinhardtii*, coding for a dynein light chain of the outer dynein arm (ODA); and *NME5* encoding an axonemal protein, Nm23-H5 homologous to nucleotide diphosphate kinases. Lc1 (22kDa) belongs to the leu-rich family protein. This protein binds at the ATP hydrolytic site (*i.e.* motor domain) of the ODA, permitting the binding with the adjacent B-microtubule, an interaction that plays a key role in microtubule sliding. In silico analysis revealed the existence of a potential human orthologous sequence on chromosome 14q24.3. This sequence designated *DNALI* (standing for dynein axonemal light chain 1) contains 8 putative exons with corresponding ESTs found in human ciliated tissues. The predicted protein, which is composed of 151AA, contains a leu-rich repeat domain. *NME5* was selected because of its expression in tissues with axonemal structures, *e.g.* trachea and testis. This gene (5q23-31) encodes a kinase (24.2 kDa) associated with central microtubules and outer doublets. We screened for mutations these two genes in our patients with KS and normal cilia. Although no mutations have been so far identified, the location and the function of the corresponding proteins make those two genes good candidates to be investigated in patients with KS characterized by immotile cilia and absence of axonemal defects.

Assessing the possible utilization of CFTR-M470V genotyping for CF risk determination. *P.F. Pignatti¹, F. Pompei², A. Bonizzato³, A. Beghini¹, B.M. Ciminelli², C. Bombieri¹, C. Ciccacci², C. Castellani³, G. Modiano².* 1) Sec. Biology and Genetics, Dpt. Mother & Child/Biol & Gen, Univ Verona, Verona; 2) Dpt. of Biology, University of Roma-Tor Vergata, Roma; 3) Veneto Regional CF Center, Hospital of Verona, Verona; Italy.

In a previous study on European non-CF individuals, we found that random CFTR gene mutations were preferentially present in the genes carrying the M allele of the M470V common polymorphism (unpublished data). Therefore, we hypothesized that CFTR alleles with the M variant should have an increased risk of carrying a CF-causing mutation. We collected 177 nuclear families (parents and a CF child) for a total of 531 subjects, selected for the presence of at least one non-DF508 mutation in the genotype of the CF child, after the screening of the most common CF mutations in the population. The haplotypes formed by the M470V polymorphism and the CF causing mutation have been established in 152 families. We had 100 DF508 alleles, 172 alleles with one non-DF508 common mutation, 32 alleles with an unidentified mutation. Giving the known association between DF508 and M allele, we focused our analysis on the 204 CF-non-DF508 alleles: 171 (84%) of these genes carried the M allele. Frequency of the M allele in the normal population is 38.5% (Hum Genet 106:172,2000), the difference is significant ($p < 0.00001$). These results confirm for the CF alleles a preferential association with the M allele, so that the risk for an MM or MV individual to be heterozygote for a CF mutation is significantly higher than for a VV subject (4.4% and 2.4% respectively, vs 0.5%). Accordingly, the risk to have a CF child increases for the couple in which both parents have at least one M allele (e.g. 0.028% for a VVxVV couple, 0.19% for a MMxMM couple, both negative for the DF508). Therefore, typing a subject for the M470V polymorphism can reduce or increase his/her risk to be heterozygote for a CF mutation, so that further analysis could be suggested only for individuals (or couples) with an increased risk. Acknowledgments: Italian CF Foundation.

DUCHENNE muscular dystrophy caused by a rare mid-intronic substitution activating a cryptic exon in the DMD gene. *N. Lannoy¹, I. Abinet¹, P. Van den Bergh², Ch. Verellen-Dumoulin¹.* 1) Dept Genetics, UCL, Saint-Luc Hosp, Brussels, Belgium; 2) Departement of Neurology, UCL, Brussels, Belgium.

The defects in the Duchenne muscular dystrophy (DMD) gene are mainly exon deletions (60%), duplications (10%) and small mutations (30%). The precise identification of the mutation in each patient is necessary to offer accurate and safe genetic counseling, prenatal diagnosis and future gene therapy. In this context, eight different mutations have been identified in 7 DMD and in 1 BMD/XLCMD patients using Protein Truncated Test (PTT), DGGE and sequencing methods. Six mutations have not been reported previously : two nonsense mutations (C569X and L654X), one frameshifting deletion (6438delG), two splicing defects (6614+1G>A, 10086+1G>A) and one mid-intronic substitution (1812+601A>G). The latter mutation was described in a family where two brothers were diagnosed with DMD at 3 years and 18 months of age after clinical examination and muscle biopsy immunofluorescence analysis. The whole dystrophin genomic gene was tested by multiplex PCR and Southern blotting without finding a gross gene defect. Mutation search was performed by PTT on total muscle RNA from the eldest brother. Aberrant mobility on PTT gel was identified from c-DNA covering exons 9 to 18. Curiously, no mutation has been found when sequencing analysis was performed on genomic exons 9 to 18 with their adjacent intronic sequences. An elongated RT-PCR fragment from this region was found on acrylamide gel . Its sequence showed a non in-frame extraneous sequence of 121 pb intercalated between exons 15 and 16. An in silico search of the whole dystrophin genomic sequence revealed that this insert corresponds to a cryptic exon flanked by consensus splice sites located in the mid-part of intron 15 due to a single intronic substitution. This mutation is also present in the brother's and mothers DNA but absent in a control population. Mid-intronic mutation may be pathogenic. At this time, the incidence of this type of mutation in the DMD gene is unknown but a preliminary proportion of 6% has been recently proposed among the non-deleted/non-duplicated cases.

SBDS Localisation and Effects of Gene Mutation on Protein Expression. *N. Richards*¹, *G.R.B. Boocock*^{1, 2}, *J.M. Rommens*^{1,2}. 1) Program in Genetics & Genomic Biology, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Molecular and Medical Genetics, University of Toronto, Toronto, Ontario, Canada.

Genetic studies have led to the identification of mutations that lead to Shwachman-Diamond syndrome (SDS) in an uncharacterised gene named *SBDS*. *SBDS* is broadly expressed and encodes a polypeptide of 250 amino acid residues with a predicted molecular mass of 28.8 kDa. Immunofluorescence microscopy of SV40-transformed fibroblasts indicated diffuse localisation throughout cells with heterologous expression of HA, *c-myc* and GFP-*SBDS* fusion polypeptides. Rabbit polyclonal antibodies have been generated to directly assess endogenous *SBDS*; one antibody was raised against recombinant protein, and two others were raised against short synthetic peptides derived from the amino and carboxyl portions. The *SBDS* antibodies detected the epitope-tagged *SBDS* in transfected fibroblasts as well as an endogenous 30 kDa band in extracts from various cell lines by western blotting. In order to assess the effects of *SBDS* mutations on expression, proteins were extracted from EBV-transformed B-lymphoblastoid cell lines derived from unrelated SDS patients and control individuals. Common mutations account for the alleles seen in more than 50% of SDS patients and corresponding cell extracts exhibited no detectable levels of the 30 kDa protein. Extracts from a patient heterozygous for a common and a rare splicing mutation [258+1G>C], also revealed no detectable protein. Patients heterozygous with rare missense mutations [97A>G] (K33E), [505C>T] (R169C) and [506G>A] (R169H) did indicate detectable levels of full-length protein. Five patients meeting diagnostic criteria, but carrying no known mutations to date, expressed levels of *SBDS* protein comparable to controls. Given that most SDS patients do not exhibit detectable levels of protein, decreased *SBDS* expression contributes to the SDS phenotype.

Expression analysis of genes from the Williams-Beuren syndrome region at 7q11.23. *W. Loo*¹, *L.R. Osborne*^{1,2}. 1) Molecular & Medical Genetics, University of Toronto, Toronto, Ontario, Canada; 2) Medicine, University of Toronto, Toronto, Ontario, Canada.

Williams-Beuren syndrome (WBS) is caused by the deletion of more than 20 genes on chromosome 7. As a first step towards identifying dosage sensitive genes that might be more likely to cause a phenotypic effect, we analyzed the expression levels of candidate genes in transformed human lymphoblast cell lines from families with WBS. By analysis of individuals with different rearrangements of 7q11.23 we hope to correlate gene expression with the phenotypic features seen in patients with WBS. Real-time RT-PCR was used to measure the transcript level of candidate genes relative to three control genes, *-actin*, *STARD7* and *HPRT*. The ratio of test to control transcript in each proband was then compared to that of first-degree relatives.

We found that the level of *WBSCR16* (outside the deletion) was not altered in individuals with a deletion or inversion, but was increased in an individual with a duplication of 7q11.23. Surprisingly, the level of *GTF2IRD1* transcript (within the common deletion) showed no difference in any of these individuals. *GTF2I* expression, however, was reduced on average to 55% in 10 WBS deletion patients (range 42%-70%) and increased to 180% in the duplication patient. No difference in expression level was seen in three parents carrying an inversion. Analysis of these genes in two previously reported individuals with WBS inversions and clinical features, did not reveal any differences in expression.

These results suggest that the WBS inversion polymorphism does not affect expression of *GTF2I*, *GTF2IRD1* or *WBSCR16*. Furthermore, it is unlikely that these genes play a role in the clinical symptoms seen in atypical WBS inversion patients. The hemizygous deletion of *GTF2I*, but not *GTF2IRD1*, however, affects the level of gene expression, at least in lymphoblasts, and suggests that *GTF2I* may be haploinsufficient in WBS. Further studies of individuals with other rearrangements of 7q11.23 and of mice with deletions of these genes will help to clarify their involvement in this syndrome.

CHARACTERISATION OF GAA REPEAT-CONTAINING FRIEDREICH ATAXIA YAC TRANSGENIC MICE: RESCUE OF THE FRATAXIN KNOCKOUT. *S. AL-MAHDAWI¹, F. YADOLLAHI¹, A. OBISESAN¹, Z. WEBSTER², H. PUCCIO³, M. KOENIG³, M.A. POOK¹.* 1) MEDICAL GENETICS, IMPERIAL COLLEGE LONDON, HARROW, UK; 2) ES CELL FACILITY, MRC CSC, HAMMERSMITH HOSPITAL, UK; 3) IGBMC, CNRS/INSERM UNIVERSITE LOUIS PASTEUR, ILLKIRCH, FRANCE.

Friedreich ataxia (FRDA) is mainly caused by a homozygous GAA repeat expansion mutation within intron 1 of the FRDA gene, resulting in reduced frataxin expression. To establish an FRDA GAA repeat mouse model, we have generated two lines of human FRDA YAC transgenic mice that contain GAA repeat expansions within the appropriate genomic context: YG8 contains two GAA sequences of 190 and 90 repeats, while YG22 contains a single 190 repeat sequence. Intergenerational instability and age-related somatic instability of the GAA repeat has been detected in both lines, with the most pronounced somatic instability arising from CNS tissues. We now show that both of the human FRDA YAC transgenic lines can successfully rescue the embryonic lethality of homozygous frataxin knockout mice. The levels of expression of frataxin mRNA and protein in different somatic tissues from the transgenic and rescued mice have been determined by RT-PCR and western blot analysis. The expression levels have then been compared with the degree of GAA repeat instability. Further histological, biochemical, metabolic and functional studies are currently underway to determine the effectiveness of these mice as a GAA-repeat based model for FRDA.

Characterization of Bardet-Biedl syndrome 2 (Bbs2) knockout mice indicate a defect in intracellular transport.

M. Fath^{1,2}, *R. Mullins*¹, *D.Y. Nishimura*¹, *C. Searby*^{1,2}, *M. Andrews*^{1,2}, *B. Yang*¹, *E.M. Stone*^{1,2}, *V.C. Sheffield*^{1,2}. 1) College of Medicine, Univ Iowa, Iowa City, IA; 2) Howard Hughes Medical Institute, Iowa City, IA.

Bardet-Biedl syndrome (BBS) is a heterogeneous, pleiotropic human disorder characterized by obesity, retinopathy, polydactyly, renal and cardiac malformations, learning disabilities, hypogenitalism, and an increased incidence of diabetes and hypertension. It has been suggested that the BBS phenotypes are the result of defective cilia formation or function. We show that mice lacking the Bbs2 protein have major components of the human phenotype including obesity. In addition, these mice have phenotypes associated with cilia dysfunction including retinopathy, renal cysts and male infertility. With the exception of male infertility, these phenotypes are not due to a general defect in cilia formation. We demonstrate that BBS2 retinopathy involves apoptotic death of photoreceptors, the primary ciliated cells of the retina. Photoreceptor cell death is associated with mislocalization of rhodopsin indicating a primary defect in transport. Finally, we demonstrate that Bbs2 heterozygous mice become obese suggesting that genes involved in intracellular transport are candidates for non-syndromic human phenotypes such as obesity.

Transgenic mice expressing Y99C-GCAP1-EGFP exhibit a cone dystrophy phenotype. *n. roychowdhury*¹, *k. zhang*¹, *y. sauve*¹, *j. frederick*¹, *w. baehr*^{1,2,3}. 1) Ophthalmology, Moran Eye Center, Salt Lake City, UT; 2) Department of Neurobiology and Anatomy, University of Utah Health Science Center, Salt Lake City, Utah 84112; 3) Department of Biology, University of Utah, Salt Lake City, UT 84112.

GCAP1, a Ca²⁺-binding protein of the calmodulin gene family with four EF hand motifs, is responsible for regulation of guanylate cyclase (GC) in photoreceptors, and production of cyclic GMP (cGMP), the internal transmitter of phototransduction. In the dark at high [Ca²⁺]_{free}, Ca²⁺-bound GCAP1 is inactive, but in light when [Ca²⁺]_{free} is reduced due to closure of cGMP-gated channels, Ca²⁺ dissociates from GCAP1, an event which turns GCAP1 into a GC-activator. A Y99C mutation in EF3 of GCAP1 was linked to autosomal dominant cone dystrophy in a British pedigree. To investigate the consequences of the mutant GCAP1 expression in the living retina, we generated mice expressing a transgene consisting of a 5 kb upstream region, the entire GCAP1 gene including all introns and the polyadenylation site, the Y99C mutation in exon 3, and a EGFP fused to the C-terminal of GCAP1 (Y99C-GCAP1-EGFP). As monitored by EGFP intrinsic fluorescence, the transgene was expressed in both rods and cones in a line that expressed wild-type and mutant GCAP1 at a ratio of (1:1 1:2). At 6 months of age, the rod ERG response in transgenic mice was normal, while the cone response showed reduced cone b-waves, and reduced cone flicker amplitudes, consistent with cone dystrophy. These results show that the phenotype of transgenic mice expressing Y99C-GCAP1-EGFP closely resembles the cone dystrophy observed in human patients.

The molecular basis of a new class of ABCR mutations in patients with Stargardt disease (STGD). W.

Wiszniewski¹, C.M. Zaremba¹, M. Jamrich², J.R. Lupski¹. 1) Department of Human and Molecular Genetics, Baylor College of Medicine, Houston, Texas; 2) Department of Cell Biology, Baylor College of Medicine, Houston, Texas.

ABCR (ABCA4) is a photoreceptor-specific member of the ATP-binding cassette (ABC) family, and mutations of ABCR are associated with many retinal phenotypes including Stargardt disease, Fundus Flavimaculatus, combined cone-rod dystrophy and retinitis pigmentosa. Our purpose is to develop an experimental system for investigating mechanisms regulating intracellular trafficking of ABCR and for testing mutations found in domains involved in cellular localization of ABCR. Our approach is to express a human ABCR transgene in photoreceptors of *Xenopus laevis* tadpoles. DNA fragments containing both wild type and mutated (L541P, R602W and C1490Y) ABCR coding sequence were cloned into the pXOP vector containing the promoter for the *X. laevis* rhodopsin gene, and used for transgenesis. The retinas of 2-4 week old tadpoles were studied for the expression and localization of transgenic ABCR by immunofluorescence methods. We found that expression was restricted to photoreceptor cells and was variable from cell to cell. In some cells very bright staining of the rims of the discs was observed in rod outer segments (ROS). We found that some pathogenic mutations cause mislocalization of ABCR with stacking of misfolded protein in the rod inner segment. We conclude that human ABCR can be expressed from a transgene in *Xenopus* photoreceptors with appropriate localization to the ROS. However, we have identified a new class of ABCR mutations, which lead to improper localization, thus rendering a null effect. Mutations responsible for this effect are found with other mutated alleles in patients with retinal degenerative phenotypes.

Program Nr: 2712 from the 2004 ASHG Annual Meeting

Risk factors of intermediate allele instability for the fragile X CGG repeat. *S. Nolin, G. Houck, A. Glicksman, S. Li, J. Silverman, W.T. Brown.* Human Genetics Dept, New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY.

Fragile X alleles with ~40 to ~60 repeats are both interesting and challenging from a diagnostic and genetic counseling perspective because of the difficulty in predicting instability. Several laboratories have shown that alleles in this repeat range may be stably inherited, expand or contract. We examined 5 risk factors that may influence instability: 1) repeat size, 2) AC polymorphisms flanking the repeat, 3) CGG repeat structure, 4) length of 3' pure repeats, and 5) parental origin of transmission. While no specific AC haplotypes were associated with instability, the larger intermediate alleles were associated with greater instability. The 3' length of CGGs without AGG interruptions was found to be a risk factor for instability; 14% of transmissions with 34-40 pure CGGs and 43% with >40 pure CGGs were unstable. We found a similar proportion of unstable maternal and paternal transmissions among families with intermediate alleles. In the 40-49 repeat sizes, 10% (4/39) unstable maternal transmissions and 13% (3/22) paternal transmissions were observed. In the 50-60 repeat sizes, 19% (10/52) unstable maternal and 18% (2/11) paternal transmissions were observed. The combined mutation rate of repeats from 40-60 was 15% for maternal or paternal transmissions. These observations are markedly different from those of Sullivan et al. (AJHG 70:1532, 2002) who observed a higher mutation rate of among paternally as compared to maternally transmitted alleles. Most strikingly, none of the families with intermediate alleles had transmission patterns resembling the large expansions observed in maternal transmissions of fragile X premutation females.

Bartter Syndrome Type II associated with a Novel Mutation in KCNJ1. A. Jeong¹, M. Merideth¹, M. Freundlich², W.A. Gahl¹, R. Kleta¹. 1) SHBG, MGB, NHGRI, NIH, Bethesda, MD; 2) Department of Pediatrics, University of Miami, Miami, FL.

Bartter syndrome type II is an autosomal recessive renal salt losing nephropathy caused by mutations in KCNJ1. Five alternatively spliced variants code for 3 different isoforms. Transcript variant 2 (also named ROM-K2), derived from exons 1 and 5 of KCNJ1, is expressed in the kidney and codes for a 372 amino acid protein. Mutations in SLC12A1 (Na²ClK cotransporter), CLCNKB (chloride channel), and BSND (chloride channel subunit) lead to Bartter syndromes type I, III, and IV, respectively. Here we report the clinical and molecular findings in a boy with renal salt wasting, neonatal hyperkalemia and subsequent hypokalemia. The patient was born at 28 weeks' gestation with a birth weight of 1402 g and a history of polyhydramnios. His same sex twin was born without maternal polyhydramnios and had an uneventful clinical course. Initially, a diagnosis of twin-twin transfusion syndrome was considered. Postnatally, a dichorionic, diamniotic, non-fused twin placenta was documented. Within 72 hours after birth the affected twin displayed marked hyperkalemia (6-7 mmol/l), hyponatremia (129 mmol/l), azotemia (BUN 44 mg/dl), natriuresis (urine Na 118 mmol/l) and polyuric renal failure (creatinine 2.0 mg/dl). The hyperkalemia gradually changed to hypokalemia (3 mmol/l). At age 6 months all blood chemistries were normal without any supplements or medications. At age 3 years the patient presented with polyuria, polydypsia, growth retardation, hypoosmolar urine, elevated prostaglandins, metabolic alkalosis, hypercalciuria and nephrocalcinosis. Treatment with potassium supplementation and the COX-2 inhibitor, rofecoxib, corrected all laboratory abnormalities and improved the anthropometric delay. Genomic DNA analysis of KCNJ1 disclosed that the patient was compound heterozygous for two missense mutations, a known R311W and a novel L359R mutation. In summary, we present a rare but important cause of neonatal salt losing tubulopathy with initial non-oliguric hyperkalemia, eventually evolving into a polyuria-polydypsia hypokalemic phenotype accompanied by hypercalciuric nephrocalcinosis.

A second locus for glaucoma associated with pigment dispersion maps to chromosome 18q22. *E.A. DelBono¹, D.S. Greenfield², R.K. Parrish², L.M. Olson³, J.L. Haines³, J.L. Wiggs¹.* 1) Dept Ophthalmology, Harvard Medical School/MEEI, Boston, MA; 2) Bascom Palmer Eye Institute, Miami, FL; 3) Center for Human Genetics, Vanderbilt University School of Medicine, Nashville, TN.

Glaucoma associated with pigment dispersion (GPDS) is the most common form of glaucoma affecting the young adult population. This disease is characterized by release of pigment granules from the iris that are distributed throughout the eye (pigment dispersion). Approximately 50% of individuals affected with pigment dispersion develop glaucoma associated with elevated intraocular pressure and degeneration of the optic nerve. In humans, GPDS is inherited as an autosomal dominant trait, while similar syndromes in mice exhibit more complex inheritance patterns. We have previously mapped one locus for this condition to chromosome 7q36, and have also identified pedigrees that do not demonstrate linkage to this region indicating genetic heterogeneity. The largest family not linked to the 7q36 region was used for a second genome-wide scan. Fifty-one family members (13 affected) were genotyped for two hundred thirty eight microsatellite repeat markers spanning the human genome at approximately 10 cM intervals. A maximum two-point lod score of 4.2 was found for marker D18S1127. Haplotype analysis identified a 13 cM (12 Mb) region extending from D18S484 to D18S483. Three smaller families also have consistent segregation of haplotypes using microsatellite markers located in this region. These results provide evidence for a new locus responsible for glaucoma associated with pigment dispersion on chromosome 18q22. Candidate genes located within this region with ocular expression are currently being screened for causative mutations.

BBS8 analysis in a cohort of 119 Bardet-Biedl families: a single multiplex homozygous family with partial triallelism. *H. Dollfus¹, C. Stoetzel², V. Laurier², D. Bonneau³, A. Verloes⁴, L. France; 5) Service de gntique, CHU Dijon, Dijon, France; 6) Laboratoire de diagnostic gntiqueCHRU,Strasbourg, France; 7) France.

Introduction : Bardet-Biedl syndrome (BBS) is a genetically heterogenous condition characterized by retinitis pigmentosa, obesity, polydactyly, renal and genital malformations and learning disabilities. To date 7 genes have been identified and triallelic inheritance demonstrated for some families. In 2003, the identification of BBS8 (TTC8) , a centrosomal and basal body protein, designated BBS as a ciliary dysfunction disorder, moreover, one patient had also situs inversus (Ansley et al, 2003). A French cohort of BBS families is currently being explored for all the BBS genes. We present herein our results for BBS8. **Families and methods:** BBS8, mapped in the 14q32.11 region and spanning 15 exons, was analyzed by DHPLC combined to direct sequencing, for 119 families. Two sporadic cases presented with a BBS phenotype plus situs inversus. **Results:** Only one consanguineous family, with three affected siblings carried a homozygous splice-site mutation at the level of the exon 4 of BBS8. Interestingly, an additional splicing mutation was detected in BBS7 from one affected child but did not cosegregate with the disorder as the two other affected patients did not carry this third allele, excluding for BBS8 and BBS7 the triallelic model in this family. To date no other mutation in BBS genes has been detected for this family. The two BBS patients with situs inversus were not found to carry a BBS8 mutation. **Conclusions:** Mutations in BBS8 are very rare in the French cohort as for a previously published cohort. It could be expected that less than 1% of the BBS families carry BBS8 mutations. The phenotype BBS plus situs inversus is not related to BBS8 mutations for our patients.

Wnt pathway gene expression changes associated with retinal degeneration in the rd1 mouse. *A.S. Hackam¹, D.J. Nolan¹, R. Strom², D. Liu², J. Qian², D. Otteson², T. Gunatilaka², R.H. Farkas², I. Chowers², M. Kageyama³, P. Campochiaro², G. Parmigiani², D.J. Zack².* 1) Bascom Palmer Eye Institute, University of Miami, Miami, FL; 2) Johns Hopkins University School of Medicine, Baltimore, MD; 3) Santen Pharmaceutical, Takayama, Japan.

Mutations in over 100 genes have been implicated in retinal degenerations. To understand the molecular events contributing to photoreceptor death and identify novel neuronal protection factors we have used custom retinal microarrays to analyze the rd1 mouse, a well-characterized model of human retinal degeneration. The custom array contains genes involved in normal retinal function, development, and disease. Gene expression in rd1 retinas was compared with age-matched controls at three time-points: peak of rod photoreceptor degeneration (Day (D) 14), and during early (D35) and late (D50) cone degeneration. The microarrays showed limited overlap of the genes with increased expression, suggesting the involvement of temporally distinct molecular pathways during rod and cone death. Increased expression of genes involved in cell proliferation pathways and oxidative stress was observed at each time-point. Additionally, the microarrays, confirmed by quantitative PCR, demonstrated marked differential expression of mediators of the Wnt signaling pathway, a multigene pathway with well-described roles in embryonic development and oncogenesis. Although Wnt signaling is anti-apoptotic in certain situations, its function during retinal degeneration has not been explored. The Wnt-related gene, Dickkopf 3 (Dkk3), which was upregulated during rod and cone death, was investigated further. We localized Dkk3 transcripts to the inner nuclear layer of the retina, potentially to Muller glia, the cells involved in photoreceptor protection in other retina damage situations. To determine the activity of Dkk3, HEK293 cell lines stably expressing Dkk3 were created. Cell death assays demonstrated that Dkk3 had a significant pro-survival effect on cells exposed to oxidative stress. These results suggest a hypothesis in which Dkk3 and Wnt signaling are activated in the retina, potentially as part of the glial response to photoreceptor injury.

LEBER CONGENITAL AMAUROSIS: COMPREHENSIVE SURVEY OF THE GENETIC HETEROGENEITY, REFINEMENT OF THE CLINICAL DEFINITION AND PHENOTYPE-GENOTYPE CORRELATIONS AS A STRATEGY FOR MOLECULAR DIAGNOSIS. *S. Hanein, I. Perrault, S. Gerber, A. Munnich, JM. Rozet, J. Kaplan.* INSERM U393, Hopital des Enfants Malades, Paris, France.

Leber congenital amaurosis (LCA) is the earliest and most severe form of all inherited retinal dystrophies, responsible for congenital blindness. Disease mutations have been hitherto reported in seven genes. These genes are all expressed preferentially in the photoreceptor cells or the retinal pigment epithelium but they are involved in strikingly different physiologic pathways resulting in an unforeseeable physiopathologic variety. This wide genetic and physiologic heterogeneity that could largely increase in the coming years, hinders the molecular diagnosis in LCA patients. The aim of the present work was to establish phenotype-genotype correlations as a pre-requisite to genotyping of patients affected with LCA. A comprehensive mutational analysis of the all known genes was performed using DHPLC and direct sequencing in 179 unrelated LCA patients, including 52 familial and 127 sporadic (27/127 consanguineous) cases. To establish phenotype-genotype correlations, the clinical history of all patients with mutations was carefully revisited in search for phenotype variations. Mutations were identified in 47.5% patients. GUCY2D appeared to account for most LCA cases of our series (21.2%), followed by CRB1 (10%), RPE65 (6.1%), RPGRIP1 (4.5%), AIPL1 (3.4%), TULP1 (1.7%) and CRX (0.6%). Sound genotype-phenotype correlations were found that allowed to divide patients into two main groups. The first one includes patients whose symptoms fit the traditional definition of LCA i.e. congenital or very early cone-rod dystrophy, while the second group gathers patients affected with severe yet progressive rod-cone dystrophy. Besides objective ophthalmologic data allowed to subdivide each group into two subtypes. Based on these findings, we have drawn decisional flowcharts directing the molecular analysis of LCA genes in a given case. This work which lightens henceforward the heavy task of large scale genotyping in LCA and makes possible to establish genetically defined subgroups of patients ready for therapy.

Human ARR-CHIP: A high throughput sequencing array for genotyping patients with autosomal recessive retinitis pigmentosa (ARRP). *M.N. Mandal¹, J.R. Heckenlively¹, L. Chen¹, T. Burch¹, P.A. Sieving², R. Ayyagari¹.* 1) Ophthalmology and Visual Sciences, University of Michigan, Ann Arbor, MI; 2) NEI/NIDCD, National Institutes of Health, Bethesda, MD.

Purpose: Retinitis Pigmentosa (RP) is a group of inherited diseases that cause degeneration of the retina leading to blindness. RP is transmitted in autosomal dominant, autosomal recessive and X-linked manners and these are genetically heterogeneous disorders. For recessive RP alone there are more than 14 known genes comprising more than 30 kb sequence. Screening all these candidate genes for mutations is expensive and time consuming. We have designed and developed sequencing arrays which can successfully screen exons and flanking intronic sequences of most of eleven recessive RP genes in a cost and time efficient manner. **Results:** The ARR-CHIP contains oligonucleotide sequencing probes that are tiled using standard Affymetrix protocol. Both strands of the coding sequence of ARR-CHIP genes are arrayed on the ARR-CHIP along with appropriate control probes. We use genomic DNA to amplify the exonic regions and amplicons are pooled, fragmented, hybridized and scanned. We have sequenced 25 samples (>665 kb sequence) using these ARR-CHIPs. This analysis was observed to assign correct base call at 97.27% of nucleotide positions. Replicate experiments demonstrated > 99% reproducibility. Approximately 20 sequence changes were detected (15-24) in each sample (30 kb) and 90% of these sequence changes matched with known SNPs, indirectly validating the performance of these chips. ABI sequencing of these samples validated the sequence changes detected by the chip in almost every cases with a few exception of false positives. These false positive calls came from regions of higher G-C or due to low hybridization signal. We found a few novel mutations in some families and alterations in more than one genes in few samples. **Conclusions:** ARR-CHIP is a high-throughput sequencing tool for reliable identification of mutations in patients with ARR-CHIP in a single assay. These chips also provide an opportunity to determine complex phenotypes, gene interactions and modifiers involving more than one gene arrayed on the chips.

Two different retinal dystrophies accounted for by different CRB1 mutations in a single nuclear family. I.

Perrault, S. Hanein, S. Gerber, A. Munnich, JM. Rozet, J. Kaplan. Dept Genetics, INSERM U393, Paris, Cedex, France.

The aim of this study was to identify the molecular bases of the occurrence of late onset retinitis pigmentosa (RP) and Leber congenital amaurosis (LCA) in a single small nuclear family. Leber congenital amaurosis was unambiguously diagnosed in the third child of a non consanguineous family of French descent. In the first months of life he was found to carry typical signs of the disease ie absence of ocular pursuit, searching nystagmus, oculo-digital signs of Franceschetti and non recordable ERG. At birth, his parents were considered healthy. Three years later, an ophthalmologic examination of the father, requested by a company doctor, detected a moderate visual loss. Complete explorations of this 38 year old man revealed typical retinitis pigmentosa. The screening of the seven already known LCA genes was first undertaken in the LCA patient using DHPLC and direct sequencing and then extended to the whole family. The LCA Patient was found to be compound heterozygote for two CRB1 mutations (p.L1107P/p.S1025I). Segregation analysis showed that each of the two mutations was inherited from one parent. The discovery of RP in the father prompted us to screen the whole CRB1 sequence. Interestingly, two other non conservative amino-acid changes were identified in the father affected with RP(V1325F, A1328V). Subsequently, the segregation analysis showed that the father carried two mutant CRB1 alleles: L1107P, inherited from his own healthy mother and transmitted to his son affected with LCA, and a complex mutant allele [V1235F and A1328V] inherited from his own healthy father. This observation emphasises that CRB1 mutations can be responsible for late-onset RP or LCA depending on the association of disease alleles in the patient. Considering that the patients in the reported family shared 50% of their genetic background, one can reasonably speculate that genotype-phenotype correlations may exist for the CRB1 gene.

Novel disease causing variations in PITX2 and CYP1B1 in secondary congenital glaucoma patients with anterior segment dysgenesis (ASD). *B. Rautenstrauss*¹, *G. Chavarria*¹, *C. Mardin*², *A. Reis*¹. 1) Institute of Human Genetics, Friedrich-Alexander-University Erlangen-Nuremberg, Germany; 2) Department of Ophthalmology, Friedrich-Alexander-University Erlangen-Nuremberg, Germany.

Glaucomas are a clinically and genetically heterogeneous group of optic neuropathies. The disease affects over 40 million people worldwide and is the second most prevalent cause of bilateral blindness in the Western world. In contrast to primary glaucomas the secondary congenital glaucomas are associated with a variety of anomalies involving different tissues of the eye summarized as anterior segment dysgenesis (ASD). Distinct subtypes of ASD include aniridia, Axenfelds anomaly, Riegers anomaly, iridogoniodysgenesis, Peters anomaly and posterior embryotoxon. Mutations in the cytochrome P450 1B1 (CYP1B1) gene are frequently found in primary congenital glaucoma (PCG) patients but have also been reported for Peters anomaly. Mutations in the transcription factors FOXC1, PITX2, and PAX6 cause different kinds of ASD. We analysed 11 Riegers anomaly patients, 11 Peters anomaly patients and 48 controls for mutations in the FOXC1, PAX6, PITX2 and CYP1B1 genes. Six CYP1B1 SNPs associated with PCG were observed with similar frequencies in ASD patients and controls. For PAX6 and FOXC1 we found intronic and exonic benign variations. For PITX2 one Riegers anomaly patient was heterozygous for a novel Ala187Thr aminoacid exchange. This novel variation is located in an evolutionary highly conserved position of PITX2. Furthermore two sporadic Riegers anomaly patients with compound heterozygous mutations in the CYP1B1 gene were identified. One patient presented the mutations Trp57Stop and Leu343del. The Trp57Stop truncates the protein by 486 aminoacids. The newly described Leucin deletion eliminates one out of three leucines, located in the highly conserved I-helix region of the protein. The second patient carries also a Trp57Stop mutation and additionally the c.1210dup10TCATGCCACC small insertion frequently observed in PCG. This variation results in a frame shift. We present a novel mutation in PITX2 and report for the first time CYP1B1 mutations as causes of the complex symptoms of Riegers anomaly.

Gene expression analysis in patients with defects in RNA splicing factors causing autosomal dominant retinitis pigmentosa. *C. Rivolta*¹, *R.V. Jensen*^{2,3}, *E.L. Berson*¹, *T.P. Dryja*¹. 1) Department of Ophthalmology, Harvard Medical School, Mass. Eye and Ear Infirmary, Boston, MA; 2) Department of Neurology, Harvard Medical School, Brigham and Women's Hospital, Boston, MA; 3) Department of Physics, Wesleyan University, Middletown, CT.

Dominant mutations in the genes RP11 (PRPF31), RP13 (PRPC8), and RP18 (HPRP3), all encoding RNA splicing factors, cause retinitis pigmentosa (RP), a form of retinal degeneration leading to blindness. RP11 mutations are incompletely penetrant. Through an analysis of patients with mutations in these genes, we investigated the molecular link between an ubiquitous biological process (RNA splicing) and a tissue-specific phenotype (RP).

We harvested RNA from cultured lymphoblast cell lines from individuals with mutations in RP11 (N=10, 3 unaffected), RP13 (4), RP18 (3), and controls (7). We used real-time PCR, qualitative RT-PCR, microarray hybridization (Affymetrix and Codelink), and in silico tests to assess variations in gene expression and differences in gene splicing.

Expression of spliced genes, normalized to single-exon histone mRNA transcripts, indicated no generalized impairment of the RNA splicing in all patients vs. all controls (difference between the medians <0.1%). Unsupervised cluster analyses showed no major branching. However, we did find that the expression of the wt RP11 allele was higher in heterozygous carriers of mutations than individual wt alleles in controls (~80% higher in 3 unaffected individuals with 2 different mutations, versus only ~40% higher in 7 affected individuals with 6 different mutations).

These results suggest that death of photoreceptors does not occur because of an indiscriminate reduction of global RNA splicing. In addition, the analysis of RP11 transcripts indicates that penetrance in patients with RP11 mutations is associated with variation in the expression level of the wild-type RP11 allele itself. This phenomenon likely compensates the currently obscure functional deficiency caused by the mutant allele.

Cosegregation analysis of mutant ABCA4 alleles in families with both Stargardt disease (STGD) and age-related macular degeneration (AMD). JM. Rozet¹, D. Ducroq¹, S. Gerber¹, JL. Dufier², A. Munnich¹, J. Kaplan¹. 1) INSERM U393, Hopital des Enfants Malades, Paris, CDX 15, France; 2) Service de Genetique, Hopital des Enfants Malades, Paris, France.

The study presented aimed to evaluate whether AMD-affected relatives of Stargardt patients are more likely to be carriers of mutant STGD alleles than predicted based only on their position in the pedigree. Sixteen unrelated families segregating both Stargardt disease and AMD were considered. In one STGD patient of each family, the ABCA4 gene was screened for the most frequent mutations in France. A segregation analysis was subsequently performed for each mutant allele in AMD-affected relatives. The observed proportion of AMD-affected relatives ABCA4 mutation carriers was compared to the expected proportion based on chance alone. So far, at least one of the most frequent ABCA4 mutations in France was found in 8/16 families. Of the ten AMD-affected relatives belonging to these eight families, 9/10 were found to be carriers of the disease allele, therefore $P_{\text{observed}} = 0.90$ while based on the genealogy only, the $P_{\text{theoretical}}$ was equal to 0.431. These proportions were compared using the Chi square test. The difference between P_{observed} and $P_{\text{theoretical}}$ is statistically significant ($\chi^2 = 9.02$, $p < 0.01$). The first results of this study indicate that ABCA4 mutation carriers are predisposed to develop AMD more frequently than the general population. The whole ABCA4 coding sequence screening is ongoing in all families using both DHPLC and direct sequencing.

A novel Filamin A D203Y point mutation in a female patient with Otopalatodigital type 1 syndrome and extremely skewed X chromosome inactivation. *A. Bravo¹, J.C. Zenteno-Ruiz¹, S. Kofman-Alfaro¹, E.N. Pompa-Mera², C. Gonzalez-Bonilla².* 1) Servicio de Genética, Hospital General de México, Facultad de Medicina, UNAM; 2) UIM en Inmunología e Infectología, CMN La Raza, IMSS.

Otopalatodigital syndrome type I (OPD I) is an X-linked semidominant disease, characterized by mild mental retardation, hearing loss, cleft palate, facial anomalies and a generalized skeletal dysplasia. Other three X-linked entities displaying features that overlap clinically with OPDI have been described and named OPD II, Melnick-Needles Syndrome and Frontometaphyseal Dysplasia. Based on this clinical overlap, several authors have proposed that the four entities are allelic disorders. The molecular basis of these four entities have shown mutations in the gene encoding the cytoskeletal protein filamin A (FLNA). Herein, we present the clinical and molecular data of a sporadic female patient clinically diagnosed with an OPD I syndrome. She consulted at 26 years old and clinical examination revealed short stature, facial features included prominent supraorbital ridges, hypertelorism, downslanting palpebral fissures, depressed nasal base, median cleft soft palate and bilateral conductive hearing loss. Bilateral elbow deformity, brachydactyly with broad thumbs, and short dysplastic nails were observed in upper extremities. In lower limbs she presented bilateral femoral bowing, short and broad great toes, gap between the second and third and between the third and fourth toes, as well as nail dystrophy. X rays demonstrated thickness of the frontal bone, bowing of long tubular bones, and short and broad distal phalanges in thumbs and great toes. A GTG-banded chromosome analysis from blood lymphocytes revealed a normal 46,XX karyotype. DNA analysis demonstrated that she carried a novel FLNA heterozygous point mutation (D203Y) that affects the actin binding domain of the protein. X-chromosome inactivation analyses demonstrated an extremely skewed pattern of inactivation. Our findings confirm an ample molecular spectrum of human malformative syndromes caused by FLNA mutations and contribute to delineate an incipient phenotype-genotype correlation in this group of X-linked disorders.

Mutation analysis in a cohort of 78 cases of Oral-facial-digital syndrome: an international collaborative effort. *B. Franco, V. Novelli, G. Giorgio, A. Barra, The international OFD collaborative research group. TIGEM, Naples, Italy.*

Oral-facial-digital syndromes (OFDs) are a heterogeneous group of developmental disorders of which at least nine different forms have been described to date. The different forms are very similar from a clinical point of view and it is difficult to ascertain the exact subtype. The only well-defined form is OFD type I (OFDI), which can be recognized for the distinctive X-linked dominant male-lethal pattern of inheritance and for the presence of a polycystic kidney. The identification of the gene responsible for OFDI has provided an important tool for genetic counseling and a molecular test is now available to patients and clinicians for OFDI diagnosis and prenatal testing. To determine the extent of the involvement of the OFD1 gene in OFDs, and to better define both the clinical spectrum of Oral-facial-digital type I syndrome and the actual number of different OFDs, we collected through an international collaborative effort a cohort of 78 patients which includes typical OFD1 and cases with more general signs of oral-facial-digital syndromes. Mutation analysis for the OFD1 gene was performed in this collection on the canonical 23 coding exons and on the alternative spliced exons by DHPLC followed by direct sequencing. The analysis has been so far completed for 65 out of 78 patients. A total of 50 mutations have been identified, these include 7 missense, 9 nonsense, 30 frameshifts and 4 splicing mutations. Mutations occur throughout the length of the transcript up to exon 16, although the majority (62%) were located in exons 3(20%), exon 8 (18%), exon 9 (10%), exon 16 (8%), exon 13 (6%). So far no clear genotype/phenotype correlation could be established. To be noted that according to our preliminary results the incidence of polycystic kidney is underestimated in this pathology. In fact, 17 out of the 49 patients in which a mutation in the OFD1 gene has been identified and for which clinical information are available have cystic kidneys, thus indicating an incidence of polycystic kidney in this condition of at least 34%.

***RPGR*, a gene mutated in patients with a complex phenotype associating X-linked primary ciliary dyskinesia and retinitis pigmentosa.** A. Moore¹, E. Escudier², G. Roger³, S. Marlin³, A. Tamalet³, M. Geremek⁴, A. Coste², M. Witt⁴, B. Duriez¹, S. Amselem¹. 1) INSERM U468, Creteil, France; 2) INSERM U492, Creteil, France; 3) Hopital Trousseau, Paris, France; 4) Institute of Human Genetics, Poznań, Poland.

Primary Ciliary Dyskinesia (PCD) is a rare disease classically transmitted as an autosomal recessive trait and characterized by recurrent airway infections due to abnormal ciliary structure and function, usually involving dynein arms. To date, only two autosomal genes, *DNAI1* and *DNAH5* encoding axonemal dynein chains have been shown to cause PCD with a total lack of outer dynein arms. We studied one non-consanguineous family composed of four children, with two boys with PCD. Patients cilia displayed an abnormal motion related to partial ciliary defects. Electroretinograms revealed that the two boys and their mother were suffering from retinitis pigmentosa (RP). These data are, therefore, compatible with an X-linked recessive transmission of PCD and RP diseases, in keeping with recent data (Krawczynski and Witt, *Pediatr. Pulmonol.* 2004;38(1):88-9). As photoreceptor and respiratory cilia share common structures, we postulated that some genes responsible for RP could also be involved in PCD. We found a perfect segregation of the disease phenotype with RP3 locus (Xp21.1). The analysis of the *RPGR* gene located at this locus showed a deletion involving the last 48bp of exon 6 and the adjacent splice site in the two boys and their mother. This deletion leads to activation of a cryptic donor splice site located within exon 6, predicting a severely truncated protein. Overall, these data provide the first clear-cut demonstration of an X-linked transmission of PCD. This unusual mode of inheritance of PCD is described in patients with particular features (i.e. partial dynein arm defects and association with RP), pointing out the importance of *RPGR* in the proper development of both axonemal structures and connecting cilia of photoreceptors. Ocular signs characteristic of RP should, therefore, be looked for in patients with PCD and vice versa.

Towards dissection of the molecular basis of Microphthalmia with linear skin lesion (MLS) syndrome. *M. Morleo*¹, *T. Pramparo*², *A. David*³, *A. Raas-Rothschild*⁴, *M. Vekemans*⁵, *G. Zaidman*⁶, *T. Ogata*⁷, *O. Zuffardi*², *A. Ballabio*¹, *B. Franco*¹. 1) TIGEM, Naples, Italy; 2) Biologia Generale e Genetica Medica, Pavia, Italy; 3) Service de Genetique medicale, Nantes, France; 4) Department of Human Genetics Hadassah University, Jerusalem, Israel; 5) Hopital Trousseau, Paris, France; 6) Department of Ophthalmology, New York Medical College and Westchester Medical Center, Valhalla, NY, USA; 7) Department of Pediatrics, Keio University School of Medicine, Tokyo, Japan.

Microphthalmia with linear skin defects (MLS) is an X-linked dominant male lethal neurodevelopmental disorder characterized by microphthalmia and linear erythematous skin lesions on the face and neck. Additional findings include sclerocornea, corneal opacities, brain abnormalities and mental retardation. This condition described in the early 90 has been associated with monosomy of the Xp22.3 region. The minimal critical region defined by deletion mapping, is estimated to span 600kb and is entirely sequenced. We have now collected and characterized by FISH analysis with available genomic clones eight newly identified MLS patients bearing cytogenetic abnormalities of the Xp22 region. Characterization of these breakpoints confirmed the critical region previously defined. Moreover we collected four patients displaying signs of MLS with a normal karyotype. FISH analysis with clones spanning the minimal critical interval (BAC/PAC/cosmids) excluded monosomy of the Xp22 region. Mutation analysis in these patients is currently ongoing to evaluate the possible involvement of genes previously isolated from the critical region (MID1, HCCS and ARHGAP6) as well as of candidate genes identified by bioinformatics means. To investigate the possibility of altered expression levels of genes localized within the MLS minimal critical region or in the surrounding area we are also performing a quantitative analysis of gene expression levels by Real-Time RT-PCR on total RNAs from MLS patients with normal karyotype. Genes to be analysed include MID1, HCCS, ARHGAP6, MSL3L1, PRPS2, TLR7, TLR8, EGFL6, AK097032, RAB9A.

Male patients with Rett syndrome-like phenotype do not present mutations in the *MECP2*, *NLGN3* and *NLGN4* genes. M. Santos^{1,2}, T. Temudo^{2,3}, C. Barbot⁴, A. Medeira⁵, H. Cabral⁶, P. Cabral⁷, I. Carrilho⁴, I. Gaspar⁷, N. Lobo-Antunes⁵, A. Moreira⁸, J. Sequeiros^{2,9}, P. Maciel^{1,2}. 1) ICVS/School Health Sciences, Univ Minho, Braga, Portugal; 2) ICBAS, Univ Porto; 3) H S António, Porto; 4) H M Pia, Porto; 5) H Sta Maria, Lisboa; 6) C H Funchal, Funchal; 7) H Egas Moniz, Lisboa; 8) H D Estefânia, Lisboa; 9) UnIGENE/IBMC, Univ Porto.

Numerous genes in the X chromosome have been reported as having a role in autistic spectrum disorders, which can be wide and include disorders such as autism with or without mental retardation, Asperger syndrome, Rett syndrome (RS), X-linked mental retardation among others. Among these are two neuroligin genes, *NLGN3* and *NLGN4* whose protein products are present in the postsynaptic compartment, interact with neuroligins and are thought to be essential in the formation of specific synapses. Mutations have also been identified in the *MECP2* gene, in patients with classical RS and Rett-like phenotypes. The MeCP2 protein binds selectively to methylated DNA and interacts with Sin3a and HDAC to repress transcription of genes, yet to be identified. We studied a group of 12 male patients (ages 6 to 19 years) whose biological samples were received in our laboratory to be tested for mutations in the *MECP2* gene. Clinically, these patients presented a RS-like phenotype with variable symptoms that included perturbations of the autistic spectrum, microcephaly, mental retardation, manual stereotypies, and neonatal epilepsy (West syndrome). We analysed this group of male patients for the complete coding region of the *MECP2* gene and for the recently reported mutations in the *NLGN3* (R451C) and *NLGN4* (1186insT and 1253delAG) genes. We did not find any pathogenic mutation in *MECP2*, *NLGN3* or *NLGN4* genes. A silent polymorphism (T299T), already described, was found in the *MECP2* gene of one patient. Another patient presented a silent mutation in the *NLGN4* gene (R417R) reported here for the first time which we are presently testing in a Portuguese control population. The genetic basis of the clinical diagnosis of these male patients was therefore not possible to identify and these results suggests that additional genes may be involved in this kind of disorders.

Genotype-phenotype correlations in Portuguese patients with Rett syndrome. T. Temudo^{1,2}, M. Santos^{2,3}, K. Dias⁴, C. Barbot⁵, P. Cabral⁶, A. Moreira⁴, I. Carrilho⁵, N. Lobo-Antunes⁷, G. Oliveira⁸, J. Sequeiros^{9,2}, P. Maciel^{2,3}. 1) Neuropediatrics, HGSA, Porto, Portugal; 2) ICBAS, Univ Porto; 3) ICVS/Health Sciences School, Univ Minho; 4) H D Estefnia, Lisboa; 5) H M Pia, Porto; 6) H Egas Moniz, Lisboa; 7) H Sta Maria, Lisboa; 8) C H Coimbra, Coimbra; 9) UnIGENe/IBMC, Univ Porto.

Rett syndrome (RS) is a neurodevelopmental disorder caused by mutations in the X-linked gene *MECP2*, which is characterized by an initially normal development of the child, followed by loss of acquisitions and growth impairment, which evolve into a clinical presentation including mental retardation, autistic behaviours and a progressive movement disorder. We have initiated the study of the genetic epidemiology of this disorder in Portugal and have analysed 61 girls, all of which were observed by the same neuropediatrician, and recorded on video. This series included 31 girls with the clinical diagnosis of classic Rett syndrome, and the remaining with variant forms of the disease. We have sequenced the complete coding region of the *MECP2* gene and identified *de novo* mutations in 37 (61%) of the patients; 22 (60%) were truncating, and 15 (40%) were missense mutations. We have tried to correlate the clinical severity of the disease with the type of mutation identified, using the Pineda score, however no association was detectable between the total score and mutation type, even when patients with the same time of disease evolution were considered. We could, however, detect an association between the type of mutation and some clinical hallmarks of RS, such as the presence of microcephaly (significantly more frequent among carriers of truncating mutations, Fisher exact test 0.0043) and the ability to walk (significantly more frequent among carriers of missense mutations, Fisher exact test 0.049).

Congenital Insensitivity to Pain with Anhidrosis (CIPA): A novel mutation among Marocon Jews. *T.C. Falik-Zaccai*^{1, 2}, *M. Khayat*¹, *M. Veiller*¹, *N. Kfir*¹, *M. Deinzer*³, *C. Aslanidis*³, *G. Schmitz*³. 1) Medical Library, Western Galilee Hosp, Nahariya, Israel; 2) Bruce Rappaport Faculty of Medicine, Technion-Israel Institute of Technology, Haifa, Israel; 3) Institut Fur Humangenetik, Universitätsklinikum der RWTH Aachen, Germany;.

Congenital Insensitivity to Pain with Anhidrosis (CIPA) is a rare autosomal recessive genetic disorder characterized by congenital insensitivity to pain, temperature sensation defect, mental retardation, self-mutilating behavior and inability to sweat. The anomalous pain and temperature sensation and anhidrosis in CIPA are due to the absence of afferent neurons activated by tissue-damaging stimuli and a loss of innervation of eccrine sweat glands, respectively. The NTRK1 gene located on chromosome 1 encodes a receptor tyrosine kinase which is autophosphorylated in response to nerve growth factor, thus, activating various pathways of intracellular signal transduction. Fourty mutations have been reported so far in the NTRK1 gene as causing CIPA. We report a novel two-nucleotide deletion mutation within the coding region of NTRK1 that result in frame shift very early in the protein and generates a premature stop codon. The mutation was detected at a homozygous state in two siblings affected with CIPA who are of Marocon Jewish origin. The non-consanguineous parents and a healthy brother were found to carry the same mutation. The CIPA causative mutation was not detected in 120 control DNA samples from Marocon Jews. The family requested prenatal diagnosis as soon as the causative mutation was identified. The fetus was found to be a heterozygous carrier of the causative mutation. This is the first report of a causative mutation for CIPA within unrelated Marocon Jews and the second time PND is documented. The prevalence of this mutation among this homogeneous ethnic group seems to be low. These results will enable to detect couples at risk within the extended family, and to provide accurate genetic counseling and prenatal diagnosis for interested couples. Identification of new mutations and the study of their pathologic impact in CIPA can serve as a useful model to determine mechanisms of development and maintenance of NGF-dependent neurons in autonomic, sensory and central nervous system in humans.

Spectrum of mutations in the CLCN1 gene in Finnish Myotonia congenita patients. *K. Kantojarvi, M-L. Vaisanen, J. Ignatius.* Dept of Clinical Genetics, Oulu University Hospital, Oulu, Finland.

Myotonia congenita (MC) is an inherited muscle disease resulting from hyperexcitability of the skeletal muscle membrane. Both autosomal dominant (Thomsen disease) and more frequent recessive (Becker disease) are caused by mutations in the skeletal muscle chloride channel gene (CLCN1). CLCN1 is mapped to chromosome 7q35 and consists of 23 exons. So far over 60 mutations has been identified, which distribute over the entire gene. No mutational hotspot regions or specific mutations with a dominant or recessive inheritance have been detected.

In northern Finnish and northern Scandinavian MC-families three common CLCN1 mutations are found (F413C, A531V, R894X). During the years 1999-2004 we have tested these three mutations in 92 patients suspected of having MC; 24 originating from North Finland and 68 sent from other parts of the country. Homozygosity or compound heterozygosity has been detected in 8/24 (33%) northern Finnish cases and in 17/68 (25%) cases coming elsewhere. In addition, several patients with mutation in only one allele has been found, which although confirming the diagnosis does not give information of the inheritance pattern, especially if family data is lacking. Compound heterozygosity of the other unknown mutation contributing to the phenotype could be the likely explanation in these cases.

In order to find out the possible other mutations, we have started heteroduplex scanning by conformation-sensitive gel electrophoresis (CSGE) of all CLCN1 exons with flanking sequences followed by direct sequencing. The material consists of 22 clinically symptomatic MC patients (3 from North Finland and 19 from other parts of Finland) with one of the common mutations found in routine mutation analysis. In addition, 44 cases with no mutations found previously are included. On the cases analysed, variant fragments has been found by CSGE in several exons, which are currently being sequenced. Several new as well as known sequence variants and/or mutations (missense, splice site, frame shift) has been found and their further characterization is in progress.

Mutation detection of CFTR gene using ARMS and SSCP methods in Iran. *M. Mojarrad¹, N. Yazdanpanahi¹, P. Derakhshandeh-Peykar^{1,2}, M. Rafiee³, R. Mirfakhraie¹, M. Jalali¹, M. Rahmani¹, D. Farhud¹, M. Hashemzadeh¹, F. Mirzajani¹, F. Mirzajani⁴.* 1) school of Public Health, Tehran, Iran; 2) Genetic Clinic, Valie-Asr Sq. 16, Keshavarz blvd., Tehran, Iran; 3) Tabriz Pediatrics Hospital, Tabriz-Iran, Tehran, Iran; 4) National Genetic Engineering and Biotechnology Center, Tehran, Iran.

Cystic fibrosis (CF) is the most common severe lethal autosomal recessive disorder in whites that is caused by mutations occurring in the CFTR gene on chromosome 7q31. The carrier frequency among Caucasians is approximately 1 in 25, with an incidence of approximately 1 in 2500 live birth. CF patients have two defective alleles and may either be heterozygous for different mutations, or homozygous for one of the mutations. Since the identification of the gene responsible for CF, more than 1300 mutations was described in CFTR gene of patients affected by cystic fibrosis, but the prevalence of the CF shows a geographical and ethnical variations in the world. The Delta F508 mutation in CFTR gene accounts for over 70 % all mutant CFTR alleles in the Europeans to 20 % in the Asians. First the DNA samples of 92 CF chromosomes have been tested for eight common mutations: F508, W1282X, 621+1G>T, 1717-1G>A, G542X, G551D, N1303K and R560T by using the ARMS method. Results from this study revealed the following frequencies: F508: 19.5%, G542X: 10%, W1282X: 6.5%, N1303K: 1.1%, 621+1G>T: 0%, 1717-1G>A: 0%, G551D: 0%, R560T 0%. Then by using SSCP method for samples which we didnt find any mutation by ARMS system, we scanned exons 4, 7, 10, 11 and intron 11 of CFTR gene. By using sequencing we find two mutations in exon 4 (R117H: one chromosome, and A120T: one chromosome), one mutation in exon 7 (R347H: one chromosome) and a novel mutation in intron 11 (1811+34 A>G: one chromosome).

Friedreich ataxia mouse models demonstrate an absence of oxidative stress concomitant to a reduction of SOD2 expression. *H. Puccio, H. Seznec, D. Simon, L. Reutenauer, M. Koenig.* Molecular Pathology, IGBMC, Illkirch, Strasbourg, France.

Friedreich ataxia (FRDA), a progressive neurodegenerative disorder associated with cardiomyopathy is caused by severely reduced frataxin, a mitochondrial protein involved in Fe-S cluster assembly. Iron-mediated oxidative stress and impairment of the stress defense proteins superoxide dismutases (SODs) have been suggested to be implicated in the pathology of FRDA. This has led to the development of pharmacological therapy using antioxidants or iron chelators. Indeed, there are evidences that idebenone, a coenzyme Q10 analog, can improve cardiac function in FRDA patients. We have generated conditional mouse models that reproduce important progressive pathological and biochemical features (cardiac and neuronal) of the human disease. We reported that idebenone has a significant effect on the cardiac function and the life-span of the murine model, with a significant reduction of oxidative stress indexes concomitant to mitochondrial iron accumulation suggesting that the iron is non-toxic. Oxidative stress markers in neuronal tissues are not change despite the presence of a pathological process. Furthermore, tetrakis-(4-benzoic acid) porphyrin (MnTBAP), a synthetic SOD mimetic, had no significant effect on the survival of the cardiac model at a dose sufficient to rescue a SOD2 null mouse. We found that there was a significant reduction in SOD2 expression and activity in tissues deleted for frataxin, suggesting that the reduced SOD2 expression by a yet unknown mechanism is probably responsible for the lack of SOD2 induction in FRDA. Taken together, these results clearly demonstrate that iron-mediated oxidative stress is not a key pathological component of the disease, and that efforts in finding new therapeutics molecules for FRDA should therefore not be limited to antioxidant and iron chelators. Furthermore, our results suggests that frataxin function is central to the cell and that it is not only necessary for the proper maintenance of the respiratory chain through Fe-S cluster assembly, but also necessary for the proper expression of the stress defense protein SOD2.

Neonatal screening of inherited non-syndromic congenital deafness: results of a pilot program in South Brazil. E.

Lewis¹, F. Amorim¹, J.F. De Mari¹, C. Castilhos¹, T. Felix², R. Giugliani^{1, 2}. 1) CTN Genetica, Porto Alegre, RS, Brazil; 2) Medical Genetics Service, HCPA, Porto Alegre, RS, Brazil.

Congenital deafness is estimated to occur in 1 of each 1,000 births. In about 70 % of the cases, deafness appears as an isolated sign and is called non-syndromic (NSD). When not early identified and treated, NSD leads to language development problems, usually severe. Mutations in several genes have been implicated on the etiology of NSD. However, a single mutation (35delG) on DFNB1, the gene that codifies Connexin 26, seems to be very frequent and could be an important cause of NSD. Our group adapted a method to extract DNA from dried-blood filter paper samples (already collected for newborn screening of metabolic diseases). We used an in-house method (based on methanol extraction) and set up a user-friendly and low-cost molecular-based technique to detect 35delG mutation, suitable for mass screening. A pilot program was carried out on DBFP samples obtained from 100 newborns. The 35delG mutation was found in 4/200 alleles (2%), indicating that the frequency of NSD due to 35delG mutation on the DFNB1 gene could be as high as 1/10,000, even higher than PKU on our region, and should be considered for introduction on neonatal screening programs for congenital diseases.

A new genetic screening test for hereditary hearing loss. *N. Navot, D. Cohen, M. Mandelman, A. Yakir, A. Eran.*
Pronto Diagnostics Ltd, Rehovot, Israel.

Profound hearing loss is the most common congenital disability in the United States; it occurs in three out of every 1000 births. 12,000 infants are born with permanent hearing loss annually, with more than 60% attributed to genetic factors. Recognizing the importance of early detection of childhood hearing loss, 38 states have passed legislative mandates requiring newborn hearing screening; most include the American College of Medical Genetics recommendation that children with confirmed hearing loss be referred for genetic testing and counseling. Nonsyndromic, recessively inherited deafness is the predominant form of inherited deafness. It is caused by mutations in the Connexin 26 (GJB2) and Connexin 30 (GJB6) genes, located at the DFNB1 locus. Recent advances in molecular genetics resulted in the addition of DFNB1 genotyping to classical Ashkenazi Jewish prenatal diagnosis panels. We have developed a large-scale screening assay for the simultaneous detection of DFNB1's three most common mutations, based on the Pronto technology. Pronto Connexin is a multiplex mutation detection method based on a single nucleotide primer extension reaction, followed by ELISA in a kit format. Each sample is tested in four wells of a 96-well microtiter plate for the 35delG and 167delT mutations in the GJB2 gene and the (GJB6-D13S1830) mutation in the GJB6 gene. This efficient screening format presents the complete genotype of the common 35delG mutation and a carrier status of the latter less frequent mutations, whose complete genotype can be detected using the Pronto Connexin Verification Strip. Each detection well contains a 5' labeled primer complementary to the upstream sequence of the mutation site, and a single biotinylated nucleotide. The primer is extended depending on the tested individual's genotype, thus becomes labeled with biotin. Reaction products are transferred to a streptavidin-coated plate and treated according to a standard ELISA protocol. Results are determined either visually or colorimetrically (O.D. 450 nm). Pronto Connexin was designed to meet the emerging needs for rapid large-scale newborn screening tools. This assay completes a 33-mutation panel yielding a uniform diagnostic tool for Ashkenazi Jewish carrier screening.

Pre-implantation Genetic Diagnosis (PGD) for Genetic Disorders in Saudi Arabia. *A.I. Al-Aqeel^{1, 2}, S. Coskun², K.A. Jaroudi², P.T. Ozand², A. Hellani².* 1) Dept Pediatrics, Riyadh Military Hosp, Riyadh, Saudi Arabia; 2) King Faisal Specialist Hospital & Research Centre.

Saudi Arabian culture is highly consanguineous, with the first cousin marriages accounting for 60-70% of all marriages. Given the difficulties in management of genetic disorders, preventive measures for the suffering families from autosomal recessive disorders by doing pre-implantation genetic diagnosis is undertaken. The first of these disorders is Sanjad-Sakati Syndrome (SSS) OMIM# 24140, which is characterized by congenital hypoparathyroidism, growth and mental retardation with a unique 12bp deletion (nucleotide 156-166) in Tubulin Cofactor E (TBCE) gene. The second is Niemann Pick Disease type B (NPD-B) OMIM# 257200,(acid sphingomyelinase (ASM) deficiency) with more than 70 mutations have been reported in (SMPD1) gene, which presents with severe phenotype in Saudi Arabia. Four unique mutations are found in our Saudi families. A family with (W533R) mutation in the (SPMDI) gene suffering from a severe phenotype underwent PGD. The third disorder is Morquios disease (MPSIV) OMIM # 253000, with severe classic phenotype with N-acetyl galactosamine-6-sulfatase deficiency (MPSIV-A). More than 20 different mutations in (GALNS) gene have been reported in (MPSIV-A). A family with three affected siblings with severe classic (MPSIV-A) with detected W195C mutation in the (GALNS) gene underwent PGD. In all these three families PGD was undertaken using fluorescent PCR(F-PCR) and/or nested PCR with sequencing on a single cell. A singleton pregnancy ensued after transfer of one heterozygous and one normal embryo and prenatal diagnosis by CVS confirmed a normal pregnancy. This is the first report of successful PGD in different genetic disorders in Saudi Arabia.

Karyotyping, immunophenotyping, and apoptosis analyses on human hematopoietic precursor cells derived from umbilical cord blood following long-term ex vivo expansion. *Z. Chen^{1,2,3}, H. Tian¹, S. Huang², F. Gong¹, L. Tian⁴.*

1) Dept. of Cell Biology, Tongji Medical College of Huazhong Univ. of Science and Technology, Wuhan, P.R. China; 2) Center for Stem Cell Research and Application, Union Hospital, Tongji Medical College, Wuhan, P.R.China; 3) Div. of Medical Genetics, Dept. of Pediatrics, Univ.of Utah School of Medicine, Salt Lake City , Utah, USA; 4) Dept. of Surgery, GuangXi Medical Univ., P. R. China.

Umbilical cord blood (UCB) has been considered an attractive alternative to bone marrow or mobilized peripheral blood for hematopoietic precursor cells engraftment. However, the number of hematopoietic stem cells (HSC) in UCB is limited. Ex vivo expansion of UCB-HSC and the stability of their biological and genetic characteristics under incubation are essential for successful UCB-HSC transplantation. However, there has been lack of extensive systemic investigations on the biological and genetic nature of UCB-derived CD34⁺/CD38⁻ stem cells following long-term ex vivo expansion. By flow cytometry CD34⁺/CD38⁻ HSC were collected from UCB of 10 healthy women at the time of delivery and cultivated in stem cell culture media supplemented with cell growth stimulating factors (IL-3,IL-6,GM-CSF,EPO,IGF-1, and SCF) for a long-period of time. In our experiments, the UCB-derived CD34⁺/CD38⁻ stem cells were able to divide and proliferate in vitro for at least six months. They did not show significantly increased apoptosis following ex vivo expansion for 20 and 32 days, respectively in two cases tested and remained the same cell surface marker expression pattern (i.e., CD34⁺ and CD38⁻) in majority of the cells of two cases tested following 20 and 37 days of incubation, respectively. In another two cases tested, chromosome analysis showed no evidence of apparent numerical and structural abnormalities on the CD34⁺/CD38⁻ stem cells obtained after 20 and 43 days in culture, respectively. Our findings indicated that UCB-derived CD34⁺/CD38⁻ stem cells are able to maintain their basic biological and genetic characteristics after proliferating in vitro over a long-period of time. UCB-derived HSC following ex vivo expansion can serve as a reliable resource for HSC transplantation.

Labor increases maternal DNA contamination in cord blood. *K. Miura, H. Masuzaki, S. Miura, K. Hiraki, S. Yoshimura, D. Nakayama, T. Ishimaru.* Dept OB/GYN, Nagasaki Univ School of Med, Nagasaki, Nagasaki, Japan.

Objective: Although maternal cells and deoxyribonucleic acids (DNAs) were reported to be present in umbilical cord blood (UCB), which factors affect on this umbilical cord blood contamination by maternal genetic materials remains unknown. In this study, we aimed to know whether labor itself influences the frequency of maternal DNA contamination in UCB. Material and Method: Ninety-seven pregnant women with normal pregnancy were divided into 19 Group-A women with C/S performed after the beginning of labor (labor with C/S), 44 Group-B women with C/S before labor (non-labor with C/S), and 34 Group-C women with normal vaginal delivery (V/D) (labor with V/D). A set of 9 highly polymorphic tetra-repeats markers in Japanese population (D21S11, D18S535, D11S2365, D8S1132, D7S1830, D4S1645, D3S1359, D3S2465 and FGA) was chosen for detection of maternal DNA. We compared the detection rate of maternal DNA in cord plasma samples between three groups. Difference in categorical variables was compared by chi-squared test, and difference between continuous variables was compared with Mann-Whitney U test. A P value .05 was considered significant. Results: When maternal DNA had 2 alleles (the mother, heterozygous) and one of them was not shared by UCB (fetal) cellular DNA, we defined this allele as informative. The presence of maternal DNA in UCB was judged when an informative allele is found for at least 2 different loci. We compared detection rates of maternal DNA in UCB plasma between the 3 groups of women. Consequently, the detection rate (16/19) in Group A was significantly higher than that (20/44) in Group B (p 0.005). Likewise, the rate (31/34) in Group C was statistically higher than that (20/44) in Group B (p 0.0001). However, there was no significant difference in the rate between Groups A and C (p 0.5). Conclusion: It became clear that labor affects on the frequency of the cord blood contamination by maternal DNA. The results also imply clinical importance of the use of cord blood at bone marrow transplantation, and may give an insight into the mechanism of feto-maternal circulation and vertical transmission of infectious agents.

Human chondrocytic lines provide a model for achondroplasia and thanatophoric dysplasia. *C. Benoist-Lasselien, J. Bonaventure, L. Gibbs, S. Heuertz, A. Munnich, L. Legeai-Mallet.* INSERM-U393, Hopital Necker, Paris, France.

Achondroplasia (ACH) and thanatophoric dysplasia (TD) are human skeletal disorders of increasing severity accounted for by mutations in the fibroblast growth factor receptor 3 (FGFR3) gene. We generated six immortalized human chondrocyte lines that express a constitutively heterozygous mutant of FGFR3. Mutation analyses showed that the chondrocytic lines carried respectively the G380R mutation (ACH phenotype), the S249C, R248C, G370C, Y373C mutations (TDI phenotype) and the K650E mutation (TDII phenotype). Chondrocytes were isolated from human fetal growth cartilage and immortalized by transfection of the SV40 large T antigen gene. The cell lines were characterized and analyzed for factors controlling chondrocyte differentiation. Cell lines, were subcloned according to the following parameters : cell morphology, mRNA and protein levels of extracellular matrix molecules to confirm a cartilage-specific and stable phenotype. We selected cell lines associated with an expression of extensive extracellular matrix components including proteoglycans (aggrecan, biglycan, decorin), collagens type II and type IX, MMP9 and signaling molecules (Ihh, Pthrp, FGFR3). Here we show the constitutive phosphorylation of FGFR3 and the activation of the STAT pathway in these immortalized cells. The cell lines provide a good model for ACH, TDI and TDII phenotypes, in addition we show for the first time the excessive activation of signaling cascades mediated by the FGFR3 mutants in human chondrocytic cell lines. Availability of this model will permit rational strategies for targeting the FGFR3 signaling pathways and to address new strategies in the treatment of achondroplasia. This work was supported by the European Skeletal Dysplasia Network (ESDN), grant CE-QLG1-CT-2001-02188.

Radiographic diagnosis of osteogenesis imperfecta type II following atypical ultrasound findings. *S.M. Carter, D. Cordero, S. Klugman, J.F. Powers, S.J. Gross.* Reproductive Genetics, Montefiore Medical Ctr, Bronx, NY.

A 19-year-old African primigravida had appeared for a routine fetal anatomy scan at 18 weeks' gestation. Initial ultrasound findings revealed a single live fetus with severe micromelia of the upper and lower limbs along with abnormally shaped ribs. A small chest cavity resulted in cardiac displacement. After the patient was counseled about the grim prognosis for the pregnancy, she requested a pregnancy termination. An ultrasound by an experienced fetal dysmorphologist confirmed the initial anomalies and demonstrated decreased bone mineralization. The ribs did not appear beaded and bone fractures were not observed. The differential diagnoses included osteogenesis imperfecta, achondrogenesis, hypophosphatasia, and thanatophoric dysplasia.

After pregnancy termination, the fetus was evaluated by the International Skeletal Dysplasia Registry (Cedars-Sinai Medical Center, Los Angeles, CA). Posttermination radiographic findings were consistent with osteogenesis imperfecta (OI) type II, a type 1 collagenopathy. The fetus had osteopenia, crumpled femurs, and other long bones with beaded ribs. The triad of bone shortening, hypomineralization, and numerous fractures are pathognomonic for OI type II. However, not all three features need be present simultaneously as fractures may not develop until later. Additionally, the fractures may have arisen iatrogenically from the dilation and evacuation procedure performed at 19 weeks. We discuss the natural history, molecular biology, and variable ultrasonographic findings of OI type II as well the recurrence risk and prenatal diagnosis modalities for future pregnancies.

Cystic Hygroma and Arthrogryposis Multiplex Congenita: An additional case. *C. Cheng¹, V. Shah¹, P. Shah¹, R. Windrim², M. Bedford⁴, D. Chitayat^{2,3}.* 1) Department of Paediatrics; 2) Department of Obstetrics and Gynecology; 3) The Prenatal Diagnosis and Medical Genetics, Mount Sinai Hospital; 4) Department of Medical Genetics, North York General Hospital, Toronto, ON, Canada.

Arthrogryposis multiplex congenita (AMC) is a term used to describe multiple joint contractures detected at or before birth. The etiology is heterogeneous and may be a presenting feature of various conditions. Cystic hygroma (CH) is a heterogeneous condition caused by abnormalities in the lymphatic system. Scott et al reported the combination of both findings once.⁽¹⁾ We report a case of this combination of findings. The infant was born at 38.5 weeks GA to a 34-year-old G4P3L3 woman of Italian descent. The couple's family histories were noncontributory. Fetal US at 18.5 weeks gestation showed CH with clenched fists. On an US repeated a week later, the fetal fingers remained clenched with no overlapping and both hands were held in extreme flexion position. Rest of the scan was normal. Amniocentesis showed a normal karyotype (46 XX) and negative DNA analysis for PTPN11 ruling out Noonan syndrome. Fetal ECHO was normal and MRI showed normal brain maturation and structure and confirmed the presence of CH. The infant was born by Cesarean section for breech position with Apgar scores of 6 and 9 at 1 and 5 minutes. On examination the infant was hypotonic, had myopathic face, droopy eyelids, retrognathia, low nuchal hair line, webbed neck, flexion contractures of both wrist joints, camptodactyly of the 2-5th fingers, partial syndactyly of the 2nd and 3rd toes, hammer great toe, hyperflexed feet and limitations in extension of both knees. Rest of the examination was normal. To date there has been one published case report of non-lethal AMC with a CH diagnosed at 13 weeks gestation.⁽¹⁾ The two female siblings had a similar presentation and the authors hypothesized an autosomal recessive condition. Our case supports the assumption that the combination is most probably a single gene disorder with a triad of CH, AMC, and hypokinesia. Reference: 1. Scott H, Hunter A, Bedard B. Non-lethal arthrogryposis multiplex congenital presenting with cystic hygroma at 13 weeks gestational age. *Prenat Diagn* 1999;19:966-71.

A case of prenatal diagnosis of Rett syndrome due to germ-line mosaicism. *F. Mari¹, F. Cogliati², R. Caselli¹, I. Longo¹, F. Ariani¹, M. Bruttini¹, I. Meloni¹, K. Schurfeld³, P. Toti³, S. Russo², L. Larizza², G. Hayek⁴, M. Zappella⁴, A. Renieri¹.* 1) Medical Genetics, Molecular Biology Department, University of Siena, Siena, Italy; 2) Laboratory of Molecular Biology, Istituto Auxologico Italiano, Milano, Italy; 3) Department of Anatomy and Pathology, University of Siena, Siena, Italy; 4) Department of Child Neuropsychiatry, Azienda Ospedaliera Senese, Siena.

Rett syndrome is an X-linked neurodevelopmental dominant disorder that almost exclusively affects girls. The vast majority of cases are sporadic and are caused by de novo mutations in MECP2 gene, located in Xq28. Only few familial cases have been reported: in four cases the mother was an asymptomatic carrier and in four cases germ-line mosaicism in the mother was postulated. Due to the above reported cases of germ-line mosaicism we decided to offer prenatal diagnosis to all expectant mothers with a Rett daughter despite the absence of the causative mutation in their blood. We describe here the out-come of the first nine cases of prenatal diagnosis followed by our center. In eight cases (5 females and 3 males) the fetus did not carry the mutation. In one case the female fetus did carry the same mutation as the affected sister. This positive prenatal test strengthens the importance of performing prenatal diagnosis in all cases of Rett syndrome even when the mutation is apparently de novo. Moreover, our results indicate that germ-line mosaicism may be considered for the assessment of recurrence risk during genetic counseling. The couple decided to interrupt the pregnancy and to devolve fetal tissues for research purposes. Taking advantage of the availability of these unique tissues we are performing a morphologic comparison between the Rett fetus and an age-matched control fetus. In addition X-chromosome inactivation studies of different brain areas (hippocampus, cortex, and cerebellum) and other organs are ongoing.

Dandy Walker malformation, aniridia, and cataracts in a 19-week fetus with partial trisomy of chromosome 15. The importance of ophthalmologic pathology in cases of fetal and neonatal demise. *C.S. Rao¹, M.A. Côté-Primac², B. Huang^{1,3}, M. Bocian¹.* 1) Division of Human Genetics, Department of Pediatrics, University of California Irvine Medical Center, Orange, CA; 2) Department of Pathology, University of California Irvine Medical Center, Orange, CA; 3) Genzyme Genetics, Orange, CA.

A 19-week fetus with Dandy Walker malformation (DWM), aniridia, cataracts, and trisomy of chromosome 15pter15q15, is described. Although DWM has been associated with multiple chromosomal defects and Mendelian disorders, chromosome 15 has not been among those reported, nor have DWM and aniridia been reported together in the same individual. Approximately a third of all cases of aniridia are sporadic, and these are often found to have cytogenetically detectable deletions involving 11p13. No locus other than 11p13 has been implicated in aniridia, either sporadic or familial, and PAX6 appears to be the major, if not the only, gene responsible (a report of reanalysis of the family on which mapping of an aniridia locus to 2p was based has excluded linkage to markers on 2p and shown strong indication of linkage to markers in the 11p13 region).

In an unrelated case, aniridia and cataracts were found in a 19-week, cytogenetically normal fetus with other anomalies, including anencephaly and diaphragmatic hernia.

The first case suggests that there are yet undiscovered genes on chromosome 15 which, either alone or through regulation of PAX6, may contribute to the development of aniridia. This case also allows inclusion of partial trisomy 15 among the heterogeneous causes of DWM.

Both cases illustrate the importance of ophthalmologic pathology evaluation of anomalous fetuses and stillborns, especially those with central nervous system abnormalities.

High risk pregnancies in Diamond Blackfan anemia : A survey of 41 pregnancies from the French registry. *L.*

*Faivre*¹, *T. Leblanc*², *L. Da Costa*³, *C. Nouvel*⁴, *F. Bauters*⁵, *B. Coiffier*⁶, *C. Berger*⁷, *P. Sagot*⁸, *B. Varet*⁹, *G. Tchernia*³. 1) Centre de Genetique, CHU Dijon, France; 2) Hematologie Pediatrique, Hopital Saint Louis, Paris, France; 3) Hematologie Biologique, CH Le Kremlin-Bicetre, France; 4) Hematologie, Hopital Purpan, Toulouse, France; 5) Hematologie, Hopital Claude Huriez, Lille, France; 6) Hematologie, CH Lyon Sud, France; 7) Hematologie, CH Saint Etienne, France; 8) Medecine foetale, CHU le Bocage, Dijon, France; 9) Hematologie, Hopital Necker-Enfants Malades, Paris, France.

Diamond Blackfan anemia (DBA) is a rare disorder characterized by red cell aplasia and inconstant congenital anomalies. Few data are available concerning pregnancies in Diamond Blackfan anemia affected women. We report on data from the French Diamond Blackfan anemia registry concerning women aged 25 years or more. Among 25 women (mean age 34.2 years, range 25-46), 14/25 experienced one or several pregnancies (56%). A total of 41 pregnancies occurred, 11 being normal and 30 being complicated (73%), including miscarriages, pre-eclampsia, in utero fetal death, intrauterine growth retardation, pre-term delivery, retro-placental hematoma and fetal malformations. As a result of those 41 pregnancies, only 18 children were born (44%). We did not find any obvious correlation between complicated pregnancies and therapeutic responses, the RPS19 status, or the affected status of the child. Such facts suggest some complications to potentially originate from the affected mother, irrespective of the DBA status of their offspring. In most cases, transfusion requirement and steroid dosage increased during pregnancy. Among the 11 women who did not present any pregnancy, 5 did not desire children for various reasons including their chronic illness, mental retardation (1), infertility (4). Infertility was likely to be treatment related. From this study together with the literature data, we conclude that pregnancies in DBA are at high risk, especially for complications of vascular-placental origin. Such pregnancies should be carefully monitored with a satisfying control of anemia and early introduction of aspirin, especially in cases where a mother experienced a previous complicated pregnancy.

Raine Syndrome Presenting Prenatally as Craniosynostosis: Histologic Findings and Discussion of Pathogenesis.

M.K. Maisenbacher, D.A. Driscoll, S. Saitta, E. Ruchelli, A. Hubbard, L. Ernst, E.H. Zackai. Division of Human Genetics, Children's Hospital of Philadelphia, Philadelphia, PA.

Raine syndrome (OMIM #259775) has been classified as a lethal osteosclerotic bone dysplasia with significant craniofacial findings. Here we review a case presenting prenatally at 23 weeks on ultrasound with craniosynostosis with cloverleaf skull, hypertelorism, proptosis, and midfacial hypoplasia. The infant died shortly after birth at 32 weeks gestation. Midsagittal and coronal synostosis was noted. The skull bones were brittle and thick. Radiographs revealed focally exuberant periosteal thickening of long bones and ribs, generalized increased bone density. Coronal sections of the brain revealed multiple foci of calcification, in the white matter, corpus callosum, basal ganglia and internal capsule. The cerebellar leptomeninges showed accumulation of pale basophilic mucinous material within mononuclear histocytes. Sections of rib and femur showed marked thickening of bony trabeculae with central non-mineralized abnormal cartilage precursor material. There was marked osteoblastic activity and periosteal reactive spindle cell proliferation including collections of multi-nucleated giant cells (presumably osteoclasts) apparently ingesting globules of pale basophilic mucoid substance. Sections of the skull showed similar irregular thickening of bony trabeculae. Mucoid material was seen focally. The mucoid substance in the bone is positive for PAS, Alcian blue (pH2.5, but not pH 1.0) and mucicarmine and with acid mucopolysaccharide stain and negative reaction with sulfated mucopolysaccharide stain suggesting that it is cartilaginous precursor material. It is postulated that the substance outside the periosteum is part of an abnormal attempt to produce bone and an attempt to resorb it by giant cells. The appearance of craniosynostosis was secondary to the thick bony trabeculae, periosteal reaction and aggregates of mucoid material and differs histologically from suture fusion of typical craniosynostosis.

Preimplantation genetic diagnosis for DiGeorge/ Velo Cardio Facial Syndrome(DGS/VCFS). A. Aviram-Goldring¹, J. Levron², E. Schiff², T. Litmanovitz¹, D. Gothelf³, M. Frydman¹, B. Farber², B. Goldman¹, O. Israeli¹, G. Barkai¹, J. Dor², S. Rienstein¹. 1) Human genetic Institute, Sheba Medical Ctr, Tel Aviv, Israel; 2) In Vitro Fertilization Unit, Department of Obstetrics and Gynecology, The Chaim Sheba Medical Center, Tel Hashomer and Sackler School of Medicine,; 3) Behavioral Neurogenetics Clinic, Feinberg Child Study Center, Schneider Children's Medical Center of Israel, Petah Tiqwa, Israel; and Sackler School of Medicine, Tel Aviv University, Israel.

Velo-cardio facial syndrome (VCFS) is a genetic syndrome caused by a microdeletion in chromosome 22q11. It is manifested clinically by typical physical manifestations and neuropsychiatric disabilities. Most cases of VCFS are sporadic (1 in 4,000 live births). Familial or inherited cases of VCFS varies from 6% to 28% of the cases. Individuals with VCFS have 50% chances of passing the micro deletion to their offspring. A family was referred for PGD after diagnosis of 22q11 micro-deletion in the mother and in their three years old daughter, and termination of pregnancy of a VCFS fetus. The couple underwent routine in vitro fertilization with biopsy of embryos on day 3. PGD was performed with LSI DiGeorge/VCFS Region probe, 22q13.3 and centromer 18 as control probes (Vysis, Downers Grove, IL). Embryo transfer was possible in two cycles. In the first cycle four embryos were biopsed and only one was normal and transferred. In the second cycle 9 embryos were biopsed. Among them 4 were with the 22q11 micro deletion and five were normal. Two embryos were replaced resulting in ongoing pregnancy. This is the first report of performing PGD in VCFS embryos derived from couple that the mother is a carrier of the diseases with a dominant mode of inheritance. Our preliminary results demonstrate that PGD using FISH analysis is a reliable technique to ensure transfer of normal embryos after in vitro fertilization. We hope that in the near future the crude method of terminating affected pregnancies in carriers of microdeletion traits, will be replaced by pre-selection of normal embryos for replacement by PGD.

CLINICAL AND GENETIC PRENATAL ASPECTS OF THE BOARDING OF THE CERVICAL CYSTIC HYGROM. *M. Baez-Reyes, G. Razo-Aguilera, D. Mayen-Molina.* Department of Genetics. National Institute of Perinatology. Mexico, D.F.

The fetal cystic hygrom associates until 70% to cromosomopatias and the prenatal diagnosis for ultrasound it allows the evaluation of the amniocentesis. The purpose of the study was correlating the phenotype-karyotype prenatally of the cystic hygrom, the clinical evolution and the propose the boarding of the same. Thus, 82 pregnant women were studied with the prenatal diagnosis of fetus with the anomaly detected by ultrasonography. Later on the genetic counseling and acceptance of the patients it was realized the amniocentesis, clinical revision of the newly born and in the event of fetal death, histopatologic study. The gestational age average of the diagnosis was of 23.5 weeks and maternal age of 27.3 years old. Out of 82 cases: 29 (35.3%) presented septal hygroms, 33 cases (40.2%) were non septals and 20 cases (24.3%) with uncertain septation. Fifty three fetus developed hidrops independently of the hygrom type, being for all them letal. The cytogenetics results obtained were: 45 normal (54.8%)(28 female and 17 male) and 32 abnormal (39.0%), being in order of frequency: 21 cases with Monosomy of the "X", 9 cases with regular trisomy 21, 1 case with a traslocation (13;18) and 1 case with one marker. In 5 cases it wasn't possible to realize cytogenetic study because they presented fetal death and not viable tissue. The fetal mortality was present in 56 cases (68.2%). For such reason the ultrasonographic discovery of cystic hygrom is indicative of fetal karyotype, likewise, it is fundamental the pursuit to see the evolution, to determine the pronostic and give real genetic advice.

Semi-quantitative fluorescent PCR (QF-PCR) for rapid aneuploidy screening on amniocentesis and CVS specimens: A blinded prospective trial using material discarded during routine cytogenetic analysis. *L. Brown*¹, *M. Abigania*¹, *D. Warburton*², *S. Brown*¹. 1) Dept OB/GYN, Columbia Univ, New York, NY; 2) Dept. Genetics and Development, Columbia Univ. New York, NY.

Successful aneuploidy screening of prenatal specimens using QF-PCR has been reported. Given that FISH is relatively expensive, a high-throughput technique such as QF-PCR is an attractive alternative. In order to validate QF-PCR for clinical testing, we have set out to determine its reliability in a blinded prospective study in our institution. Rather than obtaining consent from each patient to draw extra amniotic fluid, we have developed a protocol that uses the discarded remains of specimens received for routine cytogenetics. Our PCR protocol is a modification of published methods and consists of 15 markers that are amplified in two separate multiplexed reactions. The 15 loci we have chosen include at least 3 polymorphic markers each on 13, 18, 21 and X as well as amelogenin. PCR products are run on an ABI 310 automated sequencer and are analyzed using Genescan and Genotyper software. Our analysis criteria are based on published methods that have proven to be reliable. Each result is reviewed individually to assess data quality.

Because the study is blinded, we cannot compare QF-PCR results with cytogenetic results until completion of our target of 1000 samples. At this time, we have collected and stored ~900 samples and have completed analysis of 202. Of these, 185 are finalized as normal and 3 as abnormal (1 trisomy 21 and two trisomy 18). Six samples (3%) could not be analyzed due to maternal contamination and another seven were not fully informative despite the use of additional markers. Thus far, our data support the feasibility of QF-PCR for aneuploidy screening in prenatal samples; however, the proportion of samples that cannot be assessed is apparently greater than that reported in other series.

Rapid prenatal screening using FISH in uncultured amniocytes. *V. Catala, E. Cuatrecasas, C. Garrido, L. Vila, T. Escabias, A. Ramos, A. Seres-Santamaria.* Prenatal Genetics, Barcelona, Catalonia, Spain.

Fluorescence in situ hybridization (FISH) allows the evaluation of chromosome copy number in interphase cells. This characteristic gives FISH a great potential for the study of amniotic fluid cells in prenatal diagnosis. The major indications in prenatal diagnosis, advanced maternal age, fetal malformation detected by ultrasonography, increased risk of trisomy estimated by maternal serum screening and maternal anxiety demands a rapid and accurate result. Classical cytogenetic analysis of amniocytes is the best technique to detect numerical and structural chromosome aberrations after culture of amniotic fluid cells, but this study is not completed in less than a week. FISH in uncultured amniotic fluid cells permits the detection of most common aneuploidies in less than 24 h after amniocentesis. We present a prospective study of 4121 uncultured amniotic fluid (AF) samples by FISH, using commercial probes specific for 13, 18, 21, X and Y human chromosomes. FISH studies in AF cells were performed in our laboratory as an adjunctive of conventional cytogenetic studies using AneuVysion Test Kit (Vysis). Parallel cultures from each sample were grown and standard cytogenetics results were informed at the end of the study. We detected 2.4% of autosomal trisomies and 0.5% of sex chromosomes aneuploidy. Our results support previous studies reporting FISH in uncultured AF cells is a feasible method to assess the most common aneuploidies observed in newborns. FISH has to be considered as an adjunctive method to classical karyotyping, however FISH allows an accurate result in less than 24h, and a rapid result is very important in prenatal diagnosis.

Exocervically retrieved trophoblast cells at 5-12 gestational weeks: a new screening method for Down syndrome?

M.D. Fejgin^{1,2}, M. Liberman², M. Pomeranz¹, A. Amiel². 1) Obstetrics and Gynecology; 2) Genetic Institute, Meir Hospital, Kfar-Saba, Israel.

Currently, clinically available methods for prenatal chromosomal diagnosis (amniocentesis and cvs) are invasive, risky and costly. Screening techniques are cumbersome and carry a false negative rate of 20%. We assessed the feasibility of utilizing exocervically retrieved extra villous trophoblast cells for screening for chromosome 21-aneuploidy and gender determination. **Methods-** Exocervical sample was obtained from the external cervical os of pregnant women using a cytobrush. Eight slides were prepared using a cytopspin centrifuge. Immuno-histochemistry using HLA-G and other anti trophoblast antibodies. The marked cells were identified and scored. FISH for X and Y was applied and the previously marked cells were returned to for diagnosis. FISH for chromosome 21 was applied later to the same cells. **Results-** Initially, samples were taken from 227 women prior to pregnancy termination. In 195 (86%) were trophoblast cells detected. Gender diagnosis concurred with that of the placental in 186 (95%). Subsequently 130 on-going pregnancies were screened. Trophoblast cells were detected in 112 (86%). Sex was correctly determined in 100 (89%). There was 1 case of trisomy 21 that was correctly diagnosed. There were 2 cases of missed abortions both initially diagnosed to be XY. Placental tissue karyotyping revealed both of them to be mosaics, 46,XY/45,XO and 47,XXY/46,XY. **Conclusion-** this simple and inexpensive procedure may have the potential to replace currently available non-invasive screening techniques for Down syndrome.

Result of chromosome abnormalities in Korean population identified by triple-marker testing as screen positive for Down and Edward syndrome. J. Kim. Department of cytogenetics, GreenCross Reference Laboratory, Korea.

Background:Second-trimester serum screening can detect 60-65% of cases of Down syndrome and 60% of Edward syndrome. Previous studies reported a high frequency of chromosomal abnormalities other than trisomy 21 and trisomy 18 in the screen positive population. But rate and type of other chromosome abnormalities detected was inconsistent in each study and different between the race. This study was to determine the incidence of chromosomal abnormalities in Korean women receiving chromosome analysis after screen positive result by using maternal age and serum triple-marker testing(FP, HCG, uE₃). **Methods:**A total of 49,806 pregnant women between 15 and 23 gestational weeks received second-trimester prenatal screening. By use of a 1 : 270 Down syndrome and 1 : 100 Edward syndrome risk cutoff value, 2,116 and 196 pregnant women were screen positive for Down syndrome(screen positive rate 4.2%) and positive for Edward syndrome(screen positive rate 0.04%). Prenatal chromosomal analysis in amniotic fluid were performed for 1893(89.5%) of Down positive and 140(71.4%) of Edward positive women. **Results:**Forty-one trisomy 21(2.2%) and 42 other chromosomal abnormalities(2.2%) were identified in the Down screen-positive group. Other chromosomal abnormalities included 11 balanced translocation, 10 Robertsonian translocation, 8 inversion, 7 sex chromosome abnormality, 2 deletion, 1 isochromosome 22, 1 trisomy 20, 1 de novo marker, 1 derivative 15. Seven sex chromosome abnormalities included 4 45,X, 2 47,XYY and 1 47,XXY. For Edward screen-positive pregnancy, 9 trisomy 18(6.4%) and 1 trisomy 9(0.7%) were detected. **Conclusion:**Our study suggest that 4.4% of Down positive pregnancy and 7.1% of Edward positive pregnancy will show chromosome abnormality in Korean. Positive Down screening result reflected relatively high probability of other abnormalities except trisomy 21. The type of other chromosome abnormalities in Down screen positive group showed difference compared to other studies and the rate of chromosome abnormalities was higher than in other Asian population. Edward screen positive group did showed low frequency of other chromosome abnormalities except trisomy 18.

The prenatal diagnosis of a fetus with de novo ring chromosome 11. *J.Y. Park¹, S.Y. Park¹, M.H. Lee¹, E.H. Cho¹, B.Y. Lee¹, Y.W. Lee¹, H.M. Ryu^{1,2}.* 1) Laboratory of Medical Genetics, Samsung Cheil Hosp, Seoul, Seoul, Korea; 2) Department of Obstetrics and Gynecology, Sungkyunkwan University School of Medicine, Seoul, Korea.

We report a de novo ring chromosome 11 in prenatal diagnosis. A 36-year-old pregnant woman was referred for amniocentesis at 19.5 weeks gestation because of an advanced maternal age and increased risk for Edward syndrome in maternal serum screening test. Cytogenetic analysis of the cultured amniotic fluid cells revealed mosaicism for ring chromosome 11; 46,XX,r(11)[65]/45,XX,-11[16]/46,XX[34]. Both parents had a normal karyotype. A targeted ultrasound showed no significant abnormalities other than intrauterine growth restriction(IUGR). Cordocentesis performed to characterize of ring chromosome by high resolution and reverse banding. In this culture no normal karyotype was observed ; 46,XX,r(11)(p15.5q24.2)[229]/45,XX,-11[15]. The deletion of subtelomeric region in the ring chromosome was detected by fluorescent in situ hybridization(FISH). After genetic counseling the parents did not want to continue the pregnancy. Autopsy showed significant IUGR and rocker bottom feet. To the best of our knowledge, ring chromosome 11 is a very rare case and especially only one case which de novo ring chromosome 11 in prenatal diagnosis have been reported.

Case report of the prenatal diagnosis & management of fetal achondroplasia & Down Syndrome. *T. Prosen*^{1, 2}, *M. Kolthoff*^d. 1) Dept OB/GYN Reprod Sci, Magee Womens Hosp, Pittsburgh, PA; 2) Fetal Diagnosis & Treatment Center, Magee Womens Hosp, Pittsburgh, PA.

We report on a case of the prenatal diagnosis and management of fetal achondroplasia and Down Syndrome. A 36 year-old primagravida with maternal achondroplasia presented at 20 weeks gestational age for consultation. She was found to have an elevated risk for Down Syndrome (1 in 12) by second trimester multiple marker screening. A genetic sonogram was performed that showed mild fetal pyelectasis, increasing the risk to 1 in 6. The patient declined amniocentesis. At 27 weeks, an ultrasound for fetal biometry revealed fetal long bone measurements to be less than the 5th percentile for gestational age, consistent with fetal achondroplasia. In addition, no nasal bone was identified. At 30 weeks and 6 days, the patient presented for routine follow-up. At that time, ultrasound revealed fetal hydrops (pleural and pericardial effusions, ascites and anasarca), polyhydramnios, and abnormal umbilical artery Doppler velocimetry studies. The patient received 48 hours of beta-methasone therapy followed by a primary cesarean section for fetal hydrops and maternal achondroplasia. The premature male infant was stabilized in the neonatal intensive care unit. Neonatal survey showed characteristics of both achondroplasia and Down Syndrome. The infant exhibited trident hands, rhizomelic limb shortening, large head with frontal bossing, down-slanting eyes, and single palmar creases. The infant's karyotype was found to be 47, XY, +21. The diagnosis of achondroplasia was confirmed by the presence of the G1138A gene mutation in the FGFR3 gene. To our knowledge, this is the first reported case of fetal Down Syndrome and achondroplasia detected and managed prenatally. The combination of a mendelian disease with a chromosomal abnormality creates a complex scenario for prenatal diagnosis and management.

Program Nr: 2753 from the 2004 ASHG Annual Meeting

CYTOGENETICS PRENATAL DIAGNOSIS IN FETAL FLUIDS. *G. Razo-Aguilera, R. Baez-Reyes, JL. Saucedo, J. Zavaleta, D. Mayen-Molina, R. Garcia-Cavazos.* Department of Genetics. National Institute of Perinatology. Mexico, City.

The invasive techniques traditionally used to obtain fetal cells for chromosome analysis are chorionic villus sampling, amniocentesis and cordocentesis. However, in some cases those methods are difficult to perform, specially in the presence of structural defects in the fetus, advanced gestational age or oligoamnios, so an alternative method is required. In those cases with fetal structural defects detected by high resolution ultrasound where traditional invasive procedures are difficult to perform, we could offer to pregnant women somatocentesis. We performed fifty nine cases of somatocentesis in fetal cells from cystic hygroma, urine and pleural and ascitic fluids. The cytogenetic results in seven samples: five from cystic hygroma and two from urine. The 13 abnormal karyotypes include: 11 from cystic hygroma: 10 cases with 45,X; 1 case with 46,XY,der(13)t(13;18). The somatocentesis is a good alternative method to obtain fetal cells in cases where traditional methods represent technical difficulties and with specific modifications in cytogenetic technique according to the cell type a karyotype with good band resolution can be obtained.

First trimester Down syndrome screening: high detection rate for trisomy 21, but poor performance in structural abnormalities. *M. Ryyanen*¹, *A. Rissanen*², *J. Taskila*¹, *P. Laitinen*¹, *S. Heinonen*², *M. Suonpaa*³. 1) Dept OB/GYN, and Clin. Chemistry Oulu Univ Hosp, Oulu, OYS, Finland; 2) Dept OB/GYN, Kuopio Univ Hosp, Kuopio, Finland; 3) PerkinelmerWallac, Turku Finland.

Objective: To evaluate whether first trimester screening markers are altered in pregnancies affected both by other chromosomal defects than trisomy 21 and structural anomalies and are these pregnancies possible to detect by combined ultrasound and biochemical screening test. **Methods:** 4776 singleton pregnancies underwent first trimester screening between 10th and 13th gestation weeks. N women were screened using a combination of maternal serum free hCG, PAPP-A and nuchal translucency and N women with first trimester biochemistry without ultrasound. **Results:** Using a fixed cut-off rate of 1:25 for Down's syndrome, the detection rate of trisomy 21, 18 and 13 were 92%, 67% and 0%, respectively. All open defects, 87% of cardiac abnormalities and other minor defects were not detected in first trimester screening. Majority of these structural abnormalities occurred in women under 35 y of age. **Conclusion:** First trimester Down syndrome screening is effective in trisomy screening, but its performance in structural abnormalities is low, when used as a part of routine clinical practice. We conclude that it is too early to drop second trimester screening ultrasound entirely from antenatal care programs if a high detection rate is to be achieved also in structural defects.

Program Nr: 2755 from the 2004 ASHG Annual Meeting

Invasive Trophoblast Antigen (ITA) Clinical Utility in First and Second Trimester Prenatal Screening for Trisomy 21 and Other Chromosomal Abnormalities: Preliminary Report of a Prospective Study in Germany. *U. Sancken, D. Taube.* Inst Human Genetics, Univ Goettingen, Goettingen, Germany.

ITA is a hyperglycosylated form of human chorionic gonadotropin (hCG) found in elevated levels of blood and urine during pregnancy. Retrospective studies indicate that ITA is useful in prenatal screening for Down syndrome. We have conducted a prospective observational study to confirm this utility. Serum samples were collected from women undergoing routine prenatal care (2,927 in the first trimester and 2,233 in the second). From 7244 available cases we considered only those with gestational dating by early fetal crown-rump length measurement. Maternal ages ranged from 15 to 46 years (average: 30 years). ITA levels were determined for all samples, and outcome information was based on karyotype or phenotype following birth. Outcome information, based on 88% of the women, has identified 26 cases of trisomy 21 (Down syndrome), 7 cases of trisomy 18, 1 trisomy 13, 1 trisomy 22, 7 triploid cases, and several other chromosomal abnormalities (eg, XO, XXY, translocations). Serum ITA levels were very low (all but one below the 5th centile) in the trisomy 18, trisomy 13, and triploidy cases. ITA levels were greater than 1.0 multiple of the median (MoM) in all cases of trisomy 21 and 22. In trisomy 21 cases, the median MoM was 1.8 in the first trimester and 3.2 in the second trimester. More importantly, 33% of the Down syndrome cases had ITA levels above the 95th centile in the first trimester. In the second trimester, levels exceeded the 95th centile in 50% of the Down syndrome cases. Thus, ITA is a useful screening marker for fetal chromosomal abnormalities in both the first and second trimesters. For Down syndrome screening, ITA is most useful in the second trimester.

Variation in the Decision to Terminate Pregnancy in the Setting of an Abnormal Karyotype with Uncertain

Significance. *B.L. Shaffer*¹, *A.B. Caughey*¹, *P.D. Cotter*², *M.E. Norton*¹. 1) Dept OB/GYN, Univ Cal, San Francisco, San Francisco, CA; 2) Dept of Pediatrics, Children's Hospital, Oakland, CA.

Approximately 2-3% of karyotypes from prenatal diagnosis are abnormal and a significant proportion are of uncertain significance. An unclear prognosis poses a unique clinical situation, how much "risk" of phenotypic abnormality is too much?

To examine predictors of termination of pregnancy, we performed a retrospective cohort study at a prenatal diagnosis unit from 1984-2003. Patients with karyotypic abnormalities of marker or mosaic, balanced and unbalanced rearrangements were categorized in three groups of similar prognosis. We examined chromosomal abnormality, age, ethnicity, parity, and previous abortion as predictors of the decision to terminate.

There were 419 abnormal fetuses and the termination rate was 20%. Each group was different: 6.5% of patients with balanced rearrangements, 61% with unbalanced abnormalities, and 29% with marker/mosaic karyotypes terminated ($p < 0.001$, ²). Among patients with balanced rearrangements, those with inherited abnormalities had a termination rate of 3% versus 13% in those with a newly diagnosed balanced rearrangement ($p = 0.003$, ²). There was no difference in those with an unbalanced rearrangement, with the inherited group's rate 63% and the newly diagnosed group's rate 59%. In multivariate analysis, karyotypic abnormality was a significant predictor of termination, but age, ethnicity, parity, and previous abortion were not.

In patients with an abnormal karyotype of uncertain significance, termination rates increased with increasing chance of phenotypic abnormality. In contrast to reports of termination in common aneuploidies, we found no differences between women of different ethnicity or ages in the decision to terminate. Perhaps, when families are faced with an uncommon diagnosis of uncertain significance they have fewer preconceived biases, and their decision is unrelated to ethnicity, age, or previous reproductive choice.

Outcome of Prenatally Diagnosed Individuals with 45,X/46,XX and 45,X/46,XY Mosaicism. *L. Tan, P. Eydoux, B. McGillivray.* Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada.

Although prenatally diagnosed 45,X/46,XX and 45,X/46,XY mosaicism have been shown to have a milder prognosis when compared to non-mosaic 45,X, such results present a genetic counselling dilemma. The literature is primarily retrospective, consisting of postnatally diagnosed cases while the small number of prospective studies is limited to a short follow-up period. In this study, we evaluated the long term outcome of prenatally diagnosed cases with 45,X/46,XX mosaicism (n=12) and 45,X/46,XY mosaicism (n=14). Upon testing, mosaicism was not confirmed postnatally in 6 of the 12 prenatally diagnosed cases with 45,X/46,XX mosaicism. 3 cases had abnormal prenatal ultrasound findings. The abnormalities seen in 2 cases were not associated with 45,X/46,XX mosaicism. In the absence of prenatal ultrasound abnormalities, all were clinically normal. Mosaicism was not confirmed postnatally in 5 of the 14 prenatally diagnosed cases with 45,X/46,XY mosaicism. Postnatal cytogenetic analysis of 1 case determined an isodicentric Y chromosome previously reported as a normal Y chromosome. 12 cases were examined and found to be phenotypically normal male with no Turner syndrome stigmata. 2 cases with prenatal ultrasound abnormalities were prenatally diagnosed with non-mosaic 45,X. One was phenotypically female with streak gonads and gonadoblastoma while the other had ambiguous genitalia at birth. Prenatal counselling for 45,X/46,XX and 45,X/46,XY mosaicism in the absence of prenatal ultrasound abnormalities should take into account the expectation of a milder phenotype than that of patients ascertained postnatally. Postnatal confirmation of prenatal cytogenetic diagnosis is very important because a significant number of prenatally diagnosed mosaicism could not be documented postnatally. The present data suggest the need for follow up ultrasound examination of fetal genitalia and thorough cytogenetic and molecular analysis for Y chromosome material to rule out the possibility of 45,X/46,XY mosaicism in prenatally diagnosed cases with non-mosaic 45,X. We found no correlation between the proportion of 45,X cells in amniotic fluid and the presence or degree of abnormalities.

Prenatal detection of full and mosaic trisomy 9. Report of five new cases and review of the literature. *L. Turner¹, S. Langlois¹, L. Arbour¹, S. Lewis¹, M. van Allen¹, T. Pantar², G. Taylor², S. Yong¹*. 1) Department of Medical Genetics, University of British Columbia, Vancouver, Canada; 2) Department of Pathology, University of British Columbia, Vancouver, Canada. Children's and Women's Health Centre of British Columbia.

Trisomy 9 is a relatively uncommon chromosome abnormality that may be present in a mosaic or nonmosaic state. It involves a distinct pattern of dysmorphic features and congenital anomalies. Common facial findings include a sloping forehead, low set ears, and beaked nose. Other anomalies include heart defects, most commonly ventricular septal defects, renal and CNS anomalies. We report five new cases of trisomy 9 (4/5 cases with putative full trisomy 9 and 1/5 cases with mosaic trisomy 9). All cases were diagnosed prenatally. Two cases were ascertained due to a positive maternal serum screen for trisomy 18, two cases due to an abnormal fetal ultrasound, and one case because of an abnormal karyotype on amniocentesis, performed for maternal age indication.

We report the ultrasound (4/5) and embryopathology (4/5) findings of our cases in order to add to the described phenotype of trisomy 9. All cases in which a detailed ultrasound was done had ultrasound abnormalities. These abnormalities included various combinations of CNS (3/4), cardiac (2/4), thoracic (2/4), renal (2/4) and hand and foot (2/4) abnormalities. Additional findings at embryopathology were craniofacial dysmorphism (4/4), malrotation (1/4), coloboma (1/4), and uterine abnormalities (3/4). Anomalies seen which have been rarely reported in the literature included diaphragmatic eventration (2/3) and uterine abnormalities in three out of four females cases (didelphic uterus (2) and bicornuate uterus (1)). We describe our findings and also review published cases of prenatally detected trisomy 9. Our cases and those reported in the literature emphasize that fetuses with trisomy 9 have multiple anomalies that can be detected prenatally by ultrasound.

Blood lymphocyte chimerism associated with in vitro fertilization and monozygotic twinning. C.A. Williams¹, M.R. Wallace^{1,2}, K.C. Drury³, S. Kipersztok³, R.K. Edwards⁴, M.J. Haller⁵, D.A. Schatz⁵, J.H. Silverstein⁵, B.A. Gray¹, R.T. Zori¹. 1) Dept Pediatrics/Genetics, Univ Florida, Gainesville, FL; 2) Department of Molecular Genetics and Microbiology, Univ Florida, Gainesville, FL; 3) IVF Program and Laboratory, Division of Reproductive Endocrinology and Infertility, Univ Florida, Gainesville, FL; 4) Division of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, Univ Florida, Gainesville, FL; 5) Division of Endocrinology, Univ Florida, Gainesville, FL.

We report on dizygotic twins, conceived by IVF and intracytoplasmic sperm injection (ICSI) with assisted hatching, who each had a mixture of 46,XX and 46,XY cells in blood lymphocytes. The female twin had mild ambiguous genitalia but further study revealed anatomically normal reproductive anatomy. Chromosome and fluorescence in situ hybridization (FISH) studies of buccal, skin and ovarian tissue were normal as were buccal tissue DNA studies. Fetal ultrasound and fetal membrane pathology were consistent with a monozygotic, diamniotic placenta (MCDAP). These twins thus have blood chimerism but are not chimeric in the other tissues studied. The mechanism for the chimerism could be due to either placental vascular anastomoses (after the development of the hematoblast stem cells) or due to an admixture of trophoblast cells during early blastocyst development. Such trophoblast cell admixtures would be restricted to the extra embryonic tissues so that general physical development in the fetus is normal and without somatic cell chimerism. This case in combination with others previously reported suggests that in IVF conceptions, the prevalence of blood chimerism associated with twinning, and the occurrence of DZ twinning associated with MCDAP, is higher than previously thought.

Endometriosis and microchimerism: further expanding the association of fetomaternal cell trafficking and disease in women. *D.H. Cha^{1, 2}, K. Khosrotehrani¹, S.W. Lee², D.W. Bianchi¹, K.L. Johnson¹.* 1) Division of Genetics, Department of Pediatrics, Tufts-New England Medical Center, Boston, MA; 2) Department of Obstetrics and Gynecology, Kangnam CHA Hospital, Pochon CHA University, Seoul, Korea.

Objective. The use of fetal cells in maternal blood for genetic diagnosis has led to an appreciation of the persistence of fetal cells post-partum, creating a state of microchimerism. To date, microchimerism has been linked to some autoimmune disorders, tumors and infectious disease in women. Our objective was to determine whether fetal cell microchimerism is associated with the pathogenesis or progression of endometriosis.

Methods. Ovarian and tubal tissue were obtained from 5 women with endometriosis who had at least 1 live-born son. Control tissue was obtained from 5 women with endometriosis and no male births. Tissue sections were analyzed by FISH for the presence of male fetal cells, defined by the presence of X and Y chromosome signals. Immunolabeling using an epithelial cell marker (cytokeratin) and the leukocyte common antigen (CD45) was performed to determine the phenotype of the presumed fetal cells.

Results. Male cells were found in tissue from all five endometriosis patients with a history of male births. No male cells were found in tissue specimens from controls. Immunolabeling studies showed that 4.4% of XY cells (4/90) expressed cytokeratin and 63.3% of XY cells (57/90) expressed CD45.

Conclusions. Endometriosis may be associated with persistent fetal cells resulting from fetomaternal cell trafficking, with leukocytes being the predominant microchimeric cell type present. As previous experiments in our laboratory showed a lack of cytokeratin-positive cells in umbilical cord blood, it is also possible that some level of differentiation of pregnancy-associated progenitor cells has occurred in these women. These results further expand the potential relationship between fetal cell microchimerism and disease in women.

Cytogenetic and Molecular Analysis in male infertility. *R. Dada*¹, *N.P. Gupta*³, *K. Kucheria*². 1) Anatomy, AIIMS, New Delhi, India; 2) Anatomy and Genetics, AIIMS, New Delhi, India; 3) Urology, AIIMS, New Delhi, India.

In the last few years considerable progress has been made towards understanding sperm physiology and the biology of gamete interaction to understand the pathophysiology of male infertility. Three regions on Yq (AZFa, AZFb and AZFc) are critical for spermatogenesis. Deletions in AZF region can cause severe spermatogenic defects. These loci act at different stages of germ cell development and deletion of each loci result in a characteristic phenotype. In order to study frequency of AZF microdeletion and genotype phenotype correlation in infertile this study was undertaken. Idiopathic oligozoospermic and azoospermic cases were included in this study. Cytogenetic and semen analysis was done in each case. Testicular FNAC was collected whenever possible. On cytogenetic analysis Klinefelter Syndrome (KFS) was the major cytogenetic anomaly followed by mosaic KF, variant Klinefelter, and cases with other numerical and structural cytogenetic abnormalities. In cytogenetically normal cases (n=189) microdeletion analysis was done. Microdeletions spanning the AZF loci were found in a 6.3 percent cases (12 cases). Microdeletions were also found in one case with KFS which have not been reported yet. The FSH and LH levels were elevated in 8 of these cases with Yq microdeletion and in 4 cases were in the normal range. Thus raised FSH levels does not indicate presence of Yq microdeletion and low FSH does not indicate absence of Yq microdeletion. Thus Testicular FNAC is a must in all these cases. In one cases with Yq microdeletion cytogenetic analysis showed 46,XY and 45,XO mosaicism. Therefore presence of cytogenetic anomalies and detection of Yq microdeletions encompassing the AZF loci determines the prognosis and management of these infertile cases. All infertile men with normal or raised FSH levels should be counselled to go in for Yq microdeletion analysis. Also these infertile men with normal or low semen parameters have DNA damage secondary to other factors like oxidative stress and thus should be counselled of offspring being more prone to malignancies and having a much more severe testicular phenotype in addition to being infertile.

A rare case of possible 3:1 meiotic segregation and subsequent interchange trisomy 18 in a fetus whose mother carries a t(12;18)(p13.1;q21.1) translocation. *C.M. Coffeen¹, S. Bhatt¹, M. Thangavelu¹, D.B. Rogers¹, L.D. Platt^{2,3}.*
1) Genzyme Genetics, Orange, CA; 2) David Geffen School of Medicine at UCLA, Los Angeles, CA; 3) Center for Fetal Medicine and Women's Ultrasound, Los Angeles, CA.

A balanced reciprocal translocation can result in a variety of unbalanced products during gamete formation, depending on the segregation outcome. In meiosis I, the chromosomes involved in a translocation form a quadrivalent configuration to ensure maximum pairing of the homologous segments. The homologues subsequently segregate from each other in one of three possible ways: 2:2, 3:1 or 4:0 segregation. This meiotic behavior increases the risk for both structural rearrangements and whole chromosome aneuploidy in the offspring of carriers. We present the case of a 36 year-old G8 P4 SAb2 TAb1 woman, referred for genetic counseling at 10.4 weeks gestation for advanced maternal age and due to her karyotype of 46,XX,t(12;18)(p13.1;q21.1). Ultrasound a week later showed an increased nuchal translucency with total body edema, pleural and pericardial effusion, and an omphalocele. Cytogenetic analysis on CVS revealed an abnormal male karyotype [47,XY,t(12;18)(p13.1;q21.1)mat,+18], consistent with the diagnosis of trisomy 18. Given the poor prognosis, the patient elected to proceed with pregnancy termination. Our case represents a rare case of trisomy 18 known as interchange trisomy, which occurs secondary to 3:1 meiotic segregation of the patient's translocation during gamete formation. 3:1 segregation is most likely to occur when one of the whole chromosomes (normal or derivative) of the quadrivalent is small. In our case, both the normal chromosome 18 and der(18)t(12;18) are small when compared to the normal chromosome 12 and the der(12)t(12;18). Therefore, the origin of the additional chromosome 18, in this case, is most likely due to a 3:1 segregation in the mother, who is a carrier of the t(12;18). This case re-enforces the importance of considering the principles of segregation in estimating risk assessment to the offspring of translocation carriers.

Chromosomal abnormalities in 2078 infertile couples referred for assisted reproductive techniques (ART). G. Palka^{1,2}, P. Guanciali-Franchi^{1,2}, E. Clementini³, G.M. Tiboni³, C. Palka⁴, I. Iezzi^{1,2}, A. Di Tecco², E. Morizio², D. Fantasia^{1,2}, M. Marino¹, L. Stuppia¹, G. Calabrese^{1,2}, B. Dallapiccola⁴. 1) Dept Sci Biomediche, Univ G D'Annunzio, Chieti Scalo, Italy; 2) Genetica Umana, Ospedale Civile, Pescara, Italy; 3) Dept Medicina e Sci Invecchiamento/Ostetricia & Ginecol, Univ G D'Annunzio, Chieti Scalo, Italy; 4) CSS-Inst Mendel, Rome, Italy.

BACKGROUND: In this study the prevalence of karyotype changes and Yq11 microdeletions in a sample of couples referred for infertility was determined. **METHODS:** The studied population accounted 2078 couples ongoing treatment by either in-vitro fertilization (IVF) or intra cytoplasmic sperm injection (ICSI), in which both partners presented without any obvious phenotype related to some chromosomal changes. Cytogenetic investigation was performed on peripheral lymphocytes of both partners of each couple using GTG-banding technique. All the oligo/azoospermic men with normal karyotype were further investigated by PCR for Yq11 microdeletions. **RESULTS:** Eighty-two out of 2078 couples (3.95%) resulted to have one partner carrying a chromosomal change associated to poor gestation outcome or infertility. The frequency of the anomalies between sexes was similar, namely 42 and 40 anomalies among men and women, respectively. Ten out of 178 males studied for abnormal spermatogenesis showed Yq11 microdeletion (5.6 %). **CONCLUSIONS:** Chromosomal anomalies as translocations, inversions and complete gonosomal aneuploidies, which all may affect the reproductive fitness, recurred with a frequency greater than that reported in a large population of unselected newborns. Present data suggest that cytogenetic evaluation of couples candidate to ART is advisable, in order to identify couples at risk for poor gestational outcome.

Risk factors in abdominal wall defects. *B. Dott, M.P. Roth, C. Stoll.* Genetique Medicale, Faculte de Medecine, Strasbourg, France.

The aim of this study was to describe the prevalence at birth of two abdominal wall defects (AWD), omphalocele and gastroschisis and to identify possible etiologic factors. The AWD came from 320,984 consecutive births of known outcome registered in the registry of congenital malformations of Strasbourg for the period 1979 to 2002. Request information on the child, the pregnancy, the parents and the family was obtained for cases and for controls. Hundred twenty one cases with AWD were analysed, 55.4 % were omphalocele and 44.6 % were gastroschisis. The mean prevalence rate for omphalocele was 2.18 per 10000 and for gastroschisis 1.76 per 10000. Associated malformations were found in 74.6 % of omphalocele compared with 53.7 % of gastroschisis; 28.3 % of fetuses with omphalocele had an abnormal karyotype, 44.7 % had a recognizable syndrome, association or an unspecified malformation pattern; 51.8 % of fetuses with gastroschisis had additional malformations that were not of chromosomal origin, but 1 case. Antenatal ultrasound examination was able to detect 45 (67.2 %) cases of omphaloceles and 31 (57.4 %) cases of gastroschisis. In 35 (52.2 %) cases of omphalocele and in 8 (14.8 %) cases of gastroschisis parents opted for termination of pregnancy. The overall survival rate was 16 (23.9 %) for omphalocele and 35 (64.8 %) for gastroschisis. Weight, length and head circumference at birth of infants with AWD were less than those of controls. The weight of placenta of infants with AWD was not different from the weight of placenta of controls. Gastroschisis was associated with significantly younger maternal age than omphalocele. Pregnancies with AWD were more often complicated by threatened abortion, oligohydramnios and polyhydramnios.

Fertility potential in the cryptorchid male using spermatozoal gene expression microarray analysis. M.T.

Nguyen¹, V.G. Cheung², M. Morley², K. Wagner¹, D.P. Delaney¹, S.A. Zderic¹, T.F. Kolon¹. 1) Urology, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Pediatrics, The Children's Hospital of Philadelphia, Philadelphia, PA.

Cryptorchidism, failure of testicular descent, is associated with male infertility. Previously thought to be transcriptionally dormant, recent studies suggest spermatozoal RNA as a measure of past events during spermatogenesis. Using microarray analysis, we sought to identify significant differential gene expression patterns between adolescent males with a history of corrected cryptorchidism and normal control patients. Ejaculates were collected and a semen analysis performed on 10 control patients (normal urogenital history/exam and semen analysis by WHO criteria) and 5 cryptorchid male (3 bilateral, 2 unilateral). Motile sperm were separated from round cells and nonmotile sperm by two rounds of Percoll centrifugation, the total RNA extracted and verified using sperm-specific RT-PCR. Biotin-labeled amplified RNA was hybridized to Affymetrix Human Genome Focus Arrays, according to the Affymetrix protocol. To identify genes that are differentially expressed between sperm from cryptorchid and control patients, permutation *t* test was performed. Median semen volume was not significantly different between control and cryptorchid patients (2.1 vs 3.0 cc, $p=0.56$). Median sperm density was markedly decreased in the cryptorchid group (94 versus 10 million/cc, $p=0.06$). From the microarray expression data, we identified 91 genes/ESTs differentially expressed (permutation $p < 0.01$) between the two groups. Of these, 55 genes were under-expressed in the cryptorchid samples including a testis-specific gene (Tpx-1) involved in spermatogenic-Sertoli cell adhesion. An epididymal-specific protein (WFDC2) involved with spermatogenesis was found to be significantly over expressed in the cryptorchid patients, as well. Using microarray analysis we have identified a set of genes which are significantly under- and over-expressed in males with a history of cryptorchidism compared to normal controls. Verification with real-time PCR will aid in gaining insight into the global genetic changes that occur with cryptorchidism.

A NEWBORN BABY PRESENTED WITH SHORT EXTREMITY, THROMBUS AND MTHFR C677T

MUTATION. *N. Ozbek¹, F.B. Atac², E. Ozyurek¹, A. Tarcan¹, H. Verdi², F.I. Sahin², B. Gurakan¹*. 1) Pediatrics, Baskent University School of Medicine, Ankara-Turkey; 2) Medical Biology and Genetics, Baskent University School Of Medicine, Ankara-Turkey.

Hyperhomocysteinemia is a known risk factor for cerebrovascular, peripheral vascular, coronary heart diseases and thrombosis. Heterozygosity and/or homozygosity for mutations in the enzymes involved in homocysteine metabolism may confer an increased risk for thrombosis by leading to hyperhomocysteinemia. A common mutation in methylenetetrahydrofolate reductase (MTHFR) C677T has been known to result in increased plasma homocysteine levels thus causing a predisposition to thrombosis. We hereby report a newborn with thrombosis who is heterozygous for MTHFR C677T. The newborn was a term baby presented with right lower extremity 2 cm shorter than the left. His mother was homozygous for MTHFR C677T mutation. Thrombosis involving right iliofemoral artery was shown immediately after birth. His arterial occlusion was dilated by balloon angioplasty and patent flow was established. Anticoagulation was started with low molecular weight heparin. However, he died with sudden infant death at home when he was 28 days old. No etiologic factor was figured out except heterozygous MTHFR C677T mutation. We exclaim that the thrombotic process in this particular case has been started in utero. Despite he did well with antithrombotic treatment, sudden infant death may be induced by a fatal thrombotic problem yet not proven by postmortem study due to rejection of consent.

First trimester ultrasound diagnosis of lethal multiple pterygium syndrome. *J. Pierre-Louis¹, K. Fong², M. Gundogan², S. Keating³, D. Chitayat¹.* 1) Prenatal Diagnosis Medical Genetics; 2) Departments of Diagnostic Imaging; 3) Laboratory Medicine & Pathobiology, Mount Sinai Hospital, University of Toronto, Toronto, ON, Canada.

Lethal multiple pterygium syndrome (LMPS) is a rare autosomal recessive condition, with a recurrence risk of 25 percent. The gene/genes causing this likely genetically heterogeneous condition have not yet been delineated. We report a first trimester prenatal diagnosis of LMPS. A 38-year-old G5P2SA1SB2L1 woman was seen at 12 weeks gestation. The non-consanguineous, Ashkenazi-Jewish couple's first pregnancy resulted in spontaneous miscarriage. The second pregnancy resulted in dizygotic twins. Detailed ultrasound performed at 18 weeks gestation showed cystic hygroma, webbing and contractures of the knees and elbows, with poor movements in one twin. This twin died at 24 weeks gestation. Autopsy showed severe maceration, dysmorphic facial features, nuchal thickening, multiple flexion contractures and pterygia, kyphoscoliosis, rocker bottom feet, hypoplastic aortic arch, hypoplastic lungs and ambiguous genitalia. These findings were consistent with LMPS. The remaining twin had no apparent abnormality and was delivered at 31.5 weeks following PROM. The couple's third pregnancy had decreased fetal movements on the 24 weeks fetal ultrasound and intrauterine death occurred at 27.5 weeks gestation. Autopsy revealed a female fetus with the same findings as the previous fetus, consistent with LMPS. The patient subsequently had a ruptured ectopic pregnancy. In the couple's present pregnancy, fetal ultrasound at 12 weeks showed a markedly increased nuchal translucency and bilateral flexion deformities of the elbows, wrists, hands and knees. No limb movements were observed during the entire 30-minute examination. The parents requested termination of pregnancy by D&C. Pathology of the intact fetal parts showed flexion deformity of the right elbow with a cutaneous web, contracture deformity and ulnar deviation of the right wrist, and a cleft palate. These findings confirmed LMPS. Thus, first trimester fetal sonography is a practical and reliable method for early prenatal diagnosis of LMPS.

Descriptive epidemiology of birth defects in Malaysian births: a population-based study. *M.K. Thong¹, J. Ho², N. Noor Khatijah³*. 1) Dept Pediatrics, University of Malaya Medical Ctr, Kuala Lumpur, Malaysia; 2) Perak College of Medicine, Ipoh, Malaysia; 3) Hospital Ipoh, Perak, Malaysia.

Data on birth defects from population-based studies originating from developing countries are lacking. The objectives of this study are to determine the epidemiology of birth defects and to identify risk factors for major birth defects in Malaysian births from 22 weeks gestation till one week of life, delivered at the Kinta district, Perak, Malaysia over a 14-month period using a case-controlled population-based birth defect register. Results: There were 253 babies with major birth defects in 17720 births, giving birth prevalence of 1 in 70 (1.43%) (95% CI: 0.87-1.99). The exact syndromic diagnosis of the babies with multiple birth defects could be identified in 62 (77.5%) babies. Isolated major birth defects were cardiovascular (13.8%), cleft lip and palate (11.9%), clubfeet (9.1%) and central nervous system abnormalities (7.9%). The babies with major birth defects were lighter, more premature, had higher Caesarean section rates, required prolonged hospitalization and more specialist care and had a perinatal mortality rate of 25.2%. Mothers with affected babies were older, had birth defects themselves or in their relatives, had a consanguinity rate of 2.4%, and had higher rates of previous abortions. Risk factors identified for birth defects using multivariate logistic regression were maternal insulin-dependent diabetes, previous abortions, maternal recall of exposure to teratogens during pregnancy but not lack of periconceptional folate supplementation. Conclusions: Further investigations are required to investigate the role of periconceptional folate supplementation and to confirm the above findings. Pre-natal screening for insulin dependent diabetes, counselling and investigating causes for previous abortions and public education on avoidance of teratogens may reduce birth defects in this population. A Birth Defect Register must be set up to monitor these developments in Malaysia.

Fetal Therapy: Thoracoamniotic Shunt for Macrocystic Congenital Cystic Adenomatoid Malformation of the Lung (CCAM). *R.D. Wilson^{1,2}, M.P. Johnson^{1,2}, A.W. Flake^{1,2}, H.L. Hedrick^{1,2}, T.M. Crombleholme¹, M.W. Bebbington^{1,2}, N.S. Adzick^{1,2}.* 1) Ctr Fetal Diag/Treatment/Wood, Children's Hosp Philadelphia, Philadelphia, PA; 2) University of Pennsylvania Philadelphia PA.

Objective: To retrospectively review prenatally diagnosed fetuses with macrocystic CCAM that underwent thoracoamniotic shunting(TAS) in-utero therapy and determine the pregnancy and neonatal outcome . Methods: Retrospective chart review(1998-2003) from a single treatment center was undertaken for fetuses with prenatally diagnosed macrocystic CCAM that underwent TAS. Prenatal,delivery,postnatal factors and perinatal mortality were evaluated. Results: Total 23 cases were identified. Lung right 11,left 12; male 17,female 6; hydrops 18; polyhydramnios 11; both 9; mean gestational age(weeks) at diagnosis 22.3, shunt 24.1, delivery 36.3 with mean interval shunt to delivery of 11.8 weeks. Pre and post shunt mean CCAM volume was 70.8cc and 22.7 cc respectively. Mean CCAM volume/head circumference ratio pre and post was 2.4 and 0.7 respectively (69% reduction).Delivery was vaginal 14 , primary C/S (EXIT) 8(3) ,and repeat C/S 1. EXIT delivery with fetal thoracotomy was used in 3 cases due to risk of severe respiratory compromise at birth. Perinatal outcome was live born 22, intrauterine death 1, and neonatal death 5 . Survival was 17/23 (74%)with perinatal loss 6/23 (26%).Shunt to delivery interval for survivors was 77 days compared with 20 days for neonatal death outcome .There was no gender factor for perinatal loss(Fischer's ExactTest 2-tail 0.14)as all 6 deaths were male.All macrocystic CCAM required resection within 72 hours ,majority within 48 hrs due to air trapping and pneumothorax. Conclusion: CCAM size or laterality was not predictive of outcome . Perinatal mortality was 26% in this cohort of shunted macrocystic CCAM . Delivery of the fetus in a tertiary center with MFM/OB, neonatal and pediatric surgery MD's is necessary due to the respiratory risk factors and urgent surgery required after birth.Thoracoamniotic shunt placement should be considered as a treatment option for fetuses with macrocystic CCAM and hydrops+/- polyhydramnios .

Stepwise implementation of enhanced prenatal screening in Southwestern Ontario. *C. Campagnolo¹, S. Tokmakejian^{1,2}, R. Gagnon^{1,2}, J-A. Kane¹, K. Corley¹, D. Munavish¹, V.M. Siu^{1,2}.* 1) Medical Genetics Program of Southwestern Ontario, London Health Sciences Centre; 2) University of Western Ontario, London, ON, Canada.

Triple marker maternal serum screening for Down syndrome was introduced in Ontario in 1993. With new developments, there has been an impetus to incorporate improved screening practices into the existing program. Southwestern Ontario has a population of 1.7 million, with 40% of its population living in rural areas where access to specialized ultrasound is limited. Any improvement in prenatal screening should address the needs of the entire catchment area. In April 2003, dimeric inhibin-A (DIA) was readily added to the existing triple screen (AFP, uE3, hCG), using a 1:260 risk cut-off at term. In December 2003, after intensive community and physician education, serum-only 5-marker screening was initiated, combining first trimester pregnancy associated plasma protein-A (PAPP-A) with second trimester quadruple screen, using a 1:200 risk cut-off. As certified nuchal translucency (NT) measurements became available, more women have had access to full IPS (PAPP-A, NT, AFP, uE3, hCG). With enhanced screening, a change in the magnitude of risk reported for Down syndrome was noted - positive screens tend to have higher risks and negative screens have lower risks than with the triple screen. The reported risks have been helpful in decision-making about invasive testing. The number of women choosing to have prenatal screening for Down syndrome has increased by 22% over the past year. We hypothesize that this is due to greater acceptance and increased awareness of enhanced screening. The Medical Genetics Program of Southwestern Ontario has successfully initiated an enhanced prenatal screening program for Down syndrome through stepwise implementation, providing accessibility to improved screening for all pregnant women in its catchment area within a short time period.

Eugenics revisited: testing the limits of prenatal diagnosis. *R.R. Lebel, G.F. Guzauskas.* Greenwood Genetic Ctr, Greenwood, SC.

The roots of eugenics run deep in the culture of science and society, the word having been coined by Charles Darwin's cousin Francis Galton a century ago. As with philosophy, art, education, religion, politics, and science itself, its positive pursuit is some practical improvement of humankind. When ideologic agenda are superimposed on such pursuits, the outcomes are highly problematic. Indeed, the word eugenics is frequently treated like an obscenity. Warnings about the eugenic implications of prenatal diagnostics have been on hand since the techniques were new, exemplified by such heroes of our field as Jerome Lejeune in his Allan Award address (1969). However, Charles Epstein, a contemporary leader in genetics, could without blushing employ this vocabulary word in his Allan Award address (2001). Direct to consumer marketing of genetic tests has further complicated this dialogue by legitimizing availability of tests for conditions with moderate or indeterminate pathologic implications. This exacerbates the real or perceived "commodification" of children, violating many of our ethical commitments. Consequently, genetic counseling becomes more challenging as we encounter requests for testing (implying consequent selective pregnancy termination) aimed at traits that professional geneticists doubt are appropriate justifications for such actions. A well known example of this is sex selection on social grounds; a new example is testing for late-onset health problems that are amenable to medical amelioration and management. This problem has been noticed in the popular press, as talk of designer babies gains currency while geneticists had been accustomed to treating the idea as fanciful or hyperbolic. Any effort of genetics professionals to control such a trend appears likely futile. Perceived competition between public (consumer) goals for acceptable or desirable babies, and the professional (geneticists) desire for ethical integrity, can be a source of tension in the clinical setting. We will present suggested pathways toward a more optimistic response, one that reduces that tension.

A prenatal analysis of spinal muscular atrophy in 312 Italian families: evidence for a SMA 0 phenotype? A.

Tacconelli¹, A. Botta¹, I. Bagni¹, E. Giardina¹, F. Capon^{1,2}, G. Novelli¹. 1) Dept Biopath, Tor Vergata Univ, Rome, Italy; 2) Div of Medical Genetics, Univ of Leicester, Leicester, UK.

BACKGROUND: Spinal muscular atrophy (SMA) is a recessive neurodegenerative disorder, characterized by the loss of motor neurons in the spinal cord and death of motor neuron cells. SMA occurs with a frequency of 1 in 10,000 live births with a carrier frequency of 1 in 50 and is the leading genetic cause of infant mortality. Based on age of onset and severity of the disease, SMA patients are classified as type I, II, or III. All three forms of SMA are caused by loss or mutation of the telomeric survival motor neuron gene (SMN1) which is deleted in almost 95% of SMA patients. Prenatal diagnosis of spinal muscular atrophy is usually performed in high risk couples by detection of a homozygous deletion in the survival motor neurone gene (SMN1) and linkage analysis with microsatellites markers in the 5q13 region. **OBJECTIVES:** In our study, we determined the frequency of transmission of the disease-allele using data from our ten years experience in prenatal molecular studies of 312 Italian families. **METHODS:** foetal DNA was extracted by chorionic villus samples from high risk SMA pregnancies. Homozygous deletion of SMN1 exons 7 and 8 were detected by PCR and restriction analysis with DraI and DdeI enzymes as described (van der Steege et al., 1995). Linkage analysis with a set of microsatellites markers across the SMN region was performed in all families to confirm the direct results and to exclude maternal cells contamination. **RESULTS:** of 312 fetuses analysed, 118 were homozygous for the wild type allele (37,8%), 131 were carriers (42%) and the remaining 63 resulted homozygous for the mutated allele (20,2%). Chi square analysis demonstrated that frequency of transmission of the mutated allele is statistically deviant from the 50% expected in autosomal recessive disorders ($p=0.0026$). **CONCLUSIONS:** This study indicate a preferential transmission of the wild type SMN1 alleles in SMA pregnancy. We speculate that this observation is the consequence of an excess of embryonic lethality of SMN1 $-/-$. If this effect is a consequence of a complete absence of SMN products remain to be defined.

Fetal muscle biopsy for diagnosis of nemaline myopathy - a case report. *S.B. Kasperski¹, A.M. Brennan², J.E. Corteville², R.S. Finkel¹, J. Golden¹, M.P. Johnson¹, R.D. Wilson¹.* 1) Children's Hospital of Philadelphia, PA; 2) Metro Health Medical Center, Cleveland, OH.

Introduction: Nemaline myopathy is a rare, genetically and phenotypically heterogeneous congenital myopathy characterized by varying degrees of hypotonia and muscle weakness. Its diagnostic hallmark is the presence of rod-shaped "nemaline bodies" in the sarcoplasm of skeletal muscle. Five genes have been identified, all of which encode protein components of the muscle thin filament.

Fetal muscle biopsy can be informative in delineating the status of a fetus at risk for a congenital myopathy or dystrophy when less invasive diagnostic testing is negative or non-specific. We report the first known muscle biopsy characteristic of nemaline myopathy.

Case: A 43 year-old G3P2 female of Syrian descent was referred for fetal muscle biopsy for a history of nemaline myopathy. Specifically, the consanguineous couple's daughter was diagnosed with nemaline myopathy at age 3 by muscle biopsy. Her clinical course is characterized by infantile hypotonia, weakness and developmental motor delay. Molecular testing was undertaken and was uninformative. CVS performed in the first trimester of pregnancy revealed a normal karyotype.

Results: Fetal gluteal muscle biopsy was undertaken under ultrasound guidance at 22 weeks gestation. There were no apparent complications. Results were compatible with nemaline myopathy based on both histology and ultrastructural examination. With this information, the patient elected to terminate the pregnancy at 23 weeks gestation.

Conclusion: Pathologic changes characteristic of nemaline myopathy can be identified in second trimester fetal skeletal muscle tissue.

Higher contribution of gamma globin to the pool of circulating fetal RNA following intervention in complicated pregnancies. *M.L. Tjoa¹, K.L. Johnson¹, J. Jani², L. Lewi², J. Deprest², D.W. Bianchi¹*. 1) Dept. of Pediatrics, Division of Genetics, Tufts-NEMC, Boston, MA; 2) Dept. of Obstetrics and Gynecology, University Hospital Gasthuisberg, Leuven, Belgium.

Background: Fetal cell-free (CFF) mRNA in maternal blood can be isolated, amplified, and used for clinical applications. It is unknown whether the placenta or the fetal circulation is the main tissue source of CFF-mRNA. In this study, we assessed the levels of placenta-derived and fetal blood-derived CFF-mRNA in pregnant women undergoing treatment for twin-twin transfusion (TTTS) and polyhydramnios.

Methods: Plasma samples were collected from 6 non-pregnant female controls and 7 pregnant women before treatment, 30 minutes, one hour, 24 and 48 hours following obstetrical intervention. Cell-free mRNA was isolated and used for quantitative RT-PCR to determine levels of glyceraldehyde-3-phosphate dehydrogenase (GAPDH), gamma globin and human placental lactogen (hPL) as markers for total cell-free mRNA, fetal hemoglobin and placental mRNA, respectively.

Results: Median levels of gamma globin mRNA were significantly higher than the median levels of hPL mRNA in all patients at all time points (Wilcoxon signed rank test, $p < 0.05$). In general, median GAPDH, gamma globin and hPL mRNA levels remained stable pre- and post-procedures. However, in one woman being treated by bipolar cord procoagulation for TTTS, all 3 mRNA levels increased post-procedure. No hPL was detected in control women.

Discussion: This study shows that fetal blood contributes more significantly to the pool of CFF-mRNA than the placenta in some clinical settings. Moreover, interventional treatment does not appear to affect levels of CFF-mRNA, which is in contrast to our previous study demonstrating elevated levels of CFF-DNA following laser ablation treatment of TTTS (AJOG 2004, in press).

Placental Volume Measured by 3D Sonography Does Not Predict Levels of Maternal Plasma Cell-Free Fetal DNA during the First Trimester. *T. Wataganara*¹, *M. Metzenbauer*², *I. Peter*³, *K.L. Johnson*⁴, *D.W. Bianchi*⁴. 1) Div of Maternal-Fetal Med, Dept of Ob/Gyn, Siriraj Hospital, Mahidol University, Bangkok; 2) Ludwig Boltzmann Inst for Clinical Ob/Gyn, Danube Hospital, Vienna; 3) Inst of Clinical Research and Health Policy Studies, Tufts-New Engl Med Ctr, Boston, MA; 4) Div of Genetics, Dept of Pediatrics, Tufts-New Engl Med Ctr, Boston, MA.

Background: Measurement of cell-free fetal (cff) DNA in maternal plasma may have clinical applications in prenatal diagnosis of Down syndrome and pre-eclampsia. Little is currently known regarding the tissue of origin of these fetal sequences. We tested the hypothesis that if the placenta is the major contributor of circulating cff DNA, then increased placental volume should be associated with higher maternal plasma cff DNA levels. **Material and Methods:** We enrolled 143 pregnant women who underwent first trimester placental volume measurements using three-dimensional ultrasonography. Maternal peripheral blood samples were drawn on the day of the scan. Cff DNA in maternal plasma was quantified by real-time PCR amplification of a Y chromosome sequence. The association between the measured placental volume and maternal plasma cff DNA level was analyzed along with relevant clinical variables. **Results:** The median (25th, 75th percentiles) maternal plasma cff DNA level was 16.9 genome equivalents/mL (10.8, 28.7). We found an association between the DNA levels, gestational age, and body mass index (BMI) of the subjects; therefore, adjustment for these factors was performed prior to further analysis. The median placental volume, as measured by 3D sonography, was 53.2 mL (43.0, 64.7), and the median placental quotient (i.e. the ratio between placental volume in mL and fetal crown rump length in mm) was 1 mm^2 (0.8, 1.1). Based on linear regression analyses, neither of the above placental measurements showed a significant association with plasma cff DNA levels. **Conclusions:** Our results did not show a significant association between either placental volume or placental quotient and maternal plasma cff DNA levels. We speculate that the extent of apoptosis within the placenta primarily affects the amount of cff DNA released into the maternal circulation.

Complete characterisation of a marker chromosome by chromosome microdissection, reverse and forward chromosome painting. *F. Mahjoubi*^{1, 4}, *A. Daniel*², *G. Peters*², *P. Malafiei*², *R. Hill*⁴, *A. Turner*³. 1) Dept Clinical Genetics, NIGEB, Tehran, Iran; 2) Cytogenetics Dept., Western Sydney Genetics Program, The New Children Hospital Westmead, NSW, Australia; 3) Medical Genetics Dept., Sydney Children Hospital, Randwick, NSW; 4) Division of Molecular Science, CSIRO, North Ryde, NSW 2113 Australia.

A small, mosaic, C-band negative marker chromosome was detected on culture of amniocytes during prenatal diagnosis related to advanced maternal age. Following spontaneous premature labour at 29 weeks gestation, a dysmorphic infant was delivered, with flat nasal bridge, short palpebral fissures, micrognathia, high forehead, low-set ears, telecanthus and corneal dystrophy. Additional folds of skin were present behind the neck, and feet and fingers and toes were abnormally long. The child died at age five days, after two days in renal failure. The origin of the marker chromosome was subsequently identified from a cord blood sample, via chromosome microdissection. Through reverse FISH, we found the marker to be an inverted duplication of the region 15q26.1-qter. FISH with alphoid satellite probe was negative, while whole chromosome 15 paint was positive. Both ends of the marker were positive for the telomeric TTAGGG probe. These data, plus the G-banding pattern, identified this as an alphoid, inverted duplicated marker, lacking any conventional centromere. We discuss the aetiology and clinical effects of this marker, comparing it to the few other reported cases of tetrasomy 15q syndrome. We also discuss the possible mechanisms that are likely responsible for this neocentromere formation.

Rapid clearance of mRNA for PLAC1 gene in maternal blood after delivery. *P. Carinci, M. Concu, I. Banzola, M. Marini, E. Caramelli, F. Pezzetti, A. Farina.* Dept of Histology and Medical Embryology, University of Bologna, BOLOGNA, Italy.

The objective of this paper was to evaluate (1) whether the presence of mRNA for the specific trophoblast gene PLAC1 in maternal whole blood is pregnancy-specific, and (2) whether delivery would result in the clearance of mRNA from maternal blood. Sixteen pregnant women at term (41 completed weeks gestation) were enrolled in the study. Blood samples were obtained before the onset of labor and 24 hr after delivery. Eight healthy donors (3 males and 5 non-pregnant women) were used as controls. Total RNA was extracted by means of ABI PRISM 6100. A quantitative evaluation was obtained by means of real-time PCR. Wilcoxon test was used to evaluate differences between time intervals. Median concentrations of PLAC1 mRNA relative to the standardization curve were 44 (2.9-675) ng/mL, and 0.48 (0.05-10.7) ng/mL respectively for pre- and after- delivery samples. Male and non-pregnant female controls did not show any signal of cDNA amplification. In conclusion, mRNA transcripts from a placenta-expressed specific gene is detectable in maternal blood and rapidly disappears after delivery. Such an mRNA provides a gender-independent marker for non-invasive prenatal gene expression profiling, and can open new prospective to monitor those conditions associated to trophoblast damage as well as preeclampsia.

High-throughput gender typing using SNP genotyping technology. *T. Bettecken¹, P. Lichtner¹, T. Strom¹, S.K. Shernan², A.A. Fox², C.D. Collard³, T. Meitinger¹, S.C. Body².* 1) Human Genetik, GSF Forschungszentrum, Neuherberg, Germany; 2) Brigham and Women's Hospital, Boston, MA; 3) Texas Heart Institute, Houston, TX.

Molecular genetic typing of gender in mammals and humans has been a longstanding issue. It has its importance by numbers in animal breeding. In humans, it is widely employed in prenatal diagnosis, especially for X chromosomal recessive conditions, but also for quality control of tested materials and forensic identification. Established methods for DNA based gender typing largely rely on FISH signals of the Y and X chromosomes and on the selective amplification and visualization of either Y chromosomal loci or XY homologous regions differing in size of PCR products. With the advent of high-throughput SNP genotyping, an opportunity exists for gender identification of large numbers of samples. The assignment of a genotypic gender to a sample in the very end of the entire genotyping process allows genotypic matching to the phenotypic gender of the proband, thus considerably reducing the probability of sample mix-up, although not completely excluding them. The female/male respectively XX/XY distribution pattern on the microtiter plates entering the high throughput SNP genotyping process is a characteristic feature of the plate batches and allows unequivocal plate batch identification and potential, although not complete, recognition of sample mix-up. We present selected markers from genes on the X chromosome and their respective pseudogenes on the Y chromosome which can serve for DNA based gender identification using high-throughput MALDI-TOF, and other technology, genotyping, together with validation data from more 1000 individuals. Five non-homogenous single base pair markers were identified within the AMELX/AMELY and GYG2/GYG2P gene pairs that had sufficient sequence similarity to allow MALDI-TOF typing. Call rates for markers were between 88.6% and 99.5% (median 94.8%) with complete genetic agreement for all assigned genotypic genders. Two phenotypic genders did not match genotypic gender assignment. Both samples were processed back-to-back and were presumably inadvertently mislabelled.

Distribution of IVS8-PolyT genotypes in an archived Cystic Fibrosis patient population affirms separate testing of reflex alleles. *A.G. Hadd, I. Wolf, J. Brown, C. Novak, C.R. WalkerPeach.* Ambion Diagnostics, Austin, TX.

PURPOSE: The purpose of this study was to associate the distribution of 5/7/9T alleles with 25 common mutations in the CFTR gene using archived DNA from a CF patient population. **METHODS:** A set of 350 affected and unaffected CF patient samples from a Minnesota clinic, archived between 1986-1994, were analyzed for 25 primary CF mutations plus PolyT reflex alleles. Amplicons for primary mutations and reflex alleles were generated in a single-tube multiplex PCR and analyzed by bead-array hybridization with allele-specific capture probes. Two separate arrays, a 52-bead array for primary mutations and a 7-bead array for PolyT reflex alleles, were used to analyze unpurified, biotinylated amplicons. Four exogenous internal fluorescence control beads were included to facilitate software background and variance calculations. Following hybridization and addition of a reporter fluorophore, normal, mutant (disease indicating), and polymorphic alleles were detected using a Luminex platform. Results from the two arrays were automatically processed and linked through database management software. Unique genotypes were confirmed by DNA sequencing. **RESULTS:** The detection of primary and reflex panel alleles within a CF patient population was demonstrated using direct hybridization to separate bead-arrays. In the 700 chromosomes analyzed, a prevalence of 5.5% for 5T and 35.5% for 9T alleles was observed. The 16 samples that were 5T/7T heterozygous were wild-type normal for the primary 25 CFTR mutations tested. Conversely, two R117H heterozygous samples were 7T homozygous. Of the samples that were deltaF508 heterozygous, 99% (71/72) were detected with a 9T allele. For deltaF508 homozygous samples, 38 of 40 were homozygous 9T. **CONCLUSIONS:** The distribution of 5/7/9T alleles was associated with primary mutations detected in a CF patient population. Within this CF patient population, deltaF508 alleles were predominately associated with 9T, and an expected prevalence of 5T alleles was observed. That none of the 5T alleles were associated with a severe CF mutation affirmed the separate reflex testing recommendations for PolyT.

High frequency of carriers for maple syrup urine disease in the Ashkenazi Jewish population. *R. Kornreich, L. Edelmann, G.A. Diaz, R.J. Desnick.* Dept Human Genetics, Mount Sinai School Medicine, New York, NY.

Maple Syrup Urine Disease (MSUD) is an autosomal recessive inborn error of metabolism caused by the deficient activity of the mitochondrial multienzyme enzyme complex, branched-chained--ketoacid acid dehydrogenase (BCKD). The BCKD complex includes four proteins encoded by the E1, E1, E2 and E3 genes. As E3 is also a component of the pyruvate dehydrogenase and -ketoglutarate dehydrogenase complexes, mutations in this subunit result in a distinct phenotype that includes lactic acidosis and branched-chain amino acidemia. Mutations in the E1 or E2 genes can cause classic, intermediate, or intermittent MSUD. Newborn screening for MSUD is currently available in 31 states, but despite early diagnosis and dietary therapy, episodes of potentially life-threatening decompensation occur with metabolic stress or infection. Although MSUD is a pan-ethnic disorder, it is more frequent in the Ashkenazi Jewish (AJ) population. In previous studies of MSUD mutations in seven AJ patients in our clinic, three E1 gene mutations (R183P, G278S and E422X), and one E2 gene mutation (E2delAT) were detected, accounting for all mutant alleles. Until now, prenatal carrier screening for this disease in the AJ population has not been routinely performed despite its increased incidence. Therefore, the carrier frequency of each of these mutations was determined by allele-specific oligonucleotide hybridization in over 1,100 anonymous AJ individuals. The combined carrier frequency for the three E1 gene mutations in this population was 1/81. Of note, only a single carrier of the E2delAT mutation (1/1125) was identified. These pilot studies suggest that prenatal carrier testing for the E1 mutations R183P, G278S and E422X will detect >99% of MSUD E1 gene mutation carriers in the AJ population, providing a prenatal carrier screening assay with high detectability.

Adaptation of a Cystic Fibrosis mutation panel to incorporate population-specific alleles. *C.R. Novak, A. Hadd, J.T. Brown, C. WalkerPeach.* Ambion Diagnostics, Austin, TX.

PURPOSE: To adjust quickly to changing genetic testing recommendations and incorporate newly revealed population-specific CF indicating alleles, a bead-array testing platform was examined. Within the CFTR gene, densely positioned mutations provide unique challenges to rapid CF testing strategies. The purpose of our study was to expand a current CF carrier-screening assay for the inclusion of European population-specific alleles (3905insT, Y1092X, E60X, S549N, 2183delAA>G, Q493X, 3199del6) without detriment to the original assay. **METHODS:** A single-tube multiplex PCR for CFTR alleles was expanded from 19 to 24 amplicons. The PCR was optimized for 10-500ng of genomic DNA purified from whole blood. Detection of added mutations was accomplished by including additional allele-specific capture probes conjugated individually to fluorescently addressed microspheres. Multiplexed PCR products were directly hybridized to the bead-array (without secondary amplification or purification). Samples were analyzed for 32 mutations in 15 seconds per patient with results automatically processed for allele ratio and genotype. **RESULTS:** The expandability and resolving power of the bead-array screening approach is best demonstrated with the mutations of Exon 11. Nine capture probes were designed to resolve 4 normal and 5 mutant alleles within a single 126-bp amplicon. Despite constraints of overlapping probe sequences, successful discrimination of S549N was implemented while maintaining fluorescence values greater than 10 times that of the variance of the background. Detection of the preexisting alleles G542X, G551D, G553X, and R560T was unaffected. The assay remained at 50 minutes of hands-on time (18% of total workflow) despite the addition of 7 population-specific alleles. **CONCLUSIONS:** Using multiplex PCR, bead-array hybridization and Luminex detection, a set of 25 CF mutations was expanded to 32 with successful detection. Data generated supports the expandability of genetic screening assays designed on the Luminex platform. This enables screening assays to be modified quickly for compliance with changing policies and modified recommendations of population-specific alleles.

Canavan pregnancy following use of a gamete donor. A case report. *D.B. Rogers¹, M. Kohan¹, S. Bhatt¹, H. Danzer², L.D. Platt³.* 1) Genzyme Genetics, Orange, CA; 2) Southern California Reproductive Center, Beverly Hills, CA; 3) Center for Fetal Medicine and Woman's Ultrasound, David Geffen School of Medicine at UCLA, Los Angeles, CA.

The growing use of assisted reproductive technologies (ART) and preimplantation genetic diagnosis (PGD) have broadened the field of specialists who must be cognizant of screening for genetic disease. Our case demonstrates the need to apply the principles of genetic screening to gamete donors based on family history and ethnicity. A 49-year-old Ashkenazi Jewish (AJ) woman and her 48-year-old AJ spouse conceived via ovum donation, and IVF with ICSI. PGD to detect chromosomal aneuploidy was performed on viable embryos prior to the successful implantation of a single embryo. An abnormal Expanded AFP screen brought the couple in for genetic counseling and second trimester ultrasonography. At that time genetic screening of the father found him to carry a mutation for Canavan disease. Although the AJ egg donor was screened negative for cystic fibrosis she had not been screened for other diseases based on her ethnicity. Amniocentesis revealed a chromosomally normal female with normal AFP. However, the fetus was found to carry two copies of the E285A mutation for Canavan disease. Canavan testing was recommended on the egg donor, but she was unavailable. Biochemical testing of the amniotic fluid confirmed that the fetus was affected with Canavan disease. Molecular analysis on fetal DNA ruled out uniparental disomy as a cause of Canavan disease in the fetus. The patient elected to terminate the pregnancy. The growth of ART through fertility specialists and the increased association with programs that offer gamete donation have necessitated a greater awareness of recommendations for genetic screening based on ethnicity and family history. In 1998 both the ACMG and ACOG recommended that persons of AJ descent be offered carrier testing for Canavan disease preferably before pregnancy. This tragic case demonstrates the essential requirement of screening prospective gamete donors before they become donors.

Neonatal detection of the 35delG mutation of the GJB2 gene in Brazil. *E.L. Sartorato¹, C.A. Oliveira¹, A.T. Maciel-Guerra².* 1) Lab de Genética Humana/CBMEG - UNICAMP, Campinas - SP, Brasil; 2) Depto. Genética Médica/FCM - UNICAMP, Campinas - SP, Brasil.

Mutations in GJB2 gene represent a major cause of congenital deafness, and a single mutation 35delG accounts for the majority of nonsyndromic hearing loss in different population. The prevalence of heterozygous 35delG carriers among hearing population is high (2-4%) in several countries where this mutation analysis was performed. Universal newborn screening for hearing loss has been widely adopted since it is known that early identification and management of deafness are important for language development and social skills. Genetic testing for hearing loss is becoming an emerging public health issue although deafness may be also due to inherited or environmental factors,. We performed genetic testing for 35delG mutation on paper dried blood spots of newborn infants from different regions of Brazil, which is the largest country in South America. The country is a melting pot of different ethnic groups including European, African slaves, and autochthonous Amerindians. Our results indicate that the frequency of 35delG carriers depend on the predominant immigration in special regions of the country. The knowledge of 35delG frequency variation must be useful for genetic counseling and may propitiate an early intervention for a substantial percentage of deaf infants.

Newborn screening for cystic fibrosis: clinical evolution of children screened at birth with an atypical *CFTR* genotype. V. Scotet¹, M. Roussey², G. Rault², V. Storni², M. Dagorne², H. Journal², P. Vigneron², M. De Braekeleer¹, M.P. Audrezet¹, C. Ferec¹. 1) INSERM U 613, Brest, France; 2) Réseau Mucoviscidose Bretagne et Pays-de-Loire, France.

Newborn screening for cystic fibrosis (CF) is implemented in whole France since 2002. A pilot experience was already set up in a western area of this country in 1989 (Brittany). The screening protocol performed in this region combined the immunoreactive trypsin (IRT) assay with the systematic analysis of three exons of the *CFTR* gene, which was followed by an extensive molecular analysis when necessary. This strategy led to the detection of new mutations and some children with an atypical genotype were identified (i.e. genotypes including abnormality not previously described or genotypes whose clinical evolution remained difficult to predict). The aim of this study was to describe the clinical outcome of the children screened with an atypical *CFTR* genotype. Until December 31st 2003, 528,310 newborns were screened for CF in Brittany. The IRT/DNA protocol enabled the detection of 190 children with an elevated IRT and two *CFTR* mutations. The diagnosis of CF was unambiguous in 172 of these newborns (90.5%). The 18 remaining children presented an atypical genotype: F508del/R117H (n=6), I507del/R117H, G551D/R117H, G551D/R553G, W846X/R117C, F508del/G149R, F508del/P205S, F508del/R347L, F508del/S977F, F508del/R1070W, F508del/D1152H, N1303K/F311L and 1078delT/F311L. At this time, 15 of these children (83%) do not present any pulmonary or digestive signs (follow-up periods: 1.5-15 y.). Six of them are more than 10-year old and 4 have not evolved towards a phenotype of CF (genotypes F508del/R347L, F508del/R1070W, F508del/D1152H, G551D/R553G). None of the 8 children carrying the R117H mutation (all associated with 7T variant) has developed a symptomatology of CF (ages: 2.0-8.9 y.). On the opposite, this clinical follow-up has enabled to confirm the deleterious effect of the identified abnormality in 3 children (G149R and F311L). This longitudinal follow-up is crucial to determine the outcome of the CF children with an atypical genotype. It has enabled to associate some abnormalities with a genotype of CF.

The prevalence of antiphospholipid antibodies in 261 spanish women with recurrent spontaneous abortion. A case-control study. *J. Carbone¹, M. Orera², E. Sarmiento¹, C. Lostau², D. Micheloud¹, M. Rodriguez-Mahou¹, E. Fernandez-Cruz¹.* 1) Clinical Immunology Unit, Hospital Gregorio Maranon, C. Dr. Esquerdo N. 46, 28007 Madrid, Spain; 2) Genetic Unit, Hospital Gregorio Maranon Madrid, Spain.

Approximately 10% of all human pregnancies end in spontaneous abortions. In the majority of such cases the etiology remains unknown, but anticardiolipin antibodies (ACA) are gaining recognition as potential causes of recurrent miscarriage. According to a case and control study we determined the prevalence of moderate-high ACA in 261 women with recurrent abortions (two or more) without apparent cause after study and compared with the prevalence in 30 women whose pregnancies were successful and with no history of abortion. IgG and IgM ACA were measured by enzymelinked immunosorbent assay on microtitre plates. Plates were coated with highly purified cardiolipin and saturated with human b2-GP-I which provide results independent of endogeneous b2-GP-I. The results for IgG and IgM ACA were reported as moderate [IgG 20-80 (GPL units) and IgM 20-80 (MPL units)] or high [IgG > 80 (GPL units) and IgM > 60 (MPL units)]. We found that 47 (18.8%) of the cases with recurrent abortions showed moderate-high ACA-IgG versus 1 (3.3%) of the control group (2-sided Fishers exact test, $p = 0.038$) with an odds ratio (OR) of 6.36. Low titer IgM-ACA were observed in 2 (6.6%) controls. We found a relation with IgG-ACA ($p = 0.011$) but not with IgM-ACA ($p = 0.32$). We concluded that moderate-high IgG-ACA are associated with recurrent abortions and increases the risk approximately 6-fold. Moderate-high IgG ACA are more specific for fetal wastage than IgM-ACA.

Integrated Prenatal Screening in Eastern Ontario: Lessons From the First 18 Months. *J.Y. Al-Aama¹, N. Lepage², J. McGowan-Jordan¹, V. Hastings¹, C. Meier³, G.E. Graham¹*. 1) Department of Genetics, Children's Hospital of Eastern Ontario and University of Ottawa, Ontario, Canada; 2) Department of Laboratory Medicine, Children's Hospital of Eastern Ontario and University of Ottawa, Ontario, Canada; 3) Ontario MSS Database and North York General Hospital, Toronto, Ontario, Canada.

In July 2002 Integrated Prenatal Screening (IPS) was implemented in the Ottawa-Gatineau region. Herein we report factors influencing our choice of IPS over FTS and outcome data for the first 18 months of the IPS program. We retrospectively compared IPS outcomes to those we would have obtained with FTS and previously obtained with MSS. From July 2002 to December 2003, following a T1 ultrasound in which fetal CRL (+/- BPD) and NT were measured, peripheral blood samples from 5530 pregnant women in Eastern Ontario and Western Quebec were analyzed for T1 PAPP-A and T2 msAFP, estriol and hCG levels. All sonographers participating in the program received Fetal Medicine Foundation Canada training. NT measurements were converted to MoMs based on a comparison to baseline sonographer-specific gestational age curves. The biochemical and NT data were combined with maternal demographic data to generate a T2 risk assessment according to the method of Wald et al. Free hCG was also measured in 4430 T1 samples and retrospectively combined with maternal demographics, NT and PAPP-A results for an FTS risk assessment. A risk cutoff of greater than or equal to 1 in 200 for a screen positive result for DS was used for both IPS and FTS; a risk cutoff of 1 in 385 was used for MSS. The IPS program yielded a DS initial positive rate of 5.9%, whereas the FTS program, had it been implemented, would have yielded a comparable value of 14.9%. MSS yielded an initial positive rate of 11%. Over a period of 1 year, IPS and FTS produced detection rates of 85-90%, while the figure for MSS was 72%. Only 3.4% of women screened with IPS underwent amniocentesis, compared with 6.0% of women screened with MSS. IPS provided screening for 60% more women than MSS with a 43% reduction in the number of invasive procedures and a considerable improvement in DS detection.

ProMBP and other early first trimester maternal serum markers may be combined to a highly efficient first trimester integrated screening. *M. Christiansen.* Dept Clinical Biochemistry, Statens Serum Inst, Copenhagen, Denmark.

The proform of eosinophil major basic protein (ProMBP) is synthesized in the human placenta during pregnancy. In the circulation, proMBP is known to exist in covalent complexes with other proteins, primarily pregnancy-associated plasma protein-A (PAPP-A/proMBP), and angiotensinogen (Ang/proMBP). The discriminating potential of the maternal serum concentrations of all proMBP complexes (total proMBP) in screening for Down syndrome (DS) was evaluated. The serum concentrations of total proMBP was determined by ELISA in 39 women with a Down syndrome fetus and 123 unaffected pregnancies in week 4 -14 of gestation, and distributions of gestational ageindependent concentration values (MoMs) were established. The performance of total proMBP as first trimester marker for Down syndrome was assessed through a Monte Carlo simulation procedure. The total concentration of proMBP was reduced to a median MoM of 0.70 in week 6 - 8 ($p = 0.015$) in DS pregnancies. Using a standardized age-distribution of pregnant women and published a priori risks for giving birth to a DS child, the detection rate (DR) for DS was estimated to be 41 % for a false positive rate (FPR) of 5% for proMBP and age. With supplement of nuchal translucency(NT), a DR of 76 % for a FPR of 5% could be obtained. Further combining these markers with SP1, a DR of 84 % was estimated for a 5% FPR and 71% for a FPR of 1%. The combination of proMBP and SP1 and other new early first trimester markers, e.g. inhibin A and ADAM12 may make early first trimester screening in combination with NT and beta-hCG and PAPP-A a nearly diagnostic test for Down syndrome and with performance clearly comparable to that of "Integrated Screening" where the results of serological screenin g in first and second trimesters are combined with NT to a risk result that is communicated to the pregnant woman in second trimester.

Program Nr: 2788 from the 2004 ASHG Annual Meeting

Down syndrome detection using serum integrated screening. *S. Diment, A. Anderson-Miller, M.H. Quigg, J. Roberson.* Dept of Genetics, Henry Ford Hosp, Detroit, MI.

The Department of Medical Genetics at Henry Ford Hospital began offering Maternal Serum Integrated Screening (PAPP-A between 10-13 weeks gestation plus Quad test (AFP, estriol, hCG and inhibin-A) in the second trimester) in April 2003. Nuchal translucency measurements have not yet been incorporated into the screening program. In 14 months 800 women have completed the two-part screening test. Outcomes are pending on over half these women. Two Down syndrome cases have been identified. Both cases were detected in women less than age 35.

Patient A, age 20, had a risk for Down syndrome of 1 in 75 with Serum Integrated screening, 1 in 730 with Quad test and 1 in 2,700 with triple test. Patient B, age 30, had a risk for Down syndrome of 1 in 8 with Serum Integrated screening, 1 in 65 with Quad test and 1 in 120 with the triple test. In our screened population under age 35, the Odds of an Affected given a Positive Result (OAPR) was 1:15 with the Serum Integrated test. One third fewer women were called screen positive for Down syndrome compared to their results using the Quad test. This reduces patient anxiety, amniocentesis related costs and potential procedure-related fetal losses.

In this same group of screened women 11 (1.2%) were called screen positive for Trisomy 18. Trisomy 9 was diagnosed in the fetus of a 39 year old woman whose Trisomy 18 risk was 1 in 30 with the Serum Integrated test. Ultrasound findings included dangling choroid plexus, micrognathia, hypotelorism, absent nasal bone, multiple cardiac anomalies, abnormal skull shape, and shortened humeri and femurs.

While the number of patients screened is relatively small, Serum Integrated Screening has performed as predicted in our clinical setting. Acceptance among patients and referring physicians has been overwhelmingly positive.

An intervention trial of integrated serum testing (IST) for Down syndrome. *J. Haddow, G. Palomaki, G. Knight, E. Kloza.* Foundation for Blood Research, Scarborough, ME.

IST combines maternal serum measurements from the first (PAPP-A) and second (AFP, uE3, hCG, DIA) trimesters into a single risk calculation for interpretation in the second trimester. In this trial, IST was systematically introduced to primary care practices throughout our state. This is the first time that this more complex screening protocol has been formally assessed in the U.S. healthcare system (MCH grant MC00195). If found feasible, IST can potentially reduce the false positive rate to up to half that found with the triple test while maintaining detection. Furthermore, it sets the stage for full integrated screening, when reliable nuchal translucency measurement becomes more widely available. During 2 years of enrollment, 61% of all women screened by us in Maine 11,159 consented to IST and provided a first trimester sample. 9,723 enrollees (87%) also provided a second trimester sample; 950 of these were found to have been sampled outside of the acceptable first trimester window of 8-13 weeks (92% too early). 1,436 women did not provide a second trimester sample (40% miscarried, 31% declined further testing, 17% opted for amniocentesis. Among 8,773 women with IST interpretations, 3.2% were screen positive. This is 29% lower than the 4.5% that would have occurred if the triple test had been used (risk cut-off levels are selected to yield a 70% detection rate for each test combination). Among ultrasound-dated pregnancies, the rates were 2.7% and 4.5% (40% reduction). Follow-up to date indicates a 69% detection rate for IST, consistent with expectation. This trial shows that IST can be successfully introduced into routine practice with the following cautions: 1) IST among LMP dated pregnancies is less effective and some samples may be obtained too early; 2) additional staff time is needed to remind offices to obtain overdue samples; 3) to achieve full efficiency, ultrasound dating needs to accompany the first serum sample; 4) sample matching requires specialized software and staff involvement; 5) the PAPP-A assay requires careful monitoring and appropriate corrective actions.

Outcome analysis of pregnancies screening positive for Smith-Lemli-Opitz syndrome SLOS). *S. Langlois, S. Dougan, G. Hulait, H. Vallance, L. Armstrong, M. Van Allen.* Depts. of Medical Genetics and Pathology, Children's and Women's Health Centre, Vancouver, Canada.

SLOS is an autosomal recessive disorder characterized by growth retardation, developmental delay and minor / major anomalies. It is caused by a deficiency of 7-dehydrocholesterol reductase. Palomaki et al (2002) described a screening approach for the identification of pregnancies at high risk of having a fetus with SLOS. This study describes our experience with second trimester MSS for SLOS.

Between August 2002 and February 2004, 25,211 pregnancies had a second trimester MSS. Using a risk cut off level of 1/50, 75 MSS were positive for SLOS. 2 cases were reinterpreted due to wrong dating. Of the 73 positive screens, only 13 cases screened positive only for SLOS. The other 60 positive screens were positive for SLOS and either trisomy 18 or trisomy 21 or both. Some cases were also positive for open spina bifida. 6 cases were lost to follow up.

Prenatal investigations led to a diagnosis in 59 cases: ultrasound identified an intrauterine fetal demise in 37 pregnancies and anencephaly in 4 cases; 8 pregnancies had a chromosomal abnormality (3 trisomy 18, 1 trisomy 9, 3 triploidy and 1 case of 45,X). Steroid sulfatase deficiency (STS) was diagnosed in 10 pregnancies, four with a positive family history, 6 without. In 5 of those 6 cases, molecular analysis of amniocytes was done and a deletion of the STS gene was found in 4 cases.

Postnatally, congenital adrenal hyperplasia was diagnosed in one case. Three newborns had normal exams and neonatal courses. One of these infants is being investigated at 9 months for possible delay. Pregnancy outcome information is pending on 4 cases.

In summary, although no diagnosis of SLOS was made (FPR 0.28%), a positive MSS for SLOS is associated with a high positive predictive value for chromosomal abnormalities, intrauterine fetal demise and STS deficiency. Patients positive for SLOS on MSS require prompt referral for assessment and counselling.

Invasive Trophoblast Antigen (ITA) levels in second trimester twin pregnancies. *J.E.S. Lee¹, E. Carlton¹, P. Petersen¹, C. Maglasang²*. 1) Quest Diagnostics, San Juan Capistrano, CA; 2) Quest Diagnostics, Teterboro, NJ.

Introduction: ITA is increased in women carrying a fetus with Down syndrome. Before ITA can be incorporated into routine screening programs, the relationship between levels observed in singleton and twin pregnancies must be determined. We have compared serum ITA levels in singleton and twin pregnancies during the second trimester.

Methods: Serum samples were collected during the second trimester (14.1-22.7 weeks) from 582 women carrying one fetus and 145 women carrying twins. ITA was measured using an immunochemiluminescent assay performed on the Nichols Advantage instrument. AFP, hCG, uE3 and dimeric inhibin A (DIA) were measured using commercially available immunoassay kits. Results were converted to multiples of the median (MoM). ITA MoMs were adjusted for maternal weight. All other MoMs were adjusted for weight and race. Maternal weights ranged from 108-315 pounds and were truncated between 120-220 pounds for ITA. Women carrying twins were white (50%), black (15%), Hispanic (17%), Asian (10%) and other races (8%). The twin pregnancies were dated by ultrasound (65%) or LMP (35%).

Results: In twin pregnancies, the median ITA level was 2.19 MoM, the \log_{10} mean was 0.380, and the \log_{10} standard deviation (SD) was 0.369. In singleton pregnancies, the median, \log_{10} mean, and the \log_{10} SD were 1.00, 0.011, and 0.307, respectively. While ITA MoMs were not affected by the method of gestational dating, they were affected by race. Slightly higher MoMs (2.37) were observed in Hispanic women with twins and lower MoMs (1.26) were observed in Asians. The median MoMs of AFP, hCG, uE3 and DIA in twin pregnancies were 2.04, 1.79, 1.42 and 2.31, respectively. In singleton pregnancies, the median MoMs were all 1.00. The \log_{10} SDs in twin pregnancies were similar to those in singleton pregnancies.

Conclusions: ITA levels in twin pregnancies are approximately twice (2.19 MoM) those in singleton pregnancies in the second trimester. This relationship can be used when calculating pseudo-risks for Down syndrome in twin pregnancies.

Program Nr: 2792 from the 2004 ASHG Annual Meeting

Review of enhanced prenatal screening performance in Ontario, Canada. *C. Meier, T. Huang, A.M. Summers, P.R. Wyatt.* Ontario MSS Database, Genetics, North York General Hospital, Toronto, ON, Canada.

Ontario is Canada's most populous province with approximately 130,000 live-births per year. Traditional second trimester, three-marker maternal serum screening (MSS) for Down syndrome, open neural tube defects and trisomy 18 has been offered as a tax funded service to the women of Ontario since 1993. The utilization of MSS has remained consistent with approximately 50% of live-birth pregnancies receiving screening. In 1999, integrated prenatal screening (IPS) which combines the results of biochemistry markers in the first and second trimester with first trimester ultrasound was introduced on a small scale in one region and rapidly expanded across the entire province. First trimester screening (FTS) was introduced in 2002 and has also become widely used. Dimeric inhibin-A (DIA) was also added to IPS and MSS tests in some areas in 2003. Currently, approximately 50% of the 6,000 monthly screening results issued in Ontario are based on some form of enhanced prenatal screening test. Enhanced prenatal screening, like MSS, is more highly utilized in urban areas due to easier access to medical care, blood collection and ultrasound facilities; its use has spread to include most rural areas as well. Between July 1999 and March 2004, approximately 55,000 women had IPS or FTS and 239,000 had MSS. The performance of IPS, FTS and four-marker MSS methodologies were assessed, with respect to false-positive rates (FPR), theoretical detection rates (DR), and utilization on a regional basis. Overall, the introduction of enhanced screening in Ontario appears to have both reduced the mean FPR and increased the mean DR.

Detection of cell free placental DNA in maternal plasma: direct evidence from three cases of confined placental mosaicism. *S. Miura¹, K. Miura¹, H. Masuzaki¹, N. Niikawa², T. Ishimaru¹.* 1) Dept of OB/GYN, Nagasaki Univ Biomed. Science, Nagasaki, Japan; 2) Dept of Human Genetics, Nagasaki Univ Biomed. Science, Nagasaki, Japan.

Objective: Cell-free fetal DNA released into maternal plasma is useful for noninvasive prenatal diagnosis, but no definitive evidence has been provided for its origin. Confined placental mosaicism (CPM) is defined by the presence of abnormal karyotypes only in the placenta. If a trisomic allele is detected in maternal plasma with CPM, this is direct evidence for placental DNA in maternal circulation. Here we report the result of a study that supports the presence of placental DNA in maternal plasma. **Material and Methods:** We analyzed parent-child transmission patterns of alleles at various dinucleotide repeat polymorphism loci in 9 cases of confined placental mosaicism (CPM). Cellular DNA was extracted from leukocytes of the neonates and their parents, and cell-free DNA was from maternal plasma (1.6 ml) collected before and after delivery, using Qiagen blood mini Kit (Qiagen, Hilden, Germany). Placental DNA was extracted after delivery. All these study protocols were approved by the Committee for the Ethical Issues on Human Genome and Gene Analysis in Nagasaki University, and written informed consent was obtained from all the women. **Results:** Diploid cells in three of the 9 neonates with CPM had one each of parental alleles, whereas trisomic cell in their placentas contained one maternal and two paternal alleles. In all of them, one paternal allele that was absent in the neonates was present both in trisomic cells of the placenta and in cell-free DNA from maternal plasma. **Conclusion:** Our results not only provide direct evidence for the presence of placental DNA in maternal plasma but also indicate possible usefulness of such DNA for noninvasive prenatal diagnosis of genetic diseases and screening for placental dysfunction.

Maternal serum invasive trophoblast antigen (ITA) in first trimester trisomy 18 pregnancies. *G. Palomaki¹, G. Knight¹, L. Neveux¹, R. Pandian², J. Haddow¹.* 1) Foundation Blood Research, Scarborough, ME; 2) Quest Diagnostics Nichols Institute, San Juan Capistrano, CA.

This initial report of maternal serum ITA in first trimester trisomy 18 pregnancies indicates that ITA performs comparably to free β -subunit of hCG (free β). Elevated levels of ITA (previously called hyperglycosylated hCG) in maternal serum and urine are known to be predictive of Down syndrome in both first and second trimesters. If ITA was to be substituted for hCG (or free β) for Down syndrome screening, it would be important to define its usefulness for identifying trisomy 18 pregnancies, as well. To answer this question, we used banked sera from a prospective observational trial (Haddow JE et al., *NEJM*, 1998;338:955). Maternal serum samples were obtained prior to CVS or early amniocentesis in 4,412 women, none of whom was having the procedure because of abnormal chemistry or ultrasound measurements. Twelve first trimester maternal serum samples from trisomy 18 pregnancies were identified; each was matched with 5 controls for gestational age (between 9 and 13 weeks), maternal age and race, recruitment center, and storage time. We assayed these never-thawed aliquots for ITA per manufacturer's instructions, using Nichols Institute Diagnostics automated platform (Advantage).

We derived day-specific reference ranges from the 60 chromosomally normal pregnancies, and all 72 ITA results were expressed as weight-adjusted multiples of the median (MoM). hCG, PAPP-A and free β were measured fresh, as part of the original study. Unbiased estimates for median ITA, hCG, free β and PAPP-A levels in trisomy 18 pregnancies are 0.18, 0.40, 0.23, and 0.29 MoM, respectively. At a 5% false positive rate, corresponding univariate trisomy 18 detection rates are 58%, 50%, 58% and 67%. Detection rates for free β and PAPP-A are consistent with published reports. Substantially equivalent screening performance for trisomy 18 can therefore be achieved by substituting ITA for either hCG or free β in first trimester Down syndrome screening.

Automated Imaging versus Manual Scoring for Rare Cell Detection: Man or Machine? *K.L. Johnson, H. Stroh, K. Khosrotehrani, D.W. Bianchi.* Division of Genetics, Department of Pediatrics, Tufts-New England Medical Center, Boston, MA.

Background. Fetal cell detection for prenatal diagnosis or study of microchimerism requires an accurate, efficient and reproducible microscopy method. Our objective was to compare manual scoring to automated scanning on the same specimens for detection of either nuclear or cytoplasmic/membrane signals.

Methods. Nuclear X and Y chromosome FISH signals were detected on slides of calibrated mixtures of male umbilical cord blood cells with $\sim 10^5$ female cells, paraffin-embedded tissue specimens from women with male fetal cell microchimerism, and post-termination blood from a woman with a 47,XY,+21 fetus. Cytoplasmic or membrane signals were detected on nucleated cells isolated from first trimester maternal blood stained with FITC-anti-trophoblast antibody HLA-G and blood smears from green fluorescent protein (GFP+) mice (expressed in $\sim 50\%$ of nucleated cells). For manual scoring (at 400X), the number of cells located and scoring time were recorded. For automated scanning (Metasystems), instrument time, manual review of gallery images, and number of cells located were recorded. Nuclear and cytoplasmic/membrane signal detection were performed at 200X and 100X magnification, respectively.

Results. For nuclear signal detection in known mixtures, the number of target nuclei located by manual and automated microscopy was highly correlated ($r=0.94$). Overall, nuclear signal detection by automated scanning required 3-fold more time than manual scoring, whereas for cytoplasmic/membrane signal detection automated scanning required 3-fold less time than manual scoring.

Conclusions. In general, the accuracy of automated and manual microscopy for rare cell detection is comparable. However, automated scanning is more rapid than manual scoring when low magnification (100X) can be used, while manual scoring is more efficient when higher magnification is necessary (200X). Due to the consistency and reproducibility of automated microscopy, it may have advantages for the localization and characterization of rare cells.

Angelman Syndrome and Beckwith-Wiedemann Syndrome methylation testing in a prospective series of 84 IVF pregnancies. *L. Ross¹, L. Black², J. Johnson³, L. Beischel³, S. Bhatt¹, J. Goldberg²*. 1) Genzyme Genetics, Orange, CA; 2) California Pacific Medical Center, San Francisco, CA; 3) Shodair Children's Hospital Genetics Laboratory, Helena, MT.

Animal cloning, molecular studies of animal embryos, patient registries, and case reports have suggested an association between assisted reproduction and an increased risk for defects in epigenesis. An apparent mechanism is loss of maternal methylation of certain imprinted genes including those causing Angelman Syndrome (AS) and Beckwith-Wiedemann Syndrome (BWS). Of published postnatal gene methylation analyses of AS and BWS patients born after IVF, 3/3 AS patients had hypomethylation of the maternal SNRPN gene, and 13/14 BWS patients had hypomethylation of the maternal copy of KCNQ1OT1 (also called LIT1). Prenatal testing is available for these two conditions and the question remains whether testing should be routinely offered to patients following IVF/ICSI procedures. Our purpose is to contribute to risk determination for methylation defects causing AS and BWS in IVF pregnancies by following a large series of prospectively ascertained patients. Patients were informed of and offered this testing during prenatal genetic counseling. In our series, all patients had undergone IVF and were also of advanced maternal age. Eighty-four pregnancies were tested for AS and 79 of these were also tested for BWS. All fetuses had normal karyotypes and no ultrasound anomalies were noted. Our series included 15 pairs of twins and 2 single fetuses from different twin pregnancies. Thirteen of the samples tested were CVS, and the remaining 71 were obtained from second-trimester amniocentesis. Forty-one of the 84 pregnancies were conceived with ICSI in addition to IVF. The DNA testing was done on cultured samples and designed to detect abnormal methylation patterns of the SNRPN and KCNQ1OT1 genes. All AS and BWS methylation test results were negative. To our knowledge this is the first set of prospectively obtained prenatal data on AS and BWS methylation status in IVF pregnancies. Future studies will expand the data set and help ascertain the true risk for methylation defects after IVF/ICSI procedures.

Development of multiplex PCR, bead-array detection and automated data analysis for complex genetic testing: the Ashkenazi disease model. *J.T. Brown, A.G. Hadd, C. Lahey, C.R. Novak, C. WalkerPeach.* Ambion Diagnostics, Austin, TX.

PURPOSE: Carrier screening for large numbers of heritable mutations is challenging and frequently achieved by performing multiple laborious techniques. The purpose of our study was to develop a rapid test procedure combining single-tube amplification, single-tube detection and automated data analysis for complex genetic testing. A panel of diseases prevalent in the Ashkenazi Jewish population served as the feasibility model. Included were allelic determinations for 8 diseases that have a combined carrier rate of 1:6, Tay-Sachs, Gaucher I, Niemann-Pick A and B, mucopolidosis IV, familial dysautonomia, Canavan, Bloom syndrome, and Fanconi anemia C. **METHODS:** We amplified 20 regions of the genome in a single multiplex PCR. Detection was a single bead-array containing 47 allele-specific capture probes conjugated individually to fluorescently addressed microspheres and 4 exogenous internal fluorescence control beads (included for software calculations of background and variance). Biotinylated amplicons were hybridized to the bead-array in standard thermal cyclers without intervening purification steps. Stringency was maintained without post-hybridization washes. After incubation with reporter fluorophore, reactions were analyzed by the Luminex platform to identify microsphere/amplicon interactions. **RESULTS:** A single assay was developed that combines multiplex PCR and bead-array hybridization to identify the normal and mutant forms of 24 alleles frequent among Ashkenazim. Analysis of 96-well plates was completed in 4.5 hours with 50 minutes (18%) of hands-on time. Fluorescence values were greater than 40 times the variance of the background, indicating a reliable, robust system. The software allowed selection of specific panel alleles for analysis and reporting on a patient-by-patient basis.

CONCLUSION: Combining multiplex PCR amplification with bead-array detection is a successful strategy for rapid genetic testing and facilitates the consolidation of multiple techniques into one assay. Further, analysis software can address ethical and policy considerations by revealing only those results which have been requested by the physician or genetic counselor.

Molecular analyses of monozygotic twins with cytogenetic discordance for trisomy 21. *J.-L. Blouin^{1,2}, S. Gagos¹, M. Gagnebin², S. Deutsch², C. Bürgi², C. Gehrig², R. Lyle², M.A. Morris^{1,2}, S.E. Antonarakis^{1,2}, S. Dahoun^{1,2}.* 1) Medical Genetics, University Hospitals of Geneva, Switzerland; 2) Genetic Medicine and Development, University School of Medicine, Geneva, Switzerland.

We report here a case of discordant monochorionic/diamniotic twin pregnancy for trisomy 21 in a 31 year old, primipara mother. This pregnancy was the result of an in vitro fertilization because of male infertility. An amniocentesis (at week 13 5/7) was performed following ultrasound signs of hydrops and hygroma colli. The karyotype (transplacental) revealed a non-mosaic trisomy 21 in twin 1 (47,XX,+21[7]) and a mosaic trisomy 21 in twin 2 (47,XX,+21[2] / 46,XX[19]). After genetic counseling a non-selective termination of pregnancy was performed. Examination of post mortem tissues (skin, kidney, lung) after an informed consent, revealed a trisomy 21 in twin 1 and a normal karyotype 46,XX in twin 2 (there was only one trisomic 21 cell in 100 cells of cord blood). Microsatellite analyses and quantification by Real-Time PCR on DNAs from 2 different tissues (hand, lung) in each twin sibling confirmed common genetic background for all loci tested, and trisomy 21 in twin 1. There was chromosome 21 allele sharing in twins 1 and 2; maternal alleles were however duplicated in the trisomic twin 1. Interestingly, twins 1 and 2 received different maternal alleles for markers of the most distal 2 Mbp of 21q. There is a complicated sequence of events that could explain these data. One scenario is that of an initial trisomy 21 zygote from a non-disjunction at meiosis II (recombinant and non-recombinant chromatids), followed by an early mitotic error that resulted in normal karyotype (containing one maternal 21), and trisomy 21 cells containing two copies of the other maternal chromosome 21. Alternative mechanisms could also explain the data. Regardless of the twinning mechanism, these samples can be used to assess transcriptome differences due to the presence of an extra chromosome 21 in an otherwise identical genetic background.

Coagulation and fibrinolysis factor gene polymorphisms in women with prior preeclampsia. *J. Girouard, S. Levesque, C. Rancourt, J.C. Forest, Y. Giguere, F. Rousseau.* CHUQ, Centre de recherche de l'hopital St-Francois d'Assise, Universite Laval, Quebec, Canada.

Preeclampsia is a pregnancy disease characterised by hypertension and proteinuria occurring after 20 weeks of gestation in women. It is an important cause of foetal and maternal morbidity/mortality and there is no current treatment other than delivery. This disorder is associated with a hypercoagulable state and can sometimes evolve to coagulation complications. We studied different gene polymorphisms of proteins involved in the coagulation and fibrinolysis pathways in order to evaluate their potential role in the pathophysiology of preeclampsia. Prothrombin (G20210A), factor V (R506Q), factor VII (R353Q and -323 10 pb ins), factor XIII (V34L), beta-fibrinogen (G-455A), platelet glycoprotein IIIa (L33P) and platelet activator inhibitor-1 (promoter 4G/5G) gene polymorphisms were studied in 307 women with prior preeclampsia matched for age at the index pregnancy and BMI with 603 controls. All women in this study were of French Canadian origin. Genotypes distribution followed Hardy-Weinberg equilibrium for all polymorphisms except for the platelet glycoprotein IIIa polymorphism among cases ($p = 0,03$). Genotype and allele frequencies were similar between women with prior preeclampsia compare to controls for all the polymorphisms studied. We also look at the severe preeclampsia subgroup ($n = 185$) and their controls but no differences were found. Combined carrier status analysis for *F5* and *F2* genes showed similar frequencies between groups (3,9 % vs 4,1 % in controls). In conclusion, our results suggest that common coagulation and fibrinolysis factor gene polymorphisms do not play an important role in the pathophysiology of preeclampsia, at least in our population.

FISH validation of preimplantation genetic diagnosis (PGD). *S.A. Berend¹, D. Crenshaw¹, S. Pritchard², M. Sapeta¹, K. Ivani³, J. Russell², F. Bischoff⁴, J. Wang⁵, A. Lamb¹, J.B. Ravnan¹.* 1) Genzyme Genetics, Santa Fe, NM; 2) Delaware Institute for Reproductive Medicine, Newark, DE; 3) Reproductive Science Center, San Ramon, CA; 4) Baylor College of Medicine, Houston, TX; 5) Genzyme Genetics, Pasadena, CA.

Preimplantation genetic diagnosis (PGD) is performed in conjunction with in vitro fertilization (IVF) and allows genetic testing of embryos prior to uterine transfer. PGD allows at-risk couples to avoid the transfer of aneuploid embryos, thus decreasing the spontaneous miscarriage rate. No guidelines exist for the validation of PGD; therefore, general guidelines by the American College of Medical Genetics (ACMG) for the validation of probes for fluorescence in situ hybridization (FISH) were used. We present approaches from two different laboratories. As it is difficult to obtain blastomeres for validation purposes, initial studies were performed on cells from chorionic villus samples (CVS), blood, and products of conception (POC). The first validation protocol involved testing the FISH probe mixture (13,15,16,17,18,21,22,X,Y) on trophoblastic cells from direct preparations of CVS. Five direct-prepared CVS slides were used to determine probe sensitivity which ranged from 86% to 100% for the probes tested. We also tested the probe set on cells from known abnormal CVS and POC specimens. All abnormalities were identified using this protocol. After gaining experience of FISH on normal and abnormal CVS and POC cases, we then tested the probes on blastomeres from abnormally-fertilized embryos (64 nuclei, 1 normal, 54 abnormal, 2 inconclusive results, 7 no results). The second validation protocol involved two probe mixtures (1st-13,18,21,X,Y and 2nd-8,9,15,16,22). Probe sensitivity was tested on blood cells (1st probe mixture on 200 nuclei, 2nd probe mixture on 100 nuclei) which ranged from 98% to 100%. Initial validation of the 1st probe set was performed on dissociated frozen embryos (357 nuclei, 255 normal, 102 abnormal), then on dissociated discarded fresh embryos (185 nuclei, 155 normal, 22 abnormal, 8 no results). Finally, single blastomeres were tested with both probe sets (114 nuclei, 30 normal, 76 abnormal, 1 no results).

Analysis of single cell diagnosis: mutations in the HEXA gene. *K. Dotan, B. Goldman, G. Barkai, J. Peri, L. Peleg.*
Human Genetics, Sheba Medical Center, Ramat Gan, Israel.

Tay Sachs disease (TSD) is a severe autosomal recessive disorder, lethal in its common infantile form. Mutations in the HEXA gene which impair hexosaminidase activity underlie the disorder. TSD is relatively frequent among the Ashkenazi Jewish population, where the carrier frequency is 1/29. Two mutations are responsible to nearly 100% of the infantile form in this population: 1278 +TATC (73% of the carriers) and IVS12 +1G to C (13%). A third mutation (G805A, 4% among carriers) causes an adult-onset form usually in compound with the common one. PGD, preimplantation genetic diagnosis was performed in a few centers following previous terminations of affected pregnancies. Our aim was to study different aspects of single cell diagnosis: amplification efficiency and allele-dropout (ADO) rates in a range of multiplexes, concurrently with analyzing the most prevailing detection techniques. The study included various cell types: lymphocytes from peripheral and cord blood, cultures of amniotic fibroblasts and chorionic cells and blastomeres). A set of nested PCR protocols were designed to detect each of the three mutations and 1st round multiplex and simultaneous PCR for compound heterozygotes. In addition we surveyed the TSD carrier population for highly polymorphic markers flanking the HEXA gene. Therefore each allele could be "mini-finger printed" by two markers (D15S1050, D15S188) via multiplex reactions with each protocol. We could detect all mutations by conventional electrophoresis and computerized systems such as ALF Express (Pharmacia) and ABI Prism 3100 Analyzer using fluorescently labeled primers. 150 single cells (from heterozygous individuals) were analyzed. Amplification rate was similar in all cell types (86.7%). However ADO rates was significantly lower (1.3%) in cultured fibroblasts than in lymphocytes (12%). We think that ADO rate is low in dividing cells whose chromatin is less compact and the DNA is more accessible. PCR failures are probably due to other factors in the reactions. We anticipate reliable amplification of the two alleles in the case of blastomeres since they are in an actively dividing stage.

Preimplantation Genetic Diagnosis in Maastricht: An overview. *J. Herbergs¹, J. Dreesen¹, E. Coonen², C. De Die-Smulders¹, J. Den Hartog², M. Drüsedau¹, J. Dumoulin², G. De Wert³, J. Engelen¹, J. Evers², J. Geraedts¹, H. Smeets¹.*

Preimplantation Genetic Diagnosis (PGD) is an alternative for prenatal diagnosis for couples at risk of transmitting a genetic disorder to their offspring. The genetic diagnosis of the early cleavage stage embryo can prevent couples from making the difficult decision of pregnancy termination in case of an affected foetus after prenatal diagnosis or can significantly increase the chance of an ongoing pregnancy, in case of recurrent pregnancy loss. PGD in Maastricht started at the end of 1994 with FISH sex selection soon followed by PCR analysis of a specific single gene disorder. The first FISH translocation analysis was done in 1997. In almost nine years 237 PGD cycles were started in 106 patients. In the first year PGD was performed for only two different X-linked disorders. Currently PGD sex selection has been performed for 19 different XL disorders. Furthermore, 14 different chromosomal aberrations have been diagnosed as well as 10 different single gene disorders. This involved 177 ovum pick ups (OPU) and the analysis of 1236 embryos. Of the analysed embryos 507 were either not affected by the disorder investigated or of the female gender in case of a sex selection. In 147 cycles an embryo transfer (ET) could be performed resulting in, 37 singleton, 9 twin and one triplet pregnancy, of which 6 ended in an early abortion. From the triplet pregnancy one child was a stillborn. In total 40 healthy babies were born with no major complications. Nine pregnancies are still ongoing. Conclusion: In the past years the number of PGD cycles and different disorders for which PGD can be offered has steadily grown and PGD has proved to be a successful alternative for prenatal diagnosis with pregnancy rates of 27% per OPU and 32% per ET.

Preimplantation development of autosomal monosomies depending on their origin. *A. Kuliev, J. Cieslak, Z. Zlatopolsky, Y. Illkevitch, I. Kirilova, Y. Verlinsky.* Reproductive Genetics Inst, Chicago, IL.

We have previously demonstrated 3:1 disomy/nullisomy ratio in oocytes following meiosis I, which is in agreement with predominance of trisomies over monosomies in spontaneous abortions. With sole exception of monosomy 21, autosomal monosomies are not compatible with postimplantation development and have never been detected in recognized pregnancies or at birth. On the other hand, significantly higher prevalence of autosomal monosomies over trisomies has recently been reported in cleaving embryos, suggesting their possible postzygotic origin through mitotic nondisjunction or anaphase lag in the first cleavages. To investigate the developmental outcome of autosomal monosomies, detected by polar body or blastomere analysis, these embryos were followed up to the blastocyst stage, and the resulting blastocysts were re-analyzed for the chromosomal status by fluorescent in situ hybridization (FISH) analysis using commercial probes specific for five chromosomes, including chromosomes 13, 16, 18, 21 and 22. A total of 3140 nuclei were analyzed from oocytes and embryos, which were obtained from women of average age of 38.6 (± 3.6) years. A total of 134 monosomic embryos were followed up overall, 51 (38%) of which were detected by polar body testing (monosomy 13 3, monosomy 16 10, monosomy 18 5; monosomy 21 14; monosomy 22 17, and complex monosomies 2), and 83 (62%) by blastomere analysis (monosomy 13 10, monosomy 16 11, monosomy 18 10; monosomy 21 15; monosomy 22 21, and complex monosomies 16). The proportion of monosomy confirmation in the resulting blastocysts was significantly higher (88.1%) for prezygotic, compared to postzygotic monosomies, confirmed in 59.6%, the remaining showing normal karyotype or mosaicism. 28 (59.6%) of 47 of prezygotic monosomies developed to blastocyst stage, compared to 32 (46.4%) of 69 postzygotic monosomies, suggesting, that autosomal monosomies are compatible with preimplantation development, irrespective of the origin, and are probably being lost during implantation.

PCR-based aneuploidy testing for chromosomes 2, 3, 4, 5, 6, 7, 8, 9, 11, 12, 13, 15, 16, 17, 18, 19, 21 and 22 in cleaving embryos combined with preimplantation genetic diagnosis (PGD) for Mendelian disorders. *S. Rechitsky, A. Kuliev, T. Sharapova, K. Lazyuk, S. Ozen, O. Verlinsky, I. Barsky, Y. Verlinsky.* Reproductive Genetics Inst, Chicago, IL.

It is becoming a current PGD practice to test for single gene disorders together with chromosomal abnormalities, so the same single cell is tested for both genetic and chromosomal disorders. This is done by PCR-based testing for chromosomal aneuploidies, which is based on the patterns of alleles that uniquely identify an individual, relying on a multiplex fluorescent PCR of low template DNA. We performed single cell DNA fingerprinting for detection of aneuploidies for chromosomes 2, 3, 4, 5, 6, 7, 8, 9, 11, 12, 13, 15, 16, 17, 18, 19, 21 and 22. Overall, 2074 blastomeres were tested, the number of blastomeres tested for each chromosome ranging from a few for chromosomes 3 and 9 to over hundred for chromosomes 6, 7, 11, 13, 16, 18, 19, 21 and 22, so the individual aneuploidy prevalence was evaluated only for these chromosomes, which was 11%, 5%, 7%, 10.1%, 6.7%, 10.2%, 7%, 16.9% and 7.6%, respectively. Overall aneuploidy prevalence of 42% was evaluated based in the series of 276 blastomeres, in which copy number of chromosomes 13, 16, 18, 21 and 22 was detected in the same blastomeres. No significant monosomy/trisomy ratio differences were observed, opposite to the recently reported findings of fluorescent in situ hybridization (FISH) analysis at the cleavage stage, despite monosomy/trisomy ratio variations for individual chromosomes. Errors of two or more chromosomes were observed in one third of aneuploid blastomeres, in agreement with previous FISH data in oocytes and blastomeres. Further data collection will be required to exclude a possible monosomy overestimate due to allele drop out in single blastomere PCR, as well as trisomies underestimate due a detection failure of extra maternal or paternal chromosomes because of indistinguishable homologs sharing the same polymorphic markers. The data show that testing for copy number of chromosomes may in future allow avoiding the transfer of chromosomally abnormal embryos in PGD for single gene disorders in couples of advanced reproductive age.

Preimplantation genetic diagnosis for Myotonic Dystrophy. *P. Renbaum¹, T. Eldar Geva², G. Chicco¹, B. Brooks², E.J. Margalioth², E. Levy Lahad¹, G. Altarescu¹.* 1) Genetic Unit, Shaare Zedek Medical Center, Jerusalem, Jerusalem, Israel; 2) IVF Unit, Shaare Zedek Medical Center, Jerusalem, Israel.

Myotonic dystrophy, the most common form of inherited muscular dystrophy in adults, is an autosomal dominant disease caused by expansion of unstable CTG repeats in the 3' untranslated region of the DMPK gene. Expanded CTG repeats cannot be visualized directly by PCR, and consequently preimplantation diagnosis using PCR is based on amplification of the normal allele. This strategy alone has been shown to be susceptible to misdiagnosis in PGD. The main obstacles in single cell PCR are the high rate of allele drop out (>20% in single blastomeres) and DNA contamination. Ideally, linked STR polymorphic markers are amplified in addition to the normal DMPK allele providing for higher accuracy. We used fluorescent labeled primers for PCR followed by fragment analysis on an automated DNA sequencer for 5 STRs, and restriction enzyme analysis for additional SNP markers, for a total of 8 reactions. We report two women with myotonic dystrophy that underwent PGD. In both families the females were affected and the males healthy. We used 7 highly polymorphic markers (D19S207, D19S219, D19S595, D19S393) and SNPs in introns 9, 5, and 11, in a multiplex reaction together with the DMPK repeat allele. This analysis was performed on Polar Bodies I and II, diminishing the need to perform blastomere biopsy. One marker, D19S393, used in both families, has not been reported in PGD for myotonic dystrophy. Using only polar body biopsy, 4 out of 10 embryos were predicted to have mutation free maternal alleles in family I, and three embryos were transferred back to the patient, resulting in an ongoing singleton pregnancy. In family II only 1 out of 10 original embryos in the first cycle and 2 out of 6 embryos in the second cycle were predicted to have a mutation free maternal allele, and these embryos were transferred to the patient. These transfers did not result in pregnancy, and the family is currently undergoing an additional PGD cycle. Presented data demonstrate the usefulness of polar body analysis combined with a large number of highly polymorphic markers for PGD diagnosis.

Preimplantation genetic diagnosis (PGD) for three types of Charcot-Marie-Tooth (CMT) disease. *T. Sharapova, S. Rechitsky, Y. Verlinsky.* Reproductive Genetics Institut, Chicago, IL.

CMT represents clinically and genetically heterogeneous group of hereditary peripheral neuropathies, affecting 1 in 2,500. PGD has previously been applied in 5 couples with CMT1A, the most frequent autosomal-dominant type of CMT caused by 1.5 Mb tandem duplication on chromosome 17p11.2-12, presenting complexity of diagnosis requiring the application of multiple polymorphic markers. We developed PCR design, involving the application of 13 highly polymorphic microsatellite markers, located within the duplicated area and closely linked to PMP22 gene. Seven PGD cycles were performed for CMT type 1A, X1 and 2E. In 2 of 3 couples with paternally derived duplication, single sperms analysis was performed to determine normal and mutant haplotypes. In the remaining 4 PGD cycles performed for 3 CMT1A couples with maternal mutation, both polar bodies (PBs) (24) and blastomeres (22) were analyzed, using markers D17S1357, D17S2229, D17S2226, D17S2225, D17S839, D17S2224, D17S2221, D17S2220, D17S291, D17S2219, D17S2218, D17S2217, D17S2216, which were amplified in multiplex hemi-nested PCR system, followed by fragment analysis. These cycles resulted in transfer of 7 embryos free of PMP 22 duplication, yielding one birth of an unaffected child, and one ongoing singleton pregnancy. Two PGD cycles were performed for the X-linked form of CMT, caused by mutations in connexin-32 gene (Cx32), for which 28 PBs and 2 blastomeres were tested for the presence of the V95M mutation in Cx32 gene, simultaneously with the short tandem repeats (STR) DXS453, DXS8052, DXS8030, DXS559, DXS441, which resulted in transfer of 5 mutation normal embryos failing to yield a clinical pregnancy. The other PGD cycle was performed for maternally derived autosomal-dominant CMT type 2E, caused by mutations in the light polypeptide neurofilament protein gene (NEFL). Testing of 28 PBs and 6 blastomeres for the presence of the mutation P8R, simultaneously with microsatellite marker D8S137 resulted in transfer of 3 unaffected embryos and birth of a child with normal NEFL gene. This is the largest experience of PGD for CMT, demonstrating the reliability and accuracy of the applied PGD designs.

Segregation of mtDNA mutations during embryo-fetal life: implications for genetic counselling. *J. Steffann¹, N. Gigarel¹, C. Bouchet¹, P. Burette¹, N. Frydman², I. Giurgea¹, S. Lebon¹, A. Rotig¹, R. Frydman², G. Tachdjian², S. Masmoudi¹, J.P. Bonnefont¹, A. Munnich¹.* 1) Genetics Dept, Necker Hospital, Paris, France; 2) Gynecology and obstetrics Dept, Beclere hospital, Clamart, France.

Mitochondrial DNA (mtDNA) mutations cause a wide range of serious genetic diseases with maternal inheritance. Due to the high transmission risk and the absence of efficient therapy in these disorders, at risk couples often ask for prenatal and/or preimplantation diagnosis. The few available data point out that predictive value of a prenatal analysis for the severity of the clinical phenotype is questionable. This is likely to be due to tissue and age variation of heteroplasmy. In an attempt to retrace the natural history of mtDNA mutation segregation from conception to adult life, we developed a PCR test enabling quantification for both NARP (Neurogenic weakness, Ataxia, Retinitis Pigmentosa) 8993TG and MELAS (Mitochondrial myopathy, Encephalopathy, Lactic Acidosis, Stroke-like episodes) 3243AG mutations from low amounts of DNA. Using this test, we performed the first preimplantation diagnosis for NARP. Extremely skewed segregation of 8993TG was observed, with a 100% mutant load in one embryo and no detectable mutation in the two others. Comparative analysis of two blastomeres from each embryo did not show any variation of the mutant DNA rate. Both mutation-free embryos were transferred and a singleton pregnancy is ongoing. Result of the test is to be controlled on a next amniotic fluid sample. Additionally, 12 prenatal analysis for MELAS or NARP mutations were carried out from CVS and/or amniocytes. Maternal mutant loads ranged from 0 to 70% in blood. In 14 of 17 fetal DNA samples, the mutant DNA rate was below 10 % or over 90%. When studied, the mutant load was fairly stable at 10, 15, and 30 week- gestation. Maternal mutant load had no predictive value for the fetus status, except for women with no detectable mutant DNA. All children with 20 % of mutant DNA in prenatal period are healthy at 1-6 years of age. Collecting more data on mitochondrial segregation during embryonic and fetal stages should further help interpreting prenatal analysis results.

Improved X-linked Alport syndrome genetic testing to perform preimplantation genetic diagnosis: direct and indirect approaches. *B. Tazon-Vega¹, E. Ars¹, P. Ruiz¹, R. Torra².* 1) Molecular Biology Laboratory, Fundació Puigvert, Barcelona; 2) Nephrology Department, Fundació Puigvert. Barcelona. SPAIN.

Alport syndrome (AS) is characterized by persistent hematuria, progressive renal failure and splitting and thinning of the glomerular basement membrane. Mutations in the *COL4A5* collagen gene are responsible for X-linked AS (XLAS) that accounts for 85% of the total AS familial cases. Preimplantation genetic diagnosis (PGD) applied to patients at risk of transmitting X-linked diseases usually consists of the positive selection of female embryos. However, description of a 10-15% of XLAS female carriers suffering from chronic renal failure before 40-50 years of age has given rise to the necessity of developing a specific PGD for this disease. The purpose of this study is to develop a reliable technique in order to perform an XLAS PGD absolutely independent of the embryo's sex. First, an XLAS family is characterized by linkage analysis on Xq22-q23 followed by a mutation screening of the *COL4A5* gene. To simplify this genetic testing, total RNA is extracted from the propositus' hair-roots and the complete *COL4A5* coding sequence is amplified in 10 cDNA overlapping fragments for direct sequencing. Once a mutation is identified in the propositus and its segregation with the disease is confirmed in the genomic DNA of the family, a direct PGD can be performed. If no mutation is detected, then linkage analysis is the alternative. We have improved the XLAS indirect diagnosis for a PGD application by a co-amplification on a 5pg DNA sample of 4 different microsatellite combinations of 3 markers: 1) *DXS1120*, *DXS6802* and *COL4A5-2B6*; 2) *DXS6797*, *DXS6802* and *COL4A5-2B6*; 3) *DXS6802*, *COL4A5-2B6* and *DXS1210*; and 4) *DXS6802*, *COL4A5-2B6* and *DXS456*. It is possible to choose between these groups of markers depending on their informativity showed in the previous linkage analysis of the family. Currently, we are assessing the efficiency of both, the mutation detection approach and the multiplex-PCR of the 4 microsatellite sets on single buccal cells. Finally, we will test these protocols on blastomeres from non-viable embryos prior to offering the XLAS PGD to interested couples.

Clinical consequences of an increasing trend of preferential use of cultured villi for molecular diagnosis by CVS.

A.J. Aina, E. Wood, V. Corson, C. Boehm, S. Jari, G. Stetten, K. Blakemore. Gyn/Ob, Johns Hopkins Hosp, Baltimore, MD.

Chorionic villus sampling (CVS) allows for early prenatal diagnosis and the option of pregnancy termination by D&C at 14 weeks with significantly fewer complications than 2nd trimester termination. A direct diagnosis using intact villi yields quicker results than using villus cells expanded in culture. We examined our molecular CVS cases from 1988-2004: 76 diagnoses utilized DNA from fresh or frozen villi and 37 from cultured villi. Time from CVS to diagnosis, as expected, was longer when cultured cells were used (23.9 days vs 13.2 days for direct extraction) ($p < 0.001$). Average G.A. at diagnosis was 14 5/7 weeks for cases when cultured cells were used vs 13 1/7 weeks with uncultured villi ($p < 0.001$). Excluding 3 cases sampled at 13 4/7 weeks, 17/36 (47%) of results from cultured cells were received at 15 0/7 weeks or later vs only 8/74 (11%) using uncultured villi ($p < 0.0001$). There were no inaccuracies in the molecular diagnoses in our series despite one case of maternal contamination involving cultured cells. We then compared our first 10 years' cases to those from '99-'04. The time from CVS to diagnosis increased from 14.6 days in '88-'93 to 16.6 days in '94-'98, to 17.7 days in '99-'04. During the first decade, reference laboratories required cultured cells for the analysis in 13% of cases vs 55% of cases since 1999 ($p < 0.0001$).

Conclusions: Direct DNA extraction saves ~11 days from time of CVS to results. More women are afforded the option of an earlier and safer pregnancy termination if uncultured villi are used for molecular diagnosis. This advantage and a reduction in the anxious waiting time were forfeited in 47% of our CVS cases in which cultured cells were used. Implementation of standardized DNA extraction protocols and sample size requirements can optimize the use of uncultured villi for molecular prenatal diagnosis. Increased awareness of the importance of a rapid result and the advantages of direct DNA extraction from uncultured villi can lead to improvements that are of clinical significance for patients undergoing early prenatal diagnosis.

Second Trimester Maternal Serum Screening as a Predictor of Adverse Pregnancy Outcomes in a Venezuelan Population. *F. Álvarez Nava, M. Soto, T. Padrón, A. Morales-Machín, M.C. Martínez, A. Rojas-Atencio, K. Urdaneta.* Unidad de Genética Médica, Universidad del Zulia, Maracaibo, Venezuela.

Objective: Abnormal levels of maternal serum alphafetoprotein (AFP), human chorionic gonadotropin (hCG) and unconjugated estriol (uE₃) have been associated to fetal Down syndrome. These abnormal levels have also been implicated in spontaneous miscarriage. The purpose of this study was to examine the relationship between the abnormal maternal serum concentrations of AFP, -hCG and uE₃ in the second trimester and the presence of various adverse pregnancy outcomes in a Venezuelan population. **Study Design:** Maternal serum AFP, -hCG and uE₃ concentrations were measured in 2,621 single-fetus pregnancies from 15 to 21 weeks in Maracaibo, Venezuela. Patients with fetal anomalies or chromosome aberrations were excluded from this study. Serum marker levels were expressed as gestational age-specific multiples of the median (MoMs). The incidence of various adverse pregnancy outcomes such as spontaneous preterm labor, fetal growth restriction, pregnancy induced hypertension, intrauterine fetal demise, oligohydramnios, spontaneous miscarriage and placental abruption were evaluated. **Results:** Of the 2,621 patients in this study, pregnancy complications were observed in 296 (11.29%). There was an increase in the relative risk for spontaneous miscarriage (RR = 6.33; RR = 5.53) at -hCG <0.2 MoM and at uE₃ <0.4 MoM, respectively. In the cases of oligohydramnios, AFP concentrations were significantly increased (RR = 4.18). **Conclusion:** Low levels -hCG and uE₃ are associated with a higher incidence of spontaneous miscarriage and high levels of AFP are increased in oligohydramnios, so second trimester maternal serum screening is a good predictor of adverse pregnancy outcomes.

The majority of fetal nucleated red blood cells in maternal blood are not amenable to analysis by FISH. *T. Babochkina, S. Hristoskova, S. Mergenthaler, G. De Napoli, S. Tercanli, W. Holzgreve, S. Hahn.* University Women's Hospital, University of Basel, Basel, Switzerland.

Introduction: The analysis of fetal nucleated red blood cells (NRBCs) enriched from maternal blood is an attractive alternative for the risk-free prenatal diagnosis of aneuploidies. Current results are discouraging due to low levels of sensitivity or inability to detect fetal NRBCs by FISH analysis. We have previously shown, that single cell PCR on micro-manipulated NRBCs, could be used for the reliable determination of multiple fetal loci. Therefore, a disparity appears to exist between the analysis of fetal NRBCs by PCR and FISH.

Methods: NRBCs were enriched from maternal blood samples by anti-CD71 MACS, identified morphologically by May-Greunwald staining and examined by XY-FISH.

Results: Our analysis indicated that in samples obtained from pregnancies with male fetuses, on average approximately 5 % of the erythroblasts were XY-positive, while almost 50% were clearly of maternal origin as they contained XX-signals. The remaining erythroblasts, however, had aberrant or no FISH signals. In pregnancies with female fetuses on average only 45% of the erythroblasts were XX-positive, while the remaining erythroblasts had aberrant or no FISH signals. These results were not improved using a variety of decondensation strategies.

Conclusions: Our results indicate that only half of the NRBCs could be efficiently analysed by FISH, and that these were most likely of maternal origin, as they had a XX genotype. In this regard, our data parallel our previous PCR analysis which indicated that approximately 50% of the circulatory NRBCs were of maternal origin.

Improved Enrichment of Fetal DNA from Maternal Plasma through targeting of Apoptotic Bodies. *F. Bischoff*¹, *C. Horne*², *D. Dang*¹, *J. Scott*², *J.L. Simpson*^{1,3}, *D.E. Lewis*². 1) Depts OB/GYN; 2) Immunology; 3) and Mol/Hum Genet, Baylor Col Medicine, Houston, TX.

Fetal DNA is present in the maternal circulation, correlating positively with gestational age and showing near 100% sensitivity in detecting fetal sequences. While available techniques suffice for diagnostic studies (e.g. RhD), quantitative estimates of fetal DNA are less reliable. Yet, quantitative analysis of fetal DNA is an attractive modality for identifying pregnancy-related complications (i.e. pre-eclampsia) or for use as a novel analyte in non-invasive prenatal aneuploid screening. Better methods to improve isolation and enrich fetal DNA should logically be based on knowledge of the structural forms in which circulating plasma DNA exists. **HYPOTHESIS:** Fetal DNA circulates pre-dominantly in the form of membrane-bound apoptotic bodies which are amenable to focused enrichment strategies. **METHODS:** Maternal plasma (500 ul) specimens (n=28; mean 15.9 wks gestational) were analyzed prospectively using Acridine Orange (AO) dye to stain DNA followed by flow sorting for positive selection of labeled plasma DNA. DNA was extracted using the Qiagen DNA purification kit. Unaware of fetal status, real-time PCR quantified fetal Y-specific (DYS1) and total (GAPDH) genome equivalents (GEq/mL plasma). **RESULTS:** Testing only 150ul of the plasma processed for flow sorting, fetal DNA was still confirmed in 9 of 15 (60%) samples derived from a pregnancy carrying a male fetus. The mean GEq/ml plasma of fetal Y- and GAPDH sequences were 27.8 and 149, respectively. The ratio of fetal to total DNA was 1 to 6, significantly greater than the 1 to 1000 expected using no enrichment. In the six samples in which Y-sequence was not detected, quantity of GAPDH sequence was less than half the mean (71.3 GEq/ml plasma), indicating that with greater volume sensitivity could near 100%. Of 13 samples in which the fetus was female, one showed Y-sequence but at low quantification of 2.8 GEq/ml. **CONCLUSIONS:** Our results confirm that fetal DNA circulates pre-dominantly in apoptotic bodies and that enrichment based on this knowledge can improve quantitative approaches for clinical application.

MR imaging of the fetal cerebellar vermis *in utero*: description of some useful anatomical criteria for normal development. *S.I. Blaser*¹, *A.J. Robinson*¹, *A. Toi*², *D. Chitayat*², *M. Gundogan*¹, *S. Pantazi*², *S. Laughlin*¹, *G. Ryan*².
1) The Hospital for Sick Children, TORONTO, ON, Canada; 2) Mount Sinai Hospital, TORONTO, ON, Canada.

Purpose To produce an atlas of easily identifiable and reproducible measurements and markers of normal anatomic development of the fetal cerebellar vermis *in vivo*.

Â Â Â Materials and Methods Retrospective analysis of the midline sagittal views of the cerebellar vermis was performed in 189 fetal MR studies. Analysis included identification of the fastigial point and vermian fissures, degree of coverage of the fourth ventricle, cerebellar growth and proportions, tegmento-vermian angle, and associated abnormalities of the posterior fossa, brainstem and CNS.

Â Â Â Results Gestational age ranged from 14.0 to 38.6 weeks with a mean of 26.7 weeks. Useful midline sagittal views were obtained in 152 studies, with a total of 230 measurements. Average craniocaudal diameter of the cerebellar vermis follows growth approximately predicted by the linear equation: diameter(mm)=0.74 x gestational age(weeks)-6.11, with an R² value of 0.89. Average height above and below the fastigial point also followed a linear progression, with percentages above and below of 47.9% and 52.1% respectively, and no significant change of this ratio with gestational age. The tegmento-vermian angle was always small in normal fetuses, but was often markedly increased in abnormal fetuses. Coverage of the 4th ventricle should usually have occurred by 17-18 weeks. The declive and primary fissure were always visible in normal fetuses from 17.5 weeks. The other cerebellar vermian fissures were seen at approximately the following gestational ages: secondary at 20 weeks, prepyramidal at 21 weeks and preculmenate at 22 weeks. The other lobules became visible from 24 weeks and most were visible by 27 weeks. Correlation with *in vitro* studies shows a delay of 3-5 weeks in the gestational age at which these features are seen.

MR imaging of the fetus *in utero* I: A practical guide to systematic analysis - Central Nervous System. H.

*Branson*¹, *A. Robinson*¹, *S. Blaser*¹, *A. Toi*², *D. Chitayat*², *M. Gundogan*¹, *S. Pantazi*², *G. Ryan*². 1) Hospital for Sick Children, TORONTO, ON, Canada; 2) Mount Sinai Hospital, TORONTO, ON, Canada.

Purpose Well-established protocols exist for the sonographic examination of the fetus, encompassing differing levels of detail depending on the overall risk of the individual pregnancy (i.e., from a routine screening examination up to a tertiary-level detailed assessment of a high-risk pregnancy). No such protocols are established yet for fetal MR imaging. In our institution we have attempted to establish a protocol for reporting fetal MR examinations, in order that a systematic and methodical approach is adopted by our radiologists, including those who are not used to reading these examinations, and to avoid missing important anatomical abnormalities.

Materials & Methods Retrospective analysis was performed in over 190 consecutive fetal MR examinations performed for CNS and non-CNS indications.

Results Analysis included, but was not limited to, biometry, including biparietal diameter, transcerebellar diameter, ventricular atrial width, craniocaudal diameter of the cerebellar vermis, the presence of the cavum septum pellucidum, corpus callosum and other midline and lateral structures, cortical development and appearance of sulci and major fissures, and assessment of the spine.

Conclusion We would like to demonstrate a practical guide to analysis of the central nervous system of the fetus in utero, including how to perform the biometric measurements, and examples of normal and abnormal biometry and development. (Part 1 of 2.).

MR imaging of the fetal eyes: Normal and abnormal development. *D. Chitayat¹, A. Robinson², S. Blaser², A. Toi¹, M. Gundogan², S. Pantazi¹, G. Ryan¹.* 1) Mount Sinai Hospital, TORONTO, ON, Canada; 2) Hospital for Sick Children, TORONTO, ON, Canada.

Purpose To define easily identifiable and reproducible measurements of normal anatomic development of the fetal eyes *in vivo*. Current measurements of binocular and intraocular distances are defined by ultrasound and are measured according to the bony landmarks of the medial and lateral orbital walls. These bony landmarks cannot be seen on fetal MR, and therefore these ultrasound measurements cannot be directly applied to MR imaging, however the vitreous is well-defined.

Materials and Methods Retrospective analysis of the coronal and axial views of the orbits was performed in 197 consecutive fetal MR examinations performed for CNS and non-CNS indications. Analysis included measurement of the vitreous diameters, intraocular distance and binocular distance. These were plotted against gestational age. Fetuses with abnormalities affecting the eyes were evaluated separately.

Results Normal growth of ocular diameter, intraocular distance and binocular distance is demonstrated, with direct correlation to measurements made by ultrasound at the same gestational age. Additionally, examples of abnormal growth and development are shown including hypertelorism, hypotelorism, microphthalmia, anophthalmia, persistent hyperplastic primary vitreous, and cyclopia, with underlying diagnoses such as frontonasal dysplasia, septo-optic dysplasia holoprosencephaly spectrum, Matthew-Wood, Walker-Warburg, Cat-Eye and Pfeiffer syndromes, and trisomy 22.

The need for fetal karyotyping in anencephaly: recurrent anencephaly due to a familial unbalanced (3;5) translocation. *K.L. Ciprero¹, J.D. Hoffman¹, D.A. Driscoll¹, M. Sagi², N.B. Spinner¹, E.H. Zackai¹.* 1) Div Human Gen & Molec Biol, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Hadassah Medical Org., Jerusalem, Israel.

Prenatal diagnosis of neural tube defects (NTDs) has been greatly facilitated by maternal serum screening programs and improved sonographic techniques. Although most NTDs are shown to be multifactorial, the etiology remains heterogeneous. Recurrence risks as well as risk for other disorders and subsequent pregnancy monitoring depend on the underlying cause. Support for fetal karyotyping has come from surveys of aneuploidy among prenatally detected NTDs (7%-Hume, 1996). There are reports of recurrent anencephaly with trisomy 2p23.2-2pter with additional evidence from single cases that 2p24 is involved. Here we report another possible locus in a three-generation family with five cases of anencephaly. One of these has proven to have an unbalanced translocation with monosomy 3q26.2-3qter and trisomy 5p15.1-5pter, secondary to a familial balanced (3;5) translocation. In generation I, there was an anencephalic male whose healthy male sibling has a (3;5) balanced translocation. The latter is the father of two male fetuses with anencephaly and five healthy children. Three of these children are balanced carriers, one of whom had a child with multiple congenital anomalies with a 46,XX,der(5),t(3;5)(q26.2;p15.1) karyotype, consistent with monosomy 5p15.1-5pter and trisomy 3q26.2-3qter. The other two children each had a fetus with anencephaly, one of which was proven to have a 46,XX,der(3),t(3;5)(q26.2;p15.1) karyotype. We wish to emphasize the importance of fetal karyotyping in cases with NTDs. In addition, the anencephalic cases in our report suggest that a gene/genes in one of these chromosomal regions are associated with NTDs, especially since parietal meningocele has been previously reported in an infant with a 3q27-3qter deletion.

Increased nuchal translucency: A marker of fetal parvovirus? *J. Furnival*¹, *G. Ryan*², *J. Kingdom*², *A. Toi*³, *S. Keating*⁴, *R. Tellier*⁵, *W. Meschino*¹. 1) Genetics, North York General Hospital; 2) Fetal Medicine Unit; 3) Medical Imaging; 4) Pathology, Mount Sinai Hospital; 5) Microbiology, Hospital for Sick Children; Toronto, ON, Canada.

A 36 year-old G3P2 woman was referred to the Prenatal Genetics Clinic at 13 weeks gestation with an increased nuchal translucency (NT) measuring 3.4 cm. Following genetic counselling, an amniocentesis was done revealing normal chromosomes. Fetal ultrasound at 19⁺⁶ weeks showed cardiomegaly, a pericardial effusion and ascites. One week later a tachyarrhythmia was noted. In retrospect, the patient recalled an indirect exposure to Fifth disease midway through her first trimester. There was an outbreak in her son's daycare, but he remained asymptomatic. She also recalled having a period of extreme fatigue between 8 to 10 weeks gestation with no other symptoms. Human parvovirus B19 was detected by PCR from the reserved amniotic fluid. Cardiac function and hydrops worsened over the next 48 hours and the fetus became moribund. The pregnancy was terminated because of the grave prognosis. Fetal pathology confirmed hydrops fetalis. Hematopoietic cells and endothelial cells in the fetal heart, liver and brain showed characteristic inclusions and stained positively for parvovirus on immunohistochemistry. The finding of increased NT with a normal karyotype raises the risk for a variety of structural abnormalities. Fetal parvovirus has been associated with increased NT in 2 previous cases as well as 3 cases of first-trimester hydrops fetalis. Each resulted in the birth of a healthy infant. Several other first trimester cases had early hydrops and fetal demise. First trimester parvovirus infections have also been associated with spontaneous abortion and intrauterine growth restriction. The finding of an increased NT should alert the practitioner to the possibility of later development of hydrops, including that secondary to fetal parvovirus. Appropriate investigations with serology, serial ultrasounds, and possibly PCR testing should be undertaken, particularly if a positive history is revealed.

Prenatal diagnosis of chromosomal defects in Tunisian population. *D. H'MIDA, H. ELGHEZAL, S. MOUGOU, H. SANNANA, A. SAAD.* Cytogenetics, Farhat Hached Hospital, Sousse, Tunisia.

Objective:Increasing annual number of prenatal karyotypes carried out in our laboratory indicates that prenatal diagnosis of chromosomal abnormalities has become a large activity in handicap prevention policy in our country. In our study we report indications and results of foetal karyotypes carried out in Tunisian population during the period of 1993-2003.**Material and Methods:**During the study period, 4765 pregnant women were referred to our center for prenatal diagnostic of chromosomal abnormalities. Foetal karyotypes were performed after amniotic liquid culture according to conventional techniques.Five classical contexts indicate prenatal cytogenetic analysis: advanced maternal age, sonographic detection of foetal malformation, nuchal translucency, maternal serum markers and parental chromosomal abnormalities.**Results:**Two hundred and four chromosomal abnormalities were detected (4.2%). Autosomal abnormalities represent 81.86% of the total chromosome anomalies. Among them, trisomy 21, followed by trisomy 18 and 13 are the most frequents. Sex chromosome abnormalities constitute 18.13% of the total chromosome anomalies. Advanced maternal age (>36 years) was the most common indication (50%). However, nuchal translucency; representing the indication of chromosomal prenatal diagnosis only in 2.4% of cases; appears to have a high predictive value. Maternal serum screening represents a rare indication in our series.**Discussion:**Prenatal diagnosis of chromosome anomalies is accepted by patients and became available in routine in Tunisia as in occidental countries. However, indications and results are not similar. Advanced maternal age persist to be the most common indication. Nuchal translucency screening test and maternal serum screening represents rare indications in spite of their higher predictive value.

Prenatal Cytogenetic Diagnosis on 47,730 Amniotic Fluid Specimens. *R. Habibian¹, S. Nawaz², A. Hajianpour¹.* 1) Genzyme Genetics, Pasadena, CA; 2) USC School of Pharmacy, LA, CA.

Habibian Rezvan, Nawaz Shahbanoo, and Hajianpour Atieh Genzyme Genetics, 11 W. Del Mar Blvd, Pasadena Ca 91007A total of 47,730 amniotic fluid specimens were received at Alfigen/The Genetics Institute between the years of 1996 and 1999. The leading indications for referral were advanced maternal age (68.6%), serum marker Down Syndrome risk (10.6%), abnormal ultrasound (9.64%), and high MSAFP (3.23%). Of these 47,730 specimens, 10 specimens were cancelled, 8 specimens were for confirmation study and 92 specimens failed to grow (0.19%). The adjusted growth failure rate was 0.05% (excluding fetal demised and contaminated specimens). The average turnaround time was 7.90 days. Overall, 92.2% had a turnaround time of ten days or less. Approximately 75.29% of our cases were received by couriers on the same day of specimen collection, while the remaining 24.71% were received by overnight express mail. A total of 47,620 cases, representing 99.77% of the total amniotic fluid specimens received were used for the following data analysis. The abnormality rate, excluding inv(9), was 1582/47,620 (3.32%). Of the 1582 abnormal cases, 1230 cases (77.75%) were autosomal chromosome abnormalities; 278 cases (17.57%) were sex chromosome abnormalities; 42 cases (2.66%) had marker chromosomes; 22 cases (1.39%) were polyploidy, with 21 triploidies and one tetraploidy; and 10 cases (0.63%) had reportable variant chromosomes. The total number of mosaic abnormalities in all five major groups were 221/47,620 cases (0.46%). Of the autosomal chromosome abnormalities, 79.06% consisted of numerical abnormalities, and 20.95% consisted of structural abnormalities. Of the sex chromosome abnormalities, 88.13% were numerical abnormalities and 11.87% were structural abnormalities. Multiple cell pseudomosaicism was observed in 0.15% of the amniotic fluid results. Detailed data analysis will be presented.

Program Nr: 2820 from the 2004 ASHG Annual Meeting

Folic Acid Peri-Conceptional Supplementation: Positive Associations with Miscarriage. *E.B. Hook.* School of Public Health, University of California, Berkeley, CA 94720-7360.

In data on the association of folic acid peri-conceptional supplementation with loss of conceptions before 20 weeks Czeizel et al (*Arch Gynecol Obstet* 255:131,1994) observed a 16% increase, ($P < .05$, with 95% confidence limits of 1% to 30% increase). (See also Hook & Czeizel *Lancet* 350: 515, 1997; Hook *Am J Med Genet* 92: 301, 2000; and 104: 181, 2001). This analysis considers other reports pertinent to this association. Wald (*Ann NY Acad Sci* 678:112, 1993) interpreted MRC data as in essence indicating no association with miscarriage, but in data presented on this point (p. 126) the increase was 15%. Reanalysis of MRC data co-authored by Hackshaw indicated an increase of 6% not 15%, (not significant, but with 95 % upper confidence limit of 43% increase). In data of Windham et al. (*Am J Med Gen* 90: 261, 2000) the increase is 14%, $P = < .10$, with 95% confidence limits of 4% decrease to 34% increase. In all three there is an increase and none exclude an increase as high as 30%. Authors of the recent and largest study from Jiaying City, China, Gindler et al 2001 (*Lancet* 358: 796) interpret their data as indicating no association of miscarriage with any folic acid supplementation, indeed a 3% decrease and reject a 12% or greater possible increase. But from data they present one may calculate that those with *complete* peri-conceptional supplementation have about a 15% *increase* in miscarriage ($P < .001$, confidence interval of 7% to 25% increase), in comparison with those with *no or incomplete* supplementation (the latter including those with just trivial usage). However analyzed, *all* studies of supplementation are consistent with an increase as high as 12% and suggest strongly that folic acid *peri-conceptional* supplementation is associated with about a 15% increase in detected pregnancy loss (with likely limits of 7% to 25% increase). Such association may be due to folic acid increasing the *recognition* of such loss not in its *induction*.

Molecular Nature of Nucleic Acid Containing Bodies in Maternal Plasma. *C. Horne¹, A. Orozco¹, J. Scott¹, D. Dang², J.L. Simpson^{2,3}, D.E. Lewis¹, F.Z. Bischoff².* 1) Immunology; 2) OB/GYN; 3) Hum/Mol Genet, Baylor Col Med, Houston, TX.

Cell-free fetal DNA is present in the maternal circulation, however; the biological form in which this DNA exists and the mechanisms underlying its quantitative variation in plasma are unclear. **HYPOTHESIS:** We hypothesize that the majority of fetal DNA circulates in apoptotic bodies. Further elucidating the fundamental properties of these apoptotic bodies will enable better recovery and enrichment of DNA from these bodies. **METHODS AND RESULTS:** Maternal plasma (500ul) from 10-16 wks gestation was stained with acridine orange (AO), a nucleic acid dye. Using a Coulter XL flow cytometer, the resulting light scatter (LS) pattern suggested numerous sub-cellular particles bound to nucleic acids and scattered more light than control intact cells. To verify that the particles were not whole cells, maternal plasma was filtered through a 0.2 micron filter before staining, resulting in no change in LS or in DNA fluorescence. Additionally plasma was subjected to high-speed centrifugation (14,000xg) prior to AO staining. This treatment resulted in physical separation of the particles. That DNA fluorescence also decreased after centrifugation, indicated that the nucleic acids can be physically separated into smaller fragments. To further investigate the nature of these bodies, maternal plasma was treated with nucleases, proteinases, and detergents before staining with AO. After proteinase K treatment, the LS pattern was nearly destroyed, indicating membrane disruption. As expected, the bulk of the DNA precipitated out of solution. However, after treatment with 1% SDS, the number of events within LS gates significantly increased, as did the DNA fluorescence. In contrast, DNase and RNase treatments affected neither the LS pattern nor the fluorescent intensity, demonstrating membrane protection. **CONCLUSIONS:** Circulating cell-free DNA in maternal plasma is stable within apoptotic bodies, which serve to protect DNA from enzymatic treatment. Fetal DNA enrichment strategies can isolate fetal DNA as membrane bound bodies.

Prenatal diagnosis of Marshall syndrome by targeted sonography. *D. Iacoboni¹, BM. Karpel¹, A. Shanske², RW. Marion², SJ. Gross³.* 1) The Center for Fetal Diagnosis and Reproductive Genetics, Department of OB/GYN, North Central Bronx Hospital/North Bronx Health Network, Bronx, New York; 2) The Center for Congenital Disorders, Department of Pediatrics, Montefiore Medical Center/Albert Einstein College of Medicine, Bronx, New York; 3) Division of Reproductive Genetics, Department of OB/GYN, Montefiore Medical Center/Albert Einstein College of Medicine, Bronx, New York.

Background: Marshall syndrome (MS) is a rare, autosomal dominant syndrome characterized by ocular hypertelorism with shallow orbits, craniofacial anomalies, sensorineural hearing loss, and ectodermal dysplasia. Splicing mutations of the 54-bp exons in the C-terminal region of the COL11A1 gene have been identified in some individuals with MS (Annunen et al., 1999). Below, we present the anatomic features obtained from mid-trimester detailed fetal sonogram that was subsequently utilized for prenatal diagnosis of this syndrome.

Case Report: A 24-year-old, G5P5005, African American woman affected with Marshall syndrome presented to the reproductive genetics unit at 25 weeks of gestation. She is a member of a seven-generation family with six known affected individuals (Shanske et al., 1997); molecular analysis failed to identify a mutation in this family. Targeted anatomy was performed and revealed borderline increased intra-ocular distance and a flat profile with a wide and depressed nasal bridge. Remaining fetal anatomy was unremarkable and amniotic fluid volume was within normal limits. The patient received genetic counseling and informed that the findings were consistent with MS. She delivered a fullterm male infant and the diagnosis of MS was confirmed in the newborn period.

Conclusion: Targeted sonography with particular attention to subtle facial features is an important modality in the prenatal diagnosis of MS, particularly in families where the causative mutation remains unknown.

Time for reevaluation of intrauterine survival after prenatal diagnosis of Turner syndrome and non-immune hydrops. *K. Martin¹, J. Garcia-Heras²*. 1) Dept Ob/Gyn, Washington Univ in St. Louis, St Louis, MO; 2) Dept Ped, Washington Univ in St. Louis, St. Louis, MO.

We report 4 cases of non-mosaic Turner syndrome presenting prior to 24 weeks gestation with large, septated cystic hygromas (CH) and subcutaneous edema, with/out pericardial/pleural effusion/ascites. All cases were seen within the past 3 years. The families were counseled regarding the poor prognosis associated with this prenatal diagnosis and elected to continue the pregnancies. One fetus suffered intrauterine demise prior to 24.0 weeks. The other three fetuses demonstrated progressive resolution of the ultrasound findings and were live born at term. All livebirths had features consistent with the diagnosis of Turner syndrome and two of the three livebirths were confirmed to have congenital heart defects. Surerus et al (Ultrasound Obstet Gynecol,2003) conclude that "Turner's syndrome . . with hydrops has an extremely poor prognosis". A case report of survival of a fetus with Turner syndrome, CH and hydrops was published by Mostello et al (Obstet Gynecol,1989). Suchet et al (Can Assoc Radiol J,1992) describe survival in 1 of 4 hydropic fetuses with Turner syndrome diagnosed prenatally. A literature review demonstrates that the majority of pregnancies in which these finding were made underwent termination of pregnancy. Including our series, a total of 14 fetuses with Turner syndrome, CH and hydrops were identified. Eight were liveborn in the third trimester and six (43%) survived. Families faced with the prenatal diagnosis of Turner syndrome, CH and hydrops must be made aware of the possibility of spontaneous resolution and survival. The likelihood of livebirth associated with this finding cannot be absolutely determined, but may be as high as 43%.

Prenatal diagnosis of Budd-Chiari syndrome. *W. Meschino¹, J. Furnival¹, W. Sirkin², J. Wortsman³.* 1) Dept Genetics; 2) Dept Laboratory Medicine; 3) Dept Diagnostic Imaging, North York General Hosp, Toronto, ON, Canada.

Budd-Chiari syndrome (BCS) is characterized by functional and structural abnormalities in the liver resulting from obstruction of hepatic venous outflow. The acute syndrome is usually associated with an underlying thrombophilic process, whereas chronic BCS may be due to vascular pathology. It occurs very rarely in children. We report the first case of fetal BCS to be detected prenatally. The patient is a 32 year old, G2P1 woman of East Indian ancestry who was referred with a positive maternal serum screen for Down syndrome (1 in 8 risk) and progressive fetal ascites at 18 weeks gestation. Other ultrasound findings included polyhydramnios and an unusual pattern of fetal blood flow into the liver. Investigations revealed normal chromosomes on amniocentesis and negative fetal infection studies. The pregnancy was terminated at the parents' request. External examination of the fetus revealed mild facial dysmorphism, a narrow thorax, marked ascites, brachydactyly and a hypospadias. Internal examination revealed dilated hepatic sinusoids and a membranous obstruction of the inferior vena cava (MOVC) occluding greater than 90% of the lumen. MOVC is the single largest cause of BCS (40%) in Asian series, but is much less common in Western cases. Controversy exists as to whether the membrane is a primary malformation or whether it arises from an organizing thrombus. Maternal and paternal thrombophilia studies including Factor V Leiden and antithrombin 3 were normal in our case. The presence of dysmorphic features and congenital anomalies in our case suggest that the MOVC arose as a developmental defect rather than an organizing thrombus. Together these features may represent a new genetic syndrome.

Prenatal Diagnosis in Severe Methylenetetrahydrofolate Reductase Deficiency: Combined Biochemical and Linkage Approach. *C. Morel¹, P. Scott¹, E. Christensen², D.S. Rosenblatt¹, R. Rozen¹*. 1) Depts of Human Genetics and Pediatrics, McGill University, Montreal, Canada; 2) Dept of Clinical Genetics, Rigshospitalet, Copenhagen, Denmark.

Severe methylenetetrahydrofolate reductase (MTHFR) deficiency (MIM 236250) is characterized by varying degrees of developmental delay, motor/gait abnormalities and seizures. More than 85 patients with this condition have been reported. Biochemical abnormalities include homocystinuria, hyperhomocysteinemia and low/normal plasma methionine levels. The degree of severity correlates with residual enzyme activity. Severely affected patients die in infancy or early childhood. MTHFR activity can be assayed in cultured fibroblasts, amniocytes and chorionic villus cells (CVCs). Although close to 50 mutations have been identified in patients with this condition, they tend to be private, therefore limiting the use of direct mutation detection for prenatal diagnosis. Nine polymorphisms have been identified in MTHFR, thus making prenatal diagnosis by linkage analysis a reasonable option, with or without identification of the deleterious mutations. Two of these polymorphisms, 677CT and 1298AC, are each found in the homozygous state in about 10% of a population of European origin. We report the prenatal diagnosis for severe MTHFR deficiency in six at-risk pregnancies. We studied MTHFR activity in cultured amniocytes or CVCs and performed linkage analysis for the 677CT or 1298AC polymorphisms within the MTHFR gene. Enzyme activity was assessed in cultured amniocytes in four pregnancies and ranged from 1.4-6.5 nmols CHO/mg prot/h (U) (control 3.1-9.6U). In two pregnancies, CVCs demonstrated MTHFR enzyme activity of 3.6U and 7.7U (control 4.5-7.8U). These values were compared to the probands who had a range of 0-0.7U (control 9.6-11.7U) in cultured fibroblasts. Linkage analysis for the 677CT or 1298AC polymorphisms predicted that four of the fetuses were heterozygotes and two, homozygous unaffected. The data from both methods were concordant and predicted unaffected fetuses. We suggest that linkage analysis for severe MTHFR deficiency is a practical approach for prenatal diagnosis.

MR Imaging of the Fetus *in utero* II: A Practical Guide to Systematic Analysis - and the rest (non-CNS). S.

*Pantazi*¹, *A. Robinson*², *S. Blaser*², *A. Toi*¹, *M. Gundogan*¹, *D. Chitayat*¹, *G. Ryan*¹. 1) Mount Sinai Hospital, TORONTO, ON, Canada; 2) Hospital for Sick Children, TORONTO, ON, Canada.

Purpose Well-established protocols exist for the sonographic examination of the fetus, encompassing differing levels of detail depending on the overall risk of the individual pregnancy (i.e., from a routine screening examination up to a tertiary-level detailed assessment of a high-risk pregnancy). No such protocols are yet established for fetal MR imaging. In our institution we have attempted to establish a protocol for reporting fetal MR examinations, in order that a systematic and methodical approach is adopted by our radiologists, including those who are not used to reading these examinations, and to avoid missing important anatomical abnormalities.

Materials & Methods Retrospective analysis of was performed in over 190 consecutive fetal MR examinations performed for CNS and non-CNS indications.

Results Analysis included, but was not limited to, evaluation of thoracic and abdominal situs, lung parenchyma, diaphragms, liver and gallbladder, stomach, kidneys (including biometry), bladder, cord insertion, cord vessels, placental site and morphology, and amniotic fluid volume.

Conclusion We would like to demonstrate a practical guide for the analysis of the rest of the fetus (non-CNS), including how to perform the biometric measurements, and examples of normal and abnormal development. (Part 2 of 2.).

Rapid prenatal diagnosis of Trisomy 21 using quantitative fluorescent PCR in uncultured amniocytes. *S.Y Park¹, M.H. Lee¹, D.J. Kim¹, B.Y. Lee¹, E.H. Cho¹, M.Y. Kim², J.H. Yang², J.S. Choi², H.K. Ahn², H.M. Ryu^{1,2}.* 1) Lab Medical Genetics, Samsung Cheil Hosp, Seoul, Korea; 2) Department of Obstetrics and Gynecology, Sungkyunkwan University School of Medicine, Seoul, Korea.

Rapid prenatal diagnoses of Down syndrome have been studied using quantitative fluorescent PCR assays by small tandem repeat (STR) markers. The purpose of our study was to investigate the accuracy for rapid prenatal detection of Down syndrome using the quantitative fluorescent PCR in uncultured amniocytes. Blind prospective study was performed in 905 amniotic fluid samples. All samples were subsequently analyzed by traditional karyotyping. Trisomy 21 was identified in five samples. The informative rate for at least two STR markers was 98.7%. The amplification failure rate was 0% with our current protocol. The uninformative rate by maternal cell contamination (MCC) and inconclusive results were 0.4%, 2.3%, respectively. There were no false-positive or false-negative results. The sensitivity, specificity, and efficiency of the assay for detecting Down syndrome were 100%. QF-PCR for the rapid identification of fetus with trisomy 21 is a reliable, accurate, and speedy technique. This method is particularly valuable for minimizing parental anxiety in the wait for a diagnostic test result.

Program Nr: 2828 from the 2004 ASHG Annual Meeting

MR imaging of the fetal cerebellar vermis *in utero*: Criteria for abnormal development, with ultrasonographic and clinicopathologic correlation. A.J. Robinson¹, S.I. Blaser¹, D. Chitayat², A. Toi², W. Halliday¹, M. Gundogan¹, S. Pantazi², G. Ryan². 1) Hospital for Sick Children, TORONTO, ON, Canada; 2) Mount Sinai Hospital, TORONTO, ON, Canada.

Purpose We previously produced an atlas of easily identifiable and reproducible measurements and markers of normal anatomical development of the fetal cerebellar vermis *in vivo* from 17.5 weeks gestational age to term. This new study was to demonstrate easily identifiable and reproducible measurements and markers of abnormal development, with ultrasonographic and clinicopathologic correlation. Virtually all previous studies of development of the cerebellum have been performed on fetal specimens, and few *in vivo* studies discuss development of the cerebellar vermis *per se*.

Material & Methods Retrospective analysis of the midline sagittal views of the cerebellar vermis was performed in 189 consecutive fetal MR examinations performed for CNS and non-CNS indications. Analysis included identification of the fastigial point and vermian fissures, degree of coverage of the fourth ventricle, cerebellar growth and proportions, tegmento-vermian angle, and associated abnormalities of the posterior fossa, brainstem and CNS.

Results Gestational age ranged from 14.0 to 38.6 weeks with a mean of 26.7 weeks. Useful midline sagittal views were obtained in 152 studies; approximately one quarter had abnormalities affecting the posterior fossa. These included fetuses within the Dandy-Walker spectrum which we subdivided according to presence of dysplasia or hypoplasia, abnormal tegmento-vermian angle, size of cisterna magna, and associated CNS abnormalities. Correlation with MR and US images is demonstrated in addition to clinicopathologic and genetic diagnoses where available.

Program Nr: 2829 from the 2004 ASHG Annual Meeting

Effects of prenatal diagnosis on the birth prevalence of children with chromosomal abnormalities. *M.P. ROTH, B. DOTT, C. STOLL.* Genetique Medicale, Faculte de Medecine, Strasbourg, France.

The objectives of this study were to describe the impact of prenatal diagnosis on the birth prevalence of chromosomal abnormalities during 23 years in a well defined population. The material for this study came from the analysis of data from multiple sources on births and terminations of pregnancy (TOP) after prenatal diagnosis of chromosomal abnormalities in 321,204 consecutive pregnancies of known outcome. The study period was divided into 3 subgroups 1979-1988, 1989-1996 and 1997-2002. In the area under study prenatal diagnosis of chromosomal abnormalities is offered free of charges to all women >38 years. Maternal serum screening (triple test) is offered, free of charges, to all pregnant women since 1997 and fetal ultrasonographic scanning is routine practice. Between 1979-1988, 1989-1996 and 1997-2002 prenatal detection of chromosomal abnormalities increased from 10.5%, 59.2% and 75.0%, respectively. TOP increased in the same proportions during the 3 time periods. The birth prevalence per 10,000 of Down syndrome was 8.89, 9.50, and 4.98, respectively. However the total prevalence of Down syndrome was 11.51, 19.68 and 19.93, respectively. Therefore no significant decline in the total prevalence of Down syndrome was observed. The main reason for these observations is the increase in maternal age, from 24.8 to 30.1. In conclusion the introduction of routine prenatal diagnosis has resulted in a significant fall in the birth prevalence of children with chromosomal abnormalities, but not in the total prevalence of the fetal chromosomal aberrations. More efforts on the primary prevention of chromosomal abnormalities are needed.

Program Nr: 2830 from the 2004 ASHG Annual Meeting

No evidence of fetal DNA in maternal serum after twin pregnancy. *O. Samura, N. Fujito, N. Miharuru, M. Hyodo, M. Tanigawa, K. Ohama.* Dept OB/GYN, Hiroshima Univ Sch Medicine, Hiroshima, Hiroshima, Japan.

Fetal DNA in maternal blood has been used for non-invasive prenatal diagnosis. However, in a recent report fetal male DNA was detected in the plasma of 22% healthy women with previous sons for up to several decades after delivery. We investigated short term persistence of fetal DNA in maternal serum of twin pregnancy after delivery. Twenty seven twin pregnant women who had at least one male fetus were recruited. All of the women gave their written consent after being informed about this study. Maternal venous blood samples were taken before delivery. After delivery of the baby, 7ml maternal peripheral blood was collected at 30 minutes and 1 day postpartum. The amount of cell-free fetal DNA in maternal serum was quantified by calculating the concentration of the SRY gene sequence from the Y chromosome using taqman PCR. Median concentration of fetal DNA in serum was 153.21 copies/ml (Range 16.93-485.39 copies/ml) before delivery and 102.6 copies /ml (Range 0-391.62 copies/ml) 30 minutes after delivery. Fetal DNA was detected in only one case 24hrs after delivery. Molecular microchimerism due to circulating fetal DNA persisting from previous pregnancies should not hamper non-invasive serum-based prenatal testing.

Trisomy 17 mosaicism cases diagnosed prenatally. *G. Sekhon, B. Haas, M. Fernandez, K. Thornell, K. Collen.*
Genzyme Genetics, Santa Fe, NM.

Mosaicism for trisomy 17 in prenatal diagnosis is an uncommon finding, while postnatal cases are exceptional. Trisomy 17 mosaicism remains an uneasy situation for genetic counseling and for a decision during pregnancy. Limited medical literature has addressed the clinical significance of true CVS or amniotic fluid trisomy 17 mosaicism. Such mosaicism is more commonly of extra-embryonic origin and often associated with normal fetal development. Prior reviews have reported at least two unfavorable outcomes out of twenty prenatally diagnosed reported cases with trisomy 17 mosaicism. Although post-natal lymphocyte studies were normal in all such cases, investigators observed trisomy 17 mosaicism on cultured skin fibroblasts only in the two adverse cases. Between September 1994 and June 2004, Genzyme Genetics has diagnosed twenty (20) prenatal cases with trisomy 17 mosaicism and no additional cytogenetic anomalies. We have contacted the referring obstetricians of each case inquiring about the decision reached by the patient about continuation of the pregnancy and any additional factors besides the mosaicism that might have led to a decision of termination. The obstetricians of those cases continuing the pregnancy were asked to provide obstetrical complications, delivery details including gestational age, as well as standard newborn evaluation measurements including length of stay prior to discharge from the nursery or NICU. In addition, the referring obstetrician is asked to provide the mother of the child an invitation to participate in the survey by giving her and the child's pediatrician an evaluation form regarding the child's health. [The age range for this group of children is neonate through age 10]. To date we have gotten confirmation of a child's health from five of the twenty cases. All five are healthy and phenotypically normal infants. Additional responses are anticipated.

Prenatal detection of cystic hygroma in a pregnancy with an unbalanced translocation involving 6q monosomy and 4q trisomy. *E. Story, S. Petersen, K. Murphy, M. Spencer, K. Blakemore, G. Stetton.* Department of Gynecology & Obstetrics, Johns Hopkins Hospital, Baltimore, MD.

An unbalanced chromosome translocation is an uncommon finding with fetal cystic hygroma. We report a case of an unbalanced translocation ascertained by chorionic villus sampling at 12 6/7 weeks following a first trimester nuchal translucency ultrasound that revealed a fetal septated cystic hygroma. G-band analysis and subtelomere probe studies revealed a karyotype of 46,XX,der(6)t(4;6)(q27;q25). Parental karyotypes indicated that this chromosome rearrangement was de novo. Fetal demise in utero occurred at 14 3/7 weeks gestation.

Lymphatic obstructions resulting in an enlarged nuchal translucency of greater than 3.0 mm or septated cystic hygroma are present in approximately 0.8% of fetuses evaluated between 10 and 16 weeks gestation. The vast majority of those with a septated cystic hygroma will have an abnormal karyotype, most often monosomy X, or trisomy 21, 18, or 13. Both trisomy 4q and monosomy 6q have been described in viable offspring, although not concomitantly. Viable offspring with partial trisomy 4q have been reported to have psychomotor and mental retardation, seizures, growth restriction, short neck, dysmorphic facies, and major anomalies. Viable offspring with partial monosomy 6q have been reported to have mental retardation, retinal abnormalities, postnatal growth retardation, dysmorphic facies, and webbed neck. In addition to this case, cystic hygroma has been reported in one other case of 6q25-6qter monosomy. Postnatal webbed neck in individuals with partial monosomy 6q may represent a resolved cystic hygroma.

Given the unbalanced karyotype in this fetus with a cystic hygroma, it is possible that there may be several candidate genes involved in lymphatic development in the 6q25-6qter and/or 4q27-4qter regions. Two genes of interest in 6q25-6qter that have been identified are: Vasoactive Intestinal Peptide, which has been implicated in the regulation of lymphatic pumping activity; and the T-box gene *Brachyury*, which is involved in posterior mesodermal development.

Mosaicism in CVS revisited. *M. Thangavelu, B. Huang.* Genzyme Genetics, Orange, CA.

Most chromosome mosaicisms observed in CVS is reported to be confined to the placenta, with the incidence of confined placental mosaicism being 1%. Follow up amniocentesis or cordocentesis may be performed to confirm fetal origin of the mosaicism. We analyzed cytogenetic data on CVS analyzed at Genzyme Genetics to determine (1) the frequency of mosaicism for various chromosomal abnormalities and (2) the possibility of confirming the abnormalities in follow up investigations. Mosaic abnormalities were observed in 315 of 26,306 (1.2%) specimens investigated. Mosaicism for trisomy 2 was the most common mosaic abnormality (47 cases; 14.9% of mosaic cases). Mosaics for 45,X was the next most frequent abnormality (45,X/46,XX in 9.2% and 45,X/46,XY in 7.6%). This was followed by mosaicism for trisomy 7 (7.3%), trisomy 18 (6.7%), trisomy 8 (5.1%), trisomy 15 (4.1%), trisomy 9 (3.8%) and trisomy 12 (2.9%). Mosaicism for a marker chromosome and mosaicism for structural abnormalities were observed in 5.1% and 7.6% of cases with mosaicism, respectively. Mosaicism for complex and multiple aneuploidies was observed in 25 (7.9%) cases. Data on follow up analysis was available for 166 cases. The following mosaic abnormalities were confirmed: 45,X/46,XY (6/13), 45,X/46,XX (3/8), +21 (3/4), +18 (2/19), +7 (1/11), +8 (1/8), +9 (1/6), +12 (1/8), +13 (1/6), +14 (1/3), and tetraploidy (1/1). The marker was confirmed in 2/7 cases. Mosaicism for +2 was not confirmed in any of the 24 cases that had follow up studies. Of the 166 cases that had follow up investigations, the abnormality was confirmed in 27 (16.3%). Consistent with previous studies, our data suggests that mosaicism for certain abnormalities observed in CVS may indeed be true fetal mosaicism. It is therefore important to recommend follow up studies, particularly for those abnormalities with a higher probability of being present in the fetus. Our data also suggests that the probability of fetal mosaicism varies depending on the abnormality. Knowledge of this probability is important in determining (1) how exhaustive the follow up analysis ought to be and (2) how to interpret the results of the follow up studies, particularly when mosaicism is not confirmed.

Prenatal Finding of Trisomy 22. *M. Thomas¹, A. Toi¹, S. Keating², D. Chitayat¹*. 1) Dept Medical Genetics, Mount Sinai Hosp, Toronto, ON, Canada; 2) Dept Pathology, Mount Sinai Hosp, Toronto, ON, Canada.

We report a case of a fetus with a karyotype of trisomy 22 detected prenatally. This was a second pregnancy to a healthy couple who are non-consanguineous and of Caucasian origin. First trimester dating ultrasound was reported as normal. No first or second trimester screening was performed. Second trimester ultrasound was not done. Ultrasound at 35.7 week gestation reported a fetus of 30.9 weeks size with large 4th ventricle and cleft of lower vermis, cleft lip and primary palate, hypertelorism, flat profile, small stomach, increased amniotic fluid, absent kidneys, and two vessel umbilical cord. MRI showed bilateral PHPV, eye anomalies and microtia, unusual occiput, small cisterna magna, DWM, ventriculomegaly, narrowing of the occiput, bilateral persistent hyaloid vessels with triangular shaped lens, hypertelorism, bilateral microtia, micrognathia, flattened nose, and cleft lip and palate. Chromosome analysis revealed an abnormal karyotype, 47,XX,+22. This is an additional case to the very few reported cases, with different arrays of fetal abnormalities. As with the others, this demonstrates the merit of fetal karyotyping in view of these multiple congenital abnormalities.

Chromosome analysis of uncultured amniocytes by Comparative Genomic Hybridization: A prospective study in early amniocentesis. *C. Vuthiwong¹, N. Aranyakasemsuk¹, C. Tocharoentanaphol², A. Ketupunya¹, S. Muttamara¹.* 1) Obstetrics and Gynecology, Phramongkutklo Hospital, Bangkok, Thailand; 2) Ramathibodi Hospital, Mahidol University.

Objective: To study chromosome analysis by Comparative Genomic Hybridization method (CGH) compare with conventional method.

Study design: Cross-sectional descriptive study

Populations: 32 singleton pregnant women with gestational age between 12 and 15 weeks without medical nor obstetrical complication who have indications for chromosome analysis. The patients and husbands decide to have early amniocentesis after the genetic counseling and informed consent for participation in the study were obtained.

Methods: Complete family pedigree information and ultrasound was performed to identify gestational age, anomalies and site of puncture. Trans abdominal amniocentesis were carried out under ultrasound guidance by using 20 gauge disposable sterile spinal needles. 1 ml. of amniotic fluid was discarded to prevent maternal cell contamination and 12-15 ml. was collected and divided into 2 parts, one part 4-5 ml. was sent for CGH analysis, another part for conventional chromosome analysis. The patients were follow up in 2-3 weeks for the results, at 20 weeks gestation for ultrasound scanning and antenatal care at 28 weeks gestation.

Main outcomes: Conventional karyotypes is a gold standard technique.

Results: Chromosome analysis of 32 pregnant women by CGH technique can detect 17 female karyotypes (53.1%) and 15 male karyotypes (46.9%) which were the same as the conventional technique. No failure rate of both techniques. The mean duration of the CGH technique was 6 days and 14 days for conventional chromosome analysis.

Conclusion: The CGH technique in chromosome analysis of uncultured amniocytes can detect 32 samples which result of the tests were the same as the conventional technique and less time for analysis.

Prenatal Diagnostic Markers for Cornelia de Lange Syndrome. *D. Yaeger*¹, *D. Driscoll*^{1, 2}, *M.J.M. Nowaczyk*³, *L.G. Jackson*^{1, 4}, *I.D. Krantz*¹. 1) Division of Human Genetics and Molecular Biology, The Children's Hospital of Philadelphia; 2) Department of Obstetrics and Gynecology, The Hospital of the University of Pennsylvania, Philadelphia, PA; 3) Departments of Pathology and Molecular Medicine and Paediatrics, McMaster University and Hamilton Health Centre Corporation, Hamilton, Ontario, Canada; 4) Department of Obstetrics and Gynecology, Drexel University School of Medicine, Philadelphia, PA.

Cornelia de Lange syndrome (CdLS) is a dominant genetic disorder characterized by distinct facial features, hirsutism, growth retardation, limb abnormalities, and neurological impairment. Most cases are sporadic. Recurrence risk for families in which neither parent is affected is estimated at 1.5% due to germline mosaicism. *NIPBL* has been identified as the disease gene in approximately 50% of cases. In families where no mutation in *NIPBL* has been found, prenatal screening of future pregnancies involves serial ultrasounds looking for signs of growth retardation, limb abnormalities, or other structural defects associated with CdLS. The maternal serum marker, PAPP-A, has also been demonstrated to be reduced in the first and second trimester of CdLS pregnancies. Recent reports suggest increased nuchal translucency may be a marker in the first trimester. We present two new cases in which sonographic findings suspicious for CdLS were confirmed after delivery. One child was born to unaffected parents who had a previous child with CdLS. In the subsequent pregnancy ultrasound findings at 19 weeks demonstrated severe micrognathia and bilateral hand anomalies. The diagnosis was confirmed after termination. In the second case there was no family history and the fetus was noted to have prenatal findings consisting of IUGR and severe limb reduction defects, however the diagnosis of CdLS was not considered until late in the pregnancy. Twenty previously reported cases of prenatal findings in CdLS were reviewed to determine the spectrum of physical features and gestational age at which they are evident. These cases reveal a pattern of sonographic findings and low maternal serum PAPP-A levels that should raise the suspicion of CdLS during pregnancy.

Program Nr: 2837 from the 2004 ASHG Annual Meeting

Enrichment of fetal cells from maternal blood. *D.T. Yamanishi, P.G. Hujsak, S.F. Snyder, C. Schmitigal, G. Walker, G. Tao, M. Huang, J. Xu.* AVIVA Biosciences Corp, San Diego, CA.

Non-invasive methods to extract fetal cells from maternal peripheral blood for genetic analysis would be a significant advancement for prenatal diagnosis. To address this un-met need, AVIVA Biosciences Corporation (AVIVA) has developed a complete protocol that allows consistent enrichment and recovery of rare fetal cells from maternal peripheral blood. **OBJECTIVE:** To develop a procedure to reproducibly enrich fetal cells from maternal peripheral blood. **DESIGN:** The two-step protocol involves the Fetal Cell Enrichment Kit (FCEK), which utilizes a negative depletion approach to remove maternal cells and platelets, while minimizing the loss of fetal cells. Interphase FISH was performed to detect fetal cells. **RESULTS:** We have optimized our FCEK based on the positive results from a clinical evaluation at Baylor School of Medicine. Our results demonstrate significant improvements in sensitivity, robustness and overall performance. **CONCLUSION:** AVIVA's optimized FCEK is ideally suited for non-invasive enrichment and cytogenetic analysis of fetal cells.

Preconceptional Multivitamin/Folic Acid Use and Rates of Neural Tube Defects: FASTER Study Data. *Y. Kharbutli¹, K. Eddleman¹, R. Zinberg¹, F. Malone², R. Ball³, D. Nyberg³, C. Comstock³, G. Saade³, S. Gross³, L. Dugoff³, S. Craigo³, I. Timor³, S. Carr³, J. Vidaver⁴, M. Dalton², NICHD.* 1) Mount Sinai Medical Center, NY, NY; 2) Columbia University, NY, NY; 3) FASTER Consortium; 4) DM-STAT.

Objective: To examine rates of neural tube defects (NTDs) and preconceptional multivitamin and/or folic acid use from the FASTER trial database generated from nationally recognized perinatal referral centers. **Study Design:** Participants in the first and second trimester evaluation of risk (FASTER) trial were enrolled between 10-14 weeks of pregnancy. Preconceptional multivitamin/folic acid use and duration was documented by interview questionnaire and participants were followed for complete pregnancy outcome. Comparison of NTD rates versus preconceptional multivitamin use was done using Fishers exact test with multivitamin use defined as daily intake at least one month prior to pregnancy. **Results:** Evaluation of multivitamin use among the 37,866 participants revealed that 17,639 used multivitamins while 20,227 did not. Of the 397 diabetic patients, 155 (or 39%) took vitamins while 66 of 96 (68%) patients with a previous NTD pregnancy took vitamins. Multivitamin use among the entire patient population was found to statistically increase with age (P-value <0.0001). Analysis of usage among three age groups, 16-25, 25-35 and 35 year olds, revealed rates of 23.4%, 50.7%, and 59.8% respectively. Therefore, 33 cases (0.09%) of NTD were observed in the FASTER study population. There were 18 NTD cases (0.10%, 95% CI 0.06%-0.16%) among those that had taken vitamins and 15 NTD cases (0.07%, 95% CI 0.04%-0.12%) among those that had not and this difference was not significant. **Conclusions:** The prevalence of NTDs among our FASTER population was 33/ 37,866 (0.09%). Our data show a significant increase in multivitamin use with increasing maternal age. The NTD cases were found among 0.10% of patients that had taken multivitamins and 0.07% of patients that had not. Although this observation does not show a reduction in NTDs among those taking preconceptional multivitamins, this finding may be reflective of methodological limitations.

First PAGE: Seven year experience with screening for birth defects and genetic disorders by primary prenatal care providers. *E.M. Kloza*¹, *S. Ellingwood*¹, *J. Johnson*², *J.E. Haddow*¹. 1) Foundation Blood Research, Scarborough, ME; 2) Office of Institutional Research, University of Southern Maine, Portland, ME.

Purpose: Prenatal care providers (PCPs) are key to the identification of pregnant women at risk of delivering children with birth defects or genetic conditions. Efforts to engage PCPs in genetic risk identification have had mixed success. We report here a well-accepted strategy that has been used successfully since 1996 to identify and manage women at risk while educating PCPs about genetic issues relevant to their practice. Methods: Dubbed *ProgramME*, the approach used a 15 element self-administered Genetic History Questionnaire (GHQ) indexed to a 15 section Office Guide, and was introduced in 1996 by project staff to 212 Maine PCPs. Eighty-five percent of survey respondents used the GHQ with all new patients and gave the approach a rating of 4.4 out of 5. The number of calls for genetic information or referrals was unchanged following implementation of *ProgramME*. However, the percentage of calls initiated by family history increased from 13.2% to 27.4% ($p < 0.01$), and calls associated with a maternal condition rose from 9.9% to 19.5% ($p = 0.03$). Modified materials were introduced in an additional 7 US venues with similar success. In 2002, the March of Dimes funded a revision and update of *ProgramME*. At that time, 48% of Maine PCPs continued to use the 1996 *ProgramME* materials compared to 85% in 1996. Renamed *First PAGE*, the new materials were introduced to all Maine PCPs and mailed to all New Hampshire PCPs as well. Results: Eighty-three percent of respondents to a survey of Maine participants intended to use the approach with all or most new patients, similar to the response in 1996. Seventy-one percent said *First PAGE* made them more confident discussing genetic issues with patients, and 69% said it simplified risk assessment. It helped 60% learn more about genetics, and assisted 74% in addressing risk early in pregnancy. Conclusions: *First PAGE* is a well-accepted, useful, and important tool for engaging community PCP participation in risk identification and management, but must be introduced office by office by committed project staff to be successfully integrated.

Current prenatal genetic counseling practice with regard to sonographic markers for Down syndrome. *E. Carson, L. Cohen, N. Lazebnik, S. Schwartz, C. Curtis, A. Matthews.* Dept Human Genetics, Case Western Reserve University, Cleveland, OH.

Many studies have been published regarding the association between sonographic markers and the risk for Down syndrome (DS) however no clear guidelines exist regarding how to modify patient risk. This study examined variability of genetic counseling practice regarding significance of sonographic markers, methods of risk adjustment utilized, factors influencing methods used and circumstances under which risk adjustment and/or invasive testing are offered. According to 98% (148/151) of responding genetic counselors, level II ultrasound studies are valuable tools for DS risk assessment based on the presence or absence of markers. Variability in reported risk adjustment methods (quantitatively vs. qualitatively) was noted under two circumstances: 1) in the presence of an isolated marker with low specificity and 2) advanced maternal age. Overall, there does not appear to be consistency in how genetic counselors modify risk. Although the literature suggests that certain markers are more specific than others, counselors did not differentiate between them in terms of qualifying risk for DS. For example, 25% did not associate a thickened nuchal fold with an increased risk while 60% would elevate risk based on an isolated echogenic intracardiac focus. Responses indicated that many additional factors influence counselors practices of risk assessment, most significantly the type of center-specific guidelines regarding offering invasive testing for DS. Although 86.6% of respondents were involved in the development of these guidelines, 48% were only somewhat comfortable with them. Additional issues raised which may contribute to a lack of comfort include uncertainty of published evidence, variable skills of ultrasonographers and provoking anxiety for patients. Moreover, while most research has been conducted on high-risk women, results from this study demonstrate that high-risk assessment data is extrapolated onto a low-risk population. A lack of consensus in ultrasound literature regarding the association of markers with DS makes it difficult to establish practice guidelines at this time.

Midtrimester recurrence risk of aneuploidy in women with a previous history of Down syndrome. *T.M. Sellers, A.E. Donnenfeld, K.M. Annable.* Genzyme Genetics, Philadelphia, PA.

PURPOSE: To determine the recurrence risk of aneuploidy at the time of amniocentesis for women who have had a previous pregnancy with Down syndrome. **METHODS:** A retrospective analysis of our database was performed for all amniocentesis specimens submitted with the indication of prior pregnancy with Down syndrome. This includes a prior prenatal diagnosis or liveborn with Down syndrome. The observed frequency of aneuploidy in this group was compared to the expected rate based on maternal age using a case control comparison. **RESULTS:** There were 1567 amniocentesis specimens submitted because of a prior pregnancy with Down syndrome. Forty-one had a subsequent pregnancy diagnosed with aneuploidy at amniocentesis; 28 were trisomy 21, 6 were trisomy 18, 4 were 47,XXY and 3 were 47,XXX. The mean age of the 1567 women evaluated was 35.13 years of age. The expected frequency of aneuploidy at midtrimester based on a maternal age of 35.13 years alone was 7.68 per 1000. The observed frequency of aneuploidy at midtrimester in our population was 26.16 per 1000. A risk ratio of 3.41 was calculated. This was statistically significant ($p < 0.0001$). **CONCLUSION:** There is a significantly increased risk of aneuploidy at midtrimester in patients who have had a previous pregnancy with Down syndrome ($p < 0.0001$). The risk of aneuploidy at midtrimester in women with a history of Down syndrome is 3.41 times higher than expected based on age alone. The current practice of counseling patients that the recurrence risk of Down syndrome is 1% should be re-evaluated.

Minor dysmorphisms associated with yellow fever vaccine: just blinded association? *D.P. Cavalcanti¹, M.A. Salomao¹, J. Lopez-Camelo², M.A. Pessoto³, H. Sato⁴, E.M. Amaral⁵, P. Papaiordanou⁶*. 1) Perinatal Genetics, Dept. Medical Genetics, FCM, UNICAMP, Campinas, SP, Brazil; 2) Instituto Multidisciplinario de Biologia Celular (IMBICE), Buenos Aires, Argentina; 3) Dept. Pediatrics, FCM, UNICAMP, Campinas, SP, Brazil; 4) Health Secretary, S. Paulo State, S. Paulo, SP, Brazil; 5) Dept. Obstetrics, FCM, UNICAMP, Campinas, SP, Brazil; 6) Dept. Medical Clinics, FCM, UNICAMP, Campinas, SP, Brazil.

The Yellow Fever Vaccine (YFV) has been considered one of the safest known vaccines. However, the use of YFV in pregnant women is still not recommended because its effects are unknown. Recently in Brazil, in a governmental campaign against the disease, 67% of the population from the Campinas region at the Southeast of the country received the YFV. A number of women, unaware that they were pregnant, received the YFV during the campaign. We report a clinical investigation on 304 Brazilian children exposed intra-uterus to YFV. These children were submitted to a dysmorphological evaluation within an age range of between 1 month and 1 year. A reference population was obtained from births at the University Maternity of Campinas from the period 1997-1999, immediately before the vaccination campaign. Malformations were compared between 304 cases and 10,691 births from the previously defined period of the vaccine campaign. Exposed and non-exposed babies to YFV were also compared to other clinical and social variables. For this purpose the reference population has included 762 malformed babies and their 762 controls. The only important risk factor more frequently observed in exposed babies to YFV was vaginal bleeding in the first trimester ($p < 0.05$). The major malformation rate found in this study was 3.3%. However, minor dysmorphisms, specially pigmented naevus, were significantly more frequent ($p < 0.001$) than in the reference population. Although bias cannot be ruled out, we suggest that a remote reproductive risk hypothesis should be considered in future studies involving YFV. (Supported by FAPESP - 01/10556-9 and Health Secretary of the Sao Paulo State).

Sonographic findings in fetuses with de novo and inherited balanced chromosome rearrangements; a series of 1,955 cases. *B. Goldin*¹, *M. Shaham*², *A.E. Donnenfeld*¹. 1) Genzyme Genetics, Philadelphia, PA; 2) Genzyme Genetics, Yonkers, NY.

OBJECTIVE: To determine the frequency of sonographically detected fetal malformations among fetuses with de novo and inherited apparently balanced chromosome rearrangements.

METHODS: A review of our database for chromosome rearrangements identified at amniocentesis and CVS was performed. Indications for prenatal diagnosis were tabulated for cases in which there was knowledge of whether the rearrangement was familial or de novo. Sonographic findings were compared between fetuses with de novo and inherited apparently balanced reciprocal and Robertsonian translocations. A chi squared analysis was performed, comparing the two groups.

RESULTS: Out of a total of 3,076 chromosome rearrangements identified, information on whether the rearrangement was inherited or de novo was available for 1,955 pregnancies. Abnormal ultrasound findings were reported in 46 out of 1144 (4%) fetuses with inherited apparently balanced translocations and in 34 out of 335 (10%) fetuses with de novo apparently balanced translocations. The difference in abnormal ultrasound findings between the de novo and inherited groups was statistically significant, ($p < 0.0001$, odds ratio 2.7).

The following ultrasound findings were observed for the de novo apparently balanced translocations: choroid plexus cysts (8), intracardiac focus (4), nuchal thickening (3), a kidney abnormality (3), multiple unspecified anomalies (3), hydrocephalus (2) and one case each of echogenic bowel, clubbed feet, polyhydramnios, polyhydramnios with cleft lip/palate, esophageal atresia, holoprosencephaly with cleft lip/palate, hypoplastic right heart and posterior fossa cyst, "double bubble" sign, skeletal anomalies, gastroschisis and congenital heart disease.

CONCLUSION: A significantly higher rate of abnormal ultrasound findings was observed among fetuses with de novo compared to inherited apparently balanced translocations. This data confirms that fetuses with de novo chromosome rearrangements are at an increased risk for congenital anomalies compared to fetuses with inherited rearrangements.

Detection of sample mixture in DNA during high throughput genotyping of single nucleotide polymorphism sites.

J. Ge¹, R. Chakraborty^{1,2}. 1) Dept. Biomedical Engineering, University of Cincinnati, Cincinnati, OH; 2) Center for Genome Information, Dept. Environmental Health, Univ. Cincinnati, Cincinnati, OH.

With increasing use of high throughput platforms of single nucleotide polymorphism (SNP) genotyping, many laboratories currently handle hundreds of DNA samples for genotyping thousands of SNP sites on a routine basis. Consequently, the chance of inadvertent human or machine errors due to contamination or sample mixture has become non-trivial. This research presents a novel bioinformatic tool to detect, monitor, and control genotyping errors caused by contamination/mixture of DNA of different individuals. We developed maximum likelihood methods for detecting DNA mixture based on multilocus genotype profile and the number of (apparently) heterozygous sites in each sample. Likelihood-based inference of the presence of mixture is more reliable by using multilocus genotype profiles, compared to that based on the number of heterozygous loci. However, inference regarding the number of contributors in the mixture is more accurate on the basis of the number of heterozygous loci. Although the reliability of mixture prediction and the precision of the estimate of the number of contributors in the mixture increase with the number of SNP sites typed, mixture detection has an accuracy of over 99.9% even with 100 SNPs scored. When DNA typing is being done on samples of heterogeneous population origin (i.e., when population substructure is an issue), knowledge of the extent of population substructure (e.g., the coefficient of coancestry or gene differentiation) improves the prediction ability of mixture occurrence. The algorithm is also applicable for panels of SNP sites with variable allele frequencies. The analytical method is validated with computer simulations of different scenarios of mixtures (e.g., with varying number of contributors) constructed from actual sets of multilocus SNP genotypes. The routine can be easily integrated in any laboratory information management system (LIMS) as a module for quality control and quality assurance purposes in high throughput SNP studies. (Research supported by NIH grant GM 41399 to RC).

Program Nr: 2845 from the 2004 ASHG Annual Meeting

A methodology for hunting disease genes under linkage peaks via large scale resequencing. *S. Nelson, M. Ogdie, B. Merriman.* University of California at Los Angeles, Departement of Human Genetics, Rm 5506b Gonda, UCLA Medical Ctr, Los Angeles, CA.

A common approach to hunting genes for complex diseases is to first perform a genome-wide linkage scan, and then follow up on the resulting linkage peaks using association tests against a dense set of common SNPs to further narrow the region. However, this strategy could miss genes in which the risk is due mainly to distinct rare variants. To assay for this requires sequencing individuals to identify rare variants and mutations. Recent technological advances in high-density DNA oligonucleotide microarrays allow array-based resequencing of megabases of DNA in a cost-effective and high-throughput manner. We present an experimental strategy, statistical methodology, and power calculation software for deploying this technology to detect disease genes that involve the rare-variant mechanism, in the context of a comprehensive follow-up on all genes under a linkage peak in an IBD sharing genome scan for a complex disease. For example, by resequencing 90 select subjects, our approach has 90% power to detect rare-variant effects that impact as little as 40% of the linked individuals at a peak, under realistic linkage study parameters and a cost compatible with academic research grants.

Identification of positional candidate genes for peripheral neuropathy disorders using *in silico* subtraction. J.

*Qian*¹, *M. Khajavi*², *G. Saifi*², *D. Armstrong*³, *C. Prange*⁴, *N. Katasanis*¹, *J. Lupski*². 1) Institute of Genetic Medicine and Wilmer Eye Institute, Johns Hopkins Univ, Baltimore, MD; 2) Department of Molecular and Human Genetics; 3) Department of Pathology, Baylor College of Medicine, Houston, TX; 4) Lawrence Livermore National Laboratory, The I.M.A.G.E. Consortium, Livermore, CA 94550.

Although substantial progress has been made in the identification of genes responsible for Charcot-Marie-Tooth disease (CMT), including *PMP22* (peripheral myelin protein 22), *MPZ*, *GJB1* (gap junction protein b1), and *EGR2* (early growth response 2) many CMT patients without CMT1A duplication do not have identifiable mutations in these genes suggesting other peripheral nerve specific genes responsible for CMT. In fact, genetic studies reveal 36 loci linked to CMT phenotype with 24 of the genes having been identified to date. Due to the extreme genetic heterogeneity and rarity of some minor loci, positional cloning to identify additional genes for CMT has been difficult. As a powerful resource for identifying molecular components crucial for myelination, we have established peripheral nerve specific cDNA libraries. Utilizing these libraries as a gene pool, we performed *in silico* subtraction against the EST sequence database (dbEST) to predict EST clusters likely representing genes expressed exclusively or preferentially in peripheral nerve. We identified many known CMT genes but also uncharacterized peripheral nerve specific ESTs that map to regions of the genome that are linked to a CMT phenotype. These latter ESTs may be strong candidate genes for CMT1.

Strong evidence of a major gene with Mendelian transmission involved in Familial Mesial Temporal Lobe Epilepsy (FMTLE). *R. Secolin¹, R.G.M. Ferreira³, C.V. Maurer-Morelli¹, N.F. Santos¹, E. Kobayashi², R.B. Marchesini¹, F. Cendes², H. Kriger³, I. Lopes-Cendes¹.* 1) Medical Genetics, University of Campinas, Campinas, Brazil; 2) Department of Neurology, University of Campinas, Campinas, Brazil; 3) Department of Parasitology, University of São Paulo, São Paulo, Brazil.

Recently, we described a large group of families segregating a distinct type of temporal lobe epilepsy with familial recurrence (FMTLE). Initial pedigree analysis pointed to strong genetic predisposition for development of hippocampal atrophy in these families. The objective was to determine the type of inheritance that can most appropriately explain disease recurrence in FMTLE. We studied 29 unrelated pedigrees, divided into 98 nuclear families. A total of 602 family members, including 147 patients were analyzed. Complex segregation analysis was performed using POINTER software. Parameters estimated were: dominance, displacement, allelic frequency, multifactorial heritability and transmission probabilities. Related models were compared by likelihood coefficient tests, whereas non-related models were evaluated by Akaike Information Criteria (AIC). Minor value of AIC indicates most parsimonious data adjust. We rejected absence of genetic effect ($p = 0,000$), absence of a main gene ($p = 0,000$), autosomal recessive inheritance ($p = 0,000$) and co-dominant model ($p = 0,029$). However, absence of multifactorial inheritance ($p = 0,920$) and autosomal dominant inheritance ($p = 0,987$) were not rejected. Mendelian transmission ($p = 0,000$) and absence of Mendelian transmission models ($p = 0,000$) were rejected. However, AIC indicates that Mendelian transmission is more parsimonious (AIC = 401.603) than absence of Mendelian transmission model (AIC = 527,207). This is the first segregation studied performed in FMTLE. Our results strength evidence for genetic predisposition in this disorder. In addition our data provides additional evidence for a major gene presence with Mendelian transmission, which could be involved in development of hippocampal atrophy in these patients. Linkage studies are under way in order to identify the major gene involved in FMTLE.

A simulation Tool for False Positive Gene Replication in case-control Studies. *C. Stalens, C. Aucan, I. Elias-Billon, A. Guilbot, D. Cohen, H. Tanaka, F. Macciardi.* Serono Genetics Institute, RN7, Evry, France.

Recent improvements in high throughput genotyping technologies, allow to carry out genetic studies on several tens of thousands SNPs. Considering a classical case-control study (allelic and genotypic associations) on 100 000 SNPs, 200 000 statistical tests are performed. This large number of tests leads to a large number of false positive results as well (in this case, 10 000 false positive SNPs with a type I error = 0.05). Traditional methods to correct for multiple testing in these cases are no longer easy to apply while, as a complementary strategy, replication studies have been claimed to be useful to deal with such a multiple testing problem. Using a simulation study, we estimated the number of false positive findings before and after replication of a case-control study. In this simulation, genotypes were randomly generated without distinction between cases and controls, i.e. assuming a priori no true positive findings. We then defined a gene as a set of X consecutive SNPs and generated Y replicates of a case-control population composed by an equal Z number of cases and controls. We evaluated a complete replication design, i.e. a study where the entire set of around 30000 genes has been simulated in 2 different samples. We considered a gene "positive", i.e. associated to a hypothetical disorder, if at least two of these X SNPs presented a "significant allelic or genotypic association", significance threshold p for the p-value being variable. According to the chosen significance threshold for association, we thus tested various parameter combinations to estimate the number of false positive results remaining after replication. We investigated the effects introduced by different minor allele frequency threshold, by different number of SNPs within a gene and by varying the number of cases and controls. With the classical used significance threshold ($p=0.05$), we roughly observed a replicated false positive rate over the total number of genes from 0.4 % to 0.95 %. This rate was considerably reduced by decreasing the significance threshold for type I error at 1 %.

Longitudinal Models for Interactions between Gene and Time Varying Environments in Qualitative Traits. *M. Sun*¹, *M. Xiong*². 1) Dept Business, Univ Texas, San Antonio, San Antonio, TX; 2) Human Genetics Center, University of Texas at Houston.

Diseases are largely caused by dynamical interaction between the genes and environments. Such interactions will lead the changes of the phenotypes over time. A trait that varies as a function of a continuous variable such as age or time is referred to as a function-valued trait. Longitudinal data that are collected on a certain number of occasions for each individual can be used to study function-valued traits. Genetic studies of function-valued traits are a natural extension of classical genetics. Genetic analysis of function-valued traits will provide a powerful tool for identifying complex genetic structure of common diseases and discovering strategies for prevention of diseases. Genetic analysis of function-valued traits should be an integral part of genetic theory. However, genetic models of function-valued traits have not been well developed. In this report, we propose a general framework for genetic analysis of function-valued qualitative traits in which the relationship between the qualitative trait and DNA variation is modeled by a generalized mixed linear model. The mean and genetic effect functions are modeled as fixed effects. Correlation structure of repeat measurements is modeled as a random effect. The REML method is used to estimate the mean and genetic effect functions as well as variance components in the mixed linear model. We propose several hypotheses and test statistics to test association of candidate locus with the qualitative diseases. The methods are applied to simulation data to evaluate their performance and to illustrate their applications.

A statistical clustering method for classifying the Invader assay genotyping data. *S. Takitoh¹, S. Fujii¹, Y. Mase², N. Kamatani^{3,6}, T. Yamazaki³, Y. Ohnishi⁴, Y. Nakamura⁵, M. Yanagisawa¹.* 1) Department of Computer Science, Waseda University, Shinjuku, Tokyo, Japan; 2) NTT DATA Corporation, Tokyo, Japan; 3) Laboratory for Statistical Analysis, Research Group for Personalized Medicine, SNP Research Center, RIKEN, Tokyo, Japan; 4) Laboratory for SNP Analysis, Research Group for Personalized Medicine, SNP Research Center, RIKEN, Tokyo, Japan; 5) Research Group for Personalized Medicine, SNP Research Center, RIKEN, Tokyo, Japan; 6) Institute of Rheumatology, Tokyo Women's Medical University, Tokyo, Japan.

The Invader assay is a method for identifying SNP genotypes. Information on the genotype for each SNP is given as two fluorescent intensity values. The genotype is classified on the basis of these two-dimensional points. The classification results by the existing methods have not been necessarily identical to those by the experts. Eventually, the exact results have required large time. We propose a new statistical clustering algorithm, which is implemented in Genocluster, on the basis of maximum likelihood estimation by the Markov Chain Monte Carlo (MCMC). MCMC depends on an initial value. In the Genocluster, the nearest neighbor is applied to the initialization. The Genocluster can be effective even if the number of clusters is uncertain and the number of points in clusters is few. Genocluster is compared with the existing method by using large-scale real data. The results demonstrate high accuracy of the algorithm. Genocluster enabled us to automatically classify the Invader assay SNP genotypes more accurately than the existing methods.

Program Nr: 2851 from the 2004 ASHG Annual Meeting

Dynamical Models for Quantitative Genetics. *M. Xiong, J. Zhao, E. Boerwinkle.* Human Genetics, University of Texas Health Sci, Houston, TX.

Most phenotypic variations, including those involved in complex diseases and differences in drug response, are generated by integrated actions of multiple genetic and environmental factors, through dynamic, epigenetic, and regulatory mechanisms. A complex trait should be taken as a complex biological system that experiences dynamical changes. State-space equations in engineering are a powerful tool for modeling dynamics of the complex systems. To apply state-space approach to genetic studies of complex traits, we first formulate the quantitative genetics as a control problem in which the varying genetic effects over time are modeled as state variables, the environments are modeled as inputs, the observed quantitative phenotype is modeled as an output variable, and the genotypes are related to phenotypes via observation equation in the model. The statistical methods for estimation of the dynamically changing genetic effects have been developed. A statistic for testing the presence of the trait locus is proposed. Both analytic and simulation methods for power calculation have also been developed. Simulations of the steady-state and transient response of the trait to environmental changes have been performed. The proposed dynamical model was applied to the Coronary Heart Disease.

Program Nr: 2852 from the 2004 ASHG Annual Meeting

Global Test for Genome-Wide Association Studies. *J.Y. Zhao, M.M. Xiong.* Human Genetics Ctr, Univ Texas, Houston, Houston, TX.

With the great progresses in HapMap Project, hundreds of thousands or even millions SNPs markers have been or will be available for genome-wide association studies of complex diseases. This opens the new avenue for dissecting the genetics of complex diseases, however, this also presents great challenge. The questions arise as to how to simultaneously utilize multiple markers and how to deal with multiple testing problems. A new statistical test for genome-wide association studies has been developed, which allows (1) using any number of SNPs markers, (2) using haplotypes and (3) selecting optimal set of markers, and does not have multiple testing problem. The degree of freedom of the developed test statistic is very low even for a large number of SNPs markers used. Both theoretical analysis and simulation study show that the proposed global test for genome-wide association studies has higher power than the classical 2 test and the generalized T2 test. The proposed test was applied to genome-wide association studies of the cardiovascular disease. The results are promising.

Relationship between bone mineral density and cardiovascular disease differs by sex. *J.R. Shaffer¹, C.M.*

Kammerer¹, D.L. Rainwater², D.H. O'Leary³, R.L. Bauer⁴, B.D. Mitchell⁵. 1) University of Pittsburgh, Pittsburgh, PA; 2) Southwest Foundation for Biomedical Research, San Antonio, TX; 3) Tufts-New England Medical Center, Boston, MA; 4) University of Texas Health Science Center at San Antonio, TX; 5) University of Maryland School of Medicine, Baltimore, MD.

Previous studies have noted an association between osteoporosis or bone mineral density (BMD) and cardiovascular disease (CVD) in women, but little is known about the relationship in men, and the underlying mechanisms are unclear. We used maximum likelihood methods, conditioned on the pedigree structure, to estimate correlations between BMD, IMT (intimal-medial thickness of the carotid artery a measure of CVD), and lipid levels, while accounting for potential covariates, including age, body mass index, and menopausal status. These traits are moderately to highly heritable in men and women. Data were available on 527 women and 327 men (average age = 43 years) from 34 families recruited as part of the San Antonio Family Osteoporosis Study (a population-based study). As expected, spine BMD in women decreased with increasing IMT ($p < 0.001$). In addition, radius and hip BMD decreased with increasing IMT in older women, but increased with increasing IMT in young women ($p < 0.007$ for both traits). In men, we observed no relationship between IMT and spine or hip BMD, but the age by IMT interaction effect on radius BMD was similar to that in women ($p < 0.001$). Further investigation revealed that in women, low-density lipoprotein cholesterol (LDLC) levels were strongly negatively-correlated ($p < 0.01$) with spine and hip BMD, and accounted for much of the relationship between IMT and BMD. There was no relationship between LDLC and BMD at any site in men or between LDLC and radius BMD in women. We conclude (1) that the effects of common etiologic factors affecting BMD and CVD are mediated differently in men and women, at different bone sites, and at different ages, and (2) one or more pathways that influence hyperlipidemia may also affect spine and hip BMD in women.

Genetic and Environmental Determinants of Osteoporosis Phenotypes in Multigenerational Afro-Caribbean Pedigrees: The Tobago Family Health Study. *J.M. Zmuda¹, X.J. Wang¹, M. Kenney¹, V. Wheeler², A.L. Patrick², J.A. Cauley¹, C.H. Bunker¹, C.M. Kamerer¹.* 1) Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 2) Tobago Health Studies Office, Scarborough, Tobago.

Osteoporosis (OP) and its associated fractures is a frequent and major cause of disability and medical costs worldwide. Although the prevalence of OP is lower in African than European populations, the incidence increases considerably with age so that the absolute number of affected African individuals is expected to increase dramatically during the next half century, due to increases in life expectancy. In contrast to our understanding of bone health in European populations, there is a paucity of information about bone health in African populations. We have begun an initiative to disentangle the genetic and environmental contributions to the bone strength phenotype in multigenerational families of African origin. Dual-energy X-ray absorptiometry (DXA) is used to assess integral bone density (BMD) and cross-sectional area (CSA) at several skeletal sites. Quantitative computed tomography measures of trabecular and cortical volumetric BMD and architecture are also obtained. We present preliminary results on age and gender effects and residual heritability (h^2_{rSE}) of DXA phenotypes in the first 190 individuals (43% male) aged 18 to 86 yrs (mean, 43 yr) who are members of 7 large, extended pedigrees. Age and gender explained 13-22% of the variance in spine, femoral neck and whole body BMD and femoral neck CSA. In contrast, there was highly significant evidence ($P < 0.001$) for a genetic contribution to these traits. Residual h^2 of BMD phenotypes was: 0.420.13, 0.360.14, 0.400.14, respectively. Femoral neck CSA, an indicator of bone size, showed the highest residual heritability (0.550.17). These results establish a strong familial resemblance in integral BMD and bone size traits in pedigrees of African descent. These osteoporosis traits should be informative for genome-wide linkage studies to identify the loci contributing to the bone strength phenotype. Such analyses should greatly advance our understanding of the genetic susceptibility to osteoporosis and yield fundamental insight on bone biology.

Aneurysmal Subarachnoid Hemorrhage: Associations with variants in Apolipoprotein E and Elastin genes. R. Kaushal¹, D. Woo², P. Pal¹, M. Haverbusch², C. Moomaw², B. Kissela², Q. Zhang¹, H. Xi¹, L. Sauerbeck², G. Sun¹, R. Chakraborty¹, J. Broderick², R. DeKa¹. 1) Dept Environmental Health, Univ Cincinnati, Cincinnati, OH; 2) Dept Neurology, Univ Cincinnati, Cincinnati, OH.

Subarachnoid Hemorrhage (SAH) caused by ruptured intracranial aneurysms has an annual incidence of 6-10 per 100,000 in U.S. and a 30-day mortality rate exceeding 40%. There is strong evidence that both genetic and environmental risk factors interact in its etiology. Apolipoprotein E (*ApoE*) and Elastin (*ELN*) genes are important candidates in the pathogenesis of SAH. *ApoE* variants have been associated with lipid disorders, cardiovascular and cerebrovascular diseases. Polymorphisms in *ELN* have inconsistently been implicated in cerebral aneurysms. However, these associations remain inconclusive. We have performed a case-control (age, race, gender matched) association study of aneurysmal SAH using 12 single nucleotide polymorphisms (SNPs) located in upstream and the coding region of the *ApoE*, and 9 SNPs (8 intronic and 1 coding) in the *ELN* in a sample of 381 individuals of Caucasian and African-American ancestry (133 cases, 248 controls). Genotype frequencies were in conformity with HWE proportions at all markers. Haplotype analysis using the PHASE program revealed significant association with one major haplotype in *ApoE* in Caucasians ($p = 0.008$). When the upstream and coding haplotypes were separately inferred, we found significant association with a major upstream haplotype in both Caucasians ($p = 0.04$) and African Americans ($p = 0.02$). We did not find any association of the *ApoE* 2/3/4 variants (either at allelic or genotypic level) with aneurysmal SAH. However, haplotype data from the *ApoE* upstream region suggests that *ApoE* promoter polymorphisms significantly contribute to the risk of aneurysmal SAH in both African Americans and Caucasians. We did not find any association of *ELN* variants with aneurysmal SAH, as was previously reported by Onda et al. (*Am J Hum Genet* 2001, 69:804-819), at both allelic or haplotype level in either African Americans or Caucasians. Our results indicate that *ApoE* plays an important role in the pathogenesis of SAH. This study was supported by NIH grant NS36695.

BDNF and its specific receptor, tyrosine kinase B (NTRK2), are associated to eating disorders and related psychopathological traits. *M. Ribases¹, M. Gratacos¹, JM. Mercader¹, A. Badia², L. Jimenez², R. Solano², F. Fernandez-Aranda², X. Estivill^{1, 3}.* 1) Center for Genomic Regulation; 2) Hospital Princeps Espanya; 3) Pompeu Fabra University, Barcelona, Catalonia.

Genetic studies and animal models suggest that brain-derived neurotrophic factor (BDNF) has an essential role in eating behavior, and that alterations of this neurotrophic system could participate in eating disorders (ED). BDNF and its specific receptor tyrosine kinase B (NTRK2) knockout mice develop obesity and hyperphagia. We have reported a strong association of the -270C/T and Val66Met BDNF SNPs with anorexia (AN) and bulimia (BN) in 6 European populations. We present here association of ED with the NTRK2 receptor. The NTRK2 gene was screened in 91 ED patients and 8 SNPs and 6 single mutations were identified. Of these, six SNPs, -69G>C, IVS2+40T>C, IVS13+40G>A, IVS17-125T>C, IVS18+13G>A and 2784-2785insC, showed a minor allele frequency higher than 10% and were used to carry out a case-control study in a sample of 168 ED patients and 121 unrelated controls. We have found that the -69C allele of the -69C>G SNP is associated to purging AN (ANP; $p=0.016$) and minimum body mass index ($p=0.001$), and that the IVS13+40G>A SNP has an effect on BN ($p=0.03$). Considering the linkage disequilibrium pattern, we analyze the -69G>C, IVS13+40G>A and 2784-2785insC SNPs to estimate haplotypes and observed a positive association of the CAC haplotype with ANP ($p=0.006$). Moreover, patients with BN showed a reduced frequency of the GA- haplotype ($p=0.034$). We also analyzed the possible involvement of the NTRK2 SNPs in different psychopathological traits associated to ED. Thus, 84 ED patients completed the Symptom Checklist 90-revised questionnaire and were genotyped for the NTRK2 variants. We observed that those patients carrying the IVS17-125T allele of the IVS17-125T>C SNP showed increased symptomatology for some subscales that include somatization ($p=0.005$), obsessive-compulsiveness ($p=0.006$) and anxiety ($p=0.04$). These results suggest that not only BDNF but also its receptor NTRK2 could participate in ED, not only through its effect on eating behavior but also on related psychopathological traits..

Segregation Analysis of Thyroid Cancer using the Swedish Family Cancer Database. *A. Ding¹, A. Antoniou¹, K. Czene², K. Hemminki^{2,3}, D.F. Easton¹.* 1) Cancer Research U.K. Genetic Epidemiology Unit, University of Cambridge, Strangeways Research Laboratory, Cambridge, United Kingdom; 2) Karolinska Institute, Stockholm; 3) German Cancer Research Center (DKFZ), Heidelberg.

The Swedish Family Cancer Database is constructed by record linkage of a population-based family register with the Swedish Cancer Registry, and provides a basis for large scale pedigree analysis using population-based families. We have implemented routines in MENDEL to perform segregation analysis on these data. Survival analysis models, incorporating age- and sex-specific hazard rates and adapted to constrain overall incidence rates to agree with population rates, are fitted (1). A generalised estimating equation approach is used to account for multiple ascertainment of probands.

We have applied this approach to thyroid cancer. A total of 7465 pedigrees containing first and second degree relatives of thyroid cancer probands, 201 of which had a family history for the disease, were analysed. To date, the best fitting model postulates a rare autosomal dominant locus ($q=0.00004$). Under this model, cumulative risks to female (male) gene carriers were 63.6% (34.8%) and 87.6% (38.3%) by ages 50 and 70 years, respectively. The higher risk in female carriers mirrors the difference in rates in the general population. These models can provide the basis for counselling of relatives of thyroid cancer patients.

Evidence Against Autosomal Dominant Inheritance in Familial Beckwith-Wiedemann Syndrome. M.F.

Wangler^{1,4}, P. An², A.P. Feinberg³, M.R. DeBaun^{1, 2}. 1) Pediatrics, Washington University School of Medicine, St Louis, MO; 2) Division of Biostatistics, Washington University School of Medicine, St Louis, MO; 3) Institute of Genetic Medicine, Johns Hopkins University, Baltimore MD; 4) Doris Duke Clinical Research Fellowship for Medical Students.

Beckwith-Wiedemann syndrome (BWS) is a congenital disorder with epigenetic and genetic mutations on 11p15. A small proportion of cases are familial with an unknown pattern of inheritance, although autosomal dominant inheritance has been proposed. We tested the hypothesis that familial BWS occurs as a result of dominant inheritance. Segregation analysis based on a revised general model in which two parameters were not estimated was performed for a discrete trait in 291 families from The BWS Registry ascertained for an affected child (see Table below). Affected status was assigned using two of five major features, macroglossia, macrosomia, hypoglycemia at birth, abdominal wall defects, and ear defects. Models of inheritance were evaluated with the Likelihood Ratio Test ($-2 \ln L$) and Akaike's Information Criteria (AIC). Sporadic and environmental models were rejected. Of the Mendelian models, additive and recessive models were equally likely and were the best fit to the data while the dominant model was rejected. We have provided preliminary evidence that dominant transmission is not the most likely mode of inheritance but is still possible in a subgroup of families. The inheritance pattern of Familial BWS is likely heterogenous.

Segregation Analysis in 291 Families Ascertained for a Child with BWS

Model	Sporadic	Recessive	Additive	Dominant	Environmental	General

The effect of germline p53 mutations in segregation analysis of cancer in families with childhood soft tissue sarcoma. *C.C. Wu¹, S. Shete¹, C.I. Amos¹, L.C. Strong²*. 1) Dept Epidemiology; 2) Section Clinical Cancer Genetics, Dept Molecular Genetics, Univ Texas MD Anderson CA Ctr, Houston, TX.

The study of familial cancer incidence was performed in 159 families ascertained through childhood soft tissue sarcoma who were treated in M. D. Anderson Cancer Center. Our previous research showed that a highly significant excess of familial cancer was observed in both the first-degree relatives of the patients and the relatives of the patients with second malignant neoplasms. The tumor types occurring in close relatives were also observed as second malignant neoplasms in the patients. Germline p53 mutations have been identified in 50%-70% families with Li-Fraumeni syndrome. We have performed p53 mutation analysis in 107 of these 159 kindreds, and identified a total of 63 carriers in 7 kindreds. To test hypothetical models of disease transmission, we include confirmed invasive cancers (excluding nonmelanoma skin cancer and in situ carcinoma) as a combined phenotype. Assuming that the affection of cancer follows a logistic distribution, a segregation analysis was performed to evaluate sex effects, a generation cohort covariate, and p53 mutation covariate. Incorporating p53 as a covariate significantly increases the likelihood values for all genetic models. We found the odds of the affected individual carrying p53 mutation to be significantly high. It was over five fold higher on the logit scale for all genetic models. In contrast, we also performed additional segregation analysis in four large kindreds without p53 mutations.

Linkage Disequilibrium Structure and Selection of Tagging-SNPs are Insensitive to Phenotype: CETP and Coronary Artery Disease. *B.D. Horne^{1,2}, J.F. Carlquist^{1,3}, J.B. Muhlestein^{1,3}, J.L. Anderson^{1,3}, N.J. Camp^{1,2}.* 1) Cardiovascular Department, LDS Hospital, Salt Lake City, UT; 2) Genetic Epidemiology, University of Utah, SLC, UT; 3) Cardiology Division, University of Utah, SLC, UT.

For complex diseases such as coronary artery disease (CAD), evaluation of all common SNPs (>5%) and selection of informative subsets is recognized as best practice for association analyses. We introduced a principal component analysis (PCA) method for identification of linkage disequilibrium (LD) groups and tagging SNPs (tSNPs). However, it is unknown whether phenotype influences LD structure or tSNP selection. The current study applied the PCA method to 35 SNPs in the cholesteryl ester transfer protein (CETP) gene. Nineteen common SNPs were identified by scanning the promoter, exons, and 3' UTR in 50 unrelated individuals. A further 16 SNPs from the literature were used, with the total 35 SNPs genotyped in 529 unrelated individuals, including 339 population healthy controls (mean age 59.13yrs, 67% female) with no history of CAD and 190 non-diabetic, non-smoking patients (53.8yrs, 55% female) with significant, angiographically-determined CAD (2 lesions of 70% stenosis). In controls, 7 LD groups were identified and 11 tSNPs selected, accounting for 93.4% of the genetic variation. The LD groups were overlapping and non-contiguous, conditions violating simple 'block' methods. In the CAD patients, 8 LD groups were found, 7 essentially the same as in controls and the 8th defined by a single SNP occurring at higher frequency in CAD patients; 12 CAD tSNPs were selected (the 12th being the sole group 8 SNP), accounting for 93.9% of the variation. Three CAD tSNPs differed from the control tSNPs, but were in high LD with 3 control tSNPs and could be substituted with a negligible reduction in variance explained. This study of the CETP gene demonstrates a high correspondence of LD structure and tSNPs among two populations with divergent phenotype profiles, suggesting it may be reasonable to use varied population compositions when identifying tSNPs. It also highlights the importance for tSNP selection of methods such as PCA that allow for the increased complexity of LD structure in intragenic regions.

The Impact of Pedigree Structure on Heritability Estimates for Pulse Pressure in Three Studies. *F-C. Hsu¹, D.J. Zaccaro¹, L. Lange¹, D.K. Arnett², C.D. Langefeld¹, L.E. Wagenknecht¹, D.M. Herrington³, S.R. Beck¹, B.I. Freedman³, D.W. Bowden^{3,4,5}, S.S. Rich¹.* 1) Public Health Sciences, Wake Forest Univ, Winston-Salem, NC; 2) Epidemiology, Univ of Minnesota, Minneapolis, MN; 3) Internal Medicine, Wake Forest Univ, Winston-Salem, NC; 4) Center for Human Genomics, Wake Forest Univ, Winston-Salem, NC; 5) Biochemistry, Wake Forest Univ, Winston-Salem, NC.

Pulse pressure (PP), the difference between systolic and diastolic blood pressure, is a measure of large artery stiffness and has been shown to be an important predictor of cardiovascular morbidity and mortality. The aims of the present study were to investigate the heritability of PP in three studies, the Diabetes Heart Study (DHS), the Insulin Resistance Atherosclerosis Family Study (IRAS FS), and the NHLBI Family Heart Study (FHS), to estimate the residual heritability after inclusion of a common set of covariates, and to investigate the impact of pedigree structure on estimating heritability. DHS is primarily a sibling pair nuclear family study design, while both IRAS FS and FHS have large pedigrees. Heritability estimates of log-transformed PP were obtained using variance component models. After adjusting for age, gender, ethnicity/center, height, diabetes status, and mean arterial pressure, heritability estimates of PP were 0.400.08, 0.220.05, and 0.190.03 in DHS, IRAS FS, and FHS, respectively. The heritability estimate from DHS was significantly different from both IRAS FS and FHS. A random resampling technique (bootstrap) was used to explore the heritability in the IRAS FS and FHS data when these pedigrees were trimmed to mimic the DHS pedigree structure. Heritability estimates and their 95% confidence intervals were computed. The bootstrap method yielded PP heritability estimates of 0.37, 0.34, and 0.27 in DHS, IRAS FS, and FHS, respectively. There was no significant difference among the estimates from the three studies based on this method. These data illustrate the influence of pedigree structure can have on estimating heritability. Thoughtful comparisons of heritability estimates must consider study design factors such as pedigree structure.

A collection of nucleotide variations in SCN5A, a major arrhythmogenic gene, among the Japanese. *J. Mashiba, G. Koike, H. Kamiunten, M. Ikeda, A. Chishaki, K. Sunagawa.* Cardiovascular medicine, Kyushu University, Fukuoka, Fukuoka, Japan.

SCN5A (sodium channel, voltage-gated, type V, alpha polypeptide) is responsible for the initial upstroke of the action potential, and mutations of this gene causes a wide variety of arrhythmias, such as long QT syndrome type 3 (LQT3), Brugada syndrome (BrS), idiopathic ventricular fibrillation and other conduction disorders. In a last decade, it has been reported that various mutations and polymorphisms of SCN5A are linked to these arrhythmias, and that there may be ethnic variations of SCN5A resulting in these arrhythmias. Then, we screened SCN5A of two clinically diagnosed unrelated LQT3 patients, four unrelated BrS patients and twenty-four healthy subjects in the Japanese. Regarding our LQT3 patients, the ST-T wave patterns of their ECG were either biphasic T wave pattern or asymmetrical peaked T wave pattern. We prepared genomic DNA from blood with standard procedure after obtaining informed consent from each participant. All exons covering entire coding region and exon-intron boundaries of SCN5A were amplified by PCR followed by direct sequencing. We identified 16 variations in its coding region; 14 nucleotide variations in its coding region compared to NCBI sequence database, 5 ones compared to DDBJ sequence database. Three nucleotide variations were identical for both databases. Among these variations, two variations were novel. We also identified one novel variation at the acceptor site of exon 13 compared to NCBI database, that was found in one BrS patient. In coding regions, there were no nucleotide variations that result in amino acid substitution among our LQT3 and BrS patients, nor healthy subjects in this study. However, one variation at the acceptor site of exon 13 that was found in one BrS patient could alter its cDNA structure. Therefore, further analysis to elucidate whether this variation affects the function of SCN5A is now undergoing. In addition, our study strongly demonstrated that it is important to characterize nucleotide sequence of any disease genes, since there are ethnic differences of the gene sequence.

Genetic association study of QT interval duration in the Framingham Heart Study. *C. Newton-Cheh^{1,2,3,5}, S. Musone¹, J. Drake^{1,4}, A. Lochner¹, S. Kathiresan^{1,2,3,5}, R.S. Vasan^{2,6}, D. Levy^{2,5}, E.J. Benjamin^{2,6}, C.J. O'Donnell^{1,2,3,5}, J.N. Hirschhorn^{1,4,5}.* 1) Medical & Population Genetics, Broad Institute, Cambridge, MA; 2) NHLBI's Framingham Heart Study, Framingham, MA; 3) Massachusetts General Hospital, Boston, MA; 4) Children's Hospital of Boston, MA; 5) Harvard Medical School, Boston, MA; 6) Boston University, Boston, MA.

Electrocardiographic QT interval prolongation, a marker of delayed myocardial repolarization, is associated with increased risk of sudden cardiac death (SCD) and coronary heart disease in the general population. The congenital Long QT Syndrome (LQTS) is a rare, Mendelian syndrome characterized by syncope and SCD. QT interval duration across the normal range, adjusted for heart rate and sex, is a heritable phenotype ($h^2=0.35$). To elucidate the genetic determinants of this complex phenotype, we are carrying out candidate gene association studies. We are developing high-resolution linkage-disequilibrium (LD) maps of 6 genes previously associated with the LQTS (KCNQ1, KCNH2, SCN5A, ANK2, KCNE1 and KCNE2), encoding potassium and sodium channels and an anchoring protein. By genotyping public database single nucleotide polymorphisms (SNPs) in 93 Caucasian CEPH individuals from 12 multi-generational pedigrees, we are identifying a set of polymorphic SNPs across a combined genomic span of 875kb. A parsimonious set of tagging SNPs captures the majority of common variation in these genes. We are also identifying missense variants by re-sequencing the 108 exons of the 6 genes in a multi-ethnic panel of 40 unrelated individuals. We are testing the tagging and missense SNPs in 1811 unrelated Framingham Heart Study (FHS) participants for association with continuous QT interval variation. To date we have genotyped 1000 SNPs in the CEPH pedigrees (600 with minor allele frequency >5%) and have completed genotyping of tagging SNPs for KCNH2 and KCNE1 in FHS. The comprehensive SNP-based haplotype map of these genes and the planned genotype-phenotype association studies will offer insights into the determinants of myocardial repolarization in a large, community-based Caucasian sample and will generate candidates to test for association with arrhythmias and SCD.

Association of 12/15 Lipoxygenase gene polymorphisms with CRP levels: The Diabetes Heart Study. *S.S. Rich¹, K.P. Burdon¹, C.C. Hedrick², S.R. Beck¹, C.D. Langefeld¹, B.I. Freedman¹, J.J. Carr¹, D.M. Herrington¹, D.W. Bowden¹.* 1) Dept Public Health Sciences, Wake Forest Univ Sch Medicine, Winston-Salem, NC; 2) Cardiovascular Research Center, University of Virginia Health Sciences, Charlottesville, VA.

Atherosclerosis is a major complication of diabetes, involving arterial inflammation, recruitment and adherence of monocytes, macrophages and dendritic cells to the vessel walls, and lipid-laden plaque formation. Regulation of the 12/15 lipoxygenase (12/15 LO) pathway is an important mediator of inflammation and vascular change in the mouse *db/db* model of diabetes. In humans, 12/15 LO consists of two genes (ALOX12, ALOX15) on chromosome 17p13.2 that have recently been sequenced. The role of variants in the ALOX12 and ALOX15 genes was determined on a recognized marker of chronic inflammation, CRP, in the Diabetes Heart Study (DHS), a study of markers of atherosclerosis in families with two or more diabetic siblings with well-preserved renal function. ALOX12 was surveyed for 5 SNPs [1158 (promoter), 2987 (intron 2), 5431 (intron 6), 7605 (exon 8 [synonymous]), 17947 (3)] and ALOX15 for 3 SNPs [1054 (promoter), 6686 (intron 7), 11256 (intron 12)], chosen for high minor allele frequency and coverage of existing haplotype blocks. SNPs frequencies were consistent with Hardy-Weinberg proportions. In the DHS population, two haplotype blocks were observed for ALOX12 (1158-2987-5431-7605; 17947) and ALOX15 (1054; 6686-11256). Association analyses used GEE1 modeling and adjusted for age, gender, ethnicity, diabetic status, smoking and lipid medication use. There was consistent evidence for association of CRP with SNPs in the first ALOX12 haplotype block (1158-2987-5431-7605) spanning the promoter through exon 8 ($P < 0.05$). This effect was strongest in Caucasians, and particularly in Caucasian diabetics, with the SNP most strongly associated under a recessive model. Evidence for association was also significant for the ALOX15 promoter SNP (1054; $P < 0.05$). These results suggest that genetic variants in human lipoxygenase genes are a significant contributor to CRP levels, thereby serving as modulators of atherosclerosis.

Heritability of pulse wave velocity and carotid intima-media thickness in an extended pedigree from an isolated population. *F.A. Sayed-Tabatabaei¹, M.J. van Rijn¹, Y. Aulchenko¹, B.A. Oostra², J.C.M. Witteman¹, C.M. van Duijn¹.*
1) Department of Epidemiology & Biostatistics; 2) Department of Clinical Genetics, Erasmus Medical Center, Rotterdam, The Netherlands.

Pulse Wave Velocity (PWV) and carotid Intima Media Thickness (IMT) represent arterial wall stiffness and thickness respectively. Both traits are associated with cardiovascular diseases but little is known of their heritability. We studied the heritability of PWV and IMT in an extended pedigree from an isolated population in the Netherlands. PWV was measured in 807 and common carotid IMT in 924 individuals belonging to a single pedigree. For 801 individuals both measurements were available. Natural logarithm transformations of both traits were used in the SOLAR software to estimate heritabilities.

Covariates used in the complete multivariable-adjusted model of PWV were age, sex, mean arterial pressure, LDL-cholesterol, fasting glucose and heart rate. For IMT the covariates were age, sex, BMI, systolic and diastolic blood pressure, LDL- and HDL-cholesterol, fasting glucose, smoking and heart rate. The age and sex-adjusted and multivariable-adjusted heritability (standard error) for PWV were 0.36 (0.09) and 0.33 (0.10). For IMT these statistics were 0.41 (0.07) and 0.37 (0.08), respectively (p for all estimates <0.001). The proportion of PWV variance due to all covariates was 0.46 and for IMT was 0.66. The two traits shared between 0.30 and 0.36 of their genetic component (in multivariable-adjusted and age and sex-adjusted models respectively).

To our knowledge, this is the first report on heritability of PWV. Our findings suggest that a substantial part of variance in vessel wall stiffness and thickness are explained by genetic factors.

A multilocus model for essential hypertension susceptibility in a Japanese cohort. *S.M. Williams¹, H. Sanada², M.D. Ritchie¹, J. Yatabe², S. Midorikawa², S. Hashimoto², T. Watanabe², M. Sasaki², P.A. Jose³, R.A. Felder⁴.* 1) Center Hum Genet Research, Vanderbilt Univ Medical Ctr, Nashville, TN; 2) Third Department of Internal Medicine, Fukushima Medical University, School of Medicine, Fukushima, Japan; 3) Georgetown University Medical Center, Washington, DC; 4) University of Virginia Health Sciences Center, Charlottesville, VA.

Hypertension is a complex disease with multiple putative genetic risk factors. In order to determine the genetic architecture of essential hypertension, we evaluated 12 polymorphisms in five candidate loci in a cohort of 447 Japanese subjects (189 hypertensive subjects and 258 normotensive controls) for association to hypertension. One of the loci, G-protein coupled receptor kinase 4 (GRK4), exhibited significant allelic associations at three studied sites (R65L, A142V, A486V) in all subjects with significant genotype associations at the first two sites and a borderline value ($p=0.054$) at the third. In males there was a significant allelic association with A142V and in females there were significant allelic and genotypic associations at R65L and A142V. In females there was also a significant genotypic association for Cyp11B2 (C-344T) but no allelic association. These results indicate a complex set of genetic factors that interact with gender to predispose to hypertension. To evaluate the data we assessed all polymorphic sites simultaneously and determined the single best genetic model. This model includes GRK4 sites R65L, A486V, the insertion deletion in ACE intron 16 and the Cyp11B2 variant. This model predicts hypertension status correctly 61% of the time and is highly significant ($p=0.017$). We determined the odds ratio (OR) for the high risk genotypes from this model to be 5.05 (3.29-7.74, 95% CI, $p<0.01$). This OR is much larger than most of those for other genetic risk factors for hypertension, suggesting that a multilocus model such as the one we found is more informative than any single locus analysis in predicting hypertension status.

Multivariate genetic analysis of chronic pelvic pain and associated phenotypes. *K.T. Zondervan¹, L.R. Cardon¹, S.H. Kennedy², N.G. Martin³, S.A. Treloar³.* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, United Kingdom; 2) Nuffield Dept. of Obstetrics & Gynaecology, University of Oxford, United Kingdom; 3) Queensland Institute of Medical Research, Brisbane, Australia.

Chronic pelvic pain (CPP), a condition of uncertain aetiology involving long-standing pain localising to the lower abdomen and pelvis, is very common in women of reproductive age. It is difficult to diagnose and treat, and causes a substantial burden of functional disability. CPP has been suggested as a phenotype worth pursuing per se for gene discovery studies. Although heritability estimates have been published for some conditions potentially underlying pelvic pain, the heritability of CPP itself has never been investigated. We analysed data from 623 MZ and 377 DZ female Australian twin pairs aged 29-50 years. Univariate twin pair (tetrachoric) correlations of $r_{MZ} = 0.43$ and $r_{DZ} = 0.11$ plus subsequent univariate Cholesky decomposition model-fitting suggested that genetic influences are important in the etiology of CPP. The results of this variance components analysis suggested a heritability estimate of 0.41 (95% CI: 0.25-0.56). However, results of subsequent multivariate model-fitting showed this heritability to be attributable to additional phenotypes significantly correlated with CPP. The results questioned the value of CPP as a useful independent phenotype on which to conduct genetic studies; contributing conditions such as endometriosis and individual variation in perception of pain are likely to provide more useful phenotypes.

Program Nr: 2868 from the 2004 ASHG Annual Meeting

Estimating homozygosity by descent probabilities in large pedigrees. *M. Abney*. Dept Human Genetics, Univ Chicago, Chicago, IL.

Computing the probability of an individual being homozygous by descent (HBD) at a locus is useful when performing homozygosity type linkage analysis in inbred pedigrees. When the pedigree is extremely large, current methods become computationally intractable, particularly when multipoint genotype information is used. Here, I present a method that can perform this computation on pedigrees of extremely large size and arbitrary complexity. I build on my previous method that considered only the genotypes of the individual in question in the hidden Markov model. Now, the computation can be done conditional on the individual's genotypes, as well as all ancestral genotypes, along the chromosome. I demonstrate the method on a genome scan of 500 individuals, all of whom are interrelated via a 13 generation, 1,623 person pedigree. I also assess the accuracy of the method through simulation and compare the results, on smaller pedigrees, to exact methods.

Identification of gene-gene interactions in whole-genome linkage data by the Apriori algorithm. *S. Buervenich¹, J. Ott², F.J. McMahon¹*. 1) Mood and Anxiety Disorders Program (MAP) Genetics, NIMH, Bethesda, MD; 2) Lab Statistical Genetics, Rockefeller Univ, New York, NY.

It is generally believed that multiple interacting genes underlie most complex traits, but there is a lack of powerful analytic tools for detecting such genes. When two or more genes act epistatically to increase disease risk, allele sharing at one of these loci will be correlated with allele sharing at the other. Several techniques have recently been suggested in order to detect correlations of this kind in the human genome. The Apriori algorithm has come into wide use in many fields where fast and efficient data-mining is important, since it can handle large data sets and quickly find positive and negative correlations between any group of data points. Here we apply an implementation of Apriori (Christian Borgelt, 1996-2003) to genetic linkage data. We have 2 goals: 1) to divide the genome into optimal bins based on correlation of linkage evidence at neighboring groups of loci, rather than on arbitrary borders or bin sizes, and to determine the influence of a similarity parameter (that compares the support of each set of bins with each possible subset) on the average size of the resulting bins; 2) to test the power and efficiency of Apriori to detect interacting loci in simulated data from the Genetic Analysis Workshop 11 (GAW11; Greenberg et al.[1999]; supported by grants DK31775 and GM31575). In our preliminary analyses, Apriori was sensitive enough to identify two of the interacting loci in the simulated dataset when using a similarity parameter of 1.4, 5% best lod scores as threshold and 10% minimum support and confidence for any rule. However, sensitivity depended in part on the threshold at which a given family was considered to show linkage at a given locus. Also, specificity has to be addressed by determining the false discovery rate. We conclude that Apriori is a potential tool for binning linkage data and uncovering interacting loci. The binning procedure may also be useful for comparing linkage results across studies, as in meta-analyses. Supported by the NIMH intramural research program and extramural NIMH grant MH44292.

Improvements in a score for combined segregation and linkage analysis of complex traits. *E.W. Daw¹, S.C. Heath², J. Ma¹*. 1) UT MD Anderson CA Ctr, Houston, TX; 2) Centre National de Génotypage, Evry, France.

We have previously developed a score for combined segregation and linkage analysis, the Log of the Posterior placement probability ratio (LOP). We have used this score with the Bayesian Monte Carlo Markov chain (MCMC) techniques implemented in the program Loki (Heath, AJHG, 1997). The LOP is the log of the posterior probability of linkage to a real chromosome divided by the posterior probability of linkage to a randomly generated unlinked pseudo chromosome. The pseudo chromosome is generated with marker allele frequencies and positions based on the marker data available on the real chromosome. Preliminary studies of The LOP have indicated that it can be used to localize genes contributing to variation in complex traits in cases where traditional lod score analysis may fail (Daw et al., Genetic Epidemiology, 24:181-190, 2003). Two limitations of our previous implementation of the LOP were (1) the requirement to write a number of specialized scripts to run a series of programs for each analysis and (2) the dependence of each analysis run on a single realization of the pseudo chromosome. To address the first issue, we have incorporated and automated the generation of the pseudo chromosome within the Loki package, so that pseudo chromosomes are now part of the state space of the sampler. To address the second issue, we have enabled the re-generation of the pseudo chromosome within an analysis run in such a way that updating the pseudo chromosome data is part of a valid MCMC sampler. This has resulted in a procedure to estimate the LOP that is much easier to use and has enabled us to examine what frequency of re-generation of the pseudo chromosome is appropriate. Re-generation at intervals of 100,000, 10,000, and 1000 iterations has been examined. We find that re-generation at intervals of 10,000 iterations appears adequate. (support: CA097855).

Constructing a specialized statistical genetics computing resource: experiences with a Macintosh-based grid-computer. *R. Evans, T.J. Bates, M.M. Barmada.* Human Genetics, Univ Pittsburgh, Pittsburgh, PA.

Statistical genetics requires enormous computing resources to successfully address issues such as empirical p-value estimation, complete multipoint linkage analysis, haplotype frequency estimation, and linkage disequilibrium mapping. Statistical methodologies involving coalescent theory and Markov-Chain Monte-Carlo (MCMC) based simulation methods require long runs and are highly amenable to parallel processing strategies. In order to address these needs, we have previously described our experiences with a distributed grid-based computing system. We have recently extended this computing system dramatically. In implementing this expansion, we choose to work with a new hardware vendor choosing to purchase compute nodes from Apple Computer. Advantages of the move to Apple hardware include: (1) a unique 128-bit wide vector-processing unit; (2) Sophisticated, integrated hardware and software monitoring tools; (3) 64-bit processor architecture, allowing access to 8Gb of RAM per process; (4) Highly optimized C and Fortran compilers; and (5) A ready-to-use cluster and web portal optimized for use in life science informatics settings (iNquiry). As the Macintosh operating system (MacOS) is currently Unix based, moving common statistical genetics programs (merlin, simwalk2, vitesse, pedcheck, aspex, genehunter, allegro, transmit, and mega2, just to name a few) to this platform often requires nothing more than recompiling. Results comparing the performance of these programs on this Macintosh cluster to performance on a Pentium4 Xeon cluster will be presented, to highlight the advantage provided by optimized compilers. Specialized versions of certain programs (merlin, pedcheck, vitesse) that have been modified to take advantage of the Apple vector-processing unit (AltiVec) will be compared as well. As the cluster/web-portal tool that we are using (iNquiry) includes XML templates for the implementation of any command line tool, web-based access to many statistical genetics programs is possible, and will be demonstrated.

Estimation of Haplotype Frequencies with Pedigree Data. *D.K. Folie, D.J. Schaid.* Health Sciences Research, Mayo Clinic, Rochester, MN.

Although there are well established methods to estimate haplotype frequencies from unphased genotype data for genetically unrelated subjects, the current methods for pedigree data are limited. Most pedigree-based methods assume that the markers are in linkage equilibrium, which may not be reasonable for densely spaced markers currently available. Furthermore, many software packages for pedigree analysis output only one pair of (most likely) haplotypes per subject. This can be imprecise, because the ambiguity of haplotypes is not accounted for, and it does not provide information on the joint configuration of possible haplotype pairs for a pedigree. For large pedigrees, where there are an enormous number of configurations of pairs of haplotypes (diplotypes), complete enumeration is impractical. For small to moderate size pedigrees, however, enumeration is feasible, particularly when combined with a trimming of configurations that have small probabilities. We have developed an expectation-maximization (EM) algorithm to estimate haplotype frequencies for data comprised of many pedigrees. The pedigree structures can be fairly general, but without loops. However, memory constraints give practical limits on their sizes. The pedigrees can have multiple founders, and the non-founders can have multiple spouses. The main steps of this algorithm are as follows: 1) use genotype elimination to remove superfluous genotypes at all loci; 2) insert a batch of loci, enumerating all possible diplotypes for all pedigree members; 3) run genotype elimination to retain only non-recombinant haplotypes; 4) use a modified Elston-Stewart algorithm that drags founder diplotypes to the top of the pedigree, resulting in an enumeration of all possible diplotype configurations among founders; 5) use an EM algorithm, which uses pedigree segregation probabilities as weights, to compute haplotype frequencies, along with posterior probabilities of founders diplotype configurations; 6) trim off configurations with small probabilities; 7) repeat steps 2-6 until convergence. This algorithm is illustrated by examples and computational limits will be presented.

Program Nr: 2873 from the 2004 ASHG Annual Meeting

Statistical Analysis of Multiple Related SNPs. *K.E. McDougal, D.R. Moller, M.D. Fallin, Z. Song, G.R. Cutting, ACCESS Research Group.* Johns Hopkins Univ, Baltimore, MD.

A major challenge in association studies is deciding how to evaluate the significance of allele distribution when multiple candidate genes are analyzed. A chi-square analysis can evaluate the significance of the genotype distribution of a single SNP, but with each additional SNP analyzed, the potential for false positives due to chance increases. A Bonferroni correction for multiple testing is often too conservative and inappropriate for correlated data. Our goal was to develop a program using SAS statistical software that would take the relatedness of all SNPs evaluated into consideration when computing a p-value for a specific SNP. This program uses Monte Carlo permutations to create a study-wide threshold that eliminates the need to correct for multiple testing. The utility of this implementation was evaluated via simulation. As expected the effect size threshold was quite low for the uncorrected test and was high for the Bonferroni correction, with the permutation result lying between these. This is shown graphically to highlight the liberal interpretation of a nominal test and the too conservation Bonferroni approach. Using Monte Carlo permutations, we analyzed fifty functional variants of proteins involved in Th2 mediated inflammation in 350 patients with sarcoidosis, a multi-organ inflammatory disease, and 350 age and sex matched controls from the ACCESS (A Case Control Etiologic Study of Sarcoidosis) Study. We found a significant p-value of 0.037 for FCER1B polymorphism E237G. The nominal chi-squared p-value for this polymorphism was 0.0009. FCER1B is the beta subunit for the high affinity receptor for IgE and E237G has been linked to clinical atopy and high levels of IgE. The significance of an association with FCER1B could reflect the Th1/Th2 dysregulation that is characteristic of sarcoidosis. These results suggest that establishing significance using data randomization may be a viable alternative to other methods that require stringent corrections for multiple comparisons and do not take correlated data into account. In addition, our results implicate FCER1B in the pathogenesis of sarcoidosis. Funded in part by the NHLBI.

Multinomial Regression for Haplotype Association Analysis in NEMO. *S.K. Sieberts, A. Kong, D.F. Gudbjartsson.*
deCODE Genetics, Reykjavik, Iceland.

Log-linear regression is a powerful and flexible tool for the analysis of case-control data with more than two response categories. For the purposes of linkage disequilibrium mapping, we model the genotype counts using a log-linear approach for multinomial data. In this flexible framework, we can adjust for covariates and known population stratification and test a wide variety of hypotheses, including the typical null hypothesis in LD mapping of no allele (haplotype) frequency difference between cases and controls. Using familial data, we can also test models of genomic imprinting. For haplotype analysis, when the genotype being modeled is a phased, multilocus genotype, uncertainty often exists due to phase ambiguity and missing data at individual markers. The EM algorithm is used to maximize the likelihood with respect to the regression model parameters in the presence of this uncertainty. In each iteration of the EM algorithm, the fitted genotype probabilities are used to update the population haplotype frequencies, which are used in the E-step to infer the phased genotype probabilities for each individual. The maximization of the full likelihood is more involved than the two step approach, in which the haplotypes are first inferred and then used to fit the regression model. However, because the full likelihood model properly accounts for the uncertainty in the inferred genotypes, computed p-values and parameter uncertainty estimates are valid, which is not true in the two-step approach. These methods are implemented in NEMO (NEsted MOdels), a general tool for association mapping.

An Empirical Bayes Method for Analysis of Quantitative-Trait Loci from Multiple Genome Scans. *K. Zhang¹, H. Wiener², T.M. Beasley¹, V. George¹, C.I. Amos³, D.B. Allison¹.* 1) Section on Statistical Genetics, Department of Biosatistics, University of Alabama at Birmingham, Birmingham, AL; 2) Department of Epidemiology, University of Alabama at Birmingham, Birmingham, AL; 3) Department of Epidemiology, University of Texas, M. D. Anderson Cancer Center, Houston, Texas.

Single genome scans for Quantitative-Trait Loci (QTL) mapping often suffer from the low power and the imprecise estimation of QTL location and effect. As a consequence, the confidence interval for QTL location is often prohibitively large for subsequent fine mapping and positional cloning. Given that a large number of genome scans for the same phenotype have been available, information borrow across multiple linkage studies may allow us to detect the QTL with greater power and to estimate the QTL location and effect more precisely, therefore obtaining narrower confidence intervals. In this paper, we develop an empirical Bayes approach to integrating the same linkage statistic from multiple sib pair studies as well as not to force all studies to have an identical marker map and a common estimated QTL effect. The updated linkage statistic then can be used for the estimation of QTL location and effect. We evaluate the performance of our method using extensive simulations based on actual marker spacing and allele frequencies on chromosome 11 from the NIMH Alzheimers Diseases Genetics Initiative. The results indicate that the empirical Bayes method can account for the between-study heterogeneity and estimate the QTL location and effect more precisely as well as supply narrower confidence intervals than the individual study. We also compare it with the other related methods that have been developed.

A Permutation-Informed Bonferroni Correction for Correlated Tests. *Y. Zhao, B. Dain, C. Brain, B. Salisbury.*
Genaissance Pharmaceuticals, New Haven, CT.

A crucial statistical issue in genetic association analysis is multiple testing adjustment. Various approaches have been adopted to adjust for multiple testing. Here we propose a new method that combines the strength of permutation correction with the simplicity of Bonferroni. If the n markers in a gene were independent, a Bonferroni correction of p -values would simply consist of multiplying the observed p -value by n or dividing the significance cutoff, ALPHA , by n . However, it is almost never true that all the markers in a locus are independent of one another; this is due to linkage disequilibrium and the complex relationships between polymorphisms and haplotypes. Under the null hypothesis of no association between any of the markers in a gene and the phenotype, the expected value of the minimum marker p -value is $1/(1+n)$. We propose the following: Randomly permute the phenotypic data relative to the genetic marker, calculate all p -values and retain the minimum p -value for each permutation, doing enough permutations to accurately estimate the asymptotic average of the minima. The n for which $1/(1+n) =$ the average of the minima is the effective number of independent markers in the locus. This n could then be used in a Bonferroni procedure to accurately correct for the multiple testing. This method was tested on genetic and clinical data from Genaissance Pharmaceuticals STRENGTH study of statin response. The results were compared with those from other commonly used methods. This approach can also be used to correct for the simultaneous testing of multiple genetic models by including those in the permutations to get the effective n for the whole ensemble of tests.

Epidemiological characterization of Congenital Heart Disease in Sao Miguel island, Azores (Portugal). T.

Cymbron^{1, 4}, *R. Anjos*³, *C. Macedo*², *C.P. Duarte*², *L. Mota-Vieira*^{1, 4}. 1) Molecular Genetics & Pathology Unit, and; 2) Pediatric Depart, Hospital Divino Espirito Santo, Ponta Delgada, Azores Islands; 3) Pediatric Cardiology Depart, Hospital Santa Cruz, Carnaxide; 4) Instituto Gulbenkian de Ciencia, Oeiras, Portugal.

Congenital heart disease (CHD) are the clinical manifestation of anomalies in embryonic cardiac development, being the most frequent of all clinically significant birth defects. Here, we present an epidemiological study carried out on the population of Sao Miguel island (Azores, Portugal) during a 10 years-period (January 1992 to December 2001). The children were closely followed up by the only hospital in this island. A total of 189 patients with CHD were diagnosed in Sao Miguel population, indicating an average incidence of 9.20 per 1000 live-birth. During this period the incidence of CHD ranged from 4.77 to 12.75. The most frequent cardiac alterations found were ventricular septal defect (38.1%), atrial septal defect (12.2%), and persistent ductus arteriosus (11.6%). These three lesions amount to 61.9% of all CHD cases. Other lesions present were aortic stenosis (6.9%), atrioventricular septal defect (5.3%), pulmonary stenosis (4.8%), tetralogy of Fallot and pulmonary atresia with VSD (3.7%), coarctation of the aorta and transposition of the great arteries, both with 2.7%. The remaining cardiac malformations showed a frequency below 2%. These data agree in general with other recent studies. The main differences are a higher frequency of persistent ductus arteriosus (11.6%) and atrial septal defect (12.2%), and a lower frequency of transposition of the great arteries. Death occurred in 10.6% (n=20) of the children enrolled in this study. The cardiac lesions with higher mortality were pulmonary atresia with VSD and transposition of the great arteries. Until now, three familial clusters were detected, representing a total of 9 patients, most of which affected with VSD. The data described here represents the first characterization of congenital heart disease in the Azorean population. This work is funded by FCT (POCTI/ESP/49236/2002) and DRCT, Azores, Portugal (lmotavieira@hdes.pt).

Methylenetetrahydrofolate reductase C677T variant and non syndromic cleft lip with/without cleft palate in mestizo Mexican population. *I. Davalos^{1,2}, V. Ledezma-Gomez³, J.P. Mena^{1,2}, V. Ledezma-Rodriguez², E. Ramirez-Lizardo^{2,3}, L. Sandoval¹, N.O. Davalos², M.P. Gallegos¹, M. Salazar-Paramo⁴, L.E. Figuera^{1,2}.* 1) Division de Genetica, CIBO, IMSS; 2) Doctorado en Genetica Humana, Departamento de Fisiologia, CUCS, Universidad de Guadalajara; 3) Instituto Jalisco de Cirugia Reconstructiva Dr. JGS, SS; 4) Unidad de Investigacion Medica en Epidemiologia Clinica, HE, CMNO, IMSS. Guadalajara, Jalisco, Mexico.

MTHFR C677T variant, converting an alanine to a valine residue in the 5,10-MTHFR reductase gene, is responsible of the thermolabile form of the enzyme, reduced availability of 5-methyltetrahydrofolate (circulating form of folate) and mild hyperhomocysteinemia. MTHFR C677T variant has been associated with congenital anomalies such as neural tube defects. The role of the MTHFR-C677T and folic acid in non syndromic cleft lip with/ without cleft palate (CL/P) still controversial. It has been suggested that maternal folic acid supplementation in early pregnancy prevents CL/P. Objective: To determine the frequency of the MTHFR C677T in mestizo Mexican children with non syndromic CL/P. Method: A group of 43 mestizo Mexican children with CL/P (Group CL/P) and a group of 39 normal mestizo Mexican individuals. (Group N) were typed for the MTHFR C677T by the PCR/RFLP (HinfI) method. Genotype frequencies were analyzed (Hardy-Weinberg Expectations, chi square). Results: MTHFR C677T Genotype Frequencies GF %(n) in Group CL/P were CC 32(14), CT 63(27), TT 5(2) and GF in Group N were: CC 33(13), CT 54(21), TT 13(5). MTHFR C677T Allele Frequency AF %(n) in group CL/P were C 64(55), T 36(31) and in group N AF were C 60(47), T 40(31). The AF differences between both groups were NS ($p>0.05$). Conclusions: These results do not support an association between CL/P and MTHFR C677T genotypes in affected children.

Epidemiological study of cleft lip and palate in Cebu City, Philippines. *T. Pawar¹, M. Tolar², M. Tolarova¹.* 1) Craniofacial Genetics - Ortho, UOP Sch of Dentistry, San Francisco, CA; 2) Pediatric Clinical Research Center, PCRC Core Laboratory, Children's Medical Center, UCSF, 505 Parnassus Avenue, San Francisco, CA.

Cleft lip and palate anomalies, including syndromes and multiple congenital anomalies, affect one out of every 550 newborns. Our study population came from the island province of Cebu, Philippines. We looked at 104 individuals affected with orofacial clefts and 76 controls (patients without a congenital anomaly). A spectrum of factors such as sex, age, family history, birth order, age of the mother at the time of birth of the index child, and month of birth were evaluated. The mean age of cleft patients was 7.9 years, a majority of which (72%) had cleft lip and palate. The mean age of controls was 4.26 years. Among unilateral cases, the left side was more often affected (71%). A family history of clefting was positive in 60% of cases. The mean value for birth order was 3.4. A higher (3.9, but not statistically significant) for birth order was found in cases affected with bilateral clefts. The mean maternal age at the time of the child's birth was 27.4 years for cases and 26.1 years for controls. The majority of case mothers (23.91%) fell in the 24-26 years age-group, and the majority of control mothers fell in the 18 to 20 years age-group. A three month weighted average of the month of birth of cases and controls showed two peaks one for the months of May to July and one for the months of September to November. Projected to the time of conception, these peaks showed that a high number of affected individuals were conceived in the months of September to November (end of the rainy season in the region) and in the period from December to February (the dry season). This pilot epidemiological study evaluates several variables that are historically considered as risk factors for congenital anomalies. More extensive analysis of environmental, nutritional, and genetic factors is in progress to determine factors in the etiology of cleft lip and palate in this Southeast Asian region. The fieldwork for this study was supported by Rotaplast International Inc.

Quantitative genetic analysis of blood pressure before, during, and after isometric exercise. *A.C. Choh, S.A. Czerwinski, M. Lee, E.W. Demerath, B. Towne, R.M. Siervogel.* Wright State University School of Medicine, Dayton, OH.

Exaggerated blood pressure (BP) reactivity and diminished BP recovery in response to isometric exercise may be indicative of cardiovascular disease risk. However, characterizing differences between BP at rest, during, and after isometric exercise is difficult because these measures are presumed to be at least partly influenced by common genetic and physiological pathways. This study examines the genetic architecture of BP before, during, and after isometric exercise.

The study population consists of 448 individuals ranging in age from 7 to 72 years, distributed across 4 kindreds from Dayton, OH. Systolic (SBP) and diastolic BP (DBP) were collected while sitting, supine, during 1/3 maximal hand-grip at 1-minute intervals (up to 3 minutes), and during recovery at 2-minute intervals (up to 16 minutes). BP reactivity was calculated as BP during exercise minus BP at rest, while BP recovery was calculated as BP after exercise minus BP during the last minute of exercise. Heritabilities (h^2) were estimated using a maximum likelihood variance components method. Generally, h^2 estimates of BP before, during and after exercise were significant ($p < 0.05$), ranging from 0.18-0.45. However, the h^2 of the change scores (BP reactivity and recovery) were generally not significant.

To reduce the number of variables examined, principal components analysis was performed using mean arterial pressure (MAP, $DBP + 1/3(SBP - DBP)$) on a subset of individuals ($n = 303$). The first principal component (PC1) was interpreted as "general MAP"; PC2 as "reactivity"; and PC3 as "recovery". The h^2 for "general MAP" was 0.49 ($p < 0.05$). For BP "reactivity" and "recovery" h^2 was not significant. Age, sex and hypertensive medication use were significant covariates of "general MAP". Smoking and sex were significant covariates of BP "reactivity", while only smoking was significantly associated with BP "recovery". Unlike other physiological challenges such as the cold pressor test, reactivity to isometric exercise appears not to have a significant genetic basis. Supported by NIH-HL69995, AHA-0325371B.

Genetic and haplotype diversity of the C-reactive protein (CRP) gene in 7,000 Americans. *D.C. Crawford, J.D. Smith, Q. Yi, L. Witrack, M.J. Rieder, D.A. Nickerson.* Dept Genome Sci, Univ Washington, Seattle, WA.

C-reactive protein serves as a general marker for inflammation in humans, and elevated levels are associated with coronary artery disease. To investigate the impact genetic variation has on plasma C-reactive protein levels, *CRP* (6.7kb) was completely re-sequenced in five samples (23 European-Americans, 24 African-Americans, 24 Asians, 10 Mexicans, and 6 Indo Pakistanis) found within the U.S. We identified a total of 35 unique variants in five samples; 19 are unique to one sample. Twenty-three inferred (PHASEv2.0) haplotypes were identified, of which 2 were found in all five samples representing 47% of the chromosomes surveyed. *CRP* haplotype heterozygosity was highest in African-Americans (0.86), followed by Indo Pakistanis (0.75), European-Americans (0.75), Mexicans (0.74), and Asians (0.64). We then applied a subset of these variations (tagSNPs) to DNAs collected during the third National Health and Nutrition Examination Survey (NHANES III), a representative sample of the U.S. population conducted by the Centers for Disease Control and Prevention between 1988 and 1994. NHANES III has an extensive laboratory component that includes serum levels of C-reactive protein. DNAs from NHANES III (60% European-Americans and 30% African-Americans by self-reported race; 30% Mexican by self-reported ethnicity) were genotyped by TaqMan for 5 previously validated tagSNPs (LDSelect; $r^2 > 0.64$). On average, 94% of the 7,296 NHANES III samples were genotyped successfully. Haplotypes were inferred using all 5 tagSNPs genotyped in NHANES III and the five re-sequenced samples. All six tagSNP haplotypes observed in the re-sequenced samples were observed in NHANES III. Also, 11 rare (<5% frequency) tagSNP haplotypes were identified in NHANES III. Inclusion of the rare tagSNP haplotypes does not substantially increase tagSNP haplotype heterozygosity (0.79) compared with the re-sequenced sample (0.77). These results demonstrate the utility and necessity of exhaustive variation discovery in candidate genes prior to tagSNP selection for large epidemiological studies and serve as a primer for genotype-phenotype correlations for C-reactive protein in NHANES III.

Replicate evidence for intragenic and intergenic interactions between SNPs within the *APOA1/C3/A4/A5* gene cluster. *S.C. Hamon*¹, *S.L.R. Kardia*², *K.L. Klos*³, *K. Liu*⁴, *A.G. Clark*⁵, *E. Boerwinkle*³, *C.F. Sing*¹. 1) Department of Human Genetics, University of Michigan, Ann Arbor, MI, USA; 2) Department of Epidemiology, University of Michigan, Ann Arbor, MI, USA; 3) Human Genetics Center, University of Texas Health Science Center, Houston, TX, USA; 4) Department of Preventive Medicine, Northwestern University, Chicago, IL, USA; 5) Department of Molecular Biology and Genetics, Cornell University, Ithaca, NY, USA.

Apolipoprotein metabolic interactions are motivating the examination of SNP-SNP interactions. We considered 80 SNPs within the *apolipoprotein A1/C3/A4/A5* gene cluster using an over-parameterized general linear model to identify SNP pairs whose effects interact to influence plasma total cholesterol (TC). We analyzed population-based samples of unrelated 18 to 30 year old African-Americans (n=1858) and European-Americans (n=1973) ascertained without regard to health in four field centers (Birmingham, AL; Chicago, IL; Minneapolis, MN; and Oakland, CA) by the Coronary Artery Risk Development in Young Adults (CARDIA) study at the baseline time point (1985-1986). The effects of eight pairs of SNPs, involving nine SNPs from across the gene cluster, combine nonadditively to influence TC levels in females (p 0.05). Differences in mean TC levels of two-SNP genotypes replicated across ethnic groups and across field centers within ethnic groups. In contrast, only one of the 80 SNPs had a statistically significant influence on TC levels (p 0.05) in females within both ethnic groups. Our analyses suggest that SNP effects within the *APOA1/C3/A4/A5* gene cluster interact to influence TC levels in young adults and that this influence is contingent on the context defined by gender. Ignoring SNP-SNP interactions when modeling genotype-phenotype relationships may result in failing to detect the contribution of genetic variation to phenotypic differences in traits such as TC. This research was supported by NIH grants GM065509, HL072904, HL072905, HL072810, HC048047, HC048048, HC048049, HC048050 and HC095095.

Identification of Novel Polymorphisms in the Human ACAT2 Gene and Association Study with Plasma Lipids and Coronary Artery Disease. X. He¹, Y. Lu², N. Saha¹, H. Yang², C. Heng¹. 1) Paediatrics, National University Singapore, Singapore; 2) Biochemistry, National University Singapore, Singapore.

Acyl-CoA cholesterol Acyltransferase-2 (ACAT2) plays a critical role in the development of diet-induced hypercholesterolemia and atherosclerosis. In order to investigate the effects of ACAT2 gene on coronary artery disease (CAD) risks and plasma lipids, this gene was screened for sequence variations using cord blood from 336 neonates by the combination of PCR, denaturing-high performance liquid chromatography (DHPLC) and DNA sequencing. A total of 11 polymorphisms were detected, 9 of which were novel. There were 3 non-synonymous cSNPs: two common SNPs and one rare SNPs. These two common cSNPs (E14G in exon 1 and T254I in exon 7) and a 48-bp insertion/deletion were genotyped using PCR and/or RFLP analysis in 633 CAD patients and 813 healthy controls in Singapore population, namely, Chinese, Malays and Asian Indians. In order to observe the influence of these two polymorphisms on lipid profiles, the healthy subjects were further stratified into normolipidemic and dyslipidemic groups according to the NECP ATP III criteria. We found a significant decrease in the minor I allele frequency of T254I in the Chinese CAD patients compared with that in the controls (0.20 vs. 0.26, $P = 0.01$). It seems that I allele is protective against CAD in Chinese. This was not consistently observed in the Indians and Malays. The heterozygous carriers of T254I have statistically significantly decreased anti-atherogenic ApoA1 ($P=0.027$ and $P=0.007$, respectively) and/or increased ApoB ($P=0.007$) and lipoprotein (a) [Lp(a)] ($P=0.011$) than non-carriers in normolipidemic female Indians and Malays ($P=0.007$). Likewise, the heterozygous carriers of E14G was associated with higher total cholesterol ($P=0.042$) in the same Indian groups. T254I was in nearly complete linkage disequilibrium (LD) with Indel (> 0.9) and very strong LD with E14G (> 0.5) in the healthy three ethnic groups. Associations similar to T254Is were observed between Indel and lipids profile. Our results suggested that these three polymorphisms are associated with plasma lipids and CAD risks in an ethnic- and gender-specific manner.

The Effect of Stratification on Familial Dimensions in ASD. *P. Szatmari¹, S. Bryson², L. Zwaigenbaum³, W. Roberts⁴, S. Georgiades¹, E. Duku¹.* 1) Department of Psychiatry & Behavioural Neurosciences, McMaster University; 2) Departments of Pediatrics and Psychology, IWK Health Centre-Dalhousie University; 3) Department of Pediatrics, McMaster University; 4) Department of Pediatrics, The Hospital for Sick Children, University of Toronto.

Background: One explanation for the discouraging results of recent genetic studies in the Autism Spectrum Disorders is that the traditional DSM-IV phenotype may not be the most informative for genetic purposes. **Objectives:** to identify familial dimensions to be used as quantitative traits in linkage analysis by: a) developing empirically derived dimensions to represent the ASD phenotype, b) estimating the familial aggregation of these dimensions and c) using sample stratification to examine the heterogeneity of familiarity estimates. **Method:** Our sample consisted of 339 individuals with ASD. Four dimensions based on items from the ADI-R were derived using Principal Components Analysis (PCA). The VABS Adaptive Behaviour Composite was added as a fifth dimension to measure level of functioning (LOF). Sample stratification was applied using verbal/non-verbal status as the covariate. Intraclass Correlations (ICCs) were calculated for each dimension and across all sub-samples. **Results:** The four dimensions derived from PCA include: social communication, language, insistence on sameness (IS), repetitive sensory and motor behaviour (RSMB). Familial aggregation exists among sib pairs for all dimensions except RSMB. When the sample is stratified according to verbal or non-verbal status, the familial aggregation for the IS dimension is familial only in the verbal sub-sample. The RSMB dimension becomes familial in the nonverbal sub-sample. The familiarity of the level of functioning dimension appears to be stable across sub-samples. **Conclusions:** The five dimensions are potentially informative for genetic studies, and may be a preferable approach to the current phenotype definition represented in the DSM-IV. In addition, the use of empirical methods such as PCA combined with sample stratification methods are useful techniques for the development of informative quantitative phenotypes that can be used in genetic studies.

ASSOCIATION STUDY BETWEEN (AC)_n MICROSATELLITE POLYMORPHISM OF ALDOSE REDUCTASE GENE AND DIABETIC NEPHROPATHY IN TUNISIAN TYPE 2 DIABETIC PATIENTS. A.

Abid¹, I. Arfa², C. Amrouche-Rached¹, H. Elloumi-Zghal², B. Kaabi², S. Chakroun², S. Blousa-Chabchoub¹, K. Dellagi², S. Abdelhak². 1) Diabetology A, National Institut of Nutrition ,Tunis, Tunisia; 2) Immunology,Institut Pasteur, Tunis, Tunisia.

Aldose reductase (ALR2), the enzyme of the polyol pathway may play an important role in the pathogenesis of diabetic microvascular complications namely diabetic nephropathy. In an attempt to examine the contribution of ALR2 microsatellite polymorphism in susceptibility to diabetic nephropathy in Tunisian, a case control study was conducted among 50 type 2 diabetic patients with nephropathy and 30 diabetic patients without nephropathy in spite of a diabetes duration overt 10 years. Association studies between the (AC)_n microsatellite polymorphism localised at 2.1 Kb upstream the ALR2 promoter and diabetic nephropathy have yielded conflicting results. We identified 9 alleles in the studied diabetic population. The putative protective allele Z+2 showed an association with the diabetic group without nephropathy when compared with the diabetic nephropathy group ($\chi^2 = 5.96$, $p = 0.01$, $OR = 0.29$). These findings support the hypothesis that the polymorphism at the 5' end of the ALR2 gene contributes to the susceptibility to diabetic nephropathy in the Tunisian type 2 diabetic patients.

LACK OF ASSOCIATION BETWEEN GENETIC POLYMORPHISM IN THE RENIN ANGIOTENSIN SYSTEM AND DIABETIC NEPHROPATHY IN TUNISIAN TYPE 2 DIABETIC PATIENTS. *I. Arfa¹, A. Abid², C. Amrouche-Rached², H. Elloumi-Zghal¹, B. Kaabi¹, S. Chakroun¹, S. Blousa-Chabchoub², K. Dellagi¹, S. Abdelhak¹.*
1) Immunology, Institut Pasteur, Tunis, Tunisia; 2) National Institut of Nutrition, Tunis, Tunisia.

Diabetic nephropathy is a renal complication due to uncontrolled diabetes and genetic predisposition. It can be caused by an increase of glomerular pressure due to diabetes, the glomerular pressure is controlled by the renin angiotensin system. The genes encoding renin angiotensin system components are potent candidate genes namely ACE encoding the angiotensin converting enzyme and AGT encoding angiotensinogen. Several studies described that an insertion/deletion (I/D) polymorphism in intron 16 of ACE gene is associated with plasma and cellular ACE levels, it has also been suggested that AGT gene polymorphism is associated with plasma AGT levels. A case/control study was conducted among 59 Tunisian type 2 diabetic patients with nephropathy and 36 diabetic patients without nephropathy for ACE gene polymorphism and among 43 diabetic patients with nephropathy versus 33 diabetics without renal complication for AGT gene polymorphism. Diabetic controls without nephropathy have a diabetes duration over 10 years. The diagnosis of nephropathy was confirmed at least on two consecutive occasions on urinary albumin excretion. The other causes of albumin excretion were excluded. The I/D polymorphism of ACE gene was analysed with nested PCR in order to avoid mistyping heterozygotes individuals and the M235T polymorphism of AGT gene was analysed using PCR and allele specific restriction. There were no significant differences in allele or genotype distribution between diabetic patients with or without diabetic nephropathy for ACE and AGT genes polymorphisms. From these findings, it was concluded that these two polymorphisms are not related to the susceptibility to diabetic nephropathy in the Tunisian type 2 diabetic patients.

Incorporating compartmental models into statistical genetic models of type 2 diabetes. *Z. Guan, D.V. Conti, R.M. Watanabe.* Dept Preventive Med, Keck School of Medicine at USC, Los Angeles, CA.

In traditional statistical genetic modeling, the penetrance function linking genetic variation to phenotype typically takes a probabilistic form formulated around population-based information, such as disease risk. Detailed biologic knowledge (physiologic, cellular, or molecular) is used to derive the penetrance function, but is rarely incorporated into the function per se. We attempt to inject known biology underlying genotype-phenotype relationship in type 2 diabetes (T2DM) by incorporating a compartmental model (CM) of glucoregulation into statistical genetic models. We developed a CM capable of simulating oral glucose tolerance tests (OGTT), the most commonly used clinical protocol to assess glucose metabolism. Because our CM is physiologically based, each model parameter can be assigned to specific biologic function. As such, genes can be assigned to model parameters to simulate specific genetic defects in the glucoregulatory system. We performed simulations in which the peroxisome proliferator-activated receptor-2 (PPARG2) gene, a T2DM susceptibility gene known to alter insulin resistance, is imposed on our CM via parameter p3, a determinant of insulin signaling transduction. Mean and variance estimates and biologic limits for p3 were derived from human data. The common P12A polymorphism in PPARG2 was simulated with P corresponding to lower glucose tolerance with an allele frequency of 85%. Our CM was used to simulate 1000 OGTTs assuming an additive genetic model. AA genotype OGTT profiles fell tightly into the normal range. In contrast, the PA and PP genotype groups show considerable variability in glucose profiles, with 4% of the PA genotype having 2-hour glucose >140 mg/dl and 16% of the PP genotype group had elevated 2-hour glucose. The results are consistent with expectation based on the imposed PPARG2 risk profile and demonstrate how a physiologically based CM can replace the standard penetrance function to simulate phenotype data. Additional simulations examining other single gene and multiple gene effects are in progress.

Methylenetetrahydrofolate reductase gene C677T and A1298C polymorphisms and Neuropathy. *I. Kara¹, A. Sazci², E. Ergul², T. Yilmaz³, G. Kaya¹.* 1) Dept Neurosciences, Istanbul Univ, 34280, Istanbul, Turkey; 2) Department of Medical Biology and Genetics, Faculty of Medicine, University of Kocaeli, Derince, 41900, Kocaeli, Turkey; 3) Department of Internal Medicine, Clinics of Diabetes, Faculty of Medicine, University of Istanbul, 34280, Istanbul, Turkey.

Although the causes of diabetic neuropathy are multifactorial, limited data are available on what determine it. Polyneuropathy presents frequent and severe complication of Type 2 diabetes mellitus. The underlying etiopathophysiological mechanisms in diabetic polyneuropathy are multifactorial, and not well-defined. Homocysteine is implicated in the mechanisms underlying alterations in vascular endothelial cells, thus leading to atherosclerosis and venous thrombosis and elevated homocysteine levels may also cause production of oxidation products, thus damaging endothelium by alteration of connective tissue. The MTHFR C677T polymorphism is known to increase homocysteine levels in plasma. Therefore, we examined the MTHFR C677T and A1298C polymorphisms in association with neuropathy in patients with Type 2 diabetes mellitus. In a case-control study, we analyzed the allele and genotype frequencies of 178 diabetic patients with neuropathy and 253 healthy controls using a PCR-RFLP method. The allele frequency of MTHFR 677T was 33.43% in patients and 32.21% in controls. The frequencies of the MTHFR C677C, C677T, T677T genotypes were 44.9%, 43.3%, and 11.8% in patients, and 45.5%, 44.7%, and 9.9% in controls, respectively. The allele and genotype frequencies were not significantly distributed ($\chi^2=0.412$; $df=2$; $P=0.814$). The frequency of the MTHFR 1298C allele was 34.27% in patients, and 29.64% in controls. The allele frequency was not significantly distributed ($\chi^2=2.180$; $df=2$; $P=0.336$). The frequencies of the MTHFR A1298A, A1298C, and C1298C were 42.1%, 47.1%, and 10.7% in patients and 49.0%, 42.7%, and 8.3% in controls. In conclusion, The MTHFR C677T and A1298C polymorphisms are not associated with neuropathy in our study.

Variation in the HNF4A gene may interact with physical activity to increase risk of type 2 diabetes in Hispanic Americans from Colorado. *J.M. Norris¹, T.E. Fingerlin¹, C.D. Engelman¹, M.J. Durfee¹, L.K. Moss¹, M.M. Barmada², R.E. Ferrell².* 1) University of Colorado Health Sciences Center, Denver; 2) University of Pittsburgh, PA.

Variation in the HNF4A gene has recently been associated with type 2 diabetes mellitus (T2DM) in Finnish (FUSION) and Ashkenazi Jewish populations. We typed one of the SNPs shown to increase risk of T2DM in the original reports, rs1884614, in 277 Hispanic American and 252 Caucasian American families from the Denver and San Luis Valley areas in Colorado. We typed a total of 1028 (597 affected, 431 unaffected) Hispanic American individuals and 709 Caucasian American individuals (422 affected, 287 unaffected). Allele frequencies were very similar to those reported for the Finnish and Ashkenazi samples in our Caucasian sample. In contrast, the minor T allele was more common in our Hispanic sample than in the Finnish and Ashkenazi cases (.47 vs. .20 and .27, respectively). We tested for linkage and association between rs1884614 and T2DM using a generalization of the TDT as implemented in the FBAT software. We did not detect association in either population ($p=.10$, $.15$ for Hispanics, Caucasians, respectively). The original FUSION report showed association between the risk allele of rs2144908, a marker in nearly complete LD with rs1884614 in Finns, and insulin secretion measures. Since physical activity is associated with insulin secretion, we subsequently investigated the interaction between total physical activity and HNF4A genotype. We grouped cases based on sex-specific tertiles of total METs/wk prior to T2DM diagnosis and tested for association separately in the top and bottom tertiles. The T allele of rs1884614 was associated with T2DM in the low physical activity tertile ($p=.033$) but not in the high tertile ($p=.83$) in the Hispanic population. We did not see any such association in Caucasians, but the number of informative families in each tertile was small for that group. We are currently investigating other analytic approaches to verify the interaction between physical activity and HNF4A in conferring risk to T2DM in the Hispanic population.

Investigation of the familiarity of Diabetes Mellitus using Utah population-based mortality data. *B. Tausch*¹, *C.Q. Edwards*^{2,4}, *L.A. Cannon Albright*^{3,4}. 1) Dept of Medical Informatics, Univ of Heidelberg, Heidelberg, Germany; 2) Dept of Medicine, Univ of Utah, Salt Lake City, UT; 3) Dept of Medical Informatics, Univ of Utah, Salt Lake City, UT; 4) LDS Hospital, Salt Lake City, UT.

We used the the Utah Population Database (UPDB) to study the familial/genetic nature of diabetes mellitus (DM). The UDPB is a unique data resource that contains genealogical information of the Utah population. Therewith it is possible to examine all known genetic relationships between all DM deaths. Computerized data from Utah death certificates since 1904 have been record-linked to the genealogy data, which allows assessment of the familial contribution to disease.

We analyzed data from 14,000 individuals whose genealogical data is contained in the UPDB and whose death certificates indicated death due to DM Type 1 (T1DM) or Type 2 (T2DM). We used our previously published methods to examine the familial/genetic nature of DM, including birthyear- and sex-specific rates to estimate relative risks (RR) for DM in first- and second-degree relatives, by DM type. We also used the Genealogical Index of Familiarity (GIF), a published method that was developed by our group, to test for excess of relatedness among DM deaths. BMI data from drivers' licenses, which were also linked to the UPDB, allowed us to analyse the case group by obesity status. Our results strongly support significantly increased first- and second-degree RR for both T1DM and T2DM, analyzed independently. We observed significantly increased first- and second-degree RR for T2DM among the relatives of T1DM probands. This suggests a relationship between the phenotypes which may represent a common predisposition. We observed significantly increased RR for T2DM among the first-degree relatives of the normal, overweight, and obese weight subgroups, as well as among the second-degree relatives of the normal weight group. These results support the hypothesis that relatives of DM patients are at elevated risk for DM, independent of obesity status. We identified sets of high-risk pedigrees showing significant excess of DM, which could prove useful for predisposition gene searches.

Variation in PPARG associated with insulin sensitivity response to Troglitazone does not account for analogous response to Pioglitazone. *J.K. Wolford¹, K.A. Yeatts¹, S.K. Dhanjal², A.H. Xiang², T.A. Buchanan², R.M. Watanabe².*
1) Translational Genomics Research Institute, Phoenix, AZ; 2) Keck School of Medicine, University of Southern California, Los Angeles, CA.

We previously reported association between variation in the peroxisome proliferator-activated receptor gamma 2 (PPARG2) gene and response to troglitazone (TRO), a PPARG2 agonist and insulin-sensitizing agent used to treat type 2 diabetes. The association between PPARG2 and response to TRO was assessed in Hispanic women with previous gestational diabetes mellitus participating in the Troglitazone in the Prevention of Diabetes (TRIPOD) study, a placebo-controlled TRO trial. The recall of TRO for clinical use resulted in a new 3-year, single-arm, open-label Pioglitazone (PIO) trial, the Pioglitazone in the Prevention of Diabetes (PIPOD) study. Women who previously participated in the TRIPOD study were invited to participate in the PIPOD study. Oral (OGTT) and intravenous glucose tolerance tests (IVGTT) were performed at baseline, 1-year, and 3-years post-treatment. Non-response to PIO was assessed as a non-significant change from baseline insulin sensitivity (SI) after one year of treatment. Data are currently available for 78 PIO-treated women: 46 who took placebo and 32 who took TRO in TRIPOD. Non-response to PIO was 40%, slightly higher than that observed in TRIPOD. Only 19 of the 32 women (60%) who received active drugs in both studies showed concordance for response: 16 concordant for response, 3 concordant for non-response. We sequenced ~40 Kb of PPARG identifying 125 SNPs and 6 insertion/deletions. The six PPARG2 variants that were associated or showed trend for association ($p < 0.08$) with response to TRO were genotyped in PIPOD subjects. None of the six variants showed association with response to PIO ($p > 0.10$), nor did they show association with changes in response-related phenotypes. We conclude that variation in PPARG2 that may account for response to TRO does not account for response to PIO. Our results suggest other variants within PPARG2 or other genes in the thiazolidinedione-stimulated pathway may be responsible for response to PIO.

Large-scale epidemiological study of polymorphisms predisposing for common diseases in the Swedish

population. *U. Hannelius*^{1,2}, *C.M. Lindgren*^{1,2}, *E. Melén*^{2,3}, *A. Malmberg*⁴, *U. von Döbeln*⁴, *J. Kere*^{1,2}. 1) Department of Biosciences, Karolinska Institutet, Huddinge, Sweden; 2) Clinical Research Centre, Karolinska University Hospital, Sweden; 3) Institute of Environmental Medicine, Karolinska Institutet, Sweden; 4) Center for newborn metabolic diseases, Karolinska University Hospital, Sweden.

Neonatal screening has given rise to large libraries of biological samples in the form of dried blood spots. Our aim is to validate a method that makes these sample resources available for large genetic studies without violating the individual integrity or wasting the precious material. DNA from untraceable Guthrie spots was extracted using a saponin and chelex-100 based method. DNA yield was fluorometrically determined using OliGreen and the samples were preamplified using I-PEP-L. Genotyping was performed using the Sequenom MassArray platform. Ten samples each of fresh, 10 year-old and 25 year-old samples were extracted and preamplified. The fresh and the 10 year-old samples gave DNA yields of 105ng (SD36) and 96ng (SD37) respectively, whereas the 25 year-old samples gave yields of 57ng (SD19). After preamplification the samples were subjected to PCR for amplicons of 100, 396, 499, 599 and 762 bp in length. The 25 year-old samples were 100% successful for the 100bp amplicons and 80% successful for the 396bp amplicons. The 10 year-old samples were 100% successful for the 100bp and 396bp amplicons, 90% successful for the 499bp and 80% successful for the 599bp amplicons. The fresh samples were 100% successful for all amplicon lengths. 94 fresh samples including an unknown number of carriers of two different PKU mutations (R158Q, R252W) were genotyped in order to validate method specificity. All carriers (6 R158Q carriers, 4 R252W carriers) were found with no false positives. To determine the population frequency of several susceptibility genes we extracted and preamplified 2047 Guthrie spots representing the Swedish population. We describe a method that makes use of a preamplification step to use PKU registries for large genetic studies in an economical and ethical way. We also show that the approach is specific and applicable on old samples.

Methods for distinguishing mediating versus moderating forms of gene-environment interactions. B.M.

*Chakraborty*¹, *M.B. Rao*^{1,2}, *J. Mallik*², *R. Deka*^{1,2}, *R. Chakraborty*^{1,2}. 1) Div. Epidemiology and Biostatistics, Dept. Environmental Health, University of Cincinnati, Cincinnati, OH; 2) Center for Genome Information, Dept. Environmental Health, Univ. Cincinnati, Cincinnati, OH.

Gene-environment (GxE) interaction effect on specific phenotypes is defined by heterogeneity of environmental (E) effects across different genotypes, or by genotypes (G) having different phenotypic effects under different environmental conditions. Theoretically G x E effects may exist in spite of the absence of main effects of G and/or E. Thus, mechanistic distinctions of different forms of G x E interaction effects can be made by utilizing the concepts of mediator and moderator, used extensively in psychological and sociological studies. Structural equation models, or path diagrams describe the characteristic features of these two forms of interactions, which in turn allow their discrimination. Analysis of variance (ANOVA), or multiple/partial regression analysis (MRA/PRA) is the method of choice for data analysis, employed for different scenarios of continuous or discrete measurements of phenotypic, genotypic, and environmental variables. Necessary and sufficient conditions for moderator/mediator distinctions are derived in terms of the parameters of the ANOVA and MRA/PRA models. Parameterization of moderator/mediator forms of G x E effects also allows formal power computations for designing studies of gene-environmental interactions. With data on the effect of lead exposure on postural balance (an indicator of neuromotor function) in children of the Cincinnati Lead Program Project (CCLP), it is shown that impaired neuromotor balance under lead exposure is moderated by genotypes at a number of genetic loci implicated in susceptibility to neurological diseases. (Genotype data collected for this research was supported by a pilot project of the NIEHS grant ES-06096).

Impact of regulatory polymorphisms in genes involved in cell cycle control on the susceptibility to childhood leukemia. *J. Healy, A. Moghrabi, D. Sinnett.* Sainte-Justine Hospital Research Center, University of Montreal, Quebec, Canada.

Acute lymphoblastic leukemia (ALL) is the most frequent neoplasia in children, accountable for approximately 25% of all pediatric cancer cases. Sporadic cancers, such as ALL, are complex genetic disorders in which the effect of a series of low penetrance genes is modulated by external factors, hence modifying ones individual risk of cancer. This model implies an important interplay between genetic and environmental factors that influences inter-individual variability in the susceptibility to cancer. We wish to study the genetic determinants involved in childhood leukemogenesis, our hypothesis being that a child's individual susceptibility to ALL is associated to polymorphisms in genes involved in cell cycle control, which is crucial for maintenance of cellular homeostasis and genomic integrity. The main objective of this genetic epidemiology study is to evaluate the impact of polymorphisms in the 5' regulatory region of selected candidate genes on the susceptibility to ALL. In order to determine an association between genotype and clinical and/or molecular phenotype, 258 ALL patients and 277 control individuals, as well as 147 parental trios (father-mother-patient) were genotyped using a PCR and allele-specific oligonucleotide hybridization based approach. Preliminary results of our case-control and family based association studies have revealed that the A-593T polymorphism in CDKN2B, an important cell cycle inhibitor, is associated with ALL. The T-593 allele was shown to be significantly under-represented in ALL patients, suggesting a protective effect among carriers (OR=0,768; p=0,048). Similar studies on other candidate genes are ongoing. Our study focuses on individuals of French Canadian origin however the general population, including adult cancer patients, could benefit from the outcome of this study. Ultimately, our study will provide the ground work to understanding the role of genetic susceptibility factors, particularly those pertaining to the cell cycle, in the etiology of childhood ALL. This study is supported by the Francois-Karl Viau Chair in Pediatric Oncogenomics.

Segregation analysis of cancer in families of young onset African American breast cancer patients. *J.F. Korczak, M.S. Simon, C.L. Yee, A.G. Schwartz.* Karmanos Cancer Inst. and Wayne State Univ., Detroit, MI.

Breast cancer etiology has been understudied in young African American women, where the disease incidence and mortality exceed that of Caucasians. We recently found significant familial risk of breast and cervical cancer in 3,037 female first-degree relatives of 496 African American breast cancer patients diagnosed before 45 years of age who participated in the NICHD-sponsored Women's Contraceptive and Reproductive Experiences (CARE) Study.

To determine whether the transmission of a single major gene could account for the increased familial risk of these cancers, we considered anyone with (i) breast cancer (BR) or (ii) breast or cervical cancer (BRCV) as affected and performed complex segregation analyses of BR and BRCV using Class A logistic regressive Models 1 (type-dependent age of onset) and 2 (type-dependent susceptibility), as implemented in the computer program S.A.G.E. REGTL. For each model, hypotheses of a major genetic or environmental effect, as well as no major type effect, were tested against a general model with arbitrary transmission probabilities.

According to the Akaike Information Criterion, Model 1 fit the data as well as or better than Model 2 for all transmission hypotheses, both for BR and BRCV. The genetic Model 1 hypotheses tended to have larger P -values than the corresponding non-genetic hypotheses, especially for BRCV where P was greater than 0.01 for the genetic hypotheses but less than 0.0003 for the non-genetic hypotheses. This suggests that BRCV may have greater power to discriminate among alternative transmission hypotheses than BR. All Model 1 transmission hypotheses of BR and BRCV were rejected at the $\alpha = 0.05$ level when tested against the general model, leading us to conclude that the mode of transmission may be more complicated than a simple single gene model. We are thus evaluating the utility of several additional parameters in the above models to allow for departure from a logistic distribution of the age at exam and/or age at onset, via a Box-Cox transformation, and for residual familial correlations, via a regressive maternal effect and/or sibship covariate.

Evaluating interaction between cigarette smoking and genetic susceptibility in carcinogenesis of lung cancer using a new carcinogenesis model and case-control data. *L. Deng¹, O. Gorlova², M. Kimmel¹*. 1) Department of Statistics, Rice University, 6100 Main St. MS-138, Houston, TX 77005; 2) Department of Epidemiology, University of Texas M.D. Anderson Cancer Center, 1515 Holcombe Blvd, Houston, TX 77030.

The majority of lung cancer cases are attributed to tobacco. However, only a fraction of smokers will develop lung cancer in their lifetime. This suggests that the probability to develop lung cancer is affected also by genetic susceptibility including the ability to activate the carcinogen, detoxify the carcinogen and repair damaged DNA. We present a new carcinogenesis model and apply it to the simulated case-control data in order to make inferences on the key parameters. Our carcinogenesis model inherits some features of the two-stage clonal expansion and multi-stage models. However, it also incorporates a mechanism of cancer cell evolution, which allows different carcinogenesis pathways for different patients. This is accomplished by introducing a continuous malignancy parameter, which is incremented in steps of random durations. The pace of transformation accelerates with increasing malignancy. The resulting incidence curves are initially very flat and then rapidly increase, this biphasic character being more pronounced than in Moolgavkar-style models. We will compare the performance of our new model with Moolgavkar's carcinogenesis model using Texas Lung Cancer Registry data. We also expect that the data containing information on individual genetic make-up from an ongoing case-control study at M.D. Anderson Cancer Center will be made available to us through collaboration. This data will allow evaluating the interaction between smoking and genetic factors in the carcinogenesis of lung cancer. The research is supported by NCI grants CA97431 and by a training fellowship from the W.M. Keck Foundation to the Gulf Coast Consortia through the Keck Center for Computational and Structural Biology.

The relationship between parity and longevity in the Old Order Amish, a population characterized by large family sizes. *P. McArdle, T. Pollin, A. Shuldiner, B. Mitchell.* School of Medicine, University of Maryland, Baltimore, MD.

From theoretical perspectives, there is reason to speculate that having children might lead to decreased life span. To evaluate this issue, the authors examined the relationship between parity and longevity using genealogical data from an Old Order Amish community in Lancaster, PA, a traditional founder population who do not believe in divorce or birth control. We restricted our analysis to the set of 2338 individuals born between 1749 and 1912 and surviving until at least age 50 years. Individuals who had at least one child lived longer than those who did not though there is greater evidence among men (75.2 vs 73.3 years, $p=0.05$) than among women (76.4 vs 76.1 years, $p=0.7$). Among the 2015 individuals who had children, the average number of offspring was 7.3, with a range of 1 to 20 children. In fathers, life span increased significantly and in linear fashion with each additional child ($p=0.01$). In mothers, life span increased with increasing parity until about 11-14 children ($p=0.004$), but tended to decrease thereafter in those having more than 14 children. Among Amish women, age at last birth was independently associated with longevity, even after accounting for total number of children, with women who gave birth later in life living longer ($p=0.0001$). Late childbirth in women thus appears to be a marker for increased longevity, suggesting that genetic or environmental factors beneficial to reproductive health are also positively associated with longevity. Understanding these factors may provide insights into mechanisms underlying successful aging.

A Novel Quantitative Trait (QT) Posterior Probability of Linkage (PPL) with Specific Adaptations for QT Analysis of Autism. *C.W. Bartlett, V.J. Vieland.* Center Stat Genet Res, University of Iowa.

We have developed a new method for QT linkage analysis based on the PPL, which directly measures the probability that a disease-gene is linked to a genetic marker, using the single-locus QT likelihood implemented in LIPED with the trait parameters (allele freq, genotypic means, variances) integrated out. This framework has several advantages over pair-wise IBD sharing-based methods: it is based on the full likelihood, uses full phenotypic information, does not assume normality at the population level or require population/sample parameter estimates; and like other forms of the PPL, it is specifically tailored to accumulate linkage evidence either for or against linkage across multiple sets of heterogeneous data. Simulation evaluation of the method confirms its utility compared to other approaches and also confirms that the single-locus likelihood is robust for two-locus traits. E.g., in data of 100 nuclear families ascertained for 2 children with phenotype >1 SD above the population mean (locus effect size 0.3), we obtain mean PPLs as follows: additive-additive model, 50%, 51%; respectively for the two loci; additive-dominant, 58%, 36%; additive-recessive, 21%, 99%. These are similar to the values we obtain for comparable single-locus traits (additive 56%, dominant 45%; and recessive 100%).

We have also modified the QT PPL by adapting the threshold model to handle a mix of quantitative and dichotomous data within the same pedigree, as occurs when QT measurea can only be obtained, or appropriately normed, for clinically unaffected individuals. Repeating our simulations by recoding all QTs >1 SD above the mean as affected and using the modified likelihood, the mean PPL is reduced by only 12%. By contrast, using the same threshold but a dichotomous trait PPL reduced the mean by 30%, strongly supporting the use of this new approach when QT measures are available for a subset of individuals only. This adaptation of the PPL has been tailored to genetic studies of diseases such as autism, where quantitative endophenotypes may be measurable only in relatives, and not in severely impaired autistic individuals.

Program Nr: 2899 from the 2004 ASHG Annual Meeting

Association explaining non-parametric linkage for binary traits in general pedigrees. *L. Li, S.R. Browning.* Genetic Data Sciences, GlaxoSmithKline, RTP, NC.

A successful linkage analysis may yield a gene-mapping signal covering a large region of perhaps thirty centiMorgans in length and containing hundreds of genes. A follow-up association analysis can provide much finer resolution but is subject to greater multiple testing problems. When several weak association signals are found within a linkage region, a question of great interest is whether there is any way to distinguish the false from true positives. We present a test for determining whether an association result can help to explain a non-parametric linkage result for a binary trait in general pedigrees. The correlation between family allele/genotype frequency and family LOD score is used as a measure of whether the association between a given marker and the disease status can help to explain a significant linkage result seen in the collection of families in the region around the marker. Results from simulation studies examining type I error and power indicate the test is valid and useful for distinguishing between true and false positive association results under a linkage peak. We apply the method to analysis of real data.

Association of polymorphisms in pituitary growth hormone and IGF-1 with fetal growth restriction. *R. Adkins*¹, *T.K. Boyd*². 1) Dept Pediatrics, Univ Tennessee, Memphis, TN; 2) Dept Pathology, Children's Hospital Boston, Boston, MA.

We surveyed single nucleotide polymorphism (SNP) and microsatellite variation in the genes for pituitary growth hormone (GH) and insulin-like growth factor 1 (IGF-1) in a case-control analysis of 128 normal birth weight and 72 fetal growth restricted (FGR) full-term newborns selected using stringent inclusion/exclusion criteria. GH was found to be unusually polymorphic, with 26 SNPs in a span of 2,350 nucleotides. Most of these polymorphisms were clustered in the promoter region of the gene. Logistic regression identified association ($p=0.03$) between FGR and two C alleles in complete linkage disequilibrium located at 1 and +3 relative to the start of transcription. Separate ANOVA within normal and FGR classes demonstrated an average reduction in birth weight of 152g among normal birth weight and 97g among FGR newborns bearing C alleles at these two sites. These birth weight reduction were marginally significant ($p=0.057-0.086$) due primarily to small sample sizes. There are several biological explanations for how variation at either site 1 or +3 might affect the level of expression of GH. A survey of three microsatellites and three SNPs spanning the IGF-1 gene indicates that polymorphism in the region of intron 2 is associated with FGR. This finding is consistent with independent work in other laboratories.

Familiality of Rectal Cancer as Studied in the Utah Population Database. *J.S. Maul*¹, *L. Cannon-Albright*². 1) Division of Hematology/Oncology, University of Utah, Salt Lake City, UT; 2) Division of Medical Informatics University of Utah, Salt Lake City, Utah.

Background: The UPDB is a database linking genealogy for 2.5 million Utah individuals to 85,000 Utah cancer records. The familial nature of cancer has been well studied using this resource. Here, we investigate familiality for 2,733 individuals with rectal cancer. **Methods:** We estimated relative risk (RR) of rectal cancer, colorectal cancer (CRC), colon cancer (large intestine, excluding rectum), proximal colon cancer (proximal to the splenic flexure) and distal colon cancer (located in and distal to the splenic flexure, including rectum) in first and second degree relatives of rectal cancer cases using internal age- and site-specific rates of cancer. We considered all 2,733 rectal cancer cases and the subgroup of 222 early rectal cancers diagnosed <50yrs. **Results:** Data for first degree relatives is shown. In 1st degree relatives of rectal cancer cases, the RR for rectal cancer is 2.16 (95% CI 1.82 to 2.54), colorectal cancer 2.08 (CI 1.90 to 2.28), colon cancer 2.07 (CI 1.86 to 2.30), proximal colon cancer 1.86 (CI 1.57 to 2.19) and distal colon cancer 2.19 (CI 1.95 to 2.44). In 1st degree relatives of early rectal cancer cases, the RR for rectal cancer is 4.74 (CI 2.52 to 8.10), colorectal cancer 4.12 (CI 2.90 to 5.68), colon cancer 3.91 (CI 2.53 to 5.77), proximal colon cancer 3.39 (CI 1.63 to 6.24) and distal colon cancer 4.63 (CI 3.05 to 6.73). **Conclusions:** The UPDB provides strong evidence for a genetic component in rectal cancer, especially in early onset cases. Relatives of rectal cancer patients are at significantly increased risk of CRC in all segments of the large bowel and rectum. This risk is significantly higher in almost all segments of the colon than the increased risk for CRC among first degree relatives of CRC probands. Given a low frequency of genetic syndromes causing increased risk for rectal cancer, our findings suggest the presence of an unidentified genetic component for this disease. Multiple high risk rectal cancer pedigrees have been identified in the UPDB; study of these pedigrees could allow identification of rectal cancer predisposition genes.

Increasing power for tests of genetic association in the presence of phenotype and/or genotype error by use of double-sampling. *D. Gordon*¹, *Y. Yang*¹, *C. Haynes*¹, *S.J. Finch*², *N.R. Mendell*², *A.M. Brown*^{3,4}, *V. Haroutunian*⁵. 1) Statistical Genetics, Rockefeller University, New York, NY; 2) Applied Math and Statistics, Stony Brook University, Stony Brook, NY; 3) Burke Medical Research Institute, White Plains, NY; 4) Weill Medical College of Cornell University, New York, NY; 5) Bronx VA Medical Center, Bronx, NY.

We present a method, the likelihood ratio test allowing for errors (LRT_{ae}) that incorporates double-sample information for phenotypes and/or genotypes on a sub-sample of cases/controls. Population frequency parameters and misclassification probabilities are determined using Tenenbein's double-sample procedure (Tenenbein 1970; Tenenbein 1972) as implemented in the Expectation-Maximization (EM) method of Dempster et al. (Dempster et al. 1977). To compare our method with the standard method that makes no adjustment for errors (LRT_{std}), we perform null and power simulations assuming a SNP marker or a 4-allele marker locus, three different sets of cases/controls, two different settings each of phenotype and genotype error, and a 17% sub-sample of individuals double-sampled on either phenotype and genotype. We also apply our method to case/control ApoE genotype data for an actual Alzheimers study. The LRT_{ae} method maintains correct type I error proportions for all null simulations and all significance level thresholds (10%, 5%, 1%, 0.1%). LRT_{ae} power is always greater than or equal to LRT_{std} power. Power differences range from 0.0001 to 0.18 for the simulation parameters considered. LRT_{ae} average estimates of population frequencies and misclassification probabilities are equal to the true values, with variances of 10⁻⁷ to 10⁻⁸. For ApoE, the LRT_{ae} and LRT_{std} p-values are 5.8 x 10⁻⁵ and 1.6 x 10⁻³, respectively. The increase in significance is due to adjustment in the LRT_{ae} for misclassification of the risk allele. We also investigate cost/benefits of the two methods when budgets are fixed. We have developed freely available software that performs our LRT_{ae} statistic.

PARKIN Gene polymorphisms in Sporadic Parkinson's Disease. *M. Kasap¹, A. Sazci¹, E. Ergul¹, H. Tireli², M. Gencer², Y. Cetinkaya², G. Akpinar¹, G. Kaya³, I. Kara³.* 1) Department of Medical Biology and Genetics, Faculty of Medicine, University of Kocaeli, Kocaeli, Turkey; 2) Department of Neurology, Haydarpasa Numune Hospital, Uskudar, Istanbul; 3) Department of Neuroscience, Institute of Experimental Medical Research, University of Istanbul, Istanbul, Turkey.

Although the PARKIN gene was isolated from an autosomal recessive juvenile Parkinson patient, this gene has been reported to cause parkinsonism in sporadic late onset parkinson patients as well. Recently a polymorphism, S167N in exon 4 has been identified. We investigated the S167N polymorphism in 75 parkinson patients (36 women 48%; 39 men 52%), and 102 controls (50 women 49%; 52 men 51%). The PARKIN S167N polymorphism was amplified by PCR, followed by digestion with AlwNI restriction endonuclease. The size of the amplified fragment was 261 bp. When the fragment was digested with AlwNI, two fragments were created with a 167 bp, and 94 bp. The allele frequency of PARKIN 167N is 10% in the parkinson patients, and 5.39% in the controls. The frequencies of the PARKIN S167S, S167N, and N167N were 85.3%, 9.3%, and 5.3% in the parkinson patients and 90.2%, 8.8%, and 1.0% in the controls. Although the PARKIN N167N genotype showed an increased risk for parkinsonism in a Turkish population (OR=5.690; 95% CI= 0.623-51.986; Chi-2=2.983; df=1; P=0.084), the 95% CI range was rather wide.

Coding sequence variation in human sweet and umami taste receptor genes. *U. Kim, N. Riaz, D. Drayna.*
NIDCD/NIH, Rockville, MD.

Sweet and umami (the taste of glutamate) tastes play a major role on the perception of calorically rich and essential nutrients. In humans, three members of the T1R class of taste-specific G protein-coupled receptors (T1R1, T1R2, and T1R3), which reside on chromosome 1, are known to function in combination as heterodimeric receptors for sweet and umami tastes. We hypothesized single nucleotide polymorphisms (SNPs) or variant haplotypes of the T1R genes in humans may underlie individual differences in the perception and recognition threshold for sweeteners and amino acids. To enable study of genotype/phenotype correlations for these two tastes, we identified coding sequence variation by sequencing these genes in a cohort of unrelated individuals. To achieve maximum genetic diversity in our sample, we sequenced a panel consisting of 30 Europeans, 20 East Asians, 10 Native Americans, 8 South Asians, and 20 sub-Saharan Africans. In the combined sample, we found a total of 28 SNPs in these three genes. Sixty percent of these SNPs cause an amino acid substitution in the encoded receptor protein, and 1 SNP, in the T1R1 gene, introduces an in-frame stop codon. Although the size of these three genes is much larger than those of the T2R genes that encode bitter taste receptors, the number of cSNPs in the T1R genes is small compared to the number of cSNPs in T2R genes. This suggests that the sequence of the T1R receptor proteins are more conserved than those of T2R receptors, and may explain why individuals do not show broad variation in these taste modalities.

Program Nr: 2905 from the 2004 ASHG Annual Meeting

Test of independence of highly polymorphic haplotype blocks. *H.S. Lee, R. Chakraborty.* Center for Genome Information, Dept. Environmental Health, Univ Cincinnati, Cincinnati, OH 45267.

Although haplotype blocks are generally demarcated by lack of linkage disequilibria between them, a formal test of independence between haplotypes of different blocks by the usual tests may lead to degeneracy, particularly when the number of possible haplotypes within blocks is large. We develop a new algorithm for testing whether or not haplotypes of different haploblocks are at linkage equilibrium. This test is based on pairwise comparisons of all composite haplotypes in a sample, where each haplotype comparison is scored in reference to the number of mismatched sites within each block. This generates a $(r + 1)$ by $(c + 1)$ contingency table, with r and c being the number of polymorphic sites defining the two haploblocks. Test of independence is then carried out with a chi-square or a likelihood ratio test statistic, for which the empirical level of significance is computed by permutation. This algorithm is applied to data on genotypes at 13 short tandem repeat (STR) loci and 12 Y-chromosome STR loci for 18 populations, the objective of which was to test that autosomal genotypes are independent of Y-chromosomal haplotype in absence of population substructure. This specific application also illustrates that such tests of independence between hypervariable haploblocks can be conducted with phase unknown genotype data for one or both haploblocks, where the number of mismatched sites is replaced by the number of alleles shared between multilocus genotypes. One novel population genetic inference that emerges from this test is that in pairs of individuals from a population of restricted effective size, the number of alleles shared is larger (and consequently, the number of mismatched sites is smaller) in general compared with those in large populations, but population size restriction alone do not necessarily induce linkage disequilibrium between haplotypes of distinct blocks. (Research supported by NIH grants GM 41399 and a training grant on research in bioterror agents).

Program Nr: 2906 from the 2004 ASHG Annual Meeting

BioBank Japan for developing personalized medicine. *Y. Ohnishi*¹, *Y. Nakamura*^{1,2}. 1) SNP Research Ctr, RIKEN, Tokyo, Japan; 2) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, University of Tokyo, Tokyo, Japan.

Personalized medicine project started in June 2003 supported by Japanese government. The aims of this project are 1) discovery of genes susceptible to diseases, or those related efficacy or adverse reactions of drugs, 2) evidence-based development of drugs or diagnostic methods, 3) providing the important medical information that can be applied for establishment of Personalized Medicine and 4) studies on gene-environment interaction for prevention of diseases. To achieve these goals, we plan to collect of DNAs, sera and clinical information from 300,000 patients who mainly have common diseases by March 2007. For sample storage and clinical information database, we constructed BioBank Japan that consisted of facilities for DNAs and sera and established the computer system for clinical database. For protection of individual information, we are doing 1) two-step anonymization of individual identification code by 2D bar-code and 2) avoidance of placing individual identification information and genotyping information together. By the end of June in 2004, we have collected over 55,000 samples (a total number of disease cases is counted to be more than 70,000 due to multiple diseases in one patient) from 51 hospitals enrolled in this project. We have started systematic genomics analysis (the genome-wide association studies with 52,608 SNPs) to identify genes of medical importance using these samples. Accumulative data should provide us the basis to personalize the patients treatment.

Can we predict the risk of common complex diseases using multiple genetic tests? *C.M. Van Duijn¹, A.C.J.W. Janssens^{1,2}, Y.S. Aulchenko¹, S. Elefante¹, G.J.J.M. Borsboom², E.W. Steyerberg²*. 1) Epidemiology & Biostatistics, Erasmus University Medical Center, Rotterdam, Netherlands; 2) Department of Public Health, Erasmus University Medical Center, Rotterdam, Netherlands.

Complex diseases cannot be predicted with single genes, but there is ongoing debate on the future of multiple genetic tests. We evaluated the discriminative ability of tests including up to 400 susceptibility genes using the area under the ROC curves (AUC). We simulated three populations of 100,000 subjects in which the disease prevalence varied from 1%, 10% and 30% using R software. Allele frequencies of the risk allele varied from 10%-50% and odds ratios (ORs) from 1.25 to 3 (multiplicative effects). The number of genes involved and strength of their association with disease determined the AUC. When the frequency of disease and risk alleles are both 10%, at least 7 genes with strong effects (OR = 3.0) are needed in the tool to obtain an AUC of 0.80. When all ORs are 2.0, at least 18 genes are needed to obtain an AUC of 0.80, while 60 genes are needed when ORs are 1.5, and 170 when all ORs are 1.25. Also one can reach an AUC of 0.80 by combining a few strong genes with multiple weak genes, which is a more realistic scenario for most complex diseases. The maximum discriminative ability of a genetic screening tool could be deduced from the heritability and the prevalence of the disease. Based on our simulations studies it is unlikely that we will be able to predict common diseases with a modest heritability such as cardiovascular disease. However, predictions appear to be possible for diseases which have a higher heritability or are less common like Alzheimers disease and auto-immune diseases.

Molecular study of Alpha thalassemia in the multi-racial groups in Malaysia. *Y.C. Wee¹, J.A.M.A. Tan¹, K.L. Tan¹, W.P. Chow², S.F. Yap³.* 1) Department of Molecular Medicine, University Of Malaya, Kuala Lumpur, Malaysia; 2) Gleneagles Intan Medical Centre, Kuala Lumpur, Malaysia; 3) Department of Pathology, University of Malaya, Kuala Lumpur, Malaysia.

Thalassemia is the most common genetic blood disorder of hemoglobin synthesis in Malaysia. Alpha thalassemia is caused by deletions or mutations within the α -globin gene complex located on chromosome 16. Alpha thalassemia ($--^{SEA}$, $-^{3.7}$, $-^{4.2}$ and CS) was characterized in 670 pregnant women (MCV89 fL and/or MCH28 pg) who attended the Antenatal clinic of University Malaya Medical Centre (402 Malays, 100 Chinese, 148 Indians and 20 from other racial groups). 106 pregnant women (15.8%) were identified as α -thalassemia carriers - 3.7% (25) possess the $--^{SEA}$ deletion, 10% (67) were heterozygotes for the $-^{3.7}$ deletion, 0.6% (4) were heterozygotes for the $-^{4.2}$ deletion, 1.3% (9) were heterozygotes for Hemoglobin Constant Spring (Hb CS) and 0.2% (1) was compound heterozygous with the $-^{3.7}/^{CS}$ genotype. The $--^{SEA}$ deletion responsible for Hemoglobin Barts hydrops fetalis syndrome was found to be significantly higher (15%, $p < 0.0001$) in the Chinese, followed by a lower frequency in the Malays (2.5%). This double α -globin gene deletion was not detected in other racial groups. The $-^{3.7}/$ genotype was distributed evenly among the 3 racial groups - 10.7% of the Malays, 10% of the Chinese and 7.4% of the Indians. It was also detected in a woman with Thai nationality, an Arabic Malay woman with Yaman ancestry and in an Orang Asli (Aborigine) patient belonging to the Bidayuh tribe. The $-^{4.2}/$ genotype appeared to be at a significantly lower frequency (0.6%) as compared to the $-^{3.7}/$ genotype (10%, $p < 0.001$) and it was present only in 1% of the Malays. Only 1 Malay woman (0.15%) was found to be a compound heterozygote with the $-^{3.7}/^{CS}$ genotype and heterozygotes Hb CS ($^{CS}/$) was also detected only in the Malays (2.2%) in this study.

Program Nr: 2909 from the 2004 ASHG Annual Meeting

QTL study of non-verbal mild mental impairment using DNA pooling and microarrays to screen over 10,000 SNPs. *L.M. Butcher, E. Meaburn, L. Schalkwyk, I.W. Craig, R. Plomin.* SGDP Centre, Institute of Psychiatry, London, United Kingdom.

Mild Mental Impairment (MMI) represents the quantitative low extreme of general intelligence and is highly heritable. Quantitative Trait Loci (QTLs) that confer susceptibility to MMI are of small effect size and are likely to be the same as those that operate throughout the distribution of intelligence, as well as other related traits. Achieving satisfactory power to detect such QTLs requires an association study design to screen many thousands of single nucleotide polymorphisms (SNPs) in large samples of individuals, preferably with minimal constraints on time and cost. To screen many thousands of SNPs we used the Affymetrix 10K Mapping GeneChip. To genotype large sample sizes we employed DNA pooling. In an experiment *a priori* which combined the Affymetrix 10K Mapping GeneChip and DNA pooling, we were able to show rapid estimation of allelic frequencies in DNA pools with a high degree of accuracy and reliability. We identified 515 MMI cases and 1,028 representative controls from a community-based longitudinal research project (Twins Early Development Study; TEDS) with data for over 14,000 7-year old children assessed on a diverse battery of cognitive tests. We genotyped DNA pools consisting of MMI cases and representative controls and compared relative allele frequencies for over 10,000 SNPs. In order to reduce false-positive marker selection for subsequent testing we also genotyped DNA pools consisting of the top (n=505) and bottom (n=503) extremes of the general intelligence distribution. For each group every individual was randomly assigned to one of five DNA sub-pools. Each sub-pool was genotyped on a separate microarray and allele frequency estimates were averaged across the five microarrays to provide a group estimate of allele frequency with sample variance. 36 SNPs showing differences .1 in both studies were individually genotyped on approximately 7500 individuals from the TEDS to test their association with MMI. This strategy provides a quick, accurate and economical way to screen thousands of SNPs in large samples and represents a genuine step forward in high-throughput genotyping in the hunt for QTLs of small effect size.

Properties of ranks associated with true positives in association genome scans. *D.V. Zaykin.* Genetic Data Sciences, GlaxoSmithKline, Inc, Res Triangle Park, NC.

Deciding which markers to type in further samples following an association scan across a genomic region or entire genome is difficult. The genotyping and analysis costs of following up a large number of signals must be balanced with ensuring true associations are among those selected for further investigation. Once a genome scan is completed the results can be sorted by the association statistic value. What is the probability that true positives will be encountered among the markers with the largest association statistic? This problem can be studied using the probability distribution of ranks allowing for dependence among associations due to LD. Using this setup, the effects of multiple testing corrections on the distribution of the true association ranks can be evaluated as well. This formulation allows to calculate the number of markers required to consider in a follow-up study in order to capture true associations with high probability. The results show that LD does not considerably affect the distribution of ranks. Further, it is found that the effect of multiple testing corrections on the distribution of ranks is generally weak. Furthermore, "multiple testing corrected"; results are likely to represent false positives, unless the power associated with true positives is very high. Association genome scans with 100K or more genetic polymorphisms have been evaluated. The results suggest that it is typical for genuine strong associations to rank among first hundreds or even thousands of results sorted by the value of the association test statistic. Therefore following up on too few markers can result in missing the true associations. Finally, the required sample sizes can be calculated to ensure that genuine associations are encountered among the "first runners".

Genome-wide Admixture Mapping for Hypertension Loci: The NHLBI Family Blood Pressure Program. *X. Zhu¹, A. Luke¹, R.S. Cooper¹, T. Quertermous², C. Hanis³, T. Mosley⁴, C.C. Gu⁵, H. Tang⁶, D.C. Rao⁵, N. Risch^{7,8}, A. Weder⁹.* 1) Preventive Med & Epidemiology, Loyola Univ Medical Ctr, Maywood, IL; 2) Division of Cardiovascular Medicine, Stanford Univ School of Medicine, Stanford, CA; 3) Dept of Genet, Univ of Texas, Houston, TX; 4) Dept of Medicine, Univ of Mississippi, Jackson, MS; 5) Division of Biostatistics, Washington Univ, St. Louis, MO; 6) Division of Public Health, Fred Hutchinson Cancer Research Center, Seattle, WA; 7) Dept. of Genetics, Stanford Univ, Stanford, CA; 8) Division of Research, Kaiser Permanente, Oakland, CA; 9) Dept of Medicine, Univ. of Michigan, Ann Arbor, MI.

Discovery of genetic variants that contribute to risk of hypertension has proven to be a challenge. As a complement to linkage and candidate gene association studies, we performed genome-wide admixture mapping using microsatellite markers among the African-American participants of the NHLBI Family Blood Pressure Program (FBPP). The population sample was assumed to have experienced recent admixture from ancestral groups originating in Africa and Europe. A set of unrelated individuals from Nigeria was used to represent the African source population, while the whites in the FBPP provided estimates for Europe. Two hundred and sixty nine microsatellite markers were typed in common in the three groups at the same laboratory. The distribution of marker-specific African ancestry was shifted upward in hypertensive cases versus normotensive controls, consistent with linkage to genes conferring susceptibility. This shift was largely due to a small number of loci, including five adjacent markers on chromosome 6q and two on chromosome 21q. The results indicated that chromosome 6q24 and 21q21 harbor genes influencing risk of hypertension in African Americans.

An effective screening of informative SNP by restriction fragment mass spectrometry(RFMS). *S. Hwang¹, S.P. Hong², H.B. Oh¹.* 1) Laboratory Medicine, Asan Medical Center, Seoul, Korea; 2) GeneMatrix Inc., Seoul, Korea.

Introduction: Despite the completeness of current SNP databases, it was recently reported that almost a third of all SNP in dbSNP (www.ncbi.nlm.nih.gov/SNP) are population-specific or non-informative with a minor-allele frequency less than 10%. Thus, selecting informative SNP from public databases rather than detecting new SNP becomes an important initial step. One efficient way is DNA pooling, where allele frequencies are examined in a small number of pools rather than a large number of individuals. In this report, we applied RFMS to screen pooled DNA which is based on matrix-assisted laser desorption/ionization time-of-flight technique. **Method:** One hundred thirty-nine coding non-synonymous SNPs (cnSNP) of thirty asthma-related genes were selected from dbSNP (www.ncbi.nlm.nih.gov/SNP). The pooled DNA from 200 samples was PCR-amplified and digested with FokI and BstF5I enzymes. The restricted fragments were analyzed on a Linear MALDI-TOF MS (Bruker Daltonics Biflex IV, USA) workstation. Each 10 individual samples of patient and normal groups were genotyped to validate the results. **Result:** It was found that only thirteen of 139 selected cnSNPs (9.4%) were informative with a minor-allele frequency more than 10%;(table) in Koreans. **Conclusion:** RFMS is a very useful method in selecting informative SNPs. The restricted masses are well separated as dual peaks and thus easy to read whether the SNP is heterozygous or not. It is highly recommended that if you are planning to study with cnSNPs, selection of informative SNPs by a method as we did be preceded before a large-scale association study.

Detection of SNPs haplotypes by a Non-fluorescent multiplex DHPLC method. *S. Korem¹, V. Meiner², C. Shocaa¹, E. Leitersdorf³, D. Bercovich¹.* 1) Dept of HMG & Pharmacogenetics, MIGAL- Galilee Bioechnology Center, Kiryat Shmona; 2) Dept of Human Genetics, Hadassah-University Hospital, Jerusalem; 3) Dept of Medicine B, Hadassah-University Hospital, Jerusalem, Israel.

Over the past few decades, different approaches have been developed to identify genetic alterations. Existing procedures for the detection of unknown point mutations, has its advantages and limitations, but the technical aspects and/or cost of the operations have not made their use routine in most laboratories. Further developments of highly accurate, rapid, inexpensive, automated and easily interpreted techniques are required. Denaturing high-performance liquid chromatography (DHPLC) is a sensitive, robust and operationally inexpensive method in comparison to direct sequencing for the detection of unknown single-base substitutions and small deletions and insertions. Analysis of one fragment can take up to 5-6 min. To increase sample throughput, we have developed a non-fluorescent multiplexing strategy for the analysis of three different amplicons, using only one gradient and temperature, by identifying the most limiting parameters for distinguishing between heteroduplex and homoduplex PCR products when they are in a multiplex state. The Wavemaker or Meltdoc software routinely deduces the gradient and temperature of a given PCR amplicon, but in combining amplicons in one run, there is no guideline for which one temperature or gradient will be the most adequate for multiplexing DHPLC. Haplotypes rather than a single SNP are associated with the degree of response to the lipid-lowering therapy. We developed a multiplex DHPLC method for detecting SNPs and apply it to the Cholesteryl-ester transfer protein (CETP) and P-glycoprotein drug transporter (MDR1) genes, which are of important interest in hypercholesterolemia therapy with Statin drugs. By analyzing SNPs from the MDR1 (very AT rich) and CETP (GC rich) genes, we show that it is possible to use the same conditions for three different amplicons by designing them in appropriate sizes, by choosing the higher TM from all three fragments and the gradient percentage of the longest fragment. This technique can be adopted for GC rich and AT rich fragments.

Inbreeding coefficient estimation using only the individuals' genomic information in the Hutterite population. A. Leutenegger^{1,2}, C. Bourgain¹, C. Ober³, F. Clerget-Darpoux¹. 1) U535, INSERM, Villejuif, France; 2) U289, INSERM, Paris, France; 3) Dept Human Genetics, University of Chicago, Chicago, IL.

We have recently proposed a maximum likelihood method (Leutenegger et al, 2003) to estimate the inbreeding coefficient of an individual (the probability that two alleles at a locus are identical by descent (IBD)) using only his genomic information. From simulations, we found that we could obtain accurate estimates whenever the marker map was dense relative to the average IBD segment length expected from the genealogy. Here we further study the properties of this estimator on real data from a well characterized population isolate, the Hutterites of South Dakota. In this population, individuals derive from 64 founders living in the 18th century and are related through multiple lines of descent. Extensive pedigree information is available. We look at a large sample of > 600 individuals who have been genotyped for a dense microsatellite map (658 markers, ~5cM spacing, average het.=0.7). All the individuals are inbred: the average inbreeding coefficient estimated using the genealogical information is 0.034 with 95% of the estimates contained in [0.012, 0.059]. The correlation between our estimate and the one expected from the genealogy is not very high. This has probably two reasons. One is, as we have shown before, that the true proportion of genome IBD (which our estimator reflects) may be far from the proportion expected from the genealogy. The other one is the structure of the Hutterite pedigree: for a given inbreeding coefficient, a Hutterite individual will tend to have multiple remote common ancestors rather than a unique and more recent one. Therefore, the expected IBD segment length will tend to be smaller than in a simple pedigree and a denser map will be needed to catch the homozygous markers. Using simulations on a few individuals, we will propose a map density necessary to obtain an accurate estimation of the inbreeding coefficient with our method.

Association of Single-Nucleotide Polymorphisms with Inflammation and Risk of Cardiovascular Disease in a Dialysis Cohort. *Y. Berthier-Schaad*^{1,2}, *Y. Liu*¹, *L.C. Plantinga*¹, *N.E. Fink*¹, *M.J. Klag*¹, *J. Coresh*¹, *M.W. Smith*³. 1) Johns Hopkins Medical Institutions, Baltimore, MD; 2) Laboratory of Genomic Diversity, NCI, Frederick, MD; 3) Basic Research Program, SAIC, NCI, Frederick, MD.

Genetic analysis gives the opportunity to test the importance of inflammation in cardiovascular disease (CVD) because of a clear causative pathway. Genes from inflammatory pathways were chosen for analysis with special inclusion of those previously reported as associated with CVD. We genotyped 63 SNPs from 14 genes, in the CHOICE cohort of 775 [529 European Americans (EA), 246 African Americans (AA)] incident dialysis patients. Genotyping was done using TaqMan and haplotypes were estimated using PHASE. Linear and Cox regression were used to estimate the mean difference in inflammatory marker (IL-6, CRP, and albumin) levels and risk of CVD events, respectively, by genotype and haplotype. Adjustment variables included age, sex, race, dialysis modality, smoking, and comorbidities, plus blood pressure, HDL, and cholesterol for the risk models. Significant associations of several functional variants with CVD risk were found in IL6, LTA and TGFB1: the first two were also related to inflammation measures. Four genes showed inconsistent associations. One FGB allele (-455 A) was marginally associated with increased fibrinogen levels. One IL10 allele (-1082G) was associated with increased CRP levels in EAs, but there were no other consistent associations with inflammation or CVD. The slightly protective effect of the common PPARA haplotype in AAs was in the opposite direction of previous associations reported in an European population. IFNG -179T present only in AAs was associated with lower inflammation marker levels but not with decreased CVD mortality. In ACE, IL4, PPARG, ABCG5/G8, GNB3, and HBB (sickle cell), no associations were found between genotypes or haplotypes and inflammation marker levels or CVD risk after adjustment. Significant associations with three genes, IL6, LTA and TGFB1, support a causative role of inflammation in cardiovascular disease. Funded in part by RO1 L62985, AHA EIO140197ND, &DHHS#NO1-CO12400.

CAP70 as a possible modifier gene of Cystic Fibrosis phenotype. *S. Gambardella¹, M.R. D'Apice¹, C. Bulli¹, P. Borgiani¹, S. Russo¹, V. Lucidi², G. Castaldo³, G. Novelli¹.* 1) Biopathology , Tor Vergata University, Roma, RM, Italy; 2) Pediatric Hospital "Bambino Gesù" Rome, RM, Italy; 3) Department of Biochemistry and Medical Biotechnology, University of Naples "Federico II" and CEINGE-Biotecnologie Avanzate, Naples, Italy.

Cystic fibrosis (CF; #219700) is an autosomal recessive disorder caused by mutations in the CFTR gene that encodes a chloride conducting channel expressed in the apical plasma membrane of the epithelial cells. The disease is characterized by a wide variability of clinical expressions (pancreatic insufficiency, lung disease, hepatic manifestations, male infertility, etc.). It is possible that the wide phenotypic spectrum is modulated by modifier genes which directly or indirectly interact with CFTR gene product. Recently, biochemical and functional analysis of CFTR, revealed that this protein interacts with protein containing multiple PDZ domain (Cftr Associated Protein 70 kDa, N/H Exchanger Regulatory Factor). We studied a human homolog of the mouse PDZK1, CAP70, as a candidate CF modifier gene. CAP70 maps on 1q21 and is organized in 8 exons which encode a mRNA of 2.2Kb. The gene presents three actively transcribed copies, but one of these is translated in a functional protein product. We genotyped CAP70 in a cohort of CF patients with pancreatic insufficiency (PI=36), hepatic involvement (EI=31), and classical CF phenotype (CFC=70). Results were compared with a matched age normal controls (C=35). Genotypes at SNP IVS4 92 A/G (rs9726178) upstream of the exon 5 were examined by Pyrosequencing technology to determine the allele copies in a triplicate gene assay. This method is able to reveal seven different allele combinations (6A0G; 5A1G; 4A2G; 3A3G; 2A4G; 1A5G; 0A6G). The allelic distribution was different within CF phenotypic classes compared (Chi square test: $p=0.012$). In particular, 3A3G were underrepresented within the PI CF patients ($p=0.008$), while 5A1G, 6A0G, 0A6G, 1A5G were overrepresented in this group of patients ($p=0.007$). These data strongly suggest a role for CAP70 gene as modifier of the CF phenotype.

Comparing analytic strategies for genome wide association using real data. *K. Klos¹, A. Rosin¹, A.-H. Maitland-van der Zee¹, A.C. Morrison¹, T. Woodage², A. Litvinenko¹, E. Boerwinkle¹.* 1) Human Genetics Center, University of Texas Health Science Center, Houston, TX; 2) Applied Biosystems Inc., Foster City, CA.

We have carried out a pilot study of genome wide association for a common chronic disease using approximately 3000 SNPs spanning human chromosome 19 typed in approximately 2000 individuals. The overall goal of the study is to identify genes contributing to disease risk. For this pilot study, we compared contemporary statistical and computer science-based methods for association analyses, keeping in mind the overall goal. We observed significant concordance in the number of SNPs selected for developing a best model for predicting disease occurrence. For example, both the machine learning classification algorithms (e.g. random forests, AdaBoost) and the set association approach of Hoh and Ott selected approximately 350 SNPs as the upper bound for the dimension of the model building step. Within this set of 350 SNPs, there was also significant concordance in the identity of the selected SNPs. The rank correlation within the top 350 SNPs was 0.45 or greater between statistical and machine learning-derived metrics. There was minimal concordance between genes selected based on single site analyses and genes selected by haplotype analysis (e.g. $r=0.15$). We conclude that a hierarchical approach beginning with data exploration, then model building using SNPs or haplotypes, and then model validation is most appropriate for genome wide association studies. We have projected the computational burden of such a hierarchical approach to a data set containing up to 300,000 SNPs and find it to be scalable within the computing resources of most investigators.

Program Nr: 2918 from the 2004 ASHG Annual Meeting

Inference on Haplotype-Disease Associations in DNA Pooling Studies. *D.Y. Lin, D. Zeng.* Dept Biostatistics, Univ North Carolina, Chapel Hill, NC.

The genetic dissection of complex human diseases requires large-scale association studies which explore the population associations between genetic variants and disease phenotypes. DNA pooling can substantially reduce the cost of genotyping assays in these studies and thus enables one to examine a large number of genetic variants on a large number of subjects. The availability of pooled genotype data instead of individual data poses considerable challenges in the statistical inference, especially in the haplotype-based analysis because of increased phase uncertainty. We present a general likelihood-based approach to making inference about haplotype-disease associations based on pooled DNA data. We consider cohort and case-control studies of unrelated subjects, and allow arbitrary and unequal pool sizes. The phenotype can be discrete or continuous, univariate or multivariate. The effects of haplotypes on disease phenotypes are formulated through flexible regression models, which allow a variety of genetic hypotheses and gene-environment interactions. We construct appropriate likelihood functions for various designs and phenotypes, accommodating Hardy-Weinberg disequilibrium. The corresponding maximum likelihood estimators are approximately unbiased, normally distributed and statistically efficient. We develop simple and efficient numerical algorithms for calculating the maximum likelihood estimators and their variances, and implement these algorithms in a freely available computer program. We assess the performance of the proposed methods through simulation studies, and provide an application to the Finland-United States Investigation of NIDDM Genetics Study. The results show that DNA pooling is highly efficient in studying haplotype-disease associations.

Haplotype Diversity in the CCL18, CCL3, and CCL4 chemokine genes is Associated with HIV-1 transmission and AIDS disease progression. *W.S. Modi¹, J. Lautenberger², K. Scott⁸, A. Ping⁸, J.J. Goedert², S. Strathdee³, S. Buchbinder⁴, J. Phair⁵, S. Donfield⁶, S. O'Brien⁷, C. Winkler⁸.* 1) SAIC, NCI-ATC, Gaithersburg, MD; 2) Viral Epidemiology Branch, National Cancer Institute, Rockville, MD 20852, USA; 3) Johns Hopkins School of Hygiene and Public Health for AIDS Link to the Intravenous Experience, Baltimore, MD 21205, USA; 4) San Francisco Department of Public Health, San Francisco, CA 94102; 5) Department of Medicine, Northwestern University Medical School, Evanston, IL 60611; 6) Rho, Inc., Chapel Hill, NC 27514, for Hemophilia Growth and Development Study; 7) Laboratory of Genomic Diversity, National Cancer Institute-FCRDC, Frederick, MD 21702-1201; 8) SAIC Frederick, National Cancer Institute-FCRDC, Frederick, MD 21702-1201.

CCL3, CCL4, CCL18 are potent chemoattractants produced by macrophages, natural killer cells, fibroblasts, mast cells, CD4+ and CD8+ T-cells. CCL3 and CCL4 are natural ligands for the primary HIV-1 coreceptor CCR5. Further, CCL3 and CCL4 are known to activate and enhance the cytotoxicity of natural killer cells. Genomic DNAs from 3000 participants enrolled in five USA-based natural history AIDS cohorts were genotyped for 21 single nucleotide polymorphisms (SNPs) in the a 46 kb interval containing these genes. Seven of the 21 SNPs had minor allele frequencies less than 0.5% in European-Americans, while all 21 were variable in African-Americans. Four or eight haplotype blocks were observed in European-Americans or African-Americans, respectively. Blocks were strongly correlated with each other and haplotype diversity within blocks was limited, indicating strong linkage disequilibrium across the entire region. Frequencies of three SNPs and their haplotype in the CCL3 gene were elevated in frequency ($p=0.04$ to 0.09) among highly exposed, persistently seronegative African Americans compared to seroconvertors. Nine highly correlated SNPs spanning the CCL3 and CCL4 genes were significantly associated ($p=0.0008$ to 0.05) with more rapid disease progression in European Americans. These results reiterate the importance of chemokine gene variation in HIV-1/AIDS pathogenesis.

Heritability of Iron and Ferritin in a genetic isolate. *O.T. Njajou¹, B.Z. Alizadeh¹, B.A. Oostra¹, D. Swinkels², C.M. van Duijn¹.* 1) Epidemiology & Biostatistics, Erasmus University Medical Centre, Rotterdam, The Netherlands; 2) Clinical Chemistry, University Medical Centre, Nijmegen, The Netherlands.

BACKGROUND: Iron plays a crucial role in the pathogenesis of common complex disorders such as Parkinson's disease, Alzheimer's disease, atherosclerosis and cancer. Iron deficiency affects about 30% of the world's population and genetic iron overload or hemochromatosis is the most common inherited disorder in Caucasians. Both iron deficiency and iron overload are common public health problems. From a genetic perspective, iron metabolism is a complex trait, in which both genetic and environmental factors (nutrition) are involved. **AIM:** The purpose of the present study was to estimate the magnitude of genetic influences on iron and ferritin levels in nuclear families derived from a genetic isolate in the Netherlands (the ERF study). **METHOD:** Estimation of how much of the variation in the levels of iron and ferritin could be attributed to genetic factors was done using the variance component method in sequential oligo-genic linkage analysis routines (SOLAR). **RESULTS:** The ERF participants analysed in this study included 90 nuclear families with a total of 908 subjects. The proportion of the residual phenotypic variance due to additive genetic effects or heritability (h^2) estimates were approximately 21.34 (SE = 0.064, P 0.000001) for iron and 38.62 (SE = 0.066, P 0.000001) for ferritin. After simultaneously adjusting for sex and age, the heritability was 23.15 (SE = 0.064, P 0.000001) for iron and 39.20 (SE = 0.066, P 0.000001) for ferritin. Sex and age explained less than 5% variability in iron and ferritin level. **CONCLUSION:** A substantial proportion of the variance of iron and ferritin can be explained by heredity, independent of the effects of sex and age. These results demonstrate the influence of both genetic and environmental factors on iron levels. Identification of genes influencing iron and ferritin levels using a QTL approach is feasible.

Nonparametric Test of Association of Multiple Genes with Human Traits. *D.J. Schaid¹, S.K. McDonnell¹, S.N. Thibodeau²*. 1) Dept. Health Sciences Research, Mayo Clinic College of Medicine, Rochester, MN; 2) Dept. Laboratory Medicine and Pathology, Mayo Clinic of College Medicine, Rochester, MN.

Genetically complex traits are likely caused by multiple genes, each with small to moderate effects. Although it is now common practice to measure multiple genes by multiple markers, such as single nucleotide polymorphisms (SNPs), current statistical methods to analyze many markers are limited with weak power. For example, it is common to analyze the marginal effects of one marker at a time, or perhaps in a step-wise fashion with step-wise regression methods, or analyze all markers simultaneously with a global test that has many degrees-of-freedom. If many of the markers are causative, or in linkage disequilibrium with causative variants, yet the marginal association of each marker is weak due to low penetrance and possibly complex interactions among the causative variants, then the usual analytic methods will have weak power. This may be particularly hazardous when evaluating biologically related genes, such as genes within a common functional pathway. We developed a nonparametric statistic based on the pair-wise similarity of subjects according to their measured genotypes across all markers, and compares the average of this similarity between cases versus controls, which is expected to differ if the markers are associated with disease. Our methods account for missing marker data and correlations among the markers (i.e., linkage disequilibrium), they do not require assumptions of Hardy-Weinberg genotype proportions, and they weight the genetic markers according to their covariance structure, in order to create an optimally weighted statistic. The statistic has only one degree-of-freedom, which can give greater power than other global statistics. These new methods are applied to a large case-control study whose aim is to evaluate the association of prostate cancer with common genetic polymorphisms for enzymes within biosynthesis pathways that catalyze the synthesis and bioactivation of androgen and estrogen. In addition, simulations are used to evaluate the power and utility of these new methods.

The heritability of mammographically dense and non-dense breast tissue. *J. Stone*¹, *G.S. Dite*¹, *A. Gunasekara*², *D.R. English*⁴, *M.R.E. McCredie*⁵, *G.G. Giles*⁴, *J.N. Cawson*⁶, *R.A. Hegele*⁸, *A. Chiarelli*⁷, *M.J. Yaffe*³, *N.F. Boyd*², *J.L. Hopper*¹. 1) Centre for Genetic Epidemiology, University of Melbourne, Australia; 2) Division of Epidemiology and Statistics, Ontario Cancer Institute, Canada; 3) Imaging Research, Sunnybrook and Women's College Hospital, Canada; 4) Centre for Cancer Epidemiology, The Cancer Council Victoria, Australia; 5) Department of Preventive and Social Medicine, University of Otago, New Zealand; 6) St. Vincent's BreastScreen, St. Vincent's Hospital, Australia; 7) Cancer Care Ontario, Canada; 8) Blackburn Cardiovascular Genetics Laboratory, Robarts Research Institute, Canada.

Background: Percent mammographic density (PMD) is a strong risk factor for breast cancer. Our previous twin study showed that the heritability of PMD was about 60%. The purpose of this paper is to determine the heritabilities of the components of PMD, the areas of dense and non-dense tissue. *Methods:* We combined two twin studies comprised of 571 monozygous (MZ) and 380 dizygous (DZ) twin pairs recruited from Australia and North America. Dense and non-dense areas were measured using a computer-assisted method, and information about potential determinants obtained by questionnaire. We estimated the heritability of the log dense area and log non-dense area, and the genetic and environmental contributions to the covariance between the two traits, using maximum likelihood theory. *Results:* After adjusting for measured determinants, for each of the log dense area and the log non-dense area, the MZ correlations were greater than the DZ correlations. Heritability was estimated to be 65% (95% confidence interval (CI) 60-70%) for dense area and 66% (95% CI 61-71%) for non-dense area. The correlations (s.e.) between the two adjusted traits were -0.35 (0.023) in the same individual, -0.26 (0.026) across MZ pairs and 0.14 (0.034) across DZ pairs. *Conclusion:* Genetic factors appear to play a large role in explaining variation in the mammographic areas of both dense and non-dense tissue. About two-thirds of the negative correlation is explained by the same genetic factors influencing both traits, but in opposite directions.

Relating the ApoE locus to unobserved loci using novel association statistics with respect to the Alzheimer phenotype. *S. Boehringer*¹, *E. Nagel*², *E.R. Martin*³, *A. Steland*². 1) Dept Humangenetik, Univ Duisburg-Essen, Essen, Germany; 2) Lehrstuhl für Stochastik, Ruhr-Universität Bochum, Bochum, Germany; 3) Center for Human Genetics, Duke University Medical Center, Durham, NC, United States.

A major challenge in genetic studies of complex traits is the characterization of small genetic effects at potentially many loci. It is commonly held that genetic heterogeneity is one major obstacle in the dissection of complex diseases or phenotypes. Therefore it is desirable to distinguish effects of observed regions of association from those of unobserved loci. We propose a method to estimate haplotype frequencies that include the causative allele in a region of association in a family based setting, i.e. linkage disequilibrium (LD) of observed haplotypes with a potentially unobserved causal locus can be reconstructed. Simultaneously the effect of unobserved loci is modelled with a small set of parameters. These parameters contain information about the phenocopy rate excluding the associated region under scrutiny. Further applications of the method include selection of individuals in resequencing efforts or the evaluation of the causativeness of variants. Since several assumptions are made to establish the likelihood framework we briefly show simulation results evaluating the robustness of the method. Alzheimer's disease is one of few examples where a predisposing causal effect of an allele (ApoE ϵ ₄) could be replicated in numerous samples. We apply the proposed statistical procedures to a data set of Alzheimer's disease containing nuclear families (Martin et al., AJHG 2000) which confirms the causative effect of the ApoE locus.

Program Nr: 2924 from the 2004 ASHG Annual Meeting

Fine mapping of disease in case-control studies using haplotype-similarity measures. *M.P. Epstein*¹, *G.A. Satten*².
1) Dept Human Genetics, Emory Univ, Atlanta, GA; 2) Centers for Disease Control and Prevention, Atlanta, GA.

A popular strategy for fine mapping a disease locus uses the idea that haplotypes from affected individuals should share longer stretches of identical sequence (and hence have increased similarity) around a disease locus relative to haplotypes from unaffected individuals. For a case-control study design, one can fine map a mutation by assessing whether the average similarity of haplotype pairs around a locus in a sample of case subjects is significantly greater than the average haplotype similarity in a sample of control subjects. Here, we develop likelihood-based score statistics for fine mapping that are based on measures of haplotype similarity between pairs of haplotypes in the case and control samples. We develop both retrospective and prospective versions of these score statistics and evaluate their performance using simulated data. We also apply both score statistics to real case-control data from the Finland-United States Investigation of Non-Insulin-Dependent Diabetes Mellitus (FUSION) Genetics study.

Association of 5HT2C SNPs in binge-eating purging anorexia, bulimia nervosa, and related psychopathological traits of eating disorders. X. Estivill^{1, 2}, M. Ribases¹, JM. Mercader¹, M. Gratacos¹, A. Badia³, L. Jimenez³, R. Solano³, F. Fernandez-Aranda³. 1) Genes and Disease Program, Centre for Genomic Regulation; 2) Experimental and Health Sciences Department, Pompeu Fabra University; 3) Hospital Princeps d'Espanya, Barcelona, Catalonia, Spain.

Several lines of investigation suggest that the serotonergic system participates in eating behavior and weight regulation. Moreover, alterations in this neurotransmitter system could participate in the etiology of eating disorders (ED) and in some associated psychopathological traits. To test this hypothesis, we analyzed the potential involvement of the -995G>A, -759C>T, -697G>A and the Cys23Ser SNPs within the serotonin receptor 5HT2C gene in a total sample of 151 ED patients (75 with anorexia (AN) and 76 with bulimia (BN)) and 116 sex-matched unrelated controls. The three promoter polymorphisms were in linkage disequilibrium and no association was observed when all SNPs were independently considered. However, the GCCC haplotype showed significant association with both binge-eating/purging AN (ANP; $p=0.03$) and BN ($p=0.017$). When we considered those patients showing purging attitudes we observed that the GCCC haplotype was positive associated to the purging phenotype ($p=0.01$). We then analyze the possible involvement of these sequence variants in different psychopathological traits measured with the Symptom Checklist 90-revised (SCL90-R) questionnaire. Forty-six patients with AN and 36 with BN completed the Symptom Checklist 90-revised (SCL90-R) questionnaire and were genotyped for the four SNPs within the 5HT2C gene. No effect of the Cys23Ser SNP was detected, but BN patients carrying the -995A/-759T/-967C haplotype showed increased symptomatology for seven of the nine subscales of the SCL90R, that include somatization ($p=0.029$), obsessive-compulsiveness ($p=0.021$), depression ($p=0.032$), anxiety ($p=0.004$), hostility ($p=0.028$), phobic anxiety ($p=0.029$) and paranoid ideation ($p=0.008$). These results suggest that the 5HT2C gene could participate in the physiopathology of ANP and BN through its direct effect on eating behavior and in different psychiatric symptoms related to the anxiety and depressive traits.

A general framework for estimating haplotypes & haplotype frequencies. *K.A.B. Goddard, D. Baechle.*
Epidemiology & Biostatistics, Case Western Reserve Univ, Cleveland, OH.

Estimation of haplotypes & haplotype frequencies when phase is ambiguous is useful in a variety of situations including fine-mapping in family studies, and tests of association to detect candidate genes. Numerous methods are available to perform these functions that differ in the type of data (e.g., unrelated individuals, pools of individuals, and related individuals), and the statistical approach used to obtain the estimates, such as maximum likelihood (e.g., the EM algorithm), or Bayesian methods. We propose a general framework to incorporate four types of data into a common haplotyping procedure including unphased genotypes for unrelated individuals with or without partial molecular phase, marker allele frequencies for pools of unrelated individuals, and unphased genotypes for related individuals. Combinations of these types of data can be considered simultaneously. We have implemented this procedure, and utilize the EM algorithm to estimate haplotype frequencies once the data is in the common format. However, any statistical approach that can accommodate pooled data could be used. This procedure will provide haplotype frequency estimates, all possible haplotypes for each unit (i.e., individual or pool), and the most likely haplotypes for each unit.

We demonstrate the performance of this method for pedigrees and unrelated individuals using simulation. Estimated haplotypes & haplotype frequencies are compared to the true model parameters, and to the actual simulated sample using measures of information content. Incorporating partial phase information, obtained either from molecular haplotyping or through family data, into the estimation procedure improves the estimates of the haplotypes & haplotype frequencies. In addition, we discuss the practical limitations of this method in terms of the sample size, number of markers, and pedigree size that can be considered. The ability to utilize a common procedure for estimating haplotypes & haplotype frequencies under a broad range of circumstances will simplify haplotyping efforts, and will enable researchers to combine different types of data into a single estimation procedure.

Founder effect for the D157N mutation of the *MATP* gene with OCA4 from Japan and Korea. *K. Inagaki, T. Suzuki, S. Ito, N. Suzuki, Y. Tomita.* Dermatology, Nagoya Univ., Nagoya, Japan.

Oculocutaneous albinism type 4 (OCA4) was identified a new form of human OCA in 2001 that was a group of autosomal recessive hypopigmentary disorders in the skin, hair and eyes. The gene responsible for OCA4 is the *MATP* (Membrane-Associated Transporter Protein) gene located in chromosome segment 5p. The encoded protein, MATP is predicted to span the membrane 12 times on melanosome and likely functions as a transporter that mediates melanin synthesis. Previously, we identified 18 Japanese patients with OCA4; they harbored seven mutations (P58S, D157N, G188V, V507L, S90CGGCCA>GC, V144insAAGT and V469delG). One of them, the D(GAC)157N(AAC) mutation, was detected in 12 out of 18 Japanese patients, among whom 2 were homozygous and 10 were heterozygous. The D157N mutation allele was the most frequent; the allele frequency was 0.389 (14/36). In addition, we recently diagnosed a single Korean patient with OCA4, who was homozygous for the D157N mutation. In order to study the origin of the D157N mutation, we did haplotype analysis by means of three SNPs spanning the *MATP* gene and the flanking SNP. The 13 out of 14 alleles carrying the D157N mutation of Japanese patients shared a common haplotype, whereas the frequency of this haplotype in the Japanese control alleles (n=208) was estimated to be 0.13 using the Estimating Haplotype-frequencies (EH) software program. Statistical significance of the association was demonstrated using the Fishers exact test ($P<0.001$). The Korean patient shares this common haplotype, too. Until now, one Turkish and five German patients with OCA4 have been only reported in Western countries; they harbored one and ten mutations, respectively. However, the D157N mutation was not found in either. And furthermore, a common haplotype with the D157N mutation had the polymorphism E(GAG)272K(AAG) showed only in the Japanese and New Guinea Islander populations, but didn't have the polymorphism L(TTG)374F(TTC) existed exclusively in Caucasians. Here, we indicate that the D157N mutation of the *MATP* gene with OCA4 from Japan and Korea was a founder mutation and occurred after the divergence of East Asians and Caucasians.

Variability of haplotype-block patterns across populations: qualitative and quantitative differences. F.

Macciardi^{1, 2, 3}, *I. Elias*³, *I. Chumakov*³, *D. Cohen*³. 1) Dept Psychiatry, CAMH, U of Toronto, ON, Canada; 2) Dept. of Genetics, U of Milan, Italy; 3) Serono Genetics Institute, Evry, France.

Our best hypothesis of Linkage Disequilibrium (LD) in humans is described by a block-like pattern, where SNPs show a high pairwise LD in well-defined regions of variable size. These blocks are interspersed with shorter areas of low or no LD. SNPs in blocks create haplotypes with limited variability, making a haplotype map-based LD approach to find genes for complex traits a feasible strategy. In fact, we can select and genotype only those SNPs that best identify the block haplotypes (htSNPs) without appreciable loss of information, but with a considerable reduction of costs. However, several issues remain to clarify before considering a haplo-block approach the best strategy to map genes. We do not yet know the proportion of genome characterized by a block pattern, nor the best number and density of SNPs needed for a complete information of LD. Also we do not know the degree of variability in LD and in haplotypes across populations. In fact, since LD is also a consequence of population evolution, we do not know if a block pattern found in a given population is generalizable to other populations: the data available today mostly derive from Gabriel et al (2002) who showed the existence of a similar pattern in macro populations, with Asians and Caucasians both being different from Africans that had a mean shorter block structure. We studied 10 different haplo-block regions in 5 Caucasian populations and found that there are either qualitative and quantitative variations. Quantitative variability implies that similar haplotypes are present in all populations despite at different frequencies, with a low influence on mapping, if any. However qualitative variations result in structurally different blocks, with various size and hence SNPs composition. These qualitative variations probably emerge because of putative recombination events or because boundary SNPs can vary: in either case, they affect mapping tasks and we present a method to (1) evaluate these differences and (2) to take them into account in mapping, especially when looking at more than one population.

Program Nr: 2929 from the 2004 ASHG Annual Meeting

Candidate Gene Analysis of Cleft Lip and Palate in Japanese population. *J. Machida, Y. Suzuki, S. Suzuki, N. Matsuzawa, H. Furukawa, T. Niimi, N. Natsume, K. Shimozato.* Oral & Maxillofacial Surgery, Aichi-Gakuin Univ, Nagoya, Japan.

Nonsyndromic cleft lip with or without cleft palate (CL/P), cleft palate only (CPO) are common congenital anomalies. The incidence of these anomalies at birth vary from 1 in 1000 Caucasians , 2.1 in 1000 Asians, 0.3 in 1000 African races. Many studies suggest that both environmental and genetic factors are involved in the cause of CL/P and CPO. Candidate gene approaches are proving increasingly successful in identifying genes and mutations involved in nonsyndromic forms of CL/P and CPO. Linkage, association, and sequencing studies have all suggested the involvement of one or more candidate genes in this complex disorder. Recently, it is reported that several candidate genes of CL/P and CPO have been detected by using molecular biology technique. We will summarize our candidate study of MSX1, TGFB3, TGFA using 50 Japanese families. These study support a role for MSX1 in clefting and extend the analysis to Asian populations.

Power and Type I Error of Haplotype and Multiple Genotype Analysis: A Comparison of Methods. *K.K. Nicodemus, M.D. Fallin.* Department of Epidemiology, Johns Hopkins SPH, Baltimore, MD.

Several methods have been proposed to handle multiple SNP-disease association studies in family and case-control data. However, it is unknown how the power and type I error compare across methods; therefore, applied researchers must arbitrarily choose a method. Further, SNP-based haplotype or multiple-genotype analyses often involve many categories, resulting in a large number of parameters to estimate and loss of precision and power, if no data reduction strategy is taken. A common method to reduce the number of categories is to collapse haplotype/multiple-genotype categories with low frequencies into one set or to focus on one or a limited set of target haplotypes/set of genotypes, while collapsing all others into a single comparison set. Recently, methods using cladistic analysis as the basis for haplotype data reduction have been proposed for both case-control and case-parent data. The purpose of the present study was to evaluate several SNP and haplotype analysis and data reduction methods across many different scenarios, in order to compare the power and type I error rates. Data were simulated for a candidate gene study of 500 SNPs in with an average haplotype blocking structure of 1.5 blocks per gene (range 2-4 blocks/gene). For the case-parent trio design, the programs/methods evaluated included: HBAT, Multiple Genotype PDT, TRANSMIT, and ET-TDT. For unrelated case-control data, the methods evaluated included HAPLO.STAT, THESIAS, CLADHC, and COCAPHASE. For methods not using cladistic analysis, different data reduction strategies were tested, including no data reduction, collapsing categories with frequencies less than 1% and 5%, and collapsing all categories versus a single "at risk" category. Type 1 error was calculated under the null simulation, and power was calculated using statistical significance determined via permutation, as well as significance determined via the approach suggested for each method and/or implemented in its relevant software.

Identification and characterization of sequence variation at the human frizzled-1 (FZD1) locus. *J.I. Oakley¹, S.P. Moffett¹, C.S. Nestlerode¹, V.W. Wheeler², A.L. Patrick², C.H. Bunker¹, J.M. Zmuda¹.* 1) Dept Epidemiology, GSPH, Univ Pittsburgh, Pittsburgh, PA; 2) Tobago Health Studies Office, Scarborough, Tobago.

Members of the frizzled gene family encode 7- transmembrane domain proteins that are receptors for Wnts, secreted growth factors involved in embryonic development as well as several age-related diseases including cancer and osteoporosis. Very little is currently known about Wnt/Frizzled sequence diversity thus hampering genetic analyses of this pathway. To address this, we sequenced 3.3 kb of the FZD1 gene on human chromosome 7q21 including 1 kb upstream of the transcriptional start site, the 5' UTR, and the entire coding sequence using DNA samples from 48 individuals of West African descent. We found 23 SNPs and a proline repeat polymorphism using the Sequencher analysis package. 15 of the 23 SNPs in our analysis (65%) were not present in dbSNP database (build 120) whereas 6 of the 14 SNPs reported in dbSNP (42%) were not detected. We found 12 SNPs in the putative promoter region all within ~200 bp of each other, 3 SNPs in the 5'UTR, 5 synonymous SNPs, 3 nonsynonymous SNPs and a proline repeat in the coding sequence. The 3 nonsynonymous SNPs (Ala64Thr, Ala390Thr and Val497Gly) were each observed in only one individual in the heterozygous state (MAF~1%) and these were not previously described. We calculated allele frequencies and noted 7 SNPs with MAF 3%. For these SNPs, we calculated pairwise linkage disequilibrium (D) and then constructed haplotypes from the 7 SNPs using the expectation-maximization algorithm. Three major haplotypes were predicted to account for 85% of all possible haplotypes. These common haplotypes could be captured by a minimal subset of 2 tagging SNPs, rs2232157 and rs2232158. In summary, we have developed a high-resolution SNP map of the FZD1 gene region on chromosome 7q21. These analyses should facilitate future association studies and fine mapping of causal sequence variation for a range of conditions associated with disordered Wnt signaling.

A comparison of algorithms for haplotype inference: imputing missing data and reconstructing haplotypes. *P. Scheet, M. Stephens.* Statistics, Univ. of Washington, Seattle, WA.

Numerous algorithms have been proposed for inferring haplotypes from (phase-ambiguous) multilocus genotype data on unrelated individuals; however, there exist few experimentally-determined phase-known genotypic datasets upon which these methods can be applied and evaluated. The use of simulated data for this purpose may fail to accurately reflect characteristics of real populations. Here we compare the accuracy of several available algorithms applied to two tasks: imputation of missing data from real populations and inference of haplotypes from "pseudo-individuals". We obtained 50 genes that have been completely resequenced in 24 African-Americans and 23 individuals of European descent and masked 5% of the genotypes to assess the missing data imputation accuracy of the algorithms. We believe the imputation results have implications regarding the accuracy of haplotype inference, the extent of which will depend on the similarity of each task's reliance upon an underlying model for the features of population genetic data. It is unclear whether genotype data from two populations should be analyzed separately or pooled together prior to analysis; our results indicate the latter for these data, but we suggest a simple procedure by which to assess such strategies. We also apply the haplotype-inference methods to randomly-paired molecularly-determined male X chromosome haplotypes. For imputing missing genotypes, a new method which takes into account the decay of LD with distance and the order of genotyped markers outperforms the best available methods; its accuracy in inferring the X chromosome haplotypes is only slightly better.

Evaluation of simple methods to test for associations between traits and unphased haplotypes with correlated data. *S.L. Slager, S.K. McDonnell.* Mayo Clinic College of Medicine, Rochester, MN.

Schaid et al. (2002) developed a score test to test for associations between haplotypes and a trait for unrelated individuals. When haplotypes are ambiguous, their approach uses the expected score, which is a function of the posterior probabilities of each haplotype pair computed from the expectation-maximization (EM) algorithm. We investigate analytical approaches for when the data contain related individuals. This design arises in our study of prostate cancer in which our cases are from multiple-case families and our controls are unrelated and ascertained from Olmsted County, Minnesota. Using only one case from each multiplex family would be an inefficient use of resources. However, when using related individuals, two issues are of concern: computing expected scores for ambiguous haplotypes and computing the appropriate variance estimates. To circumvent these issues, we evaluate the performance of a bootstrap approach using simulations relative to an approach that ignores the familial relationship. We simulated seventeen multi-locus genotypes, using the program makesamples (Hudson, 2002), and phenotypes on each of our 160 prostate cancer pedigree structures. One thousand bootstrap samples were taken. Our initial findings demonstrate that correct type one error rates are obtained. More detailed evaluation of our approach will be presented.

Haplotype inference using a Hidden Markov Model with efficient Markov Chain sampling. *S. Sun¹, C.T.M. Greenwood², R.M. Neal¹*. 1) Department of Statistics, University of Toronto, Toronto, Ontario, Canada; 2) Program in Genetics and Genomic Biology, Hospital for Sick Children, Toronto, Ontario, Canada.

Knowledge of haplotypes is useful for understanding block structure and disease risk associations. Exact determination of haplotypes in the absence of family data is presently impractical. Hence, several methods have been previously developed for reconstructing haplotypes from population data. We have developed a new population-based method using a Hidden Markov Model (HMM) for the source of the ancestral haplotype segments. Parameters of the model are inferred by Bayesian methods using Markov Chain Monte Carlo (MCMC). Crucial to the efficiency of the Markov Chain sampling is the use of an efficient forward-backward algorithm for sampling state sequences of the HMM. We have used the model to reconstruct the haplotypes at 103 loci of 129 children in the data set of Daly et al (Nature Genetics 2001, 29:229-232), for which family-based reconstruction is available. Our haplotype reconstruction method does not require division into small blocks of loci and produces results that are quite close to the ones from the family-based reconstruction.

Development of an algorithm to test, by nonparametric methods, the association between haplotypes and quantitative phenotypes using MCMC algorithm. *R. Takemura*¹, *N. Kamatani*². 1) Japan Biological Information Research Center, Japan Biological Information Consortium, Tokyo, Japan; 2) Division of Genomic Medicine, Department of Applied Biomedical Engineering and Science and Institute of Rheumatology, Tokyo, Japan.

We developed an algorithm to test the association between haplotypes and quantitative phenotypes using EM-algorithm. This algorithm was implemented as a computer program QTLHAPLO (Shibata et al. Genetics in press). Taking the genotype and phenotype data as input data, QTLHAPLO estimates the parameters (such as population means) of the distributions for the two groups of the subjects classified according to a haplotype. At the same time, QTLHAPLO tests the hypothesis that the parameters (and the distributions) are different between the two groups. Dominant, recessive and additive modes can be assumed in the program. In that algorithm, the phenotype is assumed to follow a certain distribution such as normal distribution. However, in many cases, the true distribution of the quantitative phenotype is not clear. In the present study, we propose a nonparametric method to overcome the problem in QTLHAPLO. In our new algorithm, Markov Chain Monte Carlo MCMC algorithm is used. First, population haplotype frequencies are sampled using the numbers of haplotypes in the sample based on the Dirichlet distribution. Next, the diplotype configuration of each subject is stochastically determined based on both the population haplotype frequencies and the genotypes. The subjects are divided into two groups according to the haplotypes possessed by the subjects, and it is tested whether the medians of the quantitative phenotypes of the two groups are different using the nonparametric method. We have adopted the two-sample test by Kolmogorov-Smirnov and Mann-Whitney's U test. After generating sufficient numbers of MCMC samples, the nonparametric tests were performed using the samples. The overall test was performed using the average of the values of the statistic. By the simulation, we have shown that the present method can be applied to the quantitative phenotypes that are not expected to follow normal distributions.

Linkage disequilibrium analysis of microsatellite markers and HLA class I alleles associated with Seronegative Spondyloarthropathies in South India. *R. Thomas, M. Banerjee.* Human Molecular Genetics Laboratory, Rajiv Gandhi Centre for Biotechnology, Trivandrum, India.

Seronegative Spondyloarthropathies (SpA) constitute a group of disorders with common genetic and clinical characteristics. A genetic predisposition associated with HLA B*27 is common to this set of complex disorders. The strength of the disease association with B*27 varies markedly among the various spondyloarthropathies in different ethnic communities. HLA haplotype analysis coupled with microsatellite mapping in the HLA class I region could identify regions of disease associations and facilitate better diagnosis of the different spondyloarthropathies. In the present study we have used association studies to ascertain the association of microsatellite markers with various HLA class I alleles in SpA patients. We have used strict clinical, radiological and serological criteria to select 69 patients with SpA. We compared these patients with 78 healthy normal individuals from the same ethnic background. HLA class I alleles were identified using the DNA based PCR-SSP method while five microsatellite markers including C1_2_5, C1_4_1, C1_2_A, MIB and STR MICA were analysed using Genescan.

The HLA alleles present in the control samples with highest frequency were B*07 (0.192), Cw*07 (0.25), A*02 (0.186) while B*27 (0.232), Cw*14 (0.203), A*24 (0.217) had the highest frequency in the SpA patient group. The bi-locus haplotype B*27-Cw*02 occurred with significantly high frequency in the SpA samples. The microsatellite alleles occurring with a high frequency in the control samples were C1_2_5 (196 bp), C1_4_1 (217 bp), C1_2_A (232 bp), MIB (336 bp) and STR MICA (A5.1) while in the SpA samples it was C1_2_5 (178 bp), C1_4_1 (213 bp), C1_2_A (232 bp), MIB (340 bp) and STR MICA (A4). We also identified a significant association of an extended six-point haplotype block B*27 - Cw*02 - STR MICA (A4) - C1_2_5 (178 bp) - C1_4_1 (213 bp) - MIB (340 bp) in the SpA samples.

Accuracy of haplotype frequency estimates in samples of families and unrelated individuals. *Z. Ye, J. Wigginton, G. Abecasis.* Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, MI.

Haplotype frequency estimates are important for genetic association and linkage disequilibrium studies. These estimates can be derived from family samples or samples of unrelated individuals. Here we compare the relative accuracy of haplotype frequency estimates resulting from different sampling schemes. We used coalescent simulations to generate samples of haplotypes, and varied the recombination rate, proportion of missing data, as well as the number and type of families collected for genotyping. We used a generalization of the expectation maximization algorithm for estimation of haplotype frequencies that can handle simple family structures, with or without missing data. In all settings, we find that missing data and historical recombination reduce the accuracy of haplotype frequency estimates. In addition, we find a small bias on estimates of haplotype frequencies. Typically, estimates show a downward bias for rare haplotypes and an upward bias for more common haplotypes. For a fixed genotyping effort, it appears that samples of trios provide more accurate haplotype frequency estimates than samples of unrelated individuals, when there is historical recombination and/or substantial missing data, while samples of unrelated individuals have a slight advantage under circumstance without recombination and with no missing data. These results will be important for investigators planning to design or carry out gene-mapping and linkage disequilibrium studies in human populations.

Analysis of multiple error rates in haplotype-based association studies. *L. Beckmann*¹, *C. Fischer*², *J. Chang-Claude*¹. 1) Dept Clinical Epidemiology, German Cancer Research Center, Heidelberg, Germany; 2) Dept of Human Genetics, Univ. of Heidelberg, Germany.

Large-scale association studies hold substantial promise for gene mapping in complex disease. These studies involve analysis of multiple genetic markers whereby various hypotheses are tested simultaneously, resulting in both inflated false positives and failures to detect true associations. Multiple error correction is thus necessary and is important when comparing power of different methods. We aim to contrast different strategies for controlling multiple error levels in case-control scenario. We applied three strategies: 1. A permutation procedure, where multiple error is controlled either by the *step-down maxT* or the *step-down minP* adjusted p-values (Westfall and Young, Resampling-based multiple testing. John Wiley & Sons 1993). 2. The rank truncated product of p-values (*RTP*) by Dudbridge and Koeleman (Genetic Epidemiol 25:360-6, 2003). 3. The method proposed by Hoh et al. (Genome Res 11:2115-9, 2001). We performed simulation studies under the null hypothesis for different models, varying the number of genetic markers, allele frequencies and level of linkage disequilibrium. Three statistical methods for gene mapping were analyzed: 1. A new method for gene mapping based on Mantel statistics to correlate phenotypic similarity with genetic similarity, measured as the shared length between two haplotypes at a putative disease locus. 2. The single-point χ^2 -test. 3. The χ^2 -test for overlapping sliding windows consisting of 3-marker haplotypes. For a fixed pointwise error level of 5% at each marker position, the Mantel statistic showed the lowest multiple error. Multiple error was more inflated for the haplotype-based χ^2 -test and was even stronger for the single-point χ^2 -test. Permutation procedures are straightforward if the distributions of the test statistics are analytically known. If empirical p-values have to be estimated by permutation, the *step down minP* procedure must be used. *RTP* has the disadvantage that a parameter has to be chosen in advance. Our results can serve as a guideline for multiple error correction in the analysis of large-scale association studies.

Association of vitamin-D receptor (VDR) gene polymorphism (Fok-I) with calcium oxalate nephrolithiasis. *H.K. Bid¹, A. Kumar², R. Kapoor¹, R.D. Mittal¹*. 1) Department of Urology, SGPGIMS, Lucknow, Uttar Pradesh, India; 2) Department of Biochemistry, GSVM, Medical Kanpur, Uttar Pradesh, India.

Urolithiasis is a multifactorial and polygenic disease. The etiology of idiopathic calcium oxalate nephrolithiasis is heterogeneous, involving both genetic and environmental factors. The formation of urinary stones is reported to be associated with the genetic polymorphism of vitamin-D receptor (VDR) gene. In order to evaluate the role of VDR gene start codon Fok-I polymorphism in stone formation, we aimed to explore the association between calcium stone disease and the Fok-I polymorphism in North Indian population. A control group comprising of 166 healthy individuals (age range 22-58 years) and 138 patients with calcium oxalate stone disease (age range 21-72 years) were included in the study. The polymorphism was detected by using PCR based restriction analysis. An unexcisable band of 265 bp (CC) and two bands of 169 bp and 96 bp (TT) were obtained by Fok-I restriction digestion. The frequency of the genotype CT was observed to be higher in the patients (76.8%) as compared to the healthy controls (50.6%). However, the frequency of the genotypes CC and TT were higher among healthy controls (46.4% and 3%) compared to patients (21.7% and 1.5%). The results suggest a statistically significant association between calcium oxalate stone disease and VDR gene Fok-I polymorphism. It is also suggestive of a candidate gene, which could be used as a genetic marker contributing to risk factor in calcium oxalate stone disease.

Convergence of genome-wide expression analysis and genome-wide linkage analysis identifies candidate genes for atherosclerosis. *E.R. Hauser, S.G. Gregory, D. Seo, A. Dobra, E. Iversen, R. Karra, C.S. Haynes, J. Stenger, H. Xu, L. Wang, L. Huang, M. West, M. Sketch, J.M. Vance, W.E. Kraus, P.J. Goldschmidt, for the GENECARD and AGENDA Investigators.* Duke University, Durham, NC.

Genome-wide expression analysis of coronary tissues and genome-wide linkage analysis in families with early-onset CAD are unbiased methods to identify candidate genes for CAD. Both methods can result in a large number of candidate genes. Identifying genes that appear on both lists may reveal the strongest candidates. Sixty-eight genes were identified as strongly predictive of atherosclerosis from expression analysis using the Affymetrix U95 chip on 77 aortas. Regions of linkage were identified from results for 420 families in the GENECARD study. Five SNPs per gene were selected for genotyping, which has been completed on 63% of the SNPs. These genes were tested for association in an independent set from the CATHGEN sample of the Duke Catheterization Lab Database. Subjects were selected according to their CAD index (CADi), a validated angiographical measure of the extent of coronary atherosclerosis: 301 young affected subjects (age < 55, CADi > 32), 168 older affected subjects (age > 55, CADi > 74) and 204 unaffected elderly subjects (age > 60, CADi < 23). To screen for association p-values were calculated by logistic regression adjusting for sex and ethnicity for each SNP. Among 43 expression candidates with at least 1 SNP genotyped, 37 were not in regions of linkage and 6 were in regions of linkage. Of the 6 genes in regions of linkage, 5 (83%) showed evidence for association ($p < .05$) with at least one SNP. The 5 genes (chromosome, expression rank, pvalue) are: LAM5 (1, 38, .04); GM2A (5, 14, .02); BPAG (6, 29, .03); GPNMB (7, 15, .02); MMP9 (20, 44, .04). Haplotype analysis shows that approximately of these genes show evidence for haplotype associations. Of the 37 genes not in regions of linkage 13 showed evidence of association ($p < .05$) with at least one SNP (35%). The convergence of evidence from multiple genome-wide sources is a useful tool for identifying the most important candidate genes for additional analyses.

Affected males transmit multiple sclerosis more often to children than affected females: The Carter effect. *O.H. Kantarci¹, L.F. Barcellos², J.R. Oksenberg³, E.J. Atkinson¹, R.R. Lincoln³, M. deAndrade¹, B.G. Weinshenker¹, S.L. Hauser³.* 1) Neurology, Mayo Clinic, Rochester, MN; 2) Neurology, University of California, Berkley, CA; 3) Neurology, University of California, San Fransisco, CA.

Women to men ratio is 2:1 in multiple sclerosis (MS)(Mayr et al. Neurology 2003; 61(10): 1373-77). If this difference was largely genetic rather than environmental, men need a larger load of susceptibility genes to overcome this relative resistance compared to women and would transmit the disease more often to their children, a phenomenon known as the Carter effect (Carter. Br Med Bull 1961; 17:251-54). We studied the presence of Carter effect in MS. We identified 105 affected individuals with an affected father or mother (38 affected index parents) from 482 affected individuals in 185 pedigrees that were previously collected (Haines et al. Nature Genetics 1996; 13(4): 469-71). We compared transmission of MS from affected men with transmission from affected women. Significance was assessed with Fisher's Exact test. The ratio of women to men were: of all affected individuals 2.4 (342:140); of all unaffected individuals 1.0 (603:612); of index parents 2.2 (26:12), of their affected offspring 2.9 (29:10), of their unaffected offspring 1.8 (42:24); of unaffected parents 0.95 (291:305), of their affected offspring 2.5(651:260) and of their unaffected offspring 1.04 (702:672). This distribution shows that the increased frequency of MS in women is independent of parents' affected status and the threshold to develop MS in women is lower than men. Men with MS transmitted the disease to their children more often (transmitted: 18, not transmitted: 18) than affected women (transmitted: 21, not transmitted: 48) ($p=0.049$;OR: 2.29, 95%CI: 1.00-5.24). To eliminate confounding by gender of the offspring, the analysis was repeated considering only transmission to daughters. Affected men transmitted MS more often to their daughters (transmitted: 14, not transmitted: 10) than affected women (transmitted: 15, not transmitted: 32)($p=0.032$;OR: 2.99, 95%CI: 1.08-8.26). Our results confirm the presence of Carter effect in MS and suggest that larger genetic loading in men may result in excess paternal transmission.

A Pattern Discovery-Based Method for Detecting Multi-Locus Genetic Association. Z. Li¹, A. Floratos¹, D. Wang¹, A. Califano^{1,2}. 1) Computational Genetics, First Genetic Trust, Inc, Rutherford, NJ; 2) Department of Biomedical Informatics, Columbia University, New York, NY.

Methods to effectively detect multi-locus genetic association are becoming increasingly relevant in the genetic dissection of complex trait in humans. Current approaches typically consider a limited number of hypotheses, most of which are related to the effect of a single locus or of a relatively small number of neighboring loci on a chromosomal region. We have developed a method that is specifically designed to detect genetic association involving multiple disease-susceptibility loci, possibly on different chromosomes. Our approach relies on the efficient and exhaustive discovery of patterns comprising spatially unrestricted polymorphic markers and on the use of appropriate test statistics to evaluate pattern-trait association under case-control design.

A genotypic pattern describes a genetic signature (a panel of markers with particular genotypes) that is shared by numbers of individuals in the case and control populations. The statistically significant enrichment of a genotypic pattern in case population vs. control population could suggest trait association. One advantage that the pattern discovery-based method might have over existing single marker-based or haplotype-based methods is that trait-associated genetic signatures involving multiple non-continuous markers can now be identified. Power calculations using two multi-locus disease models, two sample sizes, and five affected genotype frequencies demonstrate significant gain of power by using this method in detecting multi-locus genetic association when compared to a standard single marker analysis method. When analyzing a Schizophrenia dataset, we confirmed a previously identified gene-gene interaction (DAO-G72 interaction). In addition, a less conspicuous association involving different markers on the same DAO and G72 genes was also identified, implicating genetic heterogeneity.

The 3020insC Mutation of the CARD15/NOD2 Gene Predicts Risk of Early Surgery in Pediatric Crohns Disease.

K. Maresso¹, R. Hoffmann², S. Kugathasan³, U. Broeckel¹. 1) Human & Molecular Genetics Center, Medical College of Wisconsin, Milwaukee, WI; 2) Department of Biostatistics, Medical College of Wisconsin, Milwaukee, WI; 3) Department of Pediatrics, Medical College of Wisconsin, Milwaukee, WI.

Large-scale linkage and association studies have been frequently employed to uncover the genetic underpinnings of complex diseases. Ultimately, the question remains whether these methods identify genes with significant clinical or prognostic relevance. We recently demonstrated an association of the 3020insC polymorphism of the CARD15/NOD2 gene to pediatric-onset Crohns Disease (CD) in a prospective cohort of Caucasian children. As a subset of children with CD progress to severe disease requiring surgical intervention, our goal was to determine if the 3020insC SNP could identify a subset of children at high risk for surgery who would benefit from early genetic testing and more aggressive therapy. In a prospective study, 163 Caucasian children with CD were recruited with parents and followed for up to 70 months. We used a Cox Proportional Hazards model, stratified according to the presence or absence of the 3020insC allele, to determine the effect of this mutation on surgery-free survival. A test of the proportionality assumption was performed using the Schoenfeld residuals. The Cox PH model demonstrated an unadjusted hazard ratio of 6.07 (95% C.I. 2.76-13.37, $p < 0.0001$), indicating that the hazard for surgery is six-times greater in children with the 3020insC SNP than in those without it. The hazard ratio changed marginally when adjusted for disease location and presentation at diagnosis (5.83, 95% C.I. 2.62-12.98, $p < 0.0001$). This prospective study demonstrates that children positive for the 3020insC variant are at a significantly higher risk for early surgery than children without the mutation, suggesting that this variant could act as a prognostic factor for early surgery in Caucasian CD children. While this study is specific to the particular case of pediatric-onset CD, we believe it might also serve as an example of how gene identification strategies can lead to new clinically important prognostic markers.

Correcting for population stratification using genomic control. *D. Shmulewitz*^{1, 2}, *J. Zhang*², *D.A. Greenberg*^{1, 2, 3}.
1) Department of Psychiatry; 2) Division of Statistical Genetics, Columbia University, New York, NY; 3) New York State Psychiatric Institute, New York, NY.

Case-control association studies in mixed populations can result in spurious disease-marker associations (i.e. increased false positive rate, FPR) if both disease prevalence and marker frequencies differ in the subpopulations. The Genomic Control (GC) approach uses neutral loci to correct the χ^2 to reflect the nominal p-value of 5%. Previously, in simulated association studies, we showed that applying GC using sets of markers with low average allele frequency differences (M) between the component subpopulations can restore the expected 5% FPR. Here we study the effect on GC when a few of the markers have high allele frequency differences (outlier markers). We simulated two populations with different disease and marker (1000 SNPs) frequencies and without any disease-marker association. We generated mixed populations with disease ratios (DR, disease prevalence in population1/prevalence population2) of 0-1. We selected sets of 100 markers with a small number of outlier markers. We drew 100 datasets of 100 cases/controls and calculated the χ^2 -statistic for disease association with each marker. We applied two genomic control procedures, dividing by the mean χ^2 or median- $\chi^2/0.456$, to see how effectively these procedures eliminated excess false positives. When outlier markers were present, correcting by the mean resulted in corrected FPRs (cFPRs) close to 5%. However, when the DRs were smaller (0.2), the cFPRs were conservative (4%). In contrast, correcting by the median/0.456 resulted in cFPRs that were quite anticonservative (6%) for most DRs. The conservativeness of the mean correction and the anti-conservativeness of the median correction both became more pronounced as the number of outlier markers increased. M also affected the median correction. GC, particularly using the mean correction, might be useful in certain situations to correct population stratification. In other situations, GC may lead to a notable loss of power to detect a true association (conservative) or may not completely eliminate the spurious associations (anticonservative).

Cladistic Grouping of Haplotypes in Association Analysis. *J.Y. Tzeng*^{1,2}. 1) Department of Statistics, NC State University, Raleigh, NC; 2) Bioinformatics Research Center, NC State University, Raleigh, NC.

Haplotypes represent underlying polymorphisms more than single SNPs, and are considered as a more informative format of data in studying genetic association with phenotypes. To model haplotypes, it requires high degrees of freedom, which could decrease power and limit the model capacity to incorporate other complex effects such as interactions. Even within haplotype blocks, high degrees of freedom can still be a concern unless one chooses to discard rare haplotypes. To increase the efficiency and power of haplotype analysis, we adapt the concepts of cladistic analysis and propose a grouping algorithm to cluster rare haplotypes to their corresponding ancestral haplotypes. The algorithm determines the cluster basis by reserving common haplotypes using a criterion built on Shannon information content. Each haplotype is then assigned to its appropriate clusters probabilistically according to the cladistic relationship. Through this algorithm, we calculate the maximum likelihood estimates of the regrouped haplotype frequencies from genotypes, and perform association analysis based on groups of haplotypes. Simulation results indicate increase in power for tests based on haplotype clusters obtained by the proposed algorithm comparing to tests based on original haplotypes.

Program Nr: 2946 from the 2004 ASHG Annual Meeting

Native South American genetic variation and its relationship to tuberculosis prevalence: the vitamin D receptor and SLC11A1. *A.K. Wilbur¹, L. Salter¹, A.M. Hurtado¹, K.R. Hill¹, A.C. Stone².* 1) Univ New Mexico, Albuquerque, NM; 2) Arizona State University, Tempe AZ.

Tuberculosis incidence among Native American groups since European contact has been especially high, and our ethnographic and molecular data indicate prevalence greater than 50% among the Ach and Av of Paraguay. Despite extensive evidence that host genetics help determine susceptibility and resistance to tuberculosis in various populations around the world, little research has been conducted on Native American susceptibility. This project examines the potential interplay of host genetics and environmental factors in tuberculosis susceptibility in Ach and Av. Using molecular biological techniques, sequence data and SNPs at two candidate loci (the vitamin D receptor and SLC11A1, also known as NRAMP1) are examined for potential association with tuberculosis. Our extensive longitudinal, demographic data for Ach allow for co-analysis of factors such as sex, age, and proximity to non-Native communities. Here we report on our preliminary findings.

Genetic models of tumor necrosis factor- expression and tuberculosis susceptibility. *C.M. Stein^{1,2,3}, R.D. Mugerwa^{2,4}, W.H. Boom², K.D. Russo¹, R.C. Elston¹, C.C. Whalen^{1,2,3}, S.K. Iyengar¹.* 1) Epidemiology & Biostatistics, Case Western Reserve Univ, Cleveland, OH; 2) Tuberculosis Research Unit, CWRU, Cleveland, OH; 3) Epidemiology of Infectious Diseases Center, CWRU, Cleveland, OH; 4) Makerere University School of Medicine, Kampala, Uganda.

Tuberculosis (TB) is a major public health problem in sub-Saharan Africa. Several studies suggest there is a host genetic component for TB risk. TB is a complex multifactorial genetic trait because of its heterogeneity in disease presentation, variation in severity and length of latent infection, long-term disease risk, and dependence on exposure to *M. tuberculosis*. We examined levels of tumor necrosis factor- (TNF) as an intermediate immunologic phenotype for TB because it is a key cytokine in TB pathogenesis, is correlated with the natural history of TB, and has previously demonstrated high heritability (68%). We conducted a household contact study of 172 families comprising 831 people in Kampala, Uganda, a TB-endemic community. We used path analysis to partition the components of variance due to genetic and shared environmental effects. Results suggested that TNF expression is influenced by genes (34-66% heritability), is not strongly influenced by shared environment, and is possibly influenced by gene-environment interaction. Segregation analyses showed that TNF follows a major gene model with three underlying means, in which the heterozygote mean was less than either homozygote mean, consistent with heterozygote advantage, and heterogeneity of transmission across generations was accounted for by age and HIV serostatus. Candidate region linkage analyses suggest a minor role of MHC loci in TNF regulation and TB susceptibility (D6S439, $p=.04$). Our new path model increases power to detect linkage and illustrates previously unexplored components of genetic risk to TB. Analysis of underlying immunological components of TB will yield insights into TB genetics by determining deficiencies in host immunity that ultimately predispose individuals to develop TB. Planned linkage analysis of additional candidate genes will enable the identification of early immune responses that lead to host susceptibility.

Segregation analysis of Restless Legs Syndrome (RLS). *R.A. Mathias¹, W.A. Hening², M. Washburn³, R.P. Allen³, S. Lesage³, A.F. Wilson¹, C.J. Earley³.* 1) Inherited Disease Research Branch, NHGRI/NIH, Baltimore; 2) UMDNJ-RW Johnson Medical School, New Brunswick; 3) Johns Hopkins University, Baltimore.

RLS is a sensorimotor disorder that has a prevalence of ~7% in the US. A diagnosis of RLS requires establishing an urge to move localized to the legs which is provoked by rest, relieved by activity, and accentuated late in the normal wake period and early sleep period. A segregation analysis done in German families with probands having an age of onset below 30 supported a dominant pattern of inheritance [Winkelmann J et al., *Ann Neurol*, 2002, 52:297-302]. In this study, probands were selected from consecutive RLS patients from the Neurology and Sleep clinics of the Johns-Hopkins Bayview Medical Center. Patients willing to have first and second degree relatives contacted were included. An RLS diagnosis was made in those who had the four diagnostic features of RLS [Allen RP et al., *Sleep Med*, 2003, 4:101-119] and whose symptoms could not be explained by an alternate diagnosis. There are 2060 subjects in 76 pedigrees with 534 sibships. The average pedigree size is 27 (range 6-90) with an average of 4.8 generations. Phenotype data is available on 590 subjects of whom 281 have a confirmed diagnosis of RLS. Initial examination of simple segregation ratios suggests an autosomal dominant mode of inheritance of RLS that appears to be more pronounced in families with an earlier proband age of onset. A formal segregation analysis of these pedigrees is ongoing.

Program Nr: 2949 from the 2004 ASHG Annual Meeting

GARFIELD: A Graphical Analysis and Reorganizing Interface for Linkage Disequilibrium. *J. Cazier, D.F. Gudbjartsson, M. Stefánsson, A. Kong.* Dept Statistics, deCode Genetics, Reykjavik, Iceland.

Linkage and association studies require the understanding of the underlying structure of the chromosome, an important part of which is captured by the linkage disequilibrium (*LD*) patterns. A preamble to any research over a specific region has to be its in-depth analysis, and therefore efficient tools to address the question are necessary. Coupling the genotype data from the investigator to the releases from the **Hapmap** project provides an excellent platform to identify the *LD* structure of any region. We have developed **GARFIELD**, a user-friendly, powerful, yet modular, graphical interface to make maximum use of *LD* patterns in data.

GARFIELD works with either genotypes or direct *LD* information of pre-processed data, available in text file. Typically pairwise D' , R^2 and p -val output from the **Nemo** program by **deCODE Genetics** are used. This software can quickly handle small and large data sets with various level of zooming. *LD* blocks can be easily identified and further analysed to determine haplotype diversity whenever genotypes are the input. **GARFIELD** is not only an interface to plot and analyze *LD*, but it also contains all the options to prepare ready-to-publish images.

A feature of the program is the re-organizer which allows the identification and correction of map misplacements and genotyping errors. This is possible by allowing manual permutations of the marker position in the map. Moreover an algorithm provides permutations to optimize the block structure for scores based on quantities like D' , R^2 , p -val, index- and physical- distance between marker pairs.

All sources and executables are freely available upon request.

Genetics and Homocysteine in Obese West Virginians. *M. Flood*², *J.M. Chappell*³, *C. Clark*², *S. Hesson*¹, *B. Hill*⁴, *J. Jeong*¹, *J. Nash*¹, *M. Ramey*¹, *J. Roth*¹, *P. Sekar*⁶, *B. Kahle*⁶, *G. Wright*⁵, *T. Green*⁵, *M. Studney*⁵, *P. Wehner*⁵, *E.E. Murray*¹. 1) IST, Marshall University, Huntington, WV; 2) Biology, Fairmont College, Fairmont, WV; 3) CLS, MU, Huntington, WV; 4) Biology, West Virginia State University, Institute, WV; 5) Joan C. Edwards School of Medicine, MU, Huntington, WV; 6) Biology, MU, Huntington WV.

We genotyped two functional MTHFR variants (MTHFR 677; MTHFR 1298) and Factor V Leiden (FFL 1691) in 581 subjects. All loci are on chromosome 1. The MTHFR variants (677T and 1298C) modestly elevate plasma homocysteine (HSC) with consumption of a low folate diet. HSC level is a significant risk factor for patients with CVD. FFL 1691A causes resistance to activated protein C, increasing venous thrombosis risk. Although obesity increases CVD risk, the role genotype plays in elevated HSC in the obese is unknown. 77.2% of subjects are obese (BMI 30) and 10.9% are overweight (BMI 25-30). There is no significant difference between genotype distributions in the obese compared with a WV population of European origin not selected for obesity.

MTHFR 677	MTHFR 1298	FFL 1691
CC 55.2%	AA 47.5%	GG 94.5%
CT 38%	AC 43.5%	GA 5.5%
TT 6.8%	CC 9%	AA 0%

*MTHFR 1298A allele is linked to MTHFR 677T, and 1298C allele with 677C (p 0.001). LD is observed between MTHFR 1298A and FFL 1691G and between 1298C and 1691A (p 0.05). FFL 1691 and MTHFR 677 loci had no LD. Only MTHFR1298 genotype positively correlates with obesity. 1298AA genotype is higher in normal individuals and 1298CC genotype is lower in the obese (p 0.036), indicating a possible survival benefit for 1298 AA genotype.

Assessment of Power for Association Studies to Finely Map a Locus Identified by Linkage Analysis. *R. Hanson, W. Knowler.* DAES, NIDDK, Phoenix, AZ.

Association (e.g. case-control) studies are often used to finely map loci identified by linkage analysis. We investigated the influence of various parameters on power and sample size requirements for such a study. Calculations were performed for various values of a high-risk functional allele (f_A), frequency of a marker allele associated with the high risk allele (f_1), degree of linkage disequilibrium between functional and marker alleles (D') and trait heritability attributable to the functional locus (h^2). The calculations show that if cases and controls are selected from equal but opposite extreme quantiles of a quantitative trait, the primary determinants of power are h^2 and the specific quantiles selected. For a dichotomous trait power also depends on population prevalence (P_D). For example, for $h^2=0.05$, $P_D=0.1$ and $D'=1.0$, the sample size required to detect an association with the marker at $p<0.01$ is 266 if $f_A=f_1=0.1$ (assuming an equal number of cases and controls) and 416 if $f_A=f_1=0.9$. Power is optimal if functional alleles are studied ($f_A=f_1$ and $D'=1.0$) and can decrease substantially as D' diverges from 1.0 or as f_1 diverges from f_A (even with D' near 1.0). These analyses suggest that association studies to finely map loci will most likely be successful if potential functional polymorphisms can be identified *a priori* or if markers are typed to maximize available haplotypic diversity. In the absence of such information, expected minimum power at a given location for a given sample size can be calculated by specifying a range of potential frequencies for f_A (e.g. 0.1-0.9) and determining power for all markers within the region with specification of the expected D' between the markers and the functional locus. As an illustration of this method, calculations were performed for a body mass index mapping project consisting of 662 single nucleotide polymorphisms in 24 Mb. Regions differed by marker density and allele frequencies. Thus, in some, power was near its theoretical maximum and little additional information is expected from additional markers, while in others, additional markers appear to be necessary. These methods may be useful for assessing the progress of fine-mapping studies.

Efficiency and Robustness of a Family-Based Conditional Likelihood Ratio Test for Association. *J.P. Lewinger¹, S.B. Bull^{1, 2}*. 1) Samuel Lunenfeld Research Institute, Toronto, ON, Canada; 2) Dept. of Public Health Sciences, Univ of Toronto, Toronto, ON, Canada.

In a previous report (Lewinger and Bull, 2003 *Am J Hum Genet* 73 (5S); 613) we introduced a likelihood ratio test of linkage in the presence of allelic association, based on the conditional framework of Rabinowitz and Laird (D. Rabinowitz, N. Laird, *Hum Hered* 2000). This test efficiently uses all available nuclear family information, including genotypes from both affected and unaffected siblings, as well as from homozygous parents. The test statistic is a conditional likelihood ratio based on a standard two point linkage model that includes an allelic association parameter. Estimation of the model parameters guarantees asymptotically optimal power within the set of alternatives specified by the model. The test is immune to population stratification and can be applied to families with any pattern of missing information. With complete parental genotypes, the null distribution of the test statistic is obtained by a within-family randomization scheme in which the phenotypes of all individuals are kept fixed, while the children's genotypes are randomized according to Mendelian transmission probabilities. With missing parental genotypes, a constrained randomization of the children's genotypes is required (Rabinowitz and Laird). We determined the maximum theoretical power attainable by any conditional test against a single point alternative and found through simulation that for a wide range of scenarios the proposed test has near optimal power, outperforming the TDT when data were complete and the SDT when parental genotypes were missing. In recent simulation studies we evaluated the performance of the tests under alternatives outside the likelihood model, particularly mixed populations with differing allele frequencies. We found that although the power gains are more modest, our proposed test still outperforms the TDT and the DTD in most scenarios.

Influence of Linkage Disequilibrium of High-Density SNPs on Prostate Cancer Linkage Results. *S. McDonnell¹, S. Slager¹, J. Guenther¹, G. Christensen¹, C. Rosenow², C. Hilker¹, J. Cunningham¹, D. Schaid¹, S. Thibodeau¹.* 1) Mayo Clinic College of Medicine, Rochester, MN; 2) Affymetrix, Inc., Santa Clara, California 95051.

Most genetic linkage packages assume that the markers analyzed are in linkage equilibrium. This assumption is likely to be invalid when analyzing a large number of genetic markers, such as when analyzing single nucleotide polymorphisms (SNPs) from SNP arrays. As part of a genome-wide scan for prostate cancer using the Early Access Affymetrix Mapping 10K array, we performed linkage analyses with and without SNPs in high linkage disequilibrium (LD) to investigate the effect of LD on linkage results. We computed the pair-wise LD measures r^2 and $|D|$ between all pairs of SNPs that were within 5 cM distance from each other. A threshold was set for each measure to define a cluster of SNPs in high LD. From each cluster, the most informative SNP was selected for linkage analysis. We considered thresholds of 0.01, 0.2, 0.4, 0.6, and 0.8. Multipoint model-free LOD scores, based on the Kong and Cox exponential model, were calculated for the full set of SNPs and for subsets of SNPs after removing those in high-LD, as defined by the threshold. Linkage information content was estimated using the entropy information described by Kruglyak et al. All analyses used Merlin software. Over all chromosome positions, the average information content for the full set of SNPs was 63%. The information content was similar when moderate to high levels of LD ($r^2 > 0.2$ and $|D| > 0.6$) were excluded, but dropped to 46% when only one SNP within a 5 cM region was used ($r^2 > 0.01$). Several chromosomes exhibited lod score peaks using the full set of SNPs that either disappeared or were much less striking when markers with moderate to high levels of LD were removed. For instance on chromosome 4, a lod score of over three, observed with the full set of SNPs, was reduced to a lod score of less than one when SNPs were removed using $r^2 > 0.4$ criterion. These results suggest that including high-LD SNPs in linkage analyses can lead to inflated lod scores, however removing all evidence of LD can unnecessarily decrease the information content.

Apolipoprotein E polymorphism, plasma lipids and coronary heart disease in North West India (Punjab): An Asian perspective. *P. Singh¹, M. Singh¹, S.S. Mastana², D.P. Bhatnagar¹.* 1) Dept of Human Biology, Punjabi University, Patiala, 147002 Punjab, India; 2) Human Genetics Lab., Department of Human Sciences, Loughborough University, Loughborough, LE11 3TU, UK.

The distributions of plasma lipids, lipoproteins and genetic polymorphism of Apolipoprotein E were investigated in angiographically diagnosed coronary heart disease patients (n =78) and controls (n =50) of North West State of India (Punjab). HDL-C and LDL-C/HDL-C ratio were found to be significantly different in E3-3 and E3-4 genotype patients (F = 60.11 & 23.07, p < 0.05) and controls (F=47.94 & 9.40, p < 0.05) respectively however, non-HDL-C and LDL-C were found to be dissimilar in E3-4 genotypes of patients (F = 4.72, p < 0.05) and controls (F= 4.80, p < 0.05). ApoE3-4 subjects were at 4 times higher chance of afflicting to 3 vessel disease (OR = 4.03, 95% CI; 0.91-18.83, p < 0.05). Overall the higher frequencies of E3-4 genotype reflected it to be a modest indicator of angina (OR = 2.06, 95%CI; 0.49-9.18), myocardial infarction (OR = 2.19, 95%CI; 0.41-11.86), diabetes (OR = 1.82, 95%CI; 0.29-11.01), 1 vessel (OR = 2.03, 95%CI; 0.32-12.45) and 2 vessel disease (OR = 2.88, 95%CI, 0.58-14.62). The frequencies of ApoE*2, ApoE*3 and ApoE*4 alleles in patients and controls were found to be 0.038, 0.865, 0.097 and 0.06, 0.87, 0.07 respectively. An opposite and unforeseen trend of ApoE3-4 and ApoE3-2 genotypes was observed when subjected to geographical correlates of North latitude and East longitude. E3-2 genotype was observed to be decreasing towards North ($y = -0.0017x + 0.158$, $r = 0.3429$, $p < 0.05$) where CHD prevalence is low and reverse trend was exhibited by E3-4 ($y = 0.0009x + 0.113$, $r = 0.1288$, $p > 0.05$), however the association of percent CHD mortality with ApoE3-2 and ApoE3-4 genotypes ($r = 0.3090$, 0.3460 respectively, $p < 0.05$) was found to be significantly associated in Asia.

Program Nr: 2955 from the 2004 ASHG Annual Meeting

Statistical Power of Extreme Discordant Phenotype Design. *G. Zhang, D.W. Nebert, R. Chakraborty, L. Jin.* Dept Environmental Health, Univ Cincinnati, Cincinnati, OH.

Population based case-control study of association between disease and genotype has become a major tool in the search for genes underlying complex diseases. And it has been proposed that power to detect association can be increased by using selected cases and/or controls of extreme discordant phenotype (EDP). The advantage of EDP methodology is intuitive, therefore, a rigorous mathematical analysis on its statistical performance is necessary. We developed a statistical framework to calculate the power of EDP based on quantitative genetics model and studied the statistical performance of EDP under a range of conditions. We first studied the genotype frequency changes of a trait locus under truncation selection and presented formulas for calculating power and sample size for EDP case-control design. We showed that EDP methodology is a powerful method for genetic association study both in terms of statistical power and robustness. And better statistical performance can be achieved when cases and controls are both selected from extremes and are well balanced. As a special case, we also showed EDP design by controlling on environmental exposure will also increase the power to detect association, especially when both exposure rate and relative risk are high. And finally, by simulation, we observed EDP is less sensitive to false positive discovery derived from population stratification.

Assessment of the impact of using sex-averaged genetic maps in multipoint linkage analysis when IBD status is incompletely known. *T.E. Fingerlin*¹, *G.R. Abecasis*², *M. Boehnke*². 1) University of Colorado Health Sciences Center, Denver, CO; 2) Center for Statistical Genetics, University of Michigan, Ann Arbor, MI.

The ratio of male and female recombination rates has been shown to vary dramatically across the human genome (Broman et al. 1998, Kong et al. 2002). Despite these sex differences in the genetic map, most linkage analyses use sex-averaged genetic maps for multipoint analyses. We investigated the impact of using a sex-averaged genetic map instead of sex-specific maps for multipoint linkage analysis of affected sibling pairs when identity-by-descent states are incompletely known due to missing parental genotypes or incomplete marker heterozygosity. If either all or no parental genotypes were available, for intermarker distances of 10, 5 and 1 cM, we found no important differences in the expected maximum lod score (ELOD) or location estimates of the disease locus between analyses that used the best sex-averaged map and those that used the true sex-specific map for female:male genetic map distance ratios 1/10 or 10. In the extreme case of having genotypes for only one parental sex, the ELOD for the sex-averaged map was inflated compared to the ELOD for the sex-specific map if only mothers were genotyped and deflated if only fathers were genotyped for $r=1$ and intermarker distances of 5 and 10 cM. In addition, disease location estimates were biased in some cases for disease models with modest sibling relative risks. We are currently determining the extent to which less extreme cases of imbalances in missing parental genotypes influence the ELOD and location estimate. Preliminary results suggest that for larger sibships, the change in the ELOD and the bias in location estimate due to missing genotypes for one parental sex are attenuated. In summary, at the marker density used in most linkage studies, unless there is an imbalance in the number of mothers and fathers genotyped, using a sex-averaged map rather than a sex-specific map is unlikely to result in inflated lod scores, a loss of power, or the inability to localize disease susceptibility loci using affected sibships. If such an imbalance does exist, lod scores may be inflated or deflated, and location estimates may be biased.

Interactive visualization tools for genetic data. *M.W. Logue¹, J. Park², J. Ni^{2,3}, J. Cremer², A. Segre^{1,2}, B. Knosp³, S. Beck³, V. Vieland¹.* 1) CSGR; 2) Dept of CS; 3) AT, University of Iowa, Iowa City, IA.

The interpretation of complex genetic data analyses can be facilitated by interactive visualization tools. We have built two such tools, one for exploring high-dimensional genetic likelihood surfaces and one for exploring sampling distributions of alternative genetic statistics.

LiViT (Likelihood Visualization Tool) displays the HLOD (admixture LOD score) surface as a function of 6 input variables (3 penetrances, disease allele frequency, θ , and α) simultaneously. LiViT takes as its input a grid of pre-computed LOD score values and displays a 3D graph of the HLOD as a function of two of the model parameters. Which parameters are being displayed on the axes can be changed at any time. The values of the remaining explanatory variables are manipulated using slider bars. For example, the HLOD surface as a function of θ and α can be displayed at any arbitrary genetic model which can be changed in real time.

DiViT (Distribution Visualization Tool), is used to examine the null and alternative distribution of a statistic. DiViT takes as its input the cutpoint and bar heights which define two histograms. It outputs an applet which displays these histograms, representing the distributions of a statistic under the null and the alternative hypotheses. Slider bars manipulate color-coded regions superimposed on the distributions. The percentage of both distributions falling in each region is displayed to the right. Opening multiple DiViT windows allows comparison of statistics based on power, probability of false negative scores, as well as the probability of inconclusive results, for different size tests.

These graphical methods do not display any information which can not be displayed in a series of individual graphs. However, the interactivity enables the display of complicated information in a compressed form which is quickly understood in a clear and straightforward manor. In addition, use of the Java language has resulted in platform independent visualization tools leaving open the possibility of web-based versions which can be called from and/or integrated into a web site.

Program Nr: 2958 from the 2004 ASHG Annual Meeting

Power of the ordered subset analysis (OSA) method for linkage mapping in the presence of gene-environment interaction: Familial correlations and discrete vs. continuous covariates. *S. Schmidt, M. Schmidt, E.R. Martin, E.R. Hauser.* Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC.

The ordered subset analysis (OSA) method has recently been proposed as an approach to incorporate environmental covariates into parametric or non-parametric linkage analysis. The goal of the method is to identify more homogeneous subgroups of families on the basis of disease-associated covariates or phenotypic features, which may provide evidence for linkage that is otherwise obscured by genetic heterogeneity. When linked and unlinked families are distinguished by having different means of a normally distributed covariate with high familial correlations, the method was shown to have excellent power to detect linkage in the respective subgroup of families. Here, we present results of evaluating the performance of OSA when gene-environment (GxE) interaction exists at the individual level. We have incorporated exposure to a binary environmental covariate into the simulation algorithm implemented in the SIMLA program, which generates marker genotypes and binary disease phenotypes for families of fixed size given user-specified ascertainment criteria, parameters for a disease gene model, and a map of marker loci. We have assumed variable proportions of families linked to a disease gene that interacts with an environmental covariate. In the absence of familial correlations of the covariate, OSA has correct type I error but relatively low power to detect linkage in the presence of GxE interaction. The effect of familial correlations in environmental exposure (ranging from 0.1 to 0.9) and the benefits of using continuous rather than discrete (binary) covariates will be presented.

Program Nr: 2959 from the 2004 ASHG Annual Meeting

Robust Multipoint Identical-By-Descent Mapping with Affected Relative Pairs. *J.P. Sinnwell, D.J. Schaid, S.N. Thibodeau.* Biostatistics, Mayo Clinic, Rochester, MN.

The genetic mapping of complex traits has been challenging, requiring new statistical methods that are robust to misspecified models. Liang et al. [2001] proposed a robust multipoint method that can be used to simultaneously estimate the trait-locus position and its genetic effect, based on sib pair linkage data. We extend this approach to different types of affected relative pairs (ARP's) using two approaches. One approach is to estimate a common trait-locus position, while allowing different, unconstrained, trait-locus effects for different ARP types. This may be useful for older-onset diseases, where secular changes in diagnostic methods can change the frequency of phenocopies among different types of relative pairs. Our second approach also estimates a common trait-locus position, yet constrains the genetic effects to be consistent with a single susceptibility locus. Furthermore, we develop a robust score statistic to test whether there is significant evidence against the constrained model. Our methods are robust to genetic model assumptions and computationally efficient. These methods are applied to a prostate cancer linkage study, which emphasizes their potential advantages and limitations.

Relative Pair Inference: number of markers need to confirm pairwise relationships, use of family data to improve second degree relative inference, and impact of relationship misspecification on linkage analysis. *A.D. Skol, M. Boehnke.* Univ of Michigan, Ann Arbor, MI.

Relative pair inference is used to ensure that family structure is specified correctly prior to performing linkage or association analysis. We investigate three questions on this topic: 1) How many genotyped markers are necessary to be confident the putative relationship is correct? 2) How does using additional family members improve discrimination between second degree relatives? 3) How is evidence for linkage affected when second degree relatives are misspecified, for example, half sibs as uncle-nephew.

Our results suggest that genotypes for 60 well-spaced markers are sufficient for >80% power to identify putative full sibs(FS) as twins(MZ), parent-offspring(PO), avuncular(AV), grandparent-child (GG), half-sibs(HS), cousins(CO) or unrelated(UN), 30 are sufficient to identify putative PO pairs if their true relationship is among those listed above, and <20 are required for putative MZ twins. All other relative types we considered require >300 markers to achieve 80% power.

There is almost no power to discriminate between the three second degree relatives we considered; however substantial power can be achieved when additional sibs of the 'younger' relative are typed. For example, with ~90 well-spaced autosomal markers we have power .05 and .11 to detect that a putative AV pair is actually HS and GG. When an additional sib is added power increases to .74 and .82. Adding two sibs increases power to ~1. More modest improvements are observed for resolving HS and GG.

For all genetic models examined, regardless of the true second degree relationship, we found that AV pairs show the most evidence for linkage, followed by HS and GG pairs, implying that when either HS or GG are misspecified as AV there will be upward bias in the evidence for linkage and when AV and HS are misspecified as GG there will be downward bias. The magnitude of the bias appears most extreme when true AV relationships are misspecified, while misspecifying HS and GG pairs result in more modest bias.

Program Nr: 2961 from the 2004 ASHG Annual Meeting

Fast estimation of critical values of correlated genome scans for linkage. *S. Bacanu*. Dept Psychiatry, WPIC, Pittsburgh Medical Ctr, Pittsburgh, PA.

Estimates of study specific critical values for linkage scans (suggestive and significant thresholds) are important to identify promising regions. Often, scientists must perform multipoint linkage scans for several correlated traits or the same trait under different statistical models. Consequently, the outcome consists of several correlated multipoint linkage trace and many researchers chose to present the signal peaks from all traces, i.e. they report the performance of the pointwise maximal linkage trace. In this paper I propose a fast and concrete recipe for finding study specific critical values for the maximal linkage trace. Critical values could be derived theoretically or empirically. Theoretically-derived values are often conservative due to their assumption of fully informative transmissions. Empirically-derived values are computer and skill intensive and may not even be computationally feasible for large pedigrees. I propose a method to estimate critical values for correlated multipoint linkage traces using standard, widely used statistical software. The proposed method estimates study-specific critical values by using autoregressive models to estimate the correlation between standard normal statistics at adjacent map points for each trace and then use it, along with cross correlation with the other traces, to estimate study-specific critical values. The method is evaluated using different family structures and density of markers, under both the null hypothesis of no linkage and the alternative hypothesis of linkage between marker and disease locus. Overall, the proposed method appears very accurate in predicting critical values especially when the AR models are applied to the differenced time series.

Linkage tests for affected relative-pairs with marker IBD missing at random and marker IBS known. *D.W. Buckman, Z. Li.* Department of Statistics, The George Washington University, Washington, DC.

We develop linkage test statistics that utilize both the number of marker alleles shared IBD and the number shared IBS and allow the marker IBD value to be missing at random. These linkage statistics are developed for situations where the affected-relative-pair does not have other family members available to establish the number of marker alleles that the relative-pair share IBD. For each type of relative-pair considered, a likelihood function is obtained for this missing value situation. The linkage statistics for affected sib-pairs, affected aunt(uncle)-nephew(niece)-pairs, affected half-sib-pairs, and affected first-cousin-pairs are proportional to the second derivative of the log likelihood evaluated at the recombination fraction value of one-half. For affected grandparent-grandchild-pairs, the first derivative of the log likelihood is not fixed at zero when the recombination fraction equals one-half; therefore, the usual approach for developing an efficient score test is utilized. The asymptotic distribution of each linkage statistic is derived, and power and sample size equations are obtained. The linkage statistics are evaluated using simulated data based on various values for the recombination fraction, penetrances, and allele frequencies. Although the derivation is unique for each type of relative-pair, the same test statistic is obtained for affected grandparent-grandchild-pairs, affected aunt(uncle)-nephew(niece)-pairs, and affected half-sib-pairs. Under the simplifying assumption that the marker IBD is always known, the linkage statistics, based on the second derivative of the log likelihood, are members of the general set of linkage statistics derived by Dudoit and Speed (Dudoit, 1999; Dudoit and Speed, 2000). The power and sample size results reveal that discarding the affected relative-pairs with marker IBD missing at random is an inefficient strategy when compared to our more powerful approach that utilizes the marker IBS values for these relative-pairs. Also, the required sample sizes are smaller using our approach.

Sex-Specific Genetic Effects on BMI in the NHLBI FHS Study. *J. Corbett¹, I.B. Borecki¹, M.F. Feitosa¹, C.E. Lewis², K. North³, S.C. Hunt⁴, J. Hixson⁵, R.H. Myers⁶, D.K. Arnett⁷, M.A. Province¹.* 1) Div Biostatistics, Washington Univ, St Louis, MO; 2) Div Preventive Medicine, UA-Birmingham, Birmingham, AL; 3) School of Public Health, Univ of North Carolina, Chapel Hill, NC; 4) Dept Internal Med, Univ of Utah, Salt Lake City, UT; 5) School of Public Health, UT-Houston, Houston, TX; 6) School of Medicine, Boston Univ, Boston, MA; 7) School of Public Health, Univ of Minnesota, Minneapolis, MN.

Body Mass Index (BMI) is a primary phenotype used to study obesity. Some genetic linkage analyses of BMI have been performed using phenotypic information on only one sex. These analyses have yielded evidence for sex-specific genetic heterogeneity. We test for genotype by sex interaction in an analysis of 2,420 sib-pairs from the NHLBI Family Heart Study, a multi-center study to identify genetic and non-genetic factors that influence susceptibility to coronary heart disease. We use a Variance Components method for genetic linkage, implemented in the software package Mx, that allows for sex-specific genetic effects. The heritability of BMI is lower in females than in males ($p=0.05$). The estimated ratio of female to male heritabilities (estimated at 0.40 and 0.66 respectively) was 0.61 (0.39-0.96 95% CI). We also find evidence for a sex-specific differential in QTL effect size near 158 cM on chromosome 7 ($p=0.05$). These findings serve as a proof of concept for both the practicality and utility of studying sex-specific genetic effects in general, and provide additional valuable information in the study of the genetic etiology of obesity in particular. This methodology may be extended to incorporate other covariates for genetic linkage analysis in cases where there is reason to suspect genetic heterogeneity based upon that covariate.

Statistical properties of the propensity score as a single covariate in covariate-based linkage analysis. B.Q.

Doan^{1,2}, C.E. Frangakis³, A.J.M. Sorant¹, J.E. Bailey-Wilson¹, Y.Y. Shugart². 1) Dept IDR, NHGRI/NIH, Baltimore, MD; 2) Dept Epidemiology, JHSPH, Baltimore, MD; 3) Dept Biostatistics, JHSPH, Baltimore, MD.

To increase the power to detect linkage while minimizing the degrees of freedom of the linkage test, we previously introduced the first application of the propensity score (PS) to covariate-based linkage analysis (LODPAL). The PS is defined as the logistic regression of the affection status on the covariate data, thereby collapsing multiple covariate effects into a single variable. Through simulations of genetic models with two underlying covariate effects, we showed that in 68% of the models, the PS provided the highest power when compared to the inclusion of no, one or both covariates; and in the remaining 32%, the power was extremely low (<0.10) in all situations. The type I error rates increased approximately 20% with each increasing covariate analyzed. We have since examined the independent effects of increasing numbers of underlying covariates and of increasing sample sizes. With each additional covariate analyzed in the multiple covariate models, initial results suggest that the type I error rates continued to increase approximately 20%, with an average inflated type I error rate of 0.129 (0.05 nominal level) for 5 covariates analyzed. For the two-covariate models, increasing the sample size to 1000 families was sufficient to eliminate the inflation of the type I error rates, and with the additional power, the superior performance of the propensity score was then observed. In addition to determining the appropriate sample size for models with more than two underlying covariates, we are studying the statistical properties of the PS by verifying that the distribution of the covariates are similar between affected and unaffected individuals within strata defined by PS values (balancing property of the PS) and by comparing different definitions of pair-specific PS covariate values. These results will help determine the limitations of the PS as applied to covariate-based linkage analysis.

Identity-by-descent (IBD)-based variance component method to detect multiple genetic loci responsible for the complex diseases under a threshold model. A. Narita, A. Tajima, I. Inoue. Division of Genetic Diagnosis, Institute of Medical Science, University of Tokyo.

Many researches have indicated that multiple factors, either genetic or environmental, are involved in complex diseases, and thereby difficulties in the elucidation of the complicated architecture underlying these diseases are easily expected. We developed an effective tool to conduct identity-by-descent (IBD)-based variance component analysis to detect multiple genetic loci responsible for the complex diseases under a threshold model, in which a discrete trait is actually determined by a normally distributed variable, called liability, which depends on multiple genetic and environmental effects ($liability = + G + e$). Since the method uses the IBD matrices in which each element stands for the proportion of IBD alleles shared by two relatives, it can deal with loci with various number of alleles and modes of inheritance, and is not necessary to estimate haplotype frequencies for multiple loci. In addition, loci which have epistatic effects (gene-to-gene interactions) are also able to be taken into account. In the method, by combining the Bayesian approach via the Markov chain Monte Carlo (MCMC) algorithm, variance explained by each locus and its chromosomal location can be estimated simultaneously. Moreover, the reversible jump MCMC algorithm, which is a specialized version of the MCMC algorithm for the determination of the most likely genetic model through iterative additions and deletions of variables and has been hardly used in conventional methods, enables estimation of the number of loci responsible for the diseases as an unknown parameter. Effectiveness and flexibility of the method were demonstrated by using both simulated data and an actual clinical data set. The results indicate that some potential genetic loci, which have an important role in predispositions to these complex diseases but have not been found previously, will be additionally detected.

Variability in QTL Linkage Studies of Cross-Sectional Data. *G. Perez, M. Barmada.* Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA.

Power has been always of key concern in statistical human genetics. In cross-sectional cohorts, additional model parameters and complexities further complicate identification of genetic effects, and so reduce the power of the study. Longitudinal changes in genetic effects and the choice of analytic methodology might also influence the detection of genetic effects. We have undertaken a study to quantify the power of linkage studies of a quantitative trait by using simulated data from the GAW 13 study, which was simulated to resemble a population-based cohort study of cardiovascular disease. Ninety replicates were compared. Within each replicate longitudinal data was averaged to form a single observation, as is commonly done. Fasting glucose was selected as the trait of interest. Covariate effects were identified in one of three ways: (A) using data from founders; (B) using data from all individuals as if they were unrelated samples; or (C) using relationship-adjusted data from all individuals. Finally, residuals of the three methods were used for variance components genome-wide linkage. Differences were found within each replicate such as the number and type of covariates (varying randomly from A and B to C), LOD scores (which increased from A to B to C for values greater than 4), and the location of peak LOD scores (which varied erratically for lower values). A comparison between replicates shows that the selection of covariates varies widely confirming the difficulty of replication of a linkage study. The percentage of baseline genes (those involved in trait variation no matter what the patients age) detected also varied by autosome and position. For instance, for the baseline gene Gb13 (chromosome 9) the effects were detected 28% of the time (expected as our model did not agree with the one used in the study). Of this percentage, 28% of the time by using method A, 42% of the time by method B, and 100% of the time by method C. The highest rate of detection was for slope gene Gs3 (chromosome 5) that was detected 100% of the time (for all methods). By considering the result of the rest of the genes we are aiming at quantifying the loss of information as a way of assessing the accuracy of the current statistical methods.

A novel framework for sib pair linkage analysis. *G.D. Poznik¹, K. Adamska², X. Xu³, A.S. Krolewski¹, J.J. Rogus¹*. 1) Sect Genetics & Epidemiology, Joslin Diabetes Ctr, Boston, MA; 2) Institute of Informatics, Jagiellonian University, Cracow, Poland; 3) Dept Environmental Health, Harvard School of Public Health, Boston, MA.

Sib pair linkage analysis of a dichotomous trait is a popular method for narrowing the search for genes influencing complex diseases. While the pedigree structures are uncomplicated and the underlying genetic principles straightforward, there is a surprising degree of complexity involved in implementing a sib pair study and interpreting the results. Ascertainment may be based on affected, discordant, or unaffected sib pairs, as well as on pairs defined by threshold values for quantitative traits, such as extreme discordant sib pairs. In order to optimize power, various domain restrictions and null hypotheses have been proposed for each of these designs. Permutation of these factors and others yields a vast array of choices for the analyst. To begin, we systematically classify the major sources of discretion in sib pair linkage analysis. Then, we extend the work of Kruglyak and Lander (*Am J Hum Genet* 1995; 57:439-54) to bring the various forms into a unified framework and facilitate a more general approach to the analysis. Finally, we describe a new freely-available computer program, SPLAT (Sib Pair Linkage Analysis Testing), that can perform any sib pair statistical test currently in use, as well as any user-defined test yet to be proposed. In SPLAT, inheritance information is read once and stored in memory, while phenotype definitions can be modified at will, thereby providing an exceptional degree of flexibility for exploratory analysis. The program uses the EM algorithm (subject to user-specified conditions) to calculate maximum likelihood estimates of sharing and then plots the accompanying Lod scores versus chromosomal position. It also includes a novel grid scanning capability in which the entire Lod surface can be graphed for any position. This enables the simultaneous visualization of multiple test statistics, which can effect insight into both phenotype and genetics. The application of SPLAT will be illustrated with data from studies on the genetics of diabetic nephropathy.

Program Nr: 2968 from the 2004 ASHG Annual Meeting

Using moderately discordant sib pair linkage analysis with ordinal diabetic nephropathy scores. *J.J. Rogus, G.D. Poznik, J.H. Warram, A.S. Krolewski.* Sect Genetics & Epidemiology, Joslin Diabetes Ctr, Boston, MA.

Nephropathy is a common complication of diabetes, and genes play an important role in susceptibility. The search for chromosomal regions harboring genes underlying diabetic nephropathy, however, has been complicated by a number of factors. First, mortality is high among those with diabetic nephropathy. Second, the trait is only of interest in the subpopulation of individuals with diabetes. Third, among this subpopulation, the sibling recurrence risk is particularly high (70%) relative to most other common diseases. For all of these reasons, affected sib pair analysis is an unattractive design. These obstacles were overcome with the advent of discordant sib pair analysis (Rogus and Krolewski; *Am J Hum Genet* 1996; 59:1376), which focused on sib pairs concordant for diabetes but discordant for nephropathy. One limitation of this design is its reliance on a dichotomous classification for nephropathy. To bring in additional information including duration and severity, we introduce an adaptation of the moderately discordant sib pair framework proposed by Forrest and Feingold (*Am J Hum Genet* 2000;66:1642). Specifically, we put forth an ordinal scale based on duration (above/below median) and renal status (e.g., normoalbuminuria, low/high microalbuminuria, proteinuria, end-stage renal disease) to move toward a more quantitative phenotype. This ordinal phenotype is then evaluated using both Haseman-Elston regression and allele sharing analysis, and the results are combined using a weighted composite statistic. We illustrate this procedure using data from a 10 cM scan for genes involved in nephropathy in type 2 diabetes (457 individuals with type 2 diabetes from 63 families).

An Alternative Paradigm For Statistical Evaluation of Linkage. *L.J. Strug, S.E. Hodge.* Div Stat Genetics, Dept Psych, Columbia Univ, NYSPI, New York, NY.

The lod score is central to linkage analysis and is traditionally translated into standard statistical terms such as p-values, -levels and power. However, an alternative statistical paradigm works directly with the lod or likelihood ratio (LR) (Royall, 1997, 2000), thus potentially resolving difficult issues of linkage criteria, multiple tests and low power. We applied this approach to linkage studies of a fully penetrant trait for: I. Fully informative gametes, II. Phase-unknown sib pairs, III. Nuclear families. The paradigm defines three types of evidence (whose probabilities sum to 1): strong (S), misleading (M), or weak (W), depending, respectively, on whether the observed LR exceeds k in the "right" direction, exceeds k in the "wrong" direction, or falls in between (k is a constant, e.g., 1000, corresponding to lod3.0). We calculated probabilities, $P[S]$, $P[M]$, and $P[W]$, exactly for situations I and II and via simulation for III, under no linkage and under linkage at recombination fraction $R=.01, .05, .1, .2, .3$; $k=8, 20, 32, 100, 1000$; and sample sizes $n=10, 20, \dots, 100$. $P[M]$ is analogous to type I error but has a natural upper bound ($1/k$) unrelated to R and n . The table shows $P[M]$ and $P[W]$, respectively, for situation III, for a dominant trait, testing $R=0.5$ vs. $R=0.1$. ($P[S]$, which we want to maximize, equals $1-P[M]-P[W]$.)

True R=0.5	n=10	n=20	n=30	True R=0.1	n=10	n=20	n=30
k=20	.006,.159	.003,.020	.000,.003	k=20	.004,.167	.000,.032	.000,.003
k=1000	.000,.554	.000,.113	.000,.019	k=1000	.000,.522	.000,.112	.000,.020

$P[M]$ remained small in all 3 situations (well below $1/k$). Larger k leads to lower $P[M]$ and $P[S]$ but higher $P[W]$. But as n increases, $P[W]$ and $P[M]$ converge to zero. The probability of concluding a false hypothesis is small for all n and gets smaller as n increases; thus, increasing n can adjust $P[M]$ for multiple tests. By controlling $P[W]$ with n , one can directly control the probability to detect correct linkage signals at any k .

Summarizing individual-level covariate information for covariate statistics for affected sib pair (ASP) linkage analysis. *H.-J. Tsai*^{1,2}, *D.E. Weeks*^{3,4}. 1) Lung Biology Center, San Francisco General Hospital, San Francisco, CA; 2) University of California, San Francisco, CA; 3) Human Genetics, University of Pittsburgh, Pittsburgh, PA; 4) Biostatistics, University of Pittsburgh, Pittsburgh, PA.

Genetic heterogeneity must be taken into account when geneticists search for disease genes in complex traits. Several statistical methods have been suggested for dealing with this issue by incorporating covariate information into ASP analysis. We have simulated three types of gene-environment (G x E) interaction models. We have evaluated the following covariate statistics: 1. mixture model (Devlin et al. 2002); 2. general conditional-logistic model-LODPAL (Olson 1999); 3. multinomial logistic regression-MLRM (Greenwood and Bull 1999); 4. maximum-likelihood-binomial approach-using Pearson's logistic regression residuals (Alcaï's and Abel 2001); 5. ordered subset analysis-OSA (Hauser et al. 2004); and 6. logistic regression for predicting IBD sharing probabilities-COVLINK (Saccone et al. 2001). Based on our findings, the mixture model and the OSA method perform the best of the covariate statistics when using a covariate with a G x E interaction effect.

We typically summarize individual-level covariate information by computing the mean covariate values across either the affected sib pairs or the whole family. However, it is not clear that taking the average is the best way to summarize individual-level covariate information. It is important to investigate what is the best summary for covariate information. Therefore, we applied the above covariate methods using alternative measures: taking difference of covariate values, summing the covariate values, using maximum covariate value, or using minimum covariate value. In our 8 disease models, covariate methods perform the worst when using the difference of covariate values. Individually, the mixture model is sensitive to various covariate measures and performs the best when using minimum covariate value. LODPAL has higher power when summing the covariate values. MLRM and OSA are robust to alternative covariate measures.

Recursive Partitioning Models for Affected Relative Pairs Linkage Analysis: Detecting Gene-Environment Interactions for Bipolar Disorder. *W. Xu*^{1,2}, *T. Schulze*³, *R. DePaulo*⁴, *F. McMahon*⁵, *C. Greenwood*^{1,2}. 1) University of Toronto, Canada; 2) Hospital for Sick Children, Canada; 3) Psychiatry Central Institute of Mental Health, Mannheim, GERMANY; 4) Johns Hopkins University, Baltimore; 5) National Institute of Mental Health, National Institutes of Health, Bethesda.

The interplay of environmental and genetic factors makes it difficult to distinguish the genetic effects from the background noise in phenotype variation. Here we present a novel approach that uses a recursive partitioning (RP) algorithm to search for covariates that influence linkage evidence. This method can be thought of as a data-mining approach for detecting gene-environment interactions for complex diseases. Standard concepts in RP models are modified to define the criteria for splitting as a function of the total likelihood ratio statistic for linkage in affected relative pairs across the covariate-defined subgroups. The model unifies the expressions for different types of relative pairs by using the same relative risk parameters for all relative types. The algorithm recursively splits each subgroup on pair-level covariates and cross-validation is used to choose the best tree-size at each marker. A bootstrap method is then used to get the best posterior tree-structure according to the chosen tree-size and to provide the final tree-structure for each marker. We applied this algorithm on data of 58 families from the Johns Hopkins/Dana bipolar pedigrees, for which linkage to chr. 18 has previously been reported. In this data set, we identified three suggested regions where covariates defined subgroups with stronger evidence for linkage than a standard linkage analysis. For some chromosomal locations, evidence of linkage was detected only when covariates were included. Covariates that showed strong interactions with genotype were age at onset, suicidal behavior, and alcohol/substance abuse. RP models may be a valuable tool to unveil gene-environment interactions. RP models can make use of different kind of relative pairs and a multitude of phenotypic variables at the same time.

Program Nr: 2972 from the 2004 ASHG Annual Meeting

A likelihood ratio approach to family-based association and linkage studies with covariates. *M.F. Baksh, J. Whittaker, D. Balding, T. Vyse.* Faculty of Medicine, Imperial College London, United Kingdom.

We describe a procedure for analyzing genetic association and linkage using nuclear families that allows for dichotomous and more general measurements of phenotype and inclusion of covariate information. Standard generalized linear models are used to relate phenotype and its predictors. Our test procedure, based on the likelihood ratio, yields maximum likelihood estimates of the genetic relative risk and interaction parameters and it can be applied to complex scenarios, as for instance when multiple genes are involved. Our approach is compared with recently proposed conditional score tests that include covariate information in the underlying penetrance model and is shown to have advantages in coping with the baseline genotype risk, covariate and gene-covariate interaction parameters in the model. We apply our method in a study of human systemic lupus erythematosus and the C-reactive protein gene that includes sex and ethnicity together with interactions between these variables and the candidate locus.

Localization of linked genes for type 1 diabetes: A simultaneous search for two genes. *J.M. Biernacka*^{1,2}, *L. Sun*^{1,3}, *S.B. Bull*^{1,2}. 1) Department of Public Health Sciences, University of Toronto, Toronto, Canada; 2) Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, Canada; 3) The Hospital for Sick Children, Toronto, Canada.

Methods that consider multiple susceptibility genes may increase the accuracy and precision of location estimates for disease genes involved in the predisposition to complex disorders, such as type 1 diabetes. When two genes contributing to one trait are located near one another on the same chromosome, effects of both genes must be taken into account when assessing linkage evidence for one of them. Conditional methods are designed to localize a second disease gene locus and assess evidence of linkage to it, accounting for the effect of a pre-specified first gene locus (Farrall, 1997, *Genet Epidemiol* 14:103-115; Cordell et al., 2000, *Am J Hum Genet* 66:1273-1286), whereas simultaneous methods localize two putative disease gene loci at the same time (Biernacka et al., 2003, *Am J Hum Genet* 75(5S):193). The method of Biernacka et al. (2003) applies a generalized estimating equations approach to model IBD sharing data with multiple linked markers from ASPs. Confidence intervals for gene locations can be constructed based on large sample approximations, and test statistics can be calculated for evaluating evidence for two versus one disease genes in a single region (Biernacka and Bull, 2003, *Genet Epidemiol* 25(3):239). Here we apply these methods to data from a genome scan for type 1 diabetes (Mein et al., *Nature Genetics* 19: 297-300, 1998). We estimate the locations of two putative disease genes on chromosome 6, found to be approximately 20 cM apart. Our location estimates are similar to those obtained by applying a conditional approach to the same data (Cordell et al., 2000) partially because, in this case, the effect size of the first gene is predominantly larger than that of the second one. Our simulation studies of the GEE models indicate, however, that simultaneous estimation of two linked gene locations can yield more precise localization than estimating one location at a time.

Program Nr: 2974 from the 2004 ASHG Annual Meeting

A classification method for pharmacogenetic surveillance. *C.E. Bowman.* Genetic Data Sciences, GlaxoSmithKline, Greenford, United Kingdom.

Using the practice of taxonomy as a model, a simple, sensitive, empirical diagnostic likelihood ratio-based framework is presented for the routine monitoring and detection of pharmacogenetic correlates of adverse events in pharmacovigilance. The supervised, sequential, multi-point, relative risk based classification method estimates and visualises the average objective positive evidence a reported individual gives in classifying adverse event cases as genetically different from controls. A bootstrap procedure is used to define a frequentist rule for stopping the collection of more cases. An example is given of its screening use against strong or weak signals comprised of binary patterns of large numbers of un-ordered single nucleotide polymorphisms (a high dimensional SNP profile) in real case control clinical pharmacogenetic data. Evidence for a possible genetic correlate of an adverse event may be apparent from the second case arriving. Counter-intuitively, only modest numbers of cases (less than 20) are needed, in the example used where a difference is present, to stop collection and claim such a correlate is worth investigating.

Quality check of the genealogical information in isolated populations using genetic data. *M. Ciullo¹, C. Bourgain², V. Colonna¹, A.L. Leutenegger², T. Natile¹, M.G. Persico¹.* 1) Institute of Genetics and Biophysics A. Buzzati Traverso, CNR, Naples, Italy; 2) INSERM U535, Villejuif, France.

Large pedigrees are a major advantage of isolated populations for complex trait mapping. This, in return, implies that quality of the genealogical information is a key issue for the success of these studies. However, classical approaches to validate simple relationships using genetic data are not adapted to the situation where individuals are related through multiple lines of descents. Furthermore, whereas only pairs of relatives may be informative to check the quality of the genealogy in outbred samples, inbred individuals alone may be informative. We have undertaken the genetic study of Campora population, an isolated village from the Cilento area of South Italy which dates back to the 17th century. The genealogy of the population has been carefully reconstructed using local church and town records allowing the identification of a 10,431-individual pedigree, spanning over 17 generations, and connecting all 1400 living individuals. A sample of 371 individuals, connected through a 2283-individual pedigree and with a mean inbreeding of 0.0058, has been genome screened with a 1094- microsatellite map (average marker distance : 3.4 cM, genotyping success rate : 89.6%). After classical checking for mendelian inconsistencies, we used two complementary approaches to evaluate the quality of our genealogical data. The EIBD approach proposed by Sun et al (2001) compares the pedigree-based kinship coefficient of a pair with its conditional expectation given the genetic data computed using both pedigree and genetic information. The method of Leutenegger et al (2003) only uses genetic data to estimate the inbreeding coefficient of an individual that may then be compared to its pedigree-based value. We present the results for each method and study their respective contribution in testing the accuracy of the Campora genealogy.

A locus on chromosome 13 for efficiency of real-word reading reveals complexities in ascertainment and genetic model selection. *R.P. Igo, N.H. Chapman, J.B. Thomson, M. Matsushita, Z. Brkanac, T. Holzman, M. Brown, V.W. Berninger, W.H. Raskind, E.M. Wijsman.* University of Washington, Seattle, WA.

Dyslexia is characterized by unexpected difficulty in learning to read. It has a strong genetic component but a complex mode of inheritance, with any of several specific cognitive deficits contributing to the disorder. Impairment in the efficiency and accuracy of reading single real words (word recognition, WR) is a strong predictor for dyslexia. We performed a whole-genome scan for two quantitative measures of WR: real-word reading efficiency (RWRE) and word identification (WID), which measure accuracy and speed, and accuracy alone, respectively. We describe a linkage signal on chr. 13 primarily involved in the efficiency of WR. We used variance components (VC) linkage analysis (LA), Markov chain Monte Carlo joint segregation and LA (MCMC), and parametric lod scores (pLOD) to assess linkage with a genome scan and phenotypes for 51 extended pedigrees ($n = 438$), plus only phenotypes on 57 additional pedigrees ($n = 436$). The measure of linkage for MCMC is the intensity ratio (IR), an estimate of the ratio of the posterior to prior probability of linkage. We obtained on chr. 13 two-point and multipoint VC lod scores for RWRE of 2.59 and 2.29, respectively, and an MCMC IR of 53.2. Adjusting RWRE for WID reduced but did not abolish the signal. We then obtained genetic models for RWRE, adjusted for age, sex and verbal IQ, by complex segregation analysis (CSA) and by MCMC. Using data from 108 families, the model obtained from MCMC yielded a greater max. pLOD (2.81) than did the model from CSA (2.19). The pLOD dropped when 127 additional families, ascertained under slightly different criteria, were included in segregation analyses (1.94 and 1.18 from MCMC and CSA, respectively). We attributed the differences in pLOD to differences in the ability to distinguish the heterozygous trait genotype from the major homozygote and to differences in the minor allele frequency. These comparisons show the importance of consistent criteria for ascertainment of pedigrees, and care in generating models by segregation analysis, in interpreting results from linkage studies. Supported by NIH HD33812.

Improved haplotype inference in case-control studies using genotype data. *L.C. Kwee*¹, *G.A. Satten*², *M.P. Epstein*³.
1) Dept of Biostatistics, Emory Univ, Atlanta, GA; 2) Centers for Disease Control and Prevention, Atlanta, GA; 3) Dept of Human Genetics, Emory Univ, Atlanta, GA.

Genetic association studies often use a case-control study design due to the ease of sample collection. Statistical methods that utilize prospective likelihoods for analyzing retrospective genetic data may suffer from a loss of statistical efficiency in certain situations, so it is of interest to use retrospective likelihoods when feasible. For haplotype analysis of case-control genotype data, Epstein and Satten (2003) proposed a retrospective likelihood approach that allowed for testing of both global and specific haplotype effects on disease. In Satten and Epstein (in press), they showed that their retrospective approach had optimal power for detecting haplotype-disease association relative to related prospective approaches. In the current work, we extend this powerful retrospective approach to allow for covariates, which permits us to model and test main environmental effects as well as gene-environment interaction effects. In order to accommodate the existence of ambiguous haplotypes in the genotype data, we apply a variant of the EM algorithm for proper inference. The power of this modified approach is compared to that of the prospective haplotype approach of Schaid *et al.* (2002). We also will apply our new method to case-control data from the Finland-United States Investigation of NIDDM (FUSION) genetic study.

Program Nr: 2978 from the 2004 ASHG Annual Meeting

Strategies for uncovering the genetic basis of complex diseases. *J. Marchini*¹, *P. Donnelly*¹, *L. Cardon*². 1) Dept Statistics, Oxford Univ, Oxford, United Kingdom; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford OX3 7BN, UK.

After nearly 10 years of intense academic and commercial research effort powerful genome-wide association studies are on the brink of reality. It is thus timely to discuss the fine details of study design and the relative merits of competing statistical techniques. The genetic basis of many complex diseases is likely to consist of interactions between unlinked loci. We have investigated strategies aimed at identifying the loci involved in such diseases within a genome-wide association framework. Specifically, we chose a set of realistic two locus models, fix their marginal effects at realistic levels and contrast a strategy that searches locus-by-locus against strategies that search more explicitly for interactions between pairs of loci. Very surprisingly, we find that direct interaction searches are more powerful than locus-by-locus strategies and are computationally tractable. These results should help to inform the design and analysis of genome-wide association studies. In addition, we provide a quantitative investigation of the assertion that allele frequency differences due to population structure provide a potential explanation for the lack of replication of some association studies.

Chip and cheerful? : The QTL problem of large sample sizes and large numbers of SNPs. *E. Meaburn, L. Butcher, L. Liu, C. Fernandes, R. Plomin, I. Craig, L. Schalkwyk.* SGDP, Institute of Psychiatry, London, UK.

The genetic influence found on complex traits is likely to be due to quantitative trait loci (QTLs) of small effect size. To detect QTL associations, large samples and systematic screens of thousands of DNA markers are needed, which is prohibitive in terms of time and cost. A solution is to genotype case and control DNA pools using SNP microarrays. We demonstrate that this is practical using pools of DNA from 100 individuals and the Affymetrix GeneChip Mapping 10K Array Xba 131. We constructed a control DNA pool independently three times, and assayed each on triplicate GeneChips. Each GeneChip gives two quasi-independent values for each SNP; RAS 1 & RAS 2. The average RAS was obtained for 108 SNPs located on the chip, and used to derive allele frequency estimates for the pooled DNA. These were compared to SNP allele frequencies determined by the individual genotyping of an independent Caucasian sample available from NetAffx Analysis Centre, and were found to correlate highly (0.901). They were also compared to SNP allele frequencies determined by genotyping of the 100 individuals used to construct the pool, and correlate even higher (0.94). This result indicates that RAS values can be used to provide valid quantitative measures of allele frequencies in pooled DNA. The correlations of RAS values within pool triplicates are very high (0.968 to 0.945; mean difference 0.059), as are correlations between pools (0.94 to 0.982; 0.058). 92.3% of the RAS values have a standard deviation 0.1, and 51.3% have a standard deviation 0.05. Using nine replicate chips per group would provide 98% power ($P=0.05$) to detect differences of 0.1. In addition we successfully tested the detection of allele frequency differences using reconstructed case pools spiked with 5, 10, 15 and 20% of the DNA of one genotyped individual. This innovative approach is rapid, cost effective, and accurate enough to screen the genome systematically in association studies of case and control DNA pools in order to nominate candidate QTLs for further study. We are currently applying the technique in two independent studies of Reading Disability & Mild Mental Impairment.

Confirmation of Linkage to a Genetic Susceptibility Locus on Chromosome 1 for Speech Sound Disorder and Language Impairment. *L.E. Sucheston¹, C.M. Stein¹, H.G. Taylor², L.D. Shriberg³, A. Kluge¹, C. Millard¹, K. Russo¹, N. Minich¹, A. Hansen², L.A. Freebairn², R.C. Elston¹, B.A. Lewis², S.K. Iyengar¹.* 1) Epidemiology and Biostatistics, Case Western Reserve Univ., Cleveland, OH; 2) Dept. of Pediatrics, Rainbow Babies & Childrens Hospital, Case Western Reserve Univ., Cleveland, OH; 3) Waisman Center on Mental Retardation & Human Development, University of Wisconsin-Madison, Madison, WI.

Despite the high prevalence of Speech Sound Disorder (SSD), not attributable to congenital malformations or developmental delay, the etiology has not been elucidated, although there is evidence from our previous work that dyslexia and SSD share genetic determinants (Stein et al. 2004). Specifically, dyslexia and language impairment (LI) have been shown to cosegregate in children with SSD, therefore we propose that other loci identified for dyslexia would also show linkage to SSD and LI. To test this hypothesis we examined the chromosome 1p34-36 region that was previously linked to dyslexia, specifically to single-word and phonological decoding (Grigorenko et al. 2001) and to spelling (Tzenova et al. 2004). We analyzed 10 markers spanning 78cM on chromosome 1, from D1S468 (4 cM pter) in 256 families with 367 sib pairs ascertained through a child with SSD. Using model-free linkage analysis we examined SSD, LI and Reading phenotypes. Parent-offspring allele transmission ($p=.03$) and affected sibling allele sharing ($p=.01$) for LI differed significantly from expectation at D1S199 and SSD affected IBD sharing showed significance proximal to D1S199 ($p<.03$). Using Haseman Elston regression, affection for SSD ($p=.02$) and LI ($p=.03$) showed linkage signals, as did quantitative measures of vocabulary (EOWPVT, $p=.015$; PPVT, $p=.03$), verbal short term memory (SI, $p=.01$), and word decoding (WRID, $p=.04$). Our data are the first to show that regions initially linked to dyslexia predispose to broader cognitive deficits including SSD and LI, suggesting that some segments of these disorders may be part of a broader continuum and serve to provide evidence for SSD susceptibility loci at 1p34-36.

Genetic Epidemiologic study of metabolic syndrome in a Chinese population. *Y. Feng¹, X. Hong², T. Zang², G. Tang², Z. Li², B. Wang¹, F. Hu³, L.J. Wei⁴, X. Xu^{1,2}, X. Xu¹.* 1) Prog Population Genetics, Harvard Sch Public Health, Boston, MA;; 2) Anhui Medical Univ. Institute of Medicine, Anhui, China;; 3) Nutrition Department, HSPH, Boston, MA;; 4) Biostatistic Department, HSPH, Boston, MA.

Metabolic syndrome (MS), a cluster of abdominal obesity, dyslipidemia, hyperinsulinemia, hyperglycemia and hypertension, is an important risk factor for cardiovascular disease. We have been conducting a large genetic epidemiologic study of MS in a rural community in Anhui, China since February 2004, with the ultimate goal of understanding the phenotypic structure of MS and both environmental risk factors and genetic components of MS. We'll screen 10,000 sibling pairs aged 40-64 years on traits related to MS, including BMI, fat mass, blood pressure, serum lipids, fasting plasma glucose and insulin. Meanwhile, information on lifestyle, diet intake, physical activity, and disease history are collected through a questionnaire. So far, we have enrolled a total of 5052 subjects aged 46.5+/-7.4 years from 1482 nuclear families. Preliminary analysis on the available data indicates the profiles of MS traits in this population differ significantly from that in US. The study population was quite lean with a mean BMI of 21.8 kg/m². According to Chinese criteria, 15.3% subjects were overweight ($24 \leq \text{BMI} < 28$) and 2.4% were obese ($\text{BMI} \geq 28$) in this population. By using the ATP-III criteria, the prevalence of MS was 7.9% in the study population, with a higher prevalence in women (10.6%) than in men (4.5%). The prevalence of individual component of MS was 0.3% of men and 4.3% of women with abdominal obesity; 14.3% of men and 23.4% of women with high triglyceride; 20.3% of men and 57.8% of women with low HDL; 35.9% of men and 27.4% of women with elevated blood pressure; and 8.9% of men and 10.6% of women with hyperglycemia, respectively. Our study suggests ATP-III is not appropriate as diagnosis criteria in the study population, and establishment of population specific criteria is warranted. When complete data is available in the near future, we will perform factor analysis to understand the structure of MS phenotypes in this population.

Impact of preferential mistyping of SNP heterozygotes on power to detect genetic association. *K.N. Conneely¹, P.S. Chines², M.R. Erdos², M. Boehnke¹*. 1) Dept. Biostatistics, U. Michigan, Ann Arbor, MI; 2) NHGRI, NIH, Bethesda, MD.

Low signal in one or both alleles in heterozygotes is a common source of genotyping error in SNPs. Homozygous genotypes are read as a single peak with a stronger signal and usually do not have this problem. In a sample of ~500,000 raw genotypes on 522 SNPs from the Sequenom Biomass genotyping system in the FUSION study that were ultimately resolved with confidence, 2% of heterozygotes were initially mistyped as homozygotes, while only 0.2% of homozygotes were mistyped. Mistyping is not evenly distributed. Of the mistyped heterozygotes, 83% were from plates that had >20% of heterozygotes mistyped. Heterozygotes are also more likely to be lost due to bad assays. 13% of initial assays of heterozygotes were inconclusive due to bad spectra or low probability calls compared to 10% of assays of homozygotes. We explore the impact of preferential mistyping of heterozygotes on the validity and power of association tests. The commonly used 2x2 test of equal allele frequencies between cases and controls is only a valid ² test under Hardy-Weinberg equilibrium (HWE). Under systematic mistyping of heterozygotes as homozygotes, this test is generally biased in favor of rejection, particularly for low allele frequencies. However, the test remains valid if heterozygotes are mistyped as either homozygote with equal probability. Random loss of heterozygotes from the sample also biases the 2x2 test in favor of rejection, especially for allele frequencies ~.5. The 2x3 test of equal genotype frequencies between cases and controls is robust to deviations from HWE. When heterozygotes are lost or mistyped, the 2x3 test loses power but remains a valid test. To ensure test validity and avoid loss of power due to genotyping error, it is common practice to retype plates for SNPs that deviate significantly from HWE, and those with substantial missing data. We are using our replicate genotype data to estimate the impact of redoing these assays and to build a model to determine when the cost of retyping is justified by the gains to validity and power. We also are assessing when statistical imputation of missing data based on linkage disequilibrium can eliminate the need for retyping.

Program Nr: 2983 from the 2004 ASHG Annual Meeting

The RPM: A method for testing candidate QTL for epistatic interactions. *R. Culverhouse, T. Klein, W. Shannon.*
Washington Univ School of Medicine, St. Louis, MO.

Epistatic interactions play an important role in complex diseases: a few loci with little or no single-locus effects can nonetheless control phenotype to a large degree. The Restricted Partition Method (RPM) is an algorithm for examining multi-locus genotypes as predictors of quantitative traits in unrelated individuals. Tests in simulated and real data show that the RPM can provide an efficient way to identify loci contributing epistatically to a quantitative trait, even if the loci have no single locus effects (i.e. purely epistatic models). The RPM can also be used to detect gene-environment interactions.

Our earlier work showed that the RPM can identify contributing loci from purely epistatic 2-locus models when the allele frequencies for the contributing and null loci are all 0.5. Our current simulations applying the RPM to more complex models verified three important properties of the RPM: (1) the RPM is robust to variations in allele frequencies at both the contributing loci and at null candidate loci, (2) the RPM is computationally feasible and has good statistical power for the analysis of 3-locus models, and (3) two-locus analyses of 3-locus models can have good power to identify contributing loci.

In an application of the RPM, a 2-locus analysis of leukemia data identified an interaction between genes GSTP and UGT1A1 in Caucasians explaining 29% of the variation in etoposide (a chemotherapy agent) area under the concentration vs. time curve ($p=0.036$) and an interaction between GSTP and sex in African Americans explaining 62% of the variation in etoposide clearance ($p=0.018$). None of these covariates were significant univariate predictors of trait variation.

Conclusion: The RPM is robust under variations in allele frequencies (e.g. good power, nominal false positive rates), practical for examining 2-way and 3-way interactions, and performs as expected in real data.

Power comparison of the Regression of Offspring on Mid-Parent (ROMP) method and Quantitative trait Transmission - Disequilibrium Tests (QTDT). *M.-H. Roy-Gagnon, R.A. Mathias, A.F. Wilson.* Genometrics Section, IDRB, NHGRI, NIH, Baltimore, MD.

The Regression of Offspring on Mid-Parent (ROMP) method is an extension of the linear regression of offspring on mid-parent traditionally used to estimate the heritability of a quantitative trait. ROMP also provides a test of association between the trait and a marker locus and an estimate of the heritability attributable to that locus. ROMP requires parent-offspring trios with phenotype data on both parents and offspring but genotype data on the offspring only. Transmission Disequilibrium Tests for quantitative traits (QTDT) require genotype data on both parents and offspring. Depending on the feasibility and cost of phenotyping compared to genotyping, ROMP may provide an efficient and cost effective alternative to QTDT. The goal of this study was to perform simulation experiments to compare the power of ROMP to that of QTDT.

ROMP was compared to two QTDT statistics implemented in the QTDT software: Allison's TDTQ5 and the orthogonal model of Abecasis et al. (2000). Power at the 5% significance level was estimated from 2000 simulated samples of 200 parent-offspring trios with complete phenotype and genotype data. The trait was determined in part by up to 3 biallelic loci with locus-specific heritabilities ranging from 5 to 30%. Simulations were also performed for a trait under no genetic control to investigate type I error rates. The allele responsible for an increase in the trait value had a frequency of 0.3, yielding an average of 132 trios with informative genotypes for QTDT analysis. The 200 trios were informative for ROMP but the ROMP analysis was performed only on 132 trios selected at random to obtain equal sample size on average for the two methods. Estimated type I error rates were close to the 5% nominal value for both methods. For a locus-specific heritability of 5%, the estimated power of ROMP was close to 70% on average while the power of QTDT was 62%. Both methods had over 90% power to detect locus-specific heritabilities of 10% or greater. Overall, the estimated power of ROMP was similar to, or higher than that of QTDT.

A Genotype-based Transmission/Disequilibrium Test for Tightly Linked Markers. *T. Wang, Q. Qing, R.C. Elston.*
Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH.

The transmission/disequilibrium test (TDT), which can be robust to population stratification, is a popular method to detect disease liability alleles on the basis of family data. Because only the families in which at least one parent is heterozygous are informative for transmission, in most cases extended marker haplotypes are more informative than single markers. However, there is a trade off when choosing between extended marker haplotypes and single markers: the number of degrees of freedom of the test versus the information about transmission. The degrees of freedom of a TDT test based on haplotypes increase rapidly with the number of markers and therefore may reduce the power of the test. Furthermore, the haplotypes of parents may be ambiguous and, in general, the proportion of families with ambiguous haplotypes increases with the number of markers. To avoid loss of information because of ambiguous families, the haplotypes have to be reconstructed probabilistically based on statistical inference. The potential gain in efficiency from using haplotype inference is still debatable. Here, we develop a TDT-type statistic, called gd-TDT, for tightly linked markers based on the relationship between a trait and genotype distance. The genotype distance carries information about each marker and the pair-wise linkage disequilibrium among markers. The degrees of freedom of this statistic increases only linearly with the number of markers. It is not necessary to infer haplotypes in order to calculate our statistic. The statistic can be used for nuclear pedigrees of any size, and for both quantitative and discrete traits. The performance of the gd-TDT, in terms of type I error rate and power, is examined by computer simulations.

Twin and Sibling Pair Designs for Genetic Association Studies. *J. Wessel*^{1, 2, 3}, *A.J. Schork*⁴, *N.J. Schork*¹. 1) Polymorphism Research Laboratory, Department of Psychiatry, UC, San Diego, La Jolla, CA; 2) Department of Family and Preventive Medicine, UC, San Diego, La Jolla, CA; 3) School of Public Health, San Diego State University, San Diego, CA; 4) Undergraduate Studies Program, University of California at Santa Barbara, Santa Barbara, CA.

Twins have a long and illustrious history in human genetics research; for example, exploring evidence for the overall influence of genetic factors on a trait and disease. In addition, requisite statistical analysis tools for assessing heritability and related issues have been steadily improved over the years to the point that there is no shortage of methodology a researcher can choose from. However, one area where twin analyses have not received much attention involves genetic association studies. We consider novel twin and sibling pair-based study designs for dissecting the genetic basis of quantitative traits, derive formulae for computing power, discuss computer programs for assessing these equations, and showcase the utility of our derivations on a few select study settings. The increase in power can be substantial in certain settings. In general, a smaller sample of unrelated individuals is needed compared to twins. However, it can be shown that due to the correlations that exist between monozygotic and dizygotic twin pairs, well-designed studies using samples of genotypically discordant twins investigating the impact of allelic variation at a particular polymorphic locus on a quantitative trait are more powerful than samples of unrelated individuals taken from the general population. Furthermore, DZs with opposite genotypes can substantially decrease the required sample size, particularly when DZs are sampled in equal genotype proportions. Our results are easily extended to non-twin siblings. The fact that well designed twin studies can reduce association study sample sizes combined with the fact that one can use twins to simultaneously evaluate the effects of polymorphic loci, effects of loci merely linked to a marker locus, gross polygenic background effects, and measured and unmeasured environmental covariate effects, makes the use of twins for association studies particularly flexible and compelling.

Program Nr: 2987 from the 2004 ASHG Annual Meeting

A sequential method on case-control study. *W. Yang*¹, *N. Kamatani*². 1) Genome Diversity Team, JBIRC, Tokyo, Japan; 2) Institute of Rheumatology, Tokyo Women's Medical University, Tokyo, Japan.

From an experimental point of view, one may wish to avoid unnecessary experimentation. Sequential analysis of quantitative data has never found wide application in practice, even though considering its use might be worthwhile. In the present study we propose, "sequential method", in which the sample size is not fixed in advance. We focus on the case of cohort case-control study that evaluate the lower and upper bound of the sample size based on the significant level and the power of test. Hypothesis testing in sequential method usually relates to testing for the numerical value of some unknown parameter, so we discuss it on case-control observations that the minimal sample size for detecting a true difference between case and control observations. We compare the effect of sequential method with the results of a non-sequential analysis.

Linkage Disequilibrium Mapping by the Decay of Haplotype Sharing with Samples of Related Individuals. *J. Zhang*¹, *D. Schneider*², *C. Ober*², *M.S. McPeck*^{1,2}. 1) Dept of Statistics, Univ of Chicago, Chicago, IL; 2) Dept of Human Genetics, Univ of Chicago, Chicago, IL.

We consider the problem of linkage disequilibrium mapping of a susceptibility locus for a complex trait from samples of related individuals. We work within the decay of haplotype sharing framework proposed by McPeck and Strahs (1999). For populations with dependent recombinational histories, we take a more flexible model than the conditional coalescence they considered by allowing for varying conditional correlation coefficients of ancestral-segment sharing for pairs of haplotypes in the sample. We describe how the conditional correlations can be calculated via a recursive algorithm in the case of a known 13-generation, 1623-member Hutterite pedigree. From the conditional correlations and a general estimating equation based on the marginal score functions, we obtain an approximated log-likelihood of the sample, which can be used for mapping purposes. We also make the extension of our method to trio genotype data using a hidden Markov chain formulation. The method is studied in simulated data on the basis of the Hutterite pedigree and we apply it to the problem of mapping a susceptibility locus for bronchial hyperresponsiveness (BHR) in the Hutterites. Reference: McPeck, M.S. and Strahs, A. (1999) Assessment of Linkage Disequilibrium by the Decay of Haplotype Sharing, with Application to Fine-scale Genetic Mapping. *Am. J. Hum. genet.* 65:858-875. Program Nr: 2989 from the 2004 ASHG Annual Meeting

Linkage Disequilibrium Mapping Using Block Haplotype Structure. *M. Zheng, M.S. McPeck.* Department of Statistics, University of Chicago, Chicago, IL.

We are interested in LD mapping using high-resolution haplotype block structure. For complete haplotype data, we can calculate a profile likelihood for each SNP or haplotype block and a confidence set can be constructed based on this profile likelihood. For (unphased) genotype data, the profile likelihood will not have the simple form that depends only on the data at the locus considered. Instead, a parsimonious model for background LD that actually fit for the data will be required. We tried to model the background LD by a class of Markov models where the time index is each block instead of each SNP. A parametric bootstrap method is used to assess the significance of the goodness of fit to our background LD models. We found that the traditional parametric bootstrap method to assess the goodness of fit of models does not have the right type I error in our case, where we have multinomial-type models with many cells having very low probabilities and only a moderate sample size. Error model were introduced to model the similarities between different haplotypes and to get the right type I error. We applied our method to Daly et al (2001) dataset where our confidence set covered the causal SNPs which were suggested in Rioux et al (2001). This work is supported by NIH grants HG001645 and DK55889.

Large-scale single-nucleotide polymorphism (SNP) and haplotype analyses of 199 drug-related genes in 752 subjects: Majority of uncommon SNPs within haplotype blocks were assigned to single haplotypes constructed with haplotype-tagging SNPs. *N. Kamatani¹, A. Sekine², T. Kitamoto², A. Iida², S. Saito², A. Kogame¹, E. Inoue¹, M. Kawamoto¹, M. Harigai¹, Y. Nakamura².* 1) Division of Genomic Medicine, Department of Advanced Biomedical Engineering and Science, Institute of Rheumatology, Tokyo Women's Medical University, Tokyo, Japan; 2) Laboratory of Genotyping, RIKEN SNP Research Center, Riken Yokohama Institute, Yokohama, Japan.

We extensively analyzed single-nucleotide polymorphisms (SNPs) and haplotypes in 199 drug-related genes using 4,190 SNPs in 752 control subjects to optimize the strategies for population-based pharmacogenetic studies. Drug-related genes, like other genes, have a haplotype-block structure, and a few haplotype-tagging SNPs (htSNPs) could represent most of the major haplotypes constructed with common SNPs in a block. Based on such data, we analyzed the relationship between haplotypes and uncommon (minor allele frequency 0.1) SNPs within the blocks (549 SNPs). We inferred haplotype frequencies using the data from all htSNPs and one of the uncommon SNPs within a block and calculated four joint probabilities concerning the haplotypes. We show that, irrespective of the minor allele frequency of an uncommon SNP, the majority (mean SD, 0.943 0.117) of the minor alleles were assigned to a single haplotype tagged by htSNPs if the uncommon SNP was within the block. These results support the hypothesis that recombinations occur only infrequently within blocks. The proportion of a single haplotype tagged by htSNPs to which the minor alleles of an uncommon SNP were assigned was positively correlated with the minor allele frequency when it was 0.03 (P 0.000001). The results of simulation studies suggested that haplotype analysis using htSNPs may be useful in the detection of uncommon SNPs associated with phenotypes if the frequencies of the SNPs are higher in affected than in control populations, the SNPs are within the blocks, and the frequencies of the SNPs are 0.03.

Use of recursive partitioning to identify genetic marker combinations associated with adverse events. *M. Mosteller, D. Zaykin, L. Warren, D. Yarnall, W. Spreen, T. Scott, A. Nelsen, K. Nangle, E. Lai, J. Hernandez, S. Haneline, A. Gatherum, K. Davies, A. Hughes.* GlaxoSmithKline, RTP, NC.

Abacavir (ABC) is an effective antiretroviral drug used to treat HIV-1 infection. Approximately 5% of patients treated with ABC develop a hypersensitivity reaction (HSR) that in rare cases has proved fatal. The ABC clinical risk management program has been successful in reducing serious outcomes due to ABC HSR. Performance characteristics for a prognostic ABC HSR marker set must be extremely high in order to improve upon clinical management; over-reliance on prognostic markers for ABC HSR could lead to reduced clinical vigilance and more serious outcomes for patients who do not carry the predictive markers. Thirty-eight markers were associated ($p < 0.05$) with HSR in Caucasians ($n \sim 1000$) in two retrospective case-control studies. Among these replicated markers, HLA-B*5701 had the highest performance characteristics: sensitivity=56.4%, specificity=99.1%. HLA-B*5701 was not associated with HSR in Blacks. These data imply that Caucasians who test positive for HLA-B*5701 would have a 73.0% risk of HSR while those who test negative would have 2.3% risk of HSR. Recursive Partitioning (RP), a data mining method that detects interactions within large sets of predictor variables, was used to investigate marker combinations predictive of HSR risk. Application of RP led to the identification of genotype combinations involving multiple single nucleotide polymorphisms (SNPs). For example, one RP algorithm comprised of 6 SNPs assigned patients to one of five risk categories. If this algorithm was prospectively validated and applied to a random population of ABC-treated patients, it is estimated that 19% of patients would be assigned to a risk group for which the HSR risk is estimated to be zero, 35% would be in 1-2% risk group, 38% in the 3-4% group, 4% in the 5-50% group, and 4% in the 50-100% group. Despite uncertainty around the clinical utility of markers identified to date for ABC HSR, RP may be a useful tool for the identification of genetic marker combinations that predict safety and/or efficacy of medicines.

Pairwise analysis of genetic marker combinations predictive of an adverse drug reaction. *L. Warren¹, D. Zaykin¹, K. Davies¹, D. Yarnall¹, A. Handley¹, S. Haneline¹, A. Hughes¹, E. Lai¹, K. Nangle¹, T. Scott¹, W. Spreen¹, A. Wooster².* 1) GlaxoSmithKline, RTP, NC; 2) Five Points Consulting, RTP, NC.

Abacavir (ABC) is an effective antiretroviral drug used to treat HIV-1 infection. Approximately 5% of patients treated with ABC develop a hypersensitivity reaction (HSR) that in rare cases has proved fatal. The ABC clinical risk management program has been successful in reducing serious outcomes due to ABC HSR. Performance characteristics for a prognostic ABC HSR marker set must be extremely high in order to improve upon clinical management; over-reliance on prognostic markers for ABC HSR could lead to reduced clinical vigilance and more serious outcomes for patients who do not carry the predictive markers. Thirty-eight markers were associated ($p < 0.05$) with HSR in Caucasians ($n \sim 1000$) in two retrospective case-control studies. Among these replicated markers, HLA-B*5701 possessed the highest performance characteristics: sensitivity=56.4%, specificity=99.1%. While specificity, the probability of being negative for HLA-B*5701 among individuals who did not develop HSR, was quite high, sensitivity was only moderate (e.g., about 44% of Caucasian patients who developed HSR were negative for HLA-B*5701). Thus, the goal was to improve upon the sensitivity of HLA-B*5701 while maintaining its high specificity. An algorithm was developed to systematically examine genotype combinations for all 703 marker pairs among the 38 replicated markers. This algorithm revealed marker pairs that were highly associated with HSR. 97% of the 703 pairs were significant at $p < 0.05$, 27% at $p < 10^{-10}$, and 4% at $p < 10^{-30}$. In 47% of pairs ($n=331$), sensitivity was increased compared to the contributing markers and in the remaining 53% of pairs ($n=372$) specificity increased. No pair exhibited increases in both sensitivity and specificity and no combination resulted in performance characteristics substantially superior to those of HLA-B*5701 alone. Despite uncertainty around the clinical utility of markers identified to date for ABC HSR, this analytical approach may contribute to the identification of marker pairs predictive of adverse drug reactions.

Quantifying intra-familial phenotypic variation for hereditary hearing loss: a tool for the identification of modifier genes. *E. Fransen¹, E. Van Eyken¹, L. Van Laer¹, P.L.M. Huygen², G. Van Camp¹*. 1) Department of Medical Genetics, University of Antwerp, Antwerp, Belgium; 2) Department of Otorhinolaryngology, University Medical Centre St Radboud, Nijmegen, the Netherlands.

We have previously studied five families with monogenic late-onset nonsyndromal hearing loss due to mutations in the KCNQ4 gene. This gene encodes a potassium channel involved in the K⁺ recycling pathway in the inner ear. Audiologic analysis of the families with a KCNQ4 mutation has shown a correlation between the mutation and the audiological phenotype: Four families with a missense mutation showed progressive hearing loss starting in the high frequencies, gradually affecting all frequencies at a similar annual threshold shift. In one family with a truncating mutation, only high-frequency HL was observed, while hearing in the low frequencies was conserved (De Leenheer et al. (2002) *Adv. Otolaryngol.* 61:41-46). The severity of the phenotype varied considerable within each of the five families, which may be due to genetic or environmental modifying factors. Here we have developed a quantitative measure that describes how severely a person is affected, compared to the other family members and correcting for age. We refer to this measure as the family-specific Z-score. To build a family-based Z-score, we first regressed the audiometric thresholds at each frequency on age, which showed a linear relationship between threshold and age at each frequency. Different regression equations were calculated for each family and for each frequency. For each patient, we calculated the expected hearing thresholds and the residual (observed minus expected). Hereby, a negative residual means a better hearing than expected. This residual was converted into a Z-score by dividing by the standard error of the estimate of the regression analysis. This family-based Z-score was squared, but the sign (+/-) was kept. Hence, a least-square correction for the trait as a whole is obtained. This method opens the perspective for genetic studies aiming at the identification of modifier genes for different forms of genetic hearing impairment, or even for other quantifiable monogenic disorders.

Univariate and Multivariate Genetic Analysis of Migraine Symptom Data. *D.R. Nyholt, N.G. Martin.* Genetic Epidemiology Lab, QIMR, Brisbane, QLD, Australia.

Familial typical migraine is a common, complex disorder that shows strong familial aggregation. Studies indicate that migraine affects up to 25% of females compared with 7.5% of males in Western populations.

Migraine shows both clinical and genetic heterogeneity. The exact cause is unknown and there are no recognisable, diagnostic, pathological changes. Therefore, the diagnosis of migraine is largely based on the retrospective reporting of headache characteristics and groupings of their associated symptoms. In 1988, the International Headache Society (IHS) prepared a new classification for headaches, which has made diagnosis clearer and more precisely defined. However, it is *not* clear how the diagnostic components are related both to each other and to the familial aggregation of migraine.

A twin study design was used to examine the extent of genetic influence on the expression of IHS symptoms of migraine. The symptoms were investigated using heritability as an indicator of validity. A total of 2662 (42.5%) twins screened positive for migraine or recurrent headaches.

Results show how one of the four major IHS criterion shows no heritability, and therefore should be either revised or ignored. Moreover, only 6 out of the 10 IHS criteria examined, showed significant heritability ranging from 0.26 (unilateral location) to 0.63 (moderate or severe intensity). These individual symptom heritability results will allow optimisation of the phenotype definition in molecular genetic studies of familial typical migraine, while investigation of individual clinical criteria may lead to the genetic dissection of specific migraine symptoms.

Although results from multivariate genetic analyses indicate two sets of genes are typically inherited together, they do not however indicate migraine with aura is genetically distinct from migraine without aura. These results have immediate application to both presently collected pedigree data and also to the future design of molecular genetic studies of familial typical migraine.

Semistructurate Phenotypification of Patients with ADHD in the Colombian Population. *H.M. Velasco¹, A. Julio¹, E. Espinosa², G. Casas⁴, A. Fajardo², S. Guerrero², N. Mancilla², J. Mongui⁵, P. Mancera³, C. Duran¹, J.C. Prieto^{1,3}.*
1) Instituto de Genetica Humana, Universidad Javeriana, Bogota, Cundinamarca, Colombia; 2) Universidad Militar, Bogota, Colombia; 3) Hospital la Victoria, Bogota, Colombia; 4) Instituto Franklin Delano Roosevelt, Bogota, Colombia; 5) Clinica Psiquiatrica San Juan de Dios, Manizales, Colombia.

The ADHD has a frequency in Colombia from the 8 to 18% and it is the more frequent psychiatric diagnosis infantile population. A prospective study of ADHD positive patients without mental retardation was made to characterize them in its different subtypes, comorbidity, medications response and antecedents until third degree by means of criteria of DMS IV, semistructurate interview and valuation by paediatric neurology, child psychiatry and clinical genetic using software designed for such aim. 78 patients (75.64% men and 24.36% women) were finding with ages between the 4 to 15 years evaluated themselves ($X=8.29$ $DS=2.22$). 50% of them were combined ADHD, impulsive hyperactive 19.23%, 19.23% inattentive and non-specific 11.54%. 23% did not have any comorbidity, 33% have one comorbidity and 44% have more than one comorbidity, being the most frequent oppositional defiant disorder (72%) and the of anxiety disorder (28%). 75% took some medicine and 25% were treaty by means of support therapies. The percentage of good response to the treatment was of 51.3%, to regulate 14%, none responded of 25.5%. and it does not know of 9%. 18.5% of the patients had some relative with a neurological disease, a 60.5% with psychiatric antecedents and a 17% with both. Significant differences with other similar studies in the variables of low socioeconomic layer, impulsive subtype inattentive and hyperactivity, subset oppositional defiant disorder comorbidity and depression were observed. In Conclusion the epidemiological variables were similar with other populations, however in our population the subtype inattentive and hiperactivity-impulsive were more prevalent than others countries.

ApoE gene polymorphisms in three ethnic groups living in Turkey. *G. Akpınar, E. Ergül, A. Sazci.* Department of Medical Biology & Genetics, , Faculty of Medicine, University of Kocaeli, Kocaeli, Turkey.

The ApoE gene is a polymorphic gene located at chromosome 19q13.2 with three common alleles, epsilon 2, 3, and 4, producing three isoforms of the protein E2, E3, and E4. These isoforms differ in amino acid sequence at positions 112 and 158. From these alleles arise six genotypes; ApoE3/3, E3/4, E2/3, E4/4, E2/2. To investigate the genotypes and allele frequencies of ApoE gene in three different ethnic groups in Turkey, we analysed DNA isolated from peripheral blood samples using PCR-RFLP method and digesting by HhaI restriction endonuclease, and followed by statistical analysis. The genotype frequencies in Turkey of the Bulgarian immigrants (N=136; 54 male (39.7%), 82 female (60.3%); mean age= 46.8plusminus13.6 years) with ApoE2/2, E2/3, E2/4, E3/3, E3/4, and E4/4 were 0.7%, 16.2%, 5.1%, 65.4%, 11.8%, and 0.7; respectively. The allele frequencies of the Bulgarian immigrants of Apo e2, e3, e4 were 11.40%, 79.41%, and 9.19. The genotype frequencies of the Tunceli community (N=142; 74 male (52.1%), 68 female (47.9%); mean age= 37plusminus13.56 years) with ApoE2/2, E2/3, E2/4, E3/3, E3/4, E4/4 were 9.9%, 1.4%, 77.5%, 10.6%, and 0.7; respectively. The allele frequencies of Apoe2, e3, e4 of the Tunceli community were 5.63%, 87.68%, and 6.69; respectively. The genotype frequencies of the Georgian immigrants (N=124; 55 male (44.4%), 69 female (55.6%); mean age= 49 plusminus15.67 years) living around Ordu with APOE2/2, E2/3, E2/4, E3/3, E3/4, E4/4 were 0.8%, 12.9%, 2.4%, 68.5%, 15.3; respectively. The allele frequencies of Apoe2, e3, e4 of the Ordu community were 8.47%, 82.66%, and 8.87; respectively. In conclusion, the allele frequencies of e2 ranged from 5.63% in the Tunceli community to 11.40 % among the Bulgarian immigrants. On the other hand, the allele frequencies of e3 ranged from 79.41 % in the Bulgarian immigrants to 87.68% in the Tunceli community. The allele frequencies of e4 ranged from 6.69% in the Tunceli community to 9.19% in the Bulgarian immigrants. Thus, three different ethnic groups studied in Turkey demonstrated significant variations in the three different alleles of ApoE gene.

Val-9Ala polymorphism in the manganese superoxide dismutase(MnSOD) gene is associated with increased risk of Coronary artery disease in the Korean obese male. *E.Y Cho¹, H. Cho², S. Kim^{1,3}, J.E. Lee^{1,3}, Y. Ko^{1,4}, J.H. Lee^{1,5}, H. Park^{1,4}, Y. Jang^{1,4,5}.* 1) Cardiovascular genome center, Cardiovascular Research Institute, Yonsei University, Seoul, Korea; 2) Research Institute of Science for Aging, Yonsei University; 3) DNA link, Inc, Korea; 4) Division of Cardiology, Department of Internal Medicine, Yonsei University College of Medicine, Seoul, Korea; 5) Department of Food and Nutrition, College of Human Ecology, Yonsei University, Seoul, Korea.

The Oxidative stress contribute to atherogenesis and manganese superoxide dismutase(Mn SOD) on the mitochondria are catalyzing dismutation of reactive superoxide radicals to hydrogen peroxide. The purpose of this study was evaluated the role of genetic variation in the MnSOD gene on CAD in Korean. 148 male patients with CAD and 263 healthy male controls were participated in this study. Among the study subjects 83 controls were analyzed for serum SOD activity and lipid peroxidation as measured by Malondialdehyde(MDA). The genotype was determined by SNP IT assay. The genotype frequencies of the MnSOD for Val/Val, Val/Ala, Ala/Ala were 81, 47 and 3% for control and 73.6, 25.7 and 0.7% for CAD, respectively. Overall, Odds ratio(OR : 1.40, 95% CI :0.81-2.41) were not significantly elevated in Ala carrier compared to Val/Val genotype. However, the frequencies of Ala allele(0.19 vs 0.08) and Ala carrier (15.6% vs 36.4%, $p=0.004$) of the MnSOD gene were significantly higher in obese CAD patients than in obese controls. In the multivariate logistic model as covariate with age, plasma levels of total cholesterol, triglyceride, insulin resistance index, smoking and drinking status, Ala allele was an independent risk factor for CAD(OR :3.11, 95% CI:1.29-7.71, $p<0.05$). MnSOD Val-9Ala polymorphism was not associated with severity of CAD and presences of Myocardial infarction. Mean SOD activity and MDA concentration were not significantly different between the Ala carrier and Val/Val genotype. It is concluded that the Val-9Ala polymorphism of the MnSOD gene is not associated with SOD activity and MDA, but is a genetic risk marker for obese CAD Korean.

MTHFR gene polymorphisms in four ethnic groups in Turkey. *E. Ergul, G. Akpınar, A. Sazci.* Department of Medical Biology & Genetics, Faculty of Medicine, Kocaeli University, Kocaeli, Turkey.

We investigated the allele and genotype frequencies of the MTHFR C677T and A1298C polymorphisms of four ethnic groups in Turkey using a PCR-RFLP method. The five ethnic groups studied were Bulgarian immigrants of Turkish origin (N=136; 54 male (39.7%), 82 female (60.3%); mean age= 46.8±13.6 years), Bosnian immigrant (N=110; 54 male (49.09%), 56 female (50.91%), turkmen from Horasan (N=101; 32 male (31.7%), 69 female (68.3%), mean age=50.08±15.9), Tunceli community (N=142; 74 male (52.1%), 68 female (47.9%); mean age= 37.13±5.6 years) living in Turkey. The genotype frequencies of the MTHFR C677C, C677T, and T677T of the Bulgarian immigrant were 46.3%, 46.3, and 7.4 respectively. The allele frequencies of MTHFR 677T and 677C were 30.51%, and 69.49% respectively. The genotype frequencies of the MTHFR A1298A, A1298C, and C1298C were 42.6%, 50.7, and 6.6 respectively. The allele frequencies of MTHFR 1298A and 1298C were 68.01%, and 31.99% respectively. The genotype frequencies of MTHFR C677C, C677T, and T677T of the Tunceli Community were 55.6%, 36.6, and 11 respectively. The allele frequencies of MTHFR 677C and 677T were 73.96% and 26.06% respectively. The genotype frequencies of MTHFR A1298A, A1298C, and C1298C were 30.3%, 49.3, and 20.4 respectively. The allele frequencies of MTHFR 1298A and 1298C were 54.93% and 45.07% respectively. The genotype frequencies of MTHFR C677C, C677T, and T677T of the Turkmen community were 31.7%, 52.5, and 15.8 respectively. The allele frequencies of MTHFR 677C and 677T were 67.92% and 42.08 % respectively. The genotype frequencies of MTHFR A1298A, A1298C, and C1298C were 61.4, 35.6, 3% respectively. The allele frequencies of MTHFR 1298A and 1298C were 79.21%, and 20.79% respectively. The genotype frequencies of MTHFR C677C, C677T, T677T of the Bosnian community were 37.3%, 46.4, and 16.4 respectively. The allele frequencies of MTHFR 677C and 677T were 60.45%, and 39.55% respectively. The genotype frequencies of MTHFR A1298A, A1298C, C1298C were 44.5%, 42.7, and 12.7 respectively. The allele frequencies of MTHFR 1298A and 1298C were 65.91%, and 34.09% respectively.

Additive effects of Interleukin-1B, -RN and -10 risk alleles on susceptibility for hip osteoarthritis. *I. Meulenbelt¹, J. Min¹, A. Seymour², H.A.P. Pols³, C.M. van Duijn³, P.E. Slagboom¹.* 1) Molecular Epidemiology, Leiden Univ Med Ctr, Leiden, Netherlands; 2) Pharmacogenomics and Antibacterials, Inflammation & Immunology Pfizer Global Research & Development, Croton, USA; 3) Epidemiology & Biostatistics Erasmus Univ Med School, Rotterdam Netherlands.

Osteoarthritis (OA) is characterized by degradation of articular cartilage and formation of new bone. Identification of genes that influence disease susceptibility may indicate which pathways may be involved in the onset of OA. Matrix integrity is maintained by the chondrocyte by a delicate balance between the effects of catabolic cytokines IL1 and TNF, which induce production of specific matrix degrading metalloproteases and the anabolic cytokines IL10, IL4, and IL1Ra that have been shown to prevent and reverse cartilage degradation. A failure to maintain the balance between pro- and anti-inflammatory cytokines may result in cartilage degradation. Previously the -511T allele in the promoter of the IL1B gene and allele 2 of the VNTR in the IL1RN gene were found to be independently associated with the occurrence of radiographic OA (ROA) in the hip in a random sample of 55-65 year old subjects from a population-based cohort (The Rotterdam study, N = 809). In this sample ROA has been assessed in knee, hip, hand and spine. One interesting promoter SNP in the IL10 gene is the G-2849A since the A allele was consistently negatively associated to *ex vivo* IL10 production. Here we show that this SNP was also associated to hip ROA (OR is 1.5, 95% CIL 0.9-2.7 and 2.2, 95% CIL 0.9-5.0 for respectively hetero- and homozygous carriers of allele A). An increasing risk was observed for hip ROA among carriers of increasing number of risk alleles of the C-511T, VNTR and G-2848A polymorphisms (OR is 2.0, 95% CIL 0.6-7.6 for carriers of 1 risk allele, 4.4, 95% CIL 1.3-15.2 for carriers of 2 risk alleles, 7.3, 95% CIL 2.1-25.4 for carriers of 3 risk allele and 5.8, 95% CIL 1.4-22.8 for carriers of 4 risk alleles). Together these data implicate that different alleles within the IL1B, IL1RN and IL10 genes independently and additively contribute to the susceptibility for hip ROA.

Program Nr: 3000 from the 2004 ASHG Annual Meeting

Association of CD 14 promoter polymorphism with Asthma in African Americans. *K. Yanamandra, P.B. Boggs, D. Napper, S.A. Ursin, H. Chen, R. Dhanireddy, J.A. Bocchini Jr., T.F. Thurmon.* Dept Pediatrics, LSU Medical Ctr, Shreveport, LA.

Allergic diseases such as asthma are multifactorial disorders with polygenic and environmental combinations in their etiology. Many allergic diseases have increased IgE levels in their etiology, which in turn, is under strong genetic control. Several studies have repeatedly reported association between 5q31-33 (loci containing Interleukin-4, Interleukin-5, Interleukin-13, CD 14 genes and others) and total serum IgE level and its dependent disorders such as asthma. Although many of these studies were conducted in Caucasians, there were limited studies in the African Americans. Our laboratory studies on interleukins has shown a strong association between IL-13 promoter polymorphism and asthma for the first time in African Americans. We also showed a strong association of IL-13 Arg130Gln (A398G in coding region) polymorphism with asthma in this community. Also, we showed that in the IL-4 receptor coding region (A+398G), mutant 398G allele frequency was significantly higher (0.31 vs 0.18) in patients as compared to controls. In the present investigation we have extended our asthma research to study the association of CD 14 promoter polymorphism (C-159T) in seventy-nine asthma patients and one hundred sixty controls of African American ancestry. We used microplate PCR-RFLP method with Ava II restriction enzyme. The restriction products revealed a frequency of 0.089, 0.081 of TT-159 homozygotes in patients and controls respectively. The CT-159 heterozygote frequency and CC-159 normal homozygote frequencies were 0.392, 0.059 in patients and 0.425, 0.494 in controls respectively. Our results do not show any difference in the allele frequencies of either 398C or 398T between the controls and asthma patients (398T frequency was 0.29 in patients and 0.29 in controls) in contrast to the published literature from the Caucasians. This being the first report on CD 14 polymorphism analysis in African Americans, experience from other researchers is needed to verify the validity of these initial findings. Data and statistics will be presented.

Relationship between Endometriosis and Polymorphisms of Detoxification Enzymes NAT2, GSTM1 and CYP 1A1 in the Korean female population. *H.W. Choi¹, H.-S. Lee¹, H.J. Song², S.Y. Park³, M.K. Koong², J.H. Jun¹.* 1) Infertility Research Lab., Samsung Cheil Hospital, Seoul, Korea; 2) Dept. of Ob/Gyn, Samsung Cheil Hospital, Sungkyunkwan University School of Medicine, Seoul, Korea; 3) Lab. of Medical Genetics, Samsung Cheil Hospital, Seoul, Korea.

Endometriosis is a common gynecologic disorder and inherited as a complex genetic trait, related to multiple genes interacting with each other and with the environmental factors. This study was performed to evaluate the relationship between endometriosis and polymorphisms of detoxification enzymes N-acetyl transferase 2 (NAT2), glutathione S-transferase M1 (GSTM1), and cytochrome P450 (CYP) 1A1 in the Korean female population. By laparoscopic diagnosis, they were classified into Group-I (minimal/mild endometriosis, n=166) and Group-II (moderate/severe endometriosis, n=85) and Controls (without endometriosis, n=98). DNA was extracted and amplified using PCR. The genotypes of each gene were examined with restriction fragment length polymorphism (RFLP) analysis. The frequencies of NAT2 fast-acetylation genotypes and GSTM1 active genotypes in Group-II were higher than those of Controls, respectively (91.8% vs 87.8%, p=0.5196; 58.8% vs 44.9%, p=0.0834). The frequencies of the CYP1A1 MspI polymorphism (62.4% vs 59.2%) and of the combination of the GSTM1 null mutation and the CYP1A1 MspI polymorphism (65.7% vs 64.8%) were similar between Group-II and Controls. We found that the NAT2 *4/*4, *4/*6 and *4/*7 genotypes were common in the Korean female population whereas the NAT2 *4/*5, *5/*5 and *5/*6 genotypes in the Caucasian and European population. These discrepancies between our results and the other reports could arise because of ethnic variations in allele frequency. Based on our results, detoxification enzymes, NAT2, GSTM1 and CYP1A1, might be indirectly associated with the risk for endometriosis. More studies are needed on the other detoxification systems and interactions with environmental factors for the etiology of endometriosis.

Program Nr: 3002 from the 2004 ASHG Annual Meeting

Androgen receptor and endometrial cancer risk. *I. De Vivo, M. McGrath, S.E. Hankinson, P. Kraft, D.J. Hunter.*
Dept Medicine, Channing Lab, Harvard Medical School, Boston, MA.

The androgen receptor (AR) gene is a transcription factor responsible for mediating the physiological effects of androgens. Evidence suggests that androgens and its receptor are involved in uterine cell proliferation, thus potentially affecting endometrial cancer risk. A polymorphic CAG repeat in exon 1 of the AR gene encodes a polyglutamine tract that is inversely correlated with the transcriptional activity of this gene. We assessed the association between the functional CAG repeat polymorphism and the risk of endometrial cancer in a nested case-control study within the Nurses Health Study (n = 222 cases, 666 controls). Women with one or more long AR CAG repeat alleles (> 22 repeats) were at a decreased risk of endometrial cancer (odds ratio (OR) = 0.69; 95% confidence interval (CI), 0.46-1.02). Women with one or two long alleles (> 27 repeats) compared to both alleles <22 repeats were also at a decreased risk (OR= 0.52; 95% CI, 0.27-1.01). We observed an association between average repeat length and endometrial cancer risk (OR= 0.91; 95% CI, 0.84-0.99). Additionally, six haplotype-tag polymorphisms (htSNPs) have been determined to predict the common haplotypes in the AR gene for Caucasians. We genotyped these htSNPs in our nested endometrial case-control study and found no significant associations between the haplotypes and endometrial cancer risk. Our findings suggest that the functional CAG repeat in the AR gene may be involved in endometrial carcinogenesis by possibly downregulating its target gene IGF-1.

Heritability of obesity-related traits among multigenerational Afro-Caribbean pedigrees. *I. Miljkovic-Gacic¹, C.M. Kammerer¹, X.J. Wang¹, M. Kenney¹, V. Wheeler², A.L. Patrick², J.A. Cauley¹, C.H. Bunker¹, J.M. Zmuda¹.* 1) Un. of Pittsburgh, Pittsburgh, PA; 2) Tobago Health Studies Office, Scarborough, Tobago.

Obesity, a global public health problem that has reached epidemic proportions, contributes to the development of some of the most prevalent chronic diseases in modern society. There is considerable evidence for a genetic liability to obesity and its associated phenotypes, but very little data regarding the genetics of obesity in populations of African heritage. We present preliminary results from an ongoing initiative to unravel the genetic and environmental contributions to obesity phenotypes within multigenerational Afro-Caribbean families. All family members undergo a comprehensive body composition evaluation including dual-energy X-ray absorptiometry (DEXA) assessments of total and regional body composition and quantitative computed tomography measures of muscle cross-sectional area, and subcutaneous and intermuscular fat. Weight, standing and seated height, and body mass index (BMI) are measured with standardized protocols. The heritability of DEXA phenotypes and the effects of age and gender were estimated using quantitative genetic methods and preliminary data collected on 128 individuals (43% male) aged 18 to 86 years (average age 43 years) from 7 extended pedigrees. Age and gender explained 45% of the variance of FFM, 34% of TBF, 58% of %fat and 25% of TF within these pedigrees. The DEXA derived measures of non-bone soft tissue mass (FFM), total body fat (TBF), percentage body fat (%fat) and trunk fat (TF) all showed significant residual heritability (h^2 S.E.): 0.440.23; 0.410.22; 0.760.16; and 0.370.26, respectively. In contrast, the heritability of BMI was considerably lower (0.140.14) than the heritabilities of the DEXA traits. These results suggest that FFM, TBF, TF and particularly %fat are highly heritable traits in these Afro-Caribbean pedigrees and that these DEXA phenotypes may be more informative for genetic association and linkage studies than the BMI, the more traditional index of obesity. Further analyses of these DEXA phenotypes should greatly increase our understanding of the genetic susceptibility to obesity and its related complications in populations of African descent.

Admixture Association in a Systemic Lupus Erythematosus Puerto Rican Population. *A.I. Quintero-Del-Rio*^{1,2}, *C.E. Aston*¹, *X. Mao*⁵, *D.C. Hutchings*¹, *J. Kilpatrick*¹, *A. Santiago-Cornier*³, *J.B. Harley*^{1,2,4}, *M. Shriver*⁵. 1) Oklahoma Medical Research Foundation, Oklahoma City, OK; 2) Oklahoma University Medical Center, Oklahoma City, OK; 3) Ponce School of Medicine, Ponce, PR; 4) Department of Veterans Affairs Medical Center, Oklahoma City, OK; 5) Pennsylvania State University, University Park, PA.

Admixture studies provide a means in isolated, admixed populations to localize disease susceptibility genes using approximately 100 times fewer markers than are required for whole-genome scans. Systemic lupus erythematosus (SLE) is a serious autoimmune disease with strong genetic component affecting people of all ethnic backgrounds, especially minority groups. The native population of Puerto Rico experienced a bottleneck after Western contact with as few as 2500 founders. Immigration of Europeans and Africans into the island has increased the Puerto Rican population to 4 million people today compose of 18% Taino Indians, 45% European and 37% African. Thus, the Puerto Rican population is ideal for an admixture study of SLE susceptible genes. We performed a genetic association study specifically seeking the effects predicted by population isolation and admixture. Using single nucleotide polymorphism analysis and pooling techniques in 43 Puerto Rican lupus patients and 38 controls, we observed powerful association and nucleotide variation in different chromosomes. These association included chromosomes 1, 2, 10, 13, and 18 from $p < 10^{-5}$. Ancestral informative markers were typed in the same group of Puerto Ricans and 59 genes on 14 chromosomes demonstrated significant differences in admixture proportions between cases and controls. These genes are mainly located in chromosomes 1, 2, 3, 10, 16 and 18. The preliminary results of this study draw upon the key advantage of admixture mapping that is based on directly associating sections of the genome with disease. This study provides insight in to a population not previously described and may have more power than linkage to detect the presence of modest effects not previously identified using the variants that differ strikingly in frequency across the three ancestral populations of the Puerto Ricans.

Addressing the multiple testing problem in detecting gene-gene interaction by a permutation-based method. *N. Wang, R. Chakraborty.* Ctr Genome Information, Univ Cincinnati, Cincinnati, OH.

Identification of the genetic and environmental contributions to human diseases is one of the primary goals of biomedical research. For human common complex diseases, such as cancer, heart disease, asthma, and diabetes, etc, there may be more than one underlying gene responsible for the causation, making the investigation complicated. Multiple testing is one of the potential problems in reporting a gene-gene interaction related to certain disease in population based case-control studies. In order to avoid the type I error (false positive), Bonferroni correction has been applied in many studies. However, markers of different genes under study may not be truly independent (e.g., they may exhibit linkage disequilibrium), making the adjustment too conservative. With this motivation, we developed a novel method to deal with the multiple testing problem. Given a specific genotype combination, we calculated the traditional χ^2 first, considering the sampling scheme (say, case-control study design). Next, we shuffled each marker genotype across case and control individuals with a large number of replication (say, 10,000 times), and calculated the χ^2 value of the specific genotype combination for each replicate. We assigned the preliminary significant level for the specific genotype combination as the relative frequency with which we observed χ^2 values from replicates equal to, or higher than the χ^2 from the original data. Then we applied Bonferroni correction to determine the final significant level. With the preliminary significant level being obtained from random shuffling of markers, this step helps us ensure that the follow-up Bonferroni correction is based on the assumption of independent testing. Gene-gene interactions being very common underlying many human complex diseases, the method we present may be one of the better ways to deal with the multiple testing problem that control reporting false positive results. (Research supported by NIH grant GM 41399).

Determination of population structure in the Mayo Alzheimers Disease Patient Registry. *S. Melquist¹, R. Crook¹, B. Phillips¹, J. Gass¹, J. Adamson¹, R. Mueller², R. Petersen², M. Hutton¹.* 1) Department of Neuroscience, Mayo Clinic College of Medicine, Jacksonville, FL; 2) Alzheimer Disease Research Center, Mayo Clinic College of Medicine, Rochester, MN.

Although traditional linkage analysis has identified late-onset Alzheimers disease (LOAD) candidate gene loci, no definitive risk variants (apart from APOE-e4) have been isolated. Alternative approaches, such as population-based linkage disequilibrium (LD) mapping, might be more effective in identification of risk variants. However, concerns exist regarding the validity of these types of studies, because many LOAD gene variants identified by this approach have not been replicated in subsequent studies using alternate populations. One explanation for this lack of replication may be that underlying population structure difference between case and control subjects is a confounding factor in the original studies. The Mayo Alzheimers Disease Patient Registry (ADPR), consisting of 293 case and 448 control subjects collected from Olmstead County, Minnesota, is potentially a rich resource for genome-wide LD mapping. We hypothesized that population structure may exist in the ADPR samples and underlying structure would be a confounding factor in future LOAD LD studies using this series. Therefore, we examined the extent of population structure in the ADPR series by genotyping a number of unlinked single nucleotide polymorphism and short tandem repeat markers and analyzing the genotype data using the program *structure* developed by Pritchard and colleagues. The results of the structure analysis were consistent with two major subpopulations in the ADPR. Case and control subjects were equally distributed between the two populations. These results may reflect the predominant Scandinavian origin of many individuals in this region, along with a second more general US population. We used population structure information in the series when fine mapping LOAD candidate loci. Results from these analyses will be presented.

Program Nr: 3007 from the 2004 ASHG Annual Meeting

Application of an Ancestry-Informative SNP Panel to a Large Cosmopolitan Sample. *M.S. Pungliya, B.A. Salisbury, J.C. Stephens.* Population Genomics, Genaisance Pharmaceuticals, New Haven, CT.

A genomic control panel of 38 SNPs was selected from over 100,000 candidates discovered through resequencing 79 unrelated diverse humans. The goal in creating the panel was to have an efficient tool for estimating the geographic ancestry of new subjects. The SNPs were chosen to distinguish African, European, Asian, and Native American components of ancestry. To test the utility of the panel, we applied it to a set of 256 unrelated subjects, most of whom indicated uniform ancestry from one country. The genotype data for these new subjects were submitted to the program Structure 2.0. Under the parameter setting of five populations, the program found evidence for distinct East Asian, African, and Native American ancestries. In addition, it recognized an Indo-European spectrum spanning Europe, the Indian subcontinent and the lands in between. Several outlier subjects were notable. Subjects from the Caribbean had the widest mix of ancestral proportions. Latin Americans were also quite diverse; while many of the individuals were estimated to have over 90% Native American ancestry, others were marked as having nearly none. The ancestral Native American population seems clearly characterized both by unique SNPs and by SNPs that are otherwise characteristic of East Asians. This study supports the use of carefully selected SNP panels for efficient assessment of study samples.

BIASES DUE TO POPULATION STRATIFICATION IN EPIDEMIOLOGICAL STUDIES OF GENE-GENE INTERACTIONS. *Y. Wang, R. Localio, T. Rebbeck.* Department of Biostatistics and Epidemiology University of Pennsylvania School of Medicine 904 Blockley Hall, 423 Guardian Drive Philadelphia, PA 19104-6021.

It has been widely recognized that Population stratification (PS) can result in spurious disease-gene associations in epidemiological studies, yet its roles in gene-gene interaction studies remain unfamiliar. We used logistic regression models to fit multiplicative interactions between two genes for a binary disease outcome in a hypothetical cohort of two ethnicities. Biases on main effects and interactions due to PS were evaluated by comparing regression coefficients in mis-specified models that ignored ethnicities with their counterparts in models that accounted for ethnicities. We revealed that PS could exert more bias to interaction estimates than main effects estimates. Biases in main effects and interaction estimates were bounded by the log-odds ratio and two times the log-odds ratio of disease risks in the two unobserved ethnicities, respectively. Potential biases from PS in gene-gene interaction studies were evaluated under a wide range of conditions. Biases in interaction estimates were most serious when two genes were under linkage disequilibrium, even when marginal distributions of both genes were same across ethnicities. This may be a particular concern in the studies of multiple SNPs in adjacent chromosome regions in substructured populations.

Propensity Score methods to adjust for population stratification in association studies. *E. Ziv*¹, *S. Choudhry*^{1,2}, *E. Burchard*^{1,2}. 1) Department of Medicine, University of California, San Francisco; 2) Lung Biology Center, University of California, San Francisco.

Population stratification may lead to an increased risk of false positive and false negative results in case-control studies. Several methods have been developed to adjust for population stratification in case-control studies using information from additional unlinked markers. Here we propose an alternative approach based on the concept of propensity score methods in classical epidemiology. The propensity score is a method of reducing a large number of potential confounders to one. The score is derived based on the association between the confounders and the main predictor. In a genetic association study, the propensity of having a particular genotype at the locus being tested is modeled based on the association between that genotype and other unlinked markers. The propensity of having the genotype being tested can then be compared among cases and controls. A significant difference between cases and controls implies that the association being tested is confounded by the difference between the genetic background of the cases and controls. The propensity scores can also be used in the context of model-based approaches such as logistic regression to adjust for confounding. We test the method on an existing dataset of 44 ancestry informative markers tested in a case-control study of asthma in Puerto Ricans. Without adjustment for stratification 7 of 44 markers are significantly associated with asthma. After adjustment for propensity only 2 of 44 markers are significantly associated, a rate that is consistent with usual type I error. The method may easily be applied to quantitative phenotypes. We propose that the propensity approach may be an efficient and straightforward approach to adjust for population stratification in association studies.

Modeling stochastic effects in gene regulation in eukaryotes. *P. Paszek*¹, *T. Lipniacki*^{1,2,3}, *A.R. Brasier*⁴, *M. Kimmel*^{1,5}. 1) Department of Statistics, Rice University, Houston, TX; 2) Institute of Fundamental Technological Research, Warsaw, Poland; 3) Bioinformatic Program, University of Texas Medical Branch, Galveston, TX; 4) Department of Internal Medicine, University of Texas Medical Branch, Galveston, TX; 5) Institute of Automation, Silesian Technical University, Gliwice, Poland.

Transcriptional gene enhancement and regulation is a stochastic phenomenon due to a small number of the molecules involved. Activity of a gene can be initiated by a single trans-activator molecule bound to the specific regulatory site in the targeted gene. In eukaryotes, the gene activation results in production of bursts of mRNA transcripts, hence the average mRNA level is relatively large (order of tens or hundreds of molecules). The stochasticity of activator binding and dissociation to and from the promotory region of targeted gene is then amplified by translation, since each copy of mRNA serves as a template for numerous protein molecules. In prokaryotes, the stochastic effects are attributable primarily to erratic transcription, translation and degradation of mRNA and its products. This is due to low abundance of mRNA transcript molecules (several molecules per cell), which causes that production or degradation of just one mRNA transcript molecule has significant effect on cell behavior. In the present work, we briefly discuss various stochastic effects in gene expression, and then focus on regulation of gene activity in eukaryotes. We introduce a mathematical description of the stochastic effects embedded in the ODEs framework assuming the binary nature of gene activation; at a given time a gene is switched either on or off, depending on whether trans-activator molecules are bound to the gene promoter or not. Also we develop complementary representation of the model in terms of PDEs describing probability density functions of gene being in active or inactive state. We compare and illustrate the two modeling approaches with an example of a single auto-repressive gene.

Evaluation of genetic tests for asthma susceptibility with receiver operating characteristic (ROC) curves. Y.

Suzuki¹, F. Kamada¹, C. Shao¹, M. Tamari², K. Hasegawa², Y. Aoki¹, S. Kure¹, T. Shirakawa^{2,3}, Y. Matsubara¹. 1) Department of Medical Genetics, Tohoku University School of Medicine, Sendai, Japan; 2) Laboratory for Genetics of Allergic Diseases, SNP Research Center, The Institute of Physical and Chemical Research (RIKEN), Yokohama, Japan; 3) Department of Health Promotion and Human Behavior, Kyoto University School of Public Health, Kyoto, Japan.

Susceptibility to a complex genetic disease such as bronchial asthma is not determined by a single gene but by a set of genes. To assess genetic risk of an individual, integration of many polymorphisms of susceptibility gene may be needed. Recently, Yang et al. (*Am J Hum Genet* 72: 636-649, 2003) argued that disease prediction for multifactorial diseases was greatly improved by considering multiple genetic polymorphisms with a likelihood ratio method. With this approach, they showed that three genetic polymorphisms could express 8 fold risk difference in venous thrombosis. Janssens et al., however, criticized this approach showing the low prevalence of high-risk combinations of genes, and recommended use of the standard method to evaluation of discriminative ability of a test, namely, evaluation by sensitivity and specificity (*Am J Hum Genet* 74:585-588, 2004). The changes in sensitivity and specificity of a test under different cut-off points can be overviewed by the receiver operating characteristic (ROC) curve. The area under ROC curve (AUC) indicates the discriminative ability of a test. We evaluated the usefulness of genetic tests with multiple candidate genes for asthma in the Japanese population with AUC. Use of C3, ADRB2, IL4RA, and CYSLT2R gene polymorphisms in a logistic regression model resulted in AUC of 0.83. This value was better than the values (0.76-0.77) for discrimination of patients and controls by lung functions but worse than that (0.91) by exhaled nitric oxide (Malmberg *LP Thorax* 58:494-499, 2003). The ability of the current multi-gene test for asthma seems to be compatible with conventional clinical tests. By updating susceptibility gene polymorphisms, we can expect better AUC values of genetic tests for asthma.

MAOA: A Primary Candidate Gene of Persistent, Pervasive Childhood Aggression. *S. Ehtesham, H. Mik, L. Douglas, J. Kennedy, J. Beitchman.* Neurogenetics, CAMH, Toronto, Ontario, Canada.

Monoamine oxidase A (*MAOA*) expression has a direct regulatory impact on the serotonin, norepinephrine, and dopamine systems, each of which have been implicated in the etiology of aggression. Previous studies have demonstrated that a functionally relevant variable number of tandem repeats (VNTR) in the promoter region of *MAOA* is associated, directly¹ or indirectly², with aggression in humans. In the present study, we examined the relationship between the two polymorphisms, *MAOA* VNTR and the single nucleotide polymorphism (SNP) at codon 297 and persistent, pervasive Childhood-Onset Aggression (COA).

Our clinical sample of aggressive children consisted of 57 psychiatrically referred males (mean age 9.72.6). All clinical subjects were rated above the 90th percentile on the Aggression subscale of both the Child Behaviour Checklist (mean t score 68.6013.93) and the Teacher's Report Form (mean t score 67.8513.94), with a minimum of 2-year history of aggressive behaviour. Ethnically matched adult males with no history of psychiatric illness served as controls (n=57).

Almost three-quarters of the COA sample carried the high-transcription four repeat allele (n=40, 70.2%), compared to half of the adult controls (n=28, 49.1%) in the VNTR ($\chi^2=5.25$; d.f.=1; p=0.02). In the codon 297 SNP, there was no significant difference in the allele frequencies of the two samples ($\chi^2=0.038$; d.f.=1; p=0.85). The *MAOA* VNTR and codon 297 polymorphisms were in moderate linkage disequilibrium ($D'=-0.61$).

Our findings suggest that higher transcription levels of the *MAOA* is associated with the persistent, pervasive COA. This is consistent with reports on dispositional aggressiveness among adults¹, but differs from reported² findings regarding an interaction between childhood maltreatment and the *MAOA* high- and low-transcription alleles as predictors of adult antisocial behaviour.

Age of onset for Huntington's disease with results in the range 36-39 repeats. *O. Quarrell^{1,3}, A.S. Rigby², A. Dalton³, Y. Crow³, A.E. Fryer³, F. Heydon³, E. Kinning³, A. Lashwood³, M. Losekoot⁴, L. Margerison³, S. McDonnell³, P.J. Morrison³, A. Norman³, M. Peterson³, F.L. Raymond³, S. Simpson³, J. Warner³.* 1) Dept Clinical Genetics, Sheffield Children's Hosp, Sheffield, United Kingdom; 2) Academic Cardiology, University of Hull, Hull, UK; 3) UK Huntington's Disease Consortium, UK; 4) Stichting Klinisch Genetisch Centrum, Leiden, Netherlands.

Following a genetic test for Huntington's disease (HD), a result of 36-39 repeats is considered abnormal; reduced penetrance may occur; however, the data on the degree of reduced penetrance are limited. Ethical approval was obtained for a multi-centre study to collect data anonymously on age of onset, or age last known to be unaffected, from a large cohort of individuals with such results. Wherever possible, DNA was re-analysed in a reference laboratory; Kaplan Meier analysis was used to construct an age of onset curve and penetrance figures. To date, 138 cases have been included in the analysis; of these, 119 had results concordant with the referring centre; of the remainder, DNA was not available or re-analysis failed. The median age of diagnosis was 54 years (range 31-91 years). The number of cases with 36, 37, 38 and 39 repeats was 24, 30, 30 and 54 respectively. There was no statistical difference between the age of onset curves based on individual repeat sizes, or combination of repeat sizes; therefore, penetrance figures are based on results from the whole cohort. The curve provides insight into penetrance of HD with results in this size range. At age 55 years, penetrance was 40% (31-49%); at age 65 years, penetrance was 58% (46-48%); at age 75 years, penetrance was 74% (62-86%). These data will be valuable for counselling individuals with predictive test results in this size range.

Evidence of a genetic determinant responsible for a small proportion of neonates with non-random X-inactivation (NRXI). V. Bolduc¹, P. Chagnon¹, S. Provost¹, MP. Dube², C. Belisle¹, M. Gingras¹, L. Busque¹. 1) Research Center, Maisonneuve-Rosemont Hospital, University of Montreal, Montreal, Canada; 2) Montreal Heart Institute, University of Montreal, Montreal, Canada.

X-inactivation is a random process occurring in every female cell during embryogenesis. Females are thus mosaics of 2 cell populations, usually with an approximate 1:1 distribution of cells with active paternal X (Xp) and active maternal X (Xm). However, a significant number of females present a deviation from this theoretical ratio, termed non-random X inactivation (NRXI). In the murine model, the determination of the X chromosome to be inactivated is influenced by allelic variations at the *Xce* locus. In humans, despite the fact that some rare variants in the *XIST* gene have been associated with preferential inactivation, an *XCE*-like locus has not yet been characterized. To determine the genetic basis of NRXI in humans, and eventually identify its responsible elements, we first studied the transmission of X-inactivation patterns as a qualitative trait (using a criteria for NRXI >3:1) in mother-neonate pairs. Blood samples (fetal cord or peripheral) of 350 neonates and their mother were phenotyped using the HUMARA assay. The transmission of NRXI was not observed, as the incidence of NRXI found in neonates of mothers with or without NRXI is comparable (12.0% and 11.2%, respectively). Second, we performed linear regression analysis and correlation tests on the ratio of activation of the shared HUMARA allele of mother-neonate pairs. Because the HUMARA locus is in linkage with the X-inactivation center (<5 cM), such analysis may reveal the influence of the latter on NRXI. The results show a slight, but significant, correlation ($r=0.131$, $p=0.028$) of the X-inactivation ratios between mothers and their newborn for the transmitted allele. These preliminary results suggest that aside from stochastic events, NRXI may also be determined by a genetic component. That component may regulate selection of the X that becomes inactivated, or the cell survival following X-inactivation. Future work is needed to identify the gene(s) responsible.

Familial aggregation of a broadly defined phenotype of atrial fibrillation in Iceland. *D.O. Arnar¹, S.*

Thorvaldsson², G. Thorgeirsson¹, H. Hakonarson², K. Stefansson². 1) Landspítalinn University Hospital, Reykjavik, Iceland; 2) deCODE genetics Inc., Reykjavik, Iceland.

Atrial fibrillation (AF) is a common and serious disorder with known clustering in rare selected families. However, its heritability on a broad population basis has not been widely explored. We examined the heritability of AF in Iceland utilizing the Icelandic genealogy database and population-based data on patients with electrocardiographically-documented AF diagnoses. The study population consisted of 5,269 patients diagnosed since 1987 at the single university hospital in Iceland. Age-sex-matched controls were randomly selected from the genealogy database. Kinship coefficients (KC) were calculated before and after exclusion of relatives separated by 1-5 meiotic events and expressed as the genealogical index of familiarity (GIF) = average KC x 100,000. The average pairwise KC among patients with AF was 15.8 [95%CI of controls = 13.5,14.0]; this declined to 15.3 [13.3,13.8] after exclusion of relatives separated by 1 meiosis, 13.7 [12.3,12.8] after exclusion of 2 meioses, 12.7 [11.6,12.0] after exclusion of 3 meioses, and 11.2 [10.3,10.7] after exclusion of 4 meioses (all $p < 0.01$). Risk ratios among relative pairs declined incrementally, from 1.77 [95%CI, 1.69,1.94] in first degree relatives to 1.36, 1.18, 1.09, and 1.05 [1.03,1.07] in second through fifth degree relatives, respectively, consistent with the decrement among relative pairs in proportion of alleles shared identical by descent. In conclusion; AF shows strong evidence of heritability among unselected patients in Iceland, suggesting that there may be undiscovered genetic variants underlying AF on a broad population basis.

Program Nr: 3016 from the 2004 ASHG Annual Meeting

Simulation of P-Values in MCMC-based Non-parametric Linkage Analysis. *G. Brock, D. Weeks, E. Feingold.* Dept Human Genetics, GSPH, Univ Pittsburgh, Pittsburgh, PA.

The significance level of a non-parametric linkage statistic is often found by simulation since the distribution of the test statistic is complex and unknown. Ideally, simulation occurs by assigning founder genotypes and then `dropping' genotypes through the pedigree. This situation mimics the actual pedigree data, where IBD sharing information is not known with certainty. However, this approach is usually computationally infeasible for larger pedigrees which require MCMC techniques to calculate the statistic, as an additional MCMC run is required to estimate the statistic for each gene-drop. One alternative is to drop inheritance vectors rather than genotypes, but this assumes that IBD sharing is known unambiguously and results in an overestimate of the variance and therefore a conservative significance level. In this work, we propose a novel method to estimate the significance level of the statistic. This is accomplished by estimating the Markov chain variability using the first gene drop, and then estimating the variability due to gene-dropping by running shorter MCMC chains on the additional simulated datasets. The two estimates are combined to form an overall estimate of the NPL statistic variability.

Higher heritabilities for volumetric density in weight-bearing versus non-weight-bearing bones: the Tobago

Family Study. X. Wang¹, CM. Kammerer¹, V. Wheeler³, AL. Patrick³, JA. Cauley², CH. Bunker², JM. Zmuda². 1) Dept Human Genetics, Univ Pittsburgh Sch Pub Hlth, Pittsburgh, PA; 2) Dept Epidemiology, Univ Pittsburgh Sch Pub Hlth, Pittsburgh, PA; 3) Tobago Health Studies Office, Trinidad & Tobago.

Cortical and trabecular bone density (BMD) and architecture influence the mechanical strength of the skeleton. However, genetic studies in humans have focused on areal measures of BMD, which reflect both cortical and trabecular bone. Little is known about the distinct and skeletal site specific genetic regulation of cortical and trabecular BMD in humans. Moreover, the genetic and environmental factors that affect bone strength phenotypes in populations of African ancestry, who have a very low risk of skeletal fragility, remain unclear. Using preliminary data on 120 women and 76 men (average age 42 yrs) from 7 multigenerational Afro-Caribbean families, we estimated heritability, and effects of age and sex, on cortical and trabecular volumetric BMD and cortical thickness for the distal and proximal tibia and non-dominant radius as measured by quantitative computed tomography. For both tibia and radius, age and sex effects accounted for a larger proportion of the total variation in cortical thickness (28 and 34%;), than in BMD (range from 9 to 25%). In addition, heritabilities of cortical BMD, trabecular BMD and cortical thickness of the tibia (0.570.16, 0.500.13, 0.380.13, respectively) were higher than those of the radius(0.130.11, 0.370.14, 0.280.11). Our preliminary analyses describe for the first time a major contribution of genes to interindividual variation in trabecular and cortical volumetric BMD among individuals of African descent. The results also indicate that factors such as age and sex have stronger effects on cortical thickness than on BMD. Additionally, genes appear to contribute to more of the interindividual variation in weight-bearing versus non-weight-bearing bones, indicating the presence of genotype by environment effects on bone phenotypes. Further studies of trabecular and cortical volumetric BMD should advance our understanding of the genetic and environmental determinants of bone strength.

Tetrahydrobiopterin responsiveness in phenylketonuria (PKU). *B. Burton, D. Hartung.* Genetics, Children's Memorial Hosp, Chicago, IL.

A significant fraction of patients with mild PKU respond to BH4 with a lowering of the blood phenylalanine (phe) level. Most investigators have found that very few patients with classical PKU exhibit a similar response. Recently, however, Matalon and Koch, et al (Genet Med 2004; 6:27-32) reported that 46% of classical PKU patients in their clinics responded to BH4. We tested 30 PKU patients (25 classical, 4 mild, 1 undefined) for BH4 responsiveness. Patients gave informed consent then were instructed to increase phe intake and/or decrease medical food intake for 3 days prior to taking a single dose of 6-BH4 20 mg/kg (maximum dose 1200 mg). Blood phe was measured at 0, 4, 8 and 24 hours. PKU mutation testing was performed for most subjects. BH4 responsiveness was defined as a decrease in blood phe level of at least 30%. 4 subjects were found to be BH4 responsive, 3 with mild PKU and one with an undefined phenotype. None of the 25 patients with classical PKU were BH4 responsive, although 1 subject had a 25% decline in blood phe level. The mean blood phe level at 0 time in the non-responsive subjects was 1121umol/L. The results for the BH4 responsive subjects are given below:

1	Mild	370, 200, 145, 152	L348V/R408Q
2	Mild	455, 291, 236, 339	F39del/A345S
3	Mild	394, 267, 152, 315	R408W/A345S
4	Undefined	800, 666, 297, 242	Pending

In our experience, few patients with classical PKU with high blood phe levels respond to a single high dose of BH4. Nonetheless there may be individual patients who will respond and it is possible that chronic treatment will result in a response that is not apparent after ingestion of a single dose. Further studies will be needed to address these questions.

Pediatric aspects of Fabry disease. *A. Raas-Rothschild¹, R. Backenroth², Y. Aurbach³, R. Weintraub-Shteyer⁴, A.J. Rein⁵, M. Zeigler¹, C. Thevenot⁶, G. Bach¹, D.P. Germain⁶.* 1) Human Genetics, Hadassah Hebrew University Medical Center, Jerusalem, Israel; 2) Department of Nephrology, Hebrew University Medical Center, Jerusalem, Israel; 3) Maccabi Health Services, Jerusalem, Israel; 4) Pediatric Day Care Hospital, Hebrew University Medical Center, Jerusalem, Israel; 5) Division of Pediatric Cardiology, Hebrew University Medical Center, Jerusalem, Israel; 6) Department of Genetics. Hopital Europeen Georges Pompidou. 75015 Paris, France.

Fabry disease (FD) is an X-linked lysosomal storage disorder due to the deficiency of the enzyme alpha-galactosidase with subsequent accumulation of globotriaosylceramide (Gb3) in the lysosomes of various tissues leading to clinical symptoms. The progressive nature of the disease and its time course explain why most disease features are reported in adults. Hemizygous males are invariably affected with the following clinical features: acroparesthesias, angiokeratomas, corneal and lenticular opacities, hypohydrosis and end-organ disease (kidney, heart and brain). However, findings in early childhood have been only recently reported and discussed. Here, we present our observations on 13 affected children and describe some less frequently recognized manifestations of FD, such as failure to thrive, short stature, gastro-intestinal involvement and priapism. We also present the outcome of enzyme replacement therapy with agalsidase beta in 5 children. Children were treated 18 months to 3 months with a good safety profile. We propose to evaluate treatment efficacy on pain assessment, school absenteeism, growth, abdominal pain, diarrhea and sweating. Our experience may contribute to the knowledge of FD in pediatrics and to the discussion of when to initiate ERT in children.

Enzyme Replacement Therapy with Hematopoietic Cell Transplant in Hurler syndrome: Multicenter initial experience. *S. Grewal¹, R. Wynn², J. Abdenur³, B. Burton⁴, M. Gharib², C. Haase⁵, D. Sillence⁶, G. Tiller⁷, P. Woodard⁸, N. Wulffraat⁹, G. Young³, C. Peters¹.* 1) Univ of Minnesota, Minneapolis, MN; 2) Manchester Childrens Hospital, UK; 3) CHOC, CA; 4) Childrens Memorial Hospital, Chicago, IL; 5) University of Jena, Germany; 6) Childrens Hospital Westmead, Australia; 7) Vanderbilt Medical Center, Nashville, TN; 8) SJCRH, Memphis, TN; 9) Childrens Hospital, Utrecht, NL.

Hematopoietic cell transplantation (HCT) can preserve intellectual function and improve survival in Hurler syndrome; however, it is associated with morbidity and mortality. Laronidase enzyme replacement therapy (ERT) can significantly reduce abnormal glycosaminoglycan (GAG) storage in many tissues, including the airways, leading to the hypothesis that it could mitigate HCT related complications. We report the initial multicenter experience with combined use of ERT and HCT in Hurler syndrome. Both pre- and post-HCT data were available on 10 patients. The median age at initiation of ERT was 13 months (range, 8-18 months), with a dose of 0.58 mg/kg/week. The median duration of pre-HCT ERT was 12 weeks (range, 6-24 weeks). All but 1 patient tested showed significant decrease in urinary GAG excretion during ERT. ERT infusion toxicity was mild. Development of antibodies to laronidase did not correlate with infusion reactions or responses in urinary GAG excretion. HCT preparative regimens varied by institution. Donor graft included cord blood, unrelated or sibling bone marrow. ERT was given for a median of 12 weeks (range, 4-20 weeks) after HCT. Following HCT, seven patients demonstrated complete donor engraftment; three patients suffered graft failure. Two patients required ventilator support; three developed acute GVHD. One patient died of multiple complications including pulmonary hemorrhage. Nine patients are surviving with followup of 1-6 months. We conclude that in children with Hurler syndrome, ERT with HCT is feasible and appears well tolerated. Development of antibodies against enzyme does not appear to correlate with infusion reactions or response to ERT. A systematic prospective study is needed to determine the effect of concomitant ERT on transplant outcomes.

Hematopoietic stem cell transplantation in a mouse model of gyrate atrophy: Does bone marrow transplantation correct hyperornithinemia? *B. Ross*¹, *M. Collector*², *S. Sharkis*², *D. Valle*³. 1) Dept Gynecology and Obstetrics, Johns Hopkins Univ, Baltimore, MD; 2) Sidney Kimmel Comprehensive Cancer Center at Johns Hopkins, Johns Hopkins University School of Medicine, Baltimore, MD 21287, USA; 3) Howard Hughes Medical Institute, Johns Hopkins University School of Medicine, Baltimore, MD 21205, USA.

Gyrate atrophy of the choroid and retina is an autosomal recessive disorder that results from the absence of ornithine delta-aminotransferase (OAT) and is characterized by hyperornithinemia and progressive retinal degeneration that culminates in blindness. In unaffected individuals OAT is expressed in the retina, liver, kidney, and small intestine. Although the pathophysiology of the retinal degeneration is not completely understood, studies have demonstrated that lower serum ornithine levels correlate with diminished retinal damage. A mouse model of this disorder has been previously reported. To determine if bone marrow transplantation could serve as a therapeutic option, female GA mice were transplanted with an enriched population of GFP labeled hematopoietic stem cells from healthy male mice and the percent of engraftment and serum ornithine levels were serially monitored for up to one year. The sub-population of HSCs used had been shown in a prior study to convert to hepatocytes when co-cultured with injured liver separated by a barrier. Following a standard protocol, the animals were transplanted with 1 million or 10 million cells. Despite consistently high levels of engraftment, greater than 70%, there was no drop in serum ornithine levels. We conclude that although high levels of engraftment with HSCs can be achieved and maintained without liver injury the degree of liver engraftment is insufficient, thus there is no correlating drop in serum ornithine levels.

Long-Term Outcome of Stem Cell Transplant in a Patient with Hunter Syndrome. *B.T. Tinkle¹, R.E. Harris², D.N. Franz³, L.A. Bailey¹, G.A. Grabowski¹.* 1) Divisions of Human Genetics; 2) Hematology-Oncology and; 3) Neurology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Hunter syndrome (mucopolysaccharidosis type II) is an X-linked lysosomal storage disorder resulting in the accumulation of glycosaminoglycans in multiple tissues due to the deficiency of iduronate-2-sulphatase. Patients exhibit clinical variability but present with coarse facial features, dysostosis multiplex, cardiomyopathy, hearing loss, and central nervous system involvement. Death commonly occurs in the first decade of life. Bone marrow transplantation (BMT) has been performed on more than 30 patients. The majority do not survive and those that do either are thought to have a milder phenotype or do poorly. We report a patient with severe neurobehavioral symptoms who received stem cell transplant (SCT) before the age of 2 years. The first graft failed but the second, 6 months later, has remained fully engrafted for over 4 years. Despite significant neurobehavioral problems, the patient continues to make developmental progress with intensive behavioral interventions. Bony changes are seen but are minimal as are the joint contractures. Brain MRI has shown continuing improvements in the myelination pattern and spectroscopy has returned to normal. The heart valves remained thickened, but the hypertrophy has improved overall. Liver and spleen volumes continue to decline despite a normal growth pattern suggesting continued clearance. His severe neurobehavioral patterns suggest a more severe Hunter phenotype yet, despite earlier cases of BMT, he has not only survived but does not show the deterioration as would be expected from the natural history of this disorder. The direct effects of the transplantation are hard to assess and it remains unknown whether his course is due to the phenotype of his private mutation, the transplant approach used, or by random chance. Thus, transplantation should still be considered, albeit cautiously, in children with Hunter syndrome under the age of 2 years.

Treatment of carpo-tarsal nephropathic osteolysis with zoledronic acid. *I. Kaitila, P. Arikoski, R. Karikoski, E. Marttinen.* Dept Clinical Genetics and Hospital for Children and Adolescents, Helsinki Univ Central Hosp, Helsinki, Finland.

The pathogenesis of the progressive carpo-tarsal osteolysis with nephropathy (OMIM# 166300) is unknown. No mode of treatment has been proposed. To treat the probably secondary central osteoporosis and, possibly, slow down or prevent the progression of the osteolytic process in a 15-year-old boy, we infused intravenously a potent bisphosphonate, zoledronic acid, every three months for one year. The proband was the second child of healthy unrelated parents. The osteolytic process was detected at the age of two years in studies for the cause of painful swelling in wrists, hands, ankles and feet. Proteinuria and cataracts were also observed. At the age of 12 years arterial hypertension developed, and enalapril treatment was started. Osteolytic process in the periphery of the extremities has been insidiously progressive without pain, swelling or other signs of inflammation after the initial phase: the carpal and tarsal bones, and phalanges have almost completely disappeared. Proteinuria has persisted, and renal biopsy showed hyalinisation of glomeruli, thickening of mesangial matrix, and interstitial fibrosis. The renal function tests have remained normal. Plasma Ca, Pi, ALP, and PTH have constantly been within the normal range. The skeletal radiographs suggested central osteoporosis, and BMD at the LI-IV was 0.683 g/cm² (Z-score -1.60), and femoral collum 0.715 g/cm² (Z-score -1.2) at the age of 13 years. The first infusion of zoledronic acid (1 mg in 50 cc of physiologic saline over 15 min) resulted in the expected acute phase reaction (fever, skeletal pain), whereas the following three infusions had no adverse effects. Except for mild hypocalcaemia the laboratory tests remained within the normal range. In particular, the renal function tests did not reveal any deterioration. The skeletal radiographs did not reveal any objective effect of the medication. However, BMD at the LI-IV increased to 0.993 g/cm² (Z-score 1.0), and femoral collum to 0.840 g/cm² (Z-score - 1.1). The efficacy of bisphosphonates as treatment for osteolytic disorders remains to be evaluated.

Effect of L-Arginine on the Neurotransmission and the Mitochondrial Respiration of Mice Brains Synaptosome.

K. Hirata¹, Y. Akita¹, N. Povalko^{1,2}, J. Nishioka¹, K. Ishida¹, M. Nishimura¹, C. Mitsumasu¹, Y. Koga¹. 1) Pediatrics and Child Health, Kurume Univ. School of Med., Kurume, Fukuoka, Japan; 2) Laboratory of Inherited Metabolic Disease, Research Center for Medical Genetics, RAMN, Russia.

Mitochondrial myopathy, encephalopathy, lactic acidosis and stroke-like episodes (MELAS) is a maternally inherited multi-system mitochondrial disorder characterized by stroke-like episodes before 20 years of age. L-arginine (Arg), a potent vasodilator via endothelial function through nitric oxide production (NO), has been used for therapeutic trials in MELAS patients during the acute phase of stroke-like episodes. We found that Arg therapy quickly decreased severity of stroke-like symptoms in MELAS, enhanced dynamics of the microcirculation, and also reduced tissue injury from ischemia. In this study, we elucidate the biochemical effects of Arg on nerve endings. Endbrains from wild-type mice (ICR) were used throughout this study. Crude synaptosome was analyzed for their concentration of GABA and Glutamate (Glu) after preparations of several fractions. We analyzed the contents of releasing amino acids evoked by high potassium condition and uptake of them in three separated fractions (cytosol, vesicles and intact mitochondria). The oxygen consumption was measured by oxygen electrode. The entire uptakes of GABA and Glu were inhibited by rotenone (30 nmole/mg protein) with dose-dependent manner and showed a plateau at about 70% of total uptake. Arg inhibited the uptake of Glu logarithmically, however showed no change in uptake of GABA. The contents of GABA and Glu in synaptosome were decreased in the presence of Arg by inducing their release. The up regulation of GABA release without rotenone was occurred uniquely by Arg. Arg enhanced the respiration of state II by succinate on synaptosomal respiration, although the respiration of synaptosomal mitochondria fraction and the respiratory chains enzyme activities were almost unaffected by Arg. In conclusion, these results suggest that L-arginine may modulate the neuroexcitability on nerve endings uniquely and alleviate stroke-like episodes in MELAS.

Human foamy virus based gene transfer vectors the treatment of metachromatic leukodystrophy. *T. Rupa¹, J. Liu¹, C. Regan¹, E. Dodds², G. Patton², M. McClure².* 1) Biochemical Genetics Lab, Child & Parent Resource Inst, University of Western Ontario, London, ON, Canada; 2) Imperial College, London, UK.

The human foamy virus (HFV) is a Spumavirus in the genera of Retroviridae. HFV has a wide tissue tropism and host range, large genome size and is capable of integration into both dividing and non-dividing cells. Most importantly it is not pathogenic. Metachromatic leukodystrophy (MLD) is an inherited lysosomal storage disorder caused by a defect in the arylsulfatase A (ASA) gene. ASA catalyzes the first step in the catabolism of the myelin glycolipid sulfatide. There is no cure for MLD. HFV derived vectors expressing galactosidase (BGAL), green fluorescent protein (GFP) and ASA-GFP have been produced by triple transfection of 293T cells. These vectors have been used both in vitro and in vivo to study the expression of the transgenes in cultured murine oligodendrocyte N20.1 cells, cultured human fibroblasts from controls and patients with metachromatic leukodystrophy and in a murine ASA knockout model of MLD (ASA KO). HFV-LacZ vector was used to transfect the murine oligodendrocyte N20.1 cell line and 40-80% cells expressed BGAL after 72 hours. Six clones of permanently expressing BGAL have been used to locate the sites of genomic integration. In human MLD fibroblasts transfected with HFV-ASA-GFP, GFP was expressed in 5-10% of MLD fibroblasts. The results of ASA assay in a population of transfected human fibroblasts enriched in GFP positive cells demonstrated that the overexpressed ASA could efficiently hydrolyze both bodipy sulfatide and the artificial substrate (p-nitrocatechol sulfate). ASA overexpressed in the transfected human cultured fibroblasts was taken up by both cultured fibroblasts from human MLD patients and by primary neural cell cultures of the ASA KO mouse and able to correct the ASA deficiency. HFV-lacZ, HFV-GFP and HFV-ASA-GFP gene transfer vectors were injected into the brains of ASA KO mouse. Reporter genes LacZ or GFP were expressed in cells around the injection site for at least three months without a decline in reporter signal intensity. These data indicate that HFV vectors may be effective as gene transfer vectors in the treatment of MLD.

Neural Progenitor Cells from an Adult Patient with Fragile X Syndrome. *P. Schwartz*^{1,2,3}, *F. Tassone*⁴, *C.M. Greco*⁵, *H.E. Nethercott*¹, *B. Ziaieian*², *R.J. Hagerman*⁶, *P.J. Hagerman*⁴. 1) National Human Neural Stem Cell Resource; 2) Stem Cell Research, Children's Hospital of Orange County Research Institute, Orange, CA; 3) Developmental Biology Center, School of Biological Sciences, University of California, Irvine, Irvine, CA; 4) Departments of Biochemistry and Molecular Medicine, Davis, CA; 5) Department of Pathology, Davis, CA; 6) M.I.N.D. Institute, University of California, Davis, School of Medicine, Davis, CA.

Fragile X syndrome, the leading heritable form of mental impairment, is a trinucleotide repeat disorder that is caused by methylation-coupled gene silencing for CGG repeat expansions greater than ~200. In an effort to develop a human cell-appropriate model to study this disorder, neural cells were successfully harvested and grown from post-mortem brain tissue of a 25-year-old adult male with fragile X syndrome. The cultured cells display many of the characteristics of neural progenitor cells as well as the biochemical hallmarks of fragile X syndrome. These neural progenitor cells do not express any FMR1 mRNA or FMRP. We further demonstrate initial efforts to differentiate these progenitor cells into both neuronal and astrocytic lineages. The successful production of neural cells from an individual with fragile X syndrome opens a new avenue for the scientific study of the molecular basis of this disorder, as well as an approach for studying the efficacy of new therapeutic agents.

SMN mRNA and protein: surrogate biological markers of drug-response in Spinal Muscular Atrophy (SMA)

clinical trials. L.R. Simard¹, M. Hang², S. Morissette¹, M.-C. Bélanger¹, M. Wride², J. Johnson², K.J. Swoboda². 1) Centre de recherche de l'Hôpital Sainte-Justine, Université de Montréal, Montréal, PQ, Canada; 2) University of Utah, Salt Lake City, Utah, USA.

SMN2, a duplicate copy of the *SMN1* gene, is the only known modifier gene of SMA, a devastating childhood neurodegenerative disease. The timing and extent of motoneuron cell death is most likely a dosage effect of residual SMN protein. Anticipating upcoming clinical trials using compounds that either alter SMN splicing or up-regulate SMN expression, we developed and validated sensitive methods amenable to multi-center drug trials to measure SMN mRNA and protein in specimens collected from SMA patients. Blood samples were collected from 40 patients and 23 carriers for about 4 visits per individual to assess variability in the same individual over time. Total mRNA was prepared using the PAXgene Blood RNA system and total protein from mononuclear cells, platelets, buccal cells or skin fibroblasts. Full-length (7in) and exon 7-lacking (7out) transcripts were quantified by real time RT-PCR using fluorescent probes. Normalized results indicated that SMN expression remained relatively stable over time and was quantitatively different between patients, carriers and controls. Given extensive inter-individual variability, there was no correlation between the 7in:7out ratio and *SMN2* copy number. This assay can reliably measure and distinguish the mechanism of drug-response. Analysis of SMN protein in buccal cells was aborted due to extensive non-specific cross-reactive material. While skin fibroblast yielded clean results, there was no advantage compared to blood. Thus, protein was examined by Western blot analysis using platelets and mononuclear cells prepared from whole blood. Results for SMN protein were similar to SMN mRNA in that SMA patient samples showed the lowest amount of SMN protein in both platelets and mononuclear cells whereas controls and carriers showed the highest and intermediate amounts, respectively. Our data supports the reliability and potential usefulness of these assays in assessing SMN mRNA and protein as surrogate markers in therapeutic trials. *Funded by Families of SMA.*

Systemic gene transfer of AAV6-IGF-1 slows disease progression in a mouse model of ALS. *P. Weydt¹, S. Abmayr², J. Allen², P. Calses¹, L. Meuse², A.R. La Spada^{1,2,3}, J. Chamberlain².* 1) Department of Laboratory Medicine, University of Washington, Seattle, WA; 2) Department of Neurology, University of Washington, Seattle, WA; 3) Division of Medical Genetics, Department of Medicine, University of Washington, Seattle, WA.

Amyotrophic lateral sclerosis (ALS) is a paralyzing, invariably fatal adult-onset neurodegenerative disorder, which is defined by a progressive and selective loss of the motor neurons of the spinal cord and the brain. ALS affects 8 in 100,000 people per year and there is currently no cure. Recent studies have demonstrated that intramuscular injections with viral vectors expressing neurotrophic factors such as insulin-like growth factor 1 (IGF-1) or vascular endothelial growth factor (VEGF) can substantially extend survival in the SOD1-transgenic mouse model of ALS. The therapeutic effect is thought to involve retrograde axonal transport of a small fraction of the injected vector from the intramuscular injection site to the motoneuron cell bodies in the spinal cord. Intravenous delivery of recombinant adeno-associated virus pseudotyped with serotype 6 capsids (rAAV6) is an efficient way of targeting the entire muscle mass of the body without the need and risks of multiple intramuscular injections (Gregorevic et al, Nat Med, 2004, in press). Consequentially this method has the potential to target all lower motoneurons. We explored how systemic injection of the rAAV6 vector affects disease progression in the G93A SOD-1 transgenic mouse model of ALS. These mice uniformly develop a progressive motor paralysis around 90 days of age, which is typically fatal at 120-130 days of age. We report that a single IV injection of 10^{12} viral genomes of rAAV6/CMV-mIGF1 per animal at 60 days of age slows disease progression significantly and prolongs survival by about 19 days (22%). This result demonstrates that AAV6 is a safe and useful method to deliver therapeutic doses of IGF1 to the motor system.

Correction of Hurler syndrome with a single IV administration of lentiviral vector to newborn mice. C.B.

Whitley¹, D. Pan¹, R. Gunther¹, W. Low¹, B. Larson¹, S.U. Walkely², J. Frandsen¹, D.C.C. Erickson¹, T. Kafri³, R.S. McIvor¹. 1) Gene Therapy Center, MMC 446, University of Minnesota, Minneapolis, MN 55455; 2) Sidney Weisner Laboratory of Genetic Neurological Disease, Department of Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461; 3) University of North Carolina, Chapel Hill, NC 27599.

Mucopolysaccharidosis type I is a lysosomal disorder due to deficiency of -L-iduronidase (IDUA). As illustrated here, the knockout mouse is a valid model of human disease, exhibiting metabolic defects, dysmorphology and learning defects analogous to affected children. A lentiviral vector expressing IDUA enzyme was administered intravenously to newborn mice with Hurler syndrome. After this single injection, plasma levels of IDUA enzyme were increased in all treated mice throughout the 100-day study period (0.1- to 60-fold of normal heterozygote level), and reached levels 2- to 60-fold above normal in 7 of 10 mice. In 6 of 10, hepatic IDUA enzyme levels were 4- to 17-fold above normal. Significant amounts of IDUA enzyme were found in spleen (2-20%; of normal heterozygote), heart (2-11%;), brain (1.5-7%;) and peripheral blood leukocytes (1.7-10%;). High levels of transgene were detected in liver (1-115%;, ie, 1 - 115 IDUA gene copies per 100 genome equivalents), heart (0.05-23%;) and spleen (0.06 - 4.1%;). Metabolic correction was indicated by the complete absence of pathology in liver and kidney in most mice, and by absence of facial dysmorphology in all mice. In mice with the highest circulating enzyme levels, pathologic GM2- and GM3-ganglioside were markedly reduced in the brain, and this effect was inversely related to the level of enzyme. Notably, a learning abnormality was identified, but was absent in treated mice. Transplantation of marrow into another generation of knockout mice demonstrated persistence of IDUA transgene thus demonstrating gene transfer into hematopoietic stem cells, a potential conduit for IDUA enzyme across the blood-brain barrier. These observations are the first demonstration of metabolic and phenotypic correction of a disorder by in vivo gene therapy after neonatal treatment with a lentiviral vector.

RNAi mediated gene therapy for dominantly inherited vascular Ehlers-Danlos syndrome (EDSIV). A. Watanabe^{1, 2}, K. Ter³, T. Wada⁴, Y. Fukushima⁴, T. Shimada^{1, 2}. 1) Dept Biochemistry & Molec Biol, Nippon Medical Sch, Tokyo, Japan; 2) Div clinical Genetics, Nippon Medical Sch Main Hosp, Tokyo, Japan; 3) UPBSB, Dept Biophysics & Biochem, School of Sci, Univ of Tokyo, Tokyo, Japan; 4) Div Clinical & Molec Genet, Shinshu Univ Hosp, Matsumoto, Japan.

Vascular Ehlers-Danlos syndrome (vEDS, also known as EDSIV), is a life-threatening dominantly inherited disorder caused by mutations in the gene for type III procollagen (*COL3A1*). Affected individuals are at risk for arterial, bowel and uterine rupture. There is no effective treatment to prevent the symptom associated with vEDS. Although gene therapy is an important option for treatment of genetic disorders, the current strategy based on addition of the defective gene is not applicable for dominant diseases such as vEDS. RNA interference (RNAi) may hold therapeutic promise for silencing dominantly acting genes. Approximately one third of the known mutations of vEDS occur at 5 donor splice sites. Therefore, if aberrantly spliced mRNA could be selectively destroyed by RNAi, it might be possible to reduce the mutant *COL3A1* level and increase the relative concentration of normal triple helix. In this work, we examined the feasibility of the RNAi mediated gene therapy for vEDS. The target is a substitution of A for G+ 1 at the 5 site of intron 20 of the *COL3A1* gene (G+1 IVS20) which generates mutant mRNA molecules containing either 24 nucleotides from intron 20 or the total intron 20 sequence. We synthesized several small interfering RNA (siRNA) molecules targeting the extra intron 20 sequence and introduced into patients fibroblasts with the G+1 IVS20 mutation. Expression of normal and mutant *COL3A1* mRNA were quantitatively measured after RT-PCR. The results indicated that mutant mRNA levels could be selectively decreased up to 70 % by transient transfection of one of the siRNA molecules. These studies strongly encourage the RNAi mediated allele specific gene silencing for dominant disease gene. A major shortcoming of this approach is the transient nature of the effect due to the intracellular degradation of siRNA. The use of integrating viral vector for stable expression of siRNA may be feasible for treatment of vEDS.

Congenital Leptin Deficiency due to Homozygosity for the 133G Mutation: Report of a Further Case and Evaluation of Response to Four Years of Leptin Therapy. *W. Gibson¹, I.S. Farooqi², M. Moreau³, A.M. DePaoli⁴, E. Lawrence⁴, S. O'Rahilly², R.A. Trussell³.* 1) Department of Medical Genetics, B.C. Children's Hospital, Vancouver, British Columbia, Canada; 2) University Department of Clinical Biochemistry, Cambridge Institute for Medical Research, Addenbrooke's Hospital, Cambridge, UK; 3) Department of Paediatric Endocrinology, Alberta Children's Hospital, 1820 Richmond Rd. SW, Calgary, Alberta, Canada; 4) Amgen Inc., One Amgen Center Drive, Thousand Oaks, CA, USA.

Congenital leptin deficiency is a rare, but treatable, cause of severe early-onset obesity. To date, two UK families of Pakistani origin carrying a frameshift/premature stop mutation c.398delG (133G) and one Turkish family carrying a missense mutation c.313CT (Arg105Trp) have been described. Affected subjects are homozygotes and manifest severe obesity and hyperphagia accompanied by metabolic, neuroendocrine and immune dysfunction. The effects of recombinant leptin therapy have been reported in three children with the 133G mutation, and in all cases this has led to a dramatic resolution of clinical and biochemical abnormalities. We now report a Canadian child, of Pakistani origin but unrelated to the previously reported subjects, presenting with severe hyperphagia and obesity, who was found to be homozygous for the 133G mutation. In this child, four years of therapy with subcutaneous injections of recombinant leptin provided further evidence for the sustained beneficial effects of leptin replacement on fat mass, hyperinsulinaemia and hyperlipidaemia. In addition, leptin administration corrected abnormal thyroid biochemistry and allowed the withdrawal of thyroxine treatment, providing further support for the role of leptin in the regulation of the human hypothalamic-pituitary-thyroid axis.

Clinical presentation and management of Hemoglobin Buenos Aires: conundrums. *R.M. Roberts¹, L.M.S. Resar², T. Hays³*. 1) Genetics and Prenatal Diag Ctr, Sarasota, FL; 2) Johns Hopkins University School of Medicine, Baltimore, MD; 3) University of Colorado Children's Hospital, Denver, CO.

Few case reports of Hb Buenos Aires (also known as Hb Bryn Mawr) exist. The clinical presentation varies, and only a few (possibly two) families have been tested to confirm new mutations, heterozygotes in the affected. Hb Buenos Aires is unstable because of abnormal avidity for oxygen, and the patient is at risk of significant hemolytic anemia and aplastic crisis with Parvovirus B19. Our patient presented with episodic undiagnosed splenomegaly associated with URI and streptococcal pharyngitis at ages 4 and 5, the latter with an elevated reticulocyte count as the only hematological abnormality noted. At age 6, lab workup for another strep pharyngitis associated with splenomegaly revealed evidence of chronic stable hemolytic anemia, and the diagnosis of Hb Buenos Aires was made at the Johns Hopkins DNA Diagnostic Lab after Hematologic referral. The patient moved to Denver, where at age 7 developed aplastic crisis following Parvovirus B19 infection, requiring transfusion after Hb fell to 5.0 (the first Japanese case presented with aplastic crisis in a 9-year old girl in 1992). Hb has since been in the range of 10 to 12, but fell to 7 following a minor strep infection characterized by jaundice, splenomegaly and abdominal pain. A 2nd Japanese case was reported in 2002 of compensated hemolytic anemia with jaundice, reticulocytosis, and Hb 12-13 in a 12 y.o. boy while stable, with episodes of hemolytic crisis and aplastic crisis. Some evidence suggests that tissue hypoxia does not occur because of the increased avidity to O₂, possibly contradictory to suggested presurgical management with erythrocytapheresis advocated in Hb Bryn Mawr by Larson et al in 1997. Further unresolved questions: do these patients merit splenectomy or is the surgical and post-splenectomy risk of death by bacterial sepsis too high? Are some heterozygotes asymptomatic? Is the prevalence significantly underestimated? Does splenectomy significantly decrease the risk of hemolytic crisis?

Response to Very Early Copper Treatment in Classical Menkes Disease. *S.G. Kaler, P.C. Liu, J. Tang, K.E. Lem.*
Intramural Research Program, NICHD, NIH, Bld 10, Rm 9S 261, Bethesda, MD.

Menkes disease (MD) is a X-linked recessive disorder of copper transport caused by mutations in a copper-transporting ATPase (ATP7A). From July 1995 to June 2004, we conducted a clinical trial of early copper therapy in 16 previously unreported infants with MD, using a single formulation of copper histidine (CuHis, IND #34,166). Mean age on study entry was 11.8 d (range: 5-30 d). No infant showed neurological symptoms upon entry; diagnosis was by plasma or CSF neurochemical analysis, with molecular confirmation. CuHis dose was 250 mcg by subcutaneous injection twice daily until age 12 mos, and then once daily, to 3 yrs. Primary outcome parameters included clinical neurodevelopment, brain MRI, EEG, serum and CSF copper, plasma and CSF catecholamine ratios, mutation at the ATP7A locus, and confocal microscopic imaging of cultured patient fibroblasts. Four patients with detectable ATP7A protein on confocal analysis achieved independent ambulation at or before 15 mos of age and are neurologically normal at ages ranging from 3 to 9 yrs. Twelve patients with less successful neurodevelopmental outcomes, including four who died by age 3 yrs despite very early intervention, showed little or no ATP7A on confocal imaging. The latter group included patients with large deletions and frameshift mutations. Post-mortem analysis of brain copper was available for one such patient and indicated failure of copper histidine to cross the blood-brain barrier into the central nervous system, despite restoration of normal blood copper levels. In responder patients, CSF catechol ratios were four-fold lower (indicating less profound deficiency of dopamine-beta-hydroxylase) compared to non-responders. We conclude that baseline determination of CSF catechol ratios, mutation type, and presence of residual ATP7A by confocal microscopic analysis of cultured cells predict a subset of patients with classical MD in whom early copper histidine therapy will normalize neurodevelopmental outcome. For other patients, in whom residual ATP7A activity is not evident, alternative approaches to breach the blood-brain barrier (e.g., intrathecal copper histidine administration) appear warranted.

Fetal Cells Appear to Participate in the Maternal Response to Wound Healing. *P.K. Khosrotehrani*^{1,2}, *S. Guegan*^{1,2}, *K.L. Johnson*², *G. Sahagian*³, *K. Tao*³, *D.W. Bianchi*². 1) Dept Dermatology, Hopital Tenon, Paris, France; 2) Dept Pediatrics, Division of genetics, Tufts-New England Medical Center, Boston, MA, USA; 3) Dept of Physiology, Tufts University School of Medicine, Boston, MA, USA.

Background: In humans, fetal cells with stem-cell capabilities enter the maternal circulation and persist for decades. We recently reported that fetal cells could adopt the maternal injured tissue phenotype and that they express non-hematopoietic markers (JAMA 2004; in press). Our objective was to determine whether fetal cells participate in maternal wound healing in a mouse model. **Methods:** We mated female wild-type FVB mice to males transgenic for the luciferase gene under the control of the constitutively expressed CMV promoter (CMV:Luc) (n=2) or the transcriptionally-regulated angiogenic factor VEGFR2 promoter (VEGFR2:Luc) (n=11) or to wild-type males as controls (n=2). At various times during and after pregnancy we performed a 6mm punch skin biopsy. The presence of the luciferase-expressing fetal cells in the maternal wound was assessed using in vivo whole animal imaging. **Results:** In the absence of injury, no luciferase signal could be visualized in any area outside the utero-placental signal corresponding to the transgenic fetuses. Three days after inducing injury in wild-type female mice mated with CMV:Luc males, luciferase activity, associated with the presence of transgenic fetal cells, could be visualized in the wound area but not in the surrounding healthy tissues. Similarly, a specific signal was observed in the wound of female mice mated with VEGFR2:Luc males. Luciferase activity was seen in both pregnant and post-partum mice. No signal was observed in control female mice mated to wild-type males that produced no transgenic fetuses. **Conclusions:** We demonstrate that fetal cells transferred during pregnancy specifically home to the maternal skin wound and express VEGFR2, a marker for wound healing and angiogenesis. Fetal cells appear to participate in the maternal wound healing process. Studies of adult stem cells need to consider the possibility that some of the cells with observed plasticity derive from the fetus or placenta.

Clinical response to enzyme replacement therapy in pediatric patients with type 1 Gaucher Disease. H.C.

Andersson^{1,3}, P. Kaplan^{2,3}, K. Kacena³, J. Yee³. 1) Hayward Genetics Center, Tulane Univ. Health Sci. Ctr., New Orleans, LA; 2) Childrens Hosp. of Philadelphia, Univ. of Pennsylvania School of Medicine, Philadelphia, PA; 3) Int'l. Collaborative Gaucher Group, Genzyme Corp, Cambridge, MA.

50% of type 1 Gaucher disease (GD1) patients are diagnosed before 18y. No long-term assessment of clinical response to enzyme therapy (ERT) in pediatric patients has been reported. We report the response to ERT in 433 symptomatic GD1 patients under 18y in the Gaucher Registry, an international registry established in 1991. Minimum average ERT dose was 30u/kg/infusion q2wks and none had splenectomies.

DISEASE MANIFESTATION	BASELINE PREVALENCE	PREVALENCE AFTER ERT
Anemia	42%	18% at 36mo ERT
Low platelets(<120K/cu mm)	63%	16% at 36mo ERT
Low platelets (<60K/cu mm)	9%	0% at 48mo ERT
Splenomegaly (>15MN)	69%	10% at 36mo ERT
Hepatomegaly (>1.25MN)	92%	36% at 48mo ERT
Growth, >2SD below mean ht	25%	15% at 48mo ERT
Growth, below mean ht	80%	65% at 48mo ERT

Longitudinal curves for each parameter over 10y ERT show sustained benefits. Clinical response was greatest in patients with severest pathology. These data allow the first prediction of ERT responses in pediatric GD1.

Overall treatment effects of agalsidase alfa in Fabry disease: results from FOS - the Fabry Outcome Survey. *M. Beck*¹, *A. Mehta*², *G. Sunder-Plassmann*³, *U. Widmer*⁴. 1) Department of Paediatrics, University of Mainz, Mainz, Germany; 2) Department of Haematology, Royal Free Hospital, London, UK; 3) Department of Medicine III, Medical University, Vienna, Austria; 4) Department of Medicine, University of Zurich, Zurich, Switzerland.

Fabry disease is a rare X-linked disorder caused by deficient activity of the lysosomal enzyme -galactosidase A. Progressive accumulation of the substrate globotriaosylceramide in cells throughout the body leads to major organ failure and premature death. The Fabry Outcome Survey - FOS - is a European outcomes database which was established to collect data on the natural history of this little-known disease and to monitor the long-term efficacy and safety of enzyme replacement therapy (ERT) with agalsidase alfa. We report here an analysis of the FOS database on the effects of ERT on renal function, heart size, pain and quality of life in a cohort of 314 patients (203 males, 111 females) given agalsidase alfa (0.2 mg/kg infused over 40 minutes every 2 weeks) for up to 2 years. Treatment with agalsidase alfa stabilized renal function (as assessed by estimated glomerular filtration rate) in patients with a mild or moderate deterioration in renal function at baseline, reduced left ventricular size (as assessed by echocardiography) in patients who had an enlarged heart at baseline, and improved pain scores and quality of life (as assessed by questionnaire responses to the Brief Pain Inventory and the European Quality of Life Questionnaire EQ-5D). These improvements were similar in hemizygous men and heterozygous women with Fabry disease. The incidence of infusion reactions was approximately 0.7%; these were mild and responded to slowing or temporary cessation of the infusion or to premedication where necessary. There were no serious adverse events related to treatment. In conclusion, ERT with agalsidase alfa has significant clinical benefits in patients with Fabry disease, and appears to be able to alter the natural history of the disorder.

Monthly intrathecal enzyme replacement therapy improves lysosomal storage in the brain and spinal cord in canine MPS I. *P. Dickson¹, M. McEntee², C. Vogler³, S. Le¹, B. Levy³, P. Belichenko⁴, W. Mobley⁴, S. Hanson⁵, M. Peinovich¹, M. Passage¹, E. Kakkis^{1,6}.* 1) Harbor-UCLA Medical Ctr., Torrance, CA; 2) Dept. of Pathol., Coll. of Vet. Med., U. of Tenn., Knoxville, TN; 3) Dept. of Pathol., St. Louis U., MO; 4) Dept. of Neurol., Stanford Univ., Stanford, CA; 5) Veterinary Neurol. Ctr., Tustin, CA; 6) BioMarin Pharmaceutical Inc., Novato, CA.

Intrathecal recombinant human -L-iduronidase (IT rhIDU) given weekly in canine mucopolysaccharidosis I (MPS I) reduces CNS (central nervous system) glycosaminoglycan (GAG) storage. Monthly IT rhIDU was tested to determine whether the frequency of IT injections could be reduced while maintaining efficacy. Three MPS I dogs received ~1 mg of IT rhIDU in 4 monthly doses along with weekly intravenous (IV) rhIDU. Iduronidase levels reached 23-fold normal in brain, 7-fold in spinal cord, and 423-fold in meninges (vs. 23, 13, and 300-fold in 4 dogs treated with only IT rhIDU in 4 weekly doses). Brain GAG was 4.07 ± 0.70 g/mg tissue weight, vs. 8.26 ± 1.23 in 4 untreated MPS I dogs (p=0.003). Brain GAG with monthly IT and weekly IV rhIDU was not significantly different from weekly IT (4.47 ± 0.69, p=0.48), and approached levels in untreated normal dogs (5.40 ± 1.82, p=0.22). GAG levels in spinal cord were 3.93 ± 0.70 g/mg dry weight in monthly treated MPS I dogs, versus 5.04 ± 0.93 in untreated MPS I dogs and 3.02 ± 0.71 in untreated, normal dogs (p=NS). One dog had neurologic signs, including depressed mental status, ataxic gait, absent gag reflex, and head tilt, which improved with monthly rhIDU treatment. Two of three monthly-treated dogs developed a mild antibody response in blood and CSF. One dog had been made tolerant to rhIDU using a new method and had virtually no immune response in blood or CSF, and only a minimal response pathologically. Monthly IT with weekly IV rhIDU may be as effective as weekly IT alone in correcting the enzyme deficiency and lysosomal storage (measured by GAG levels) in the CNS in canine MPS I.

Marked improvement of leukodystrophy in a child with Hurler-Scheie Disease treated by enzyme substitution therapy. *B. Heron-Longe*¹, *C. Baumann*³, *S. Magnier*⁴, *P. Wicart*², *A. Verloes*³, *G. Ponsot*¹. 1) Pediatric Neurology Department, Hopital St Vincent de Paul, Paris, France; 2) Paediatric Surgery Department, Hopital St Vincent de Paul, Paris; 3) Clinical Genetics Department, Hopital Robert Debre, Paris; 4) Pediatric Cardiology Department, Hopital Robert Debre, Paris.

Type I mucopolysaccharidosis (MPS I) is a lysosome storage disease due to a deficiency in α -L-iduronidase. It gives rise to the onset and gradual worsening of joint and bone, cardiac, respiratory, digestive, sensorial and neurological complications. A distinction can be made between the most severe forms, or Hurler Disease with involvement of the central nervous system (CNS) and premature death, attenuated forms without dysmorphism and CNS damage or Scheie Disease, and intermediate forms, or Hurler-Scheie Disease. The only therapy available until recently was bone marrow transplant, on condition that a compatible donor could be found and that CNS damage was absent or moderate; even so, there was a high risk of fatality. Laronidase, a recombinant form of human α -L-iduronidase (Aldurazyme) is an enzyme replacement therapy for MPS 1. Studies of its efficacy concerned the non-neurological symptoms of the disease in patients aged between 5 and 65 years. The effects of this treatment on the central neurological symptoms of MPS 1 have not yet been studied and it seems to be no diffusion of the enzyme through the brain blood barrier. We report herewith on the case of a young, 7-year-old boy suffering from an intermediate form of MPS I, with retarded learning skills and leukodystrophy detected on a cerebral MRI scan. Enzyme replacement therapy was initiated and current experience of the outcome under treatment is now 18 months. No adverse effects have been observed. There was an improvement in the patient's general status and joint function, and a disappearance of visceromegaly. A clear regression of leukodystrophy was also observed. The latter observation is suggestive of a beneficial intracerebral effect of intravenous Aldurazyme and may also be suggestive of its passage into the brain.

The role of enzyme replacement therapy in the management of Hurler's syndrome. *J. Hersh¹, S. Soni², M. Hente², S. Bertolone², N. Breslin², C. Whitley³, A. Cheerva².* 1) Dept Pediatrics/WCEC, Univ Louisville, Louisville, KY; 2) Division of Pediatric Hematology/Oncology and BMT, Univ Louisville, Louisville, KY; 3) Gene Therapy Program, Univ Minnesota Medical School, Minneapolis, MN.

Hurler's syndrome (mucopolysaccharidosis type I) is a progressive multisystem disorder that results from deficient (alpha)-1-iduronidase. Major manifestations include mental retardation, macrocephaly, corneal clouding, coarse facies, hearing loss, joint stiffness, hepatosplenomegaly, obstructive airway disease, valvular heart disease and short stature. The diagnosis usually is established early in life based on clinical manifestations. Hematopoietic stem-cell transplantation is the treatment of choice in affected children under age 2 years, when there is minimal or no central nervous system disease. Enzyme replacement therapy (ERT) with recombinant (alpha)-1-iduronidase (laronidase) has been recommended for milder or attenuated forms of mucopolysaccharidosis type I. We present a Hispanic male diagnosed with Hurler's syndrome at age 7 months. Although donor cells were available, he was unable to undergo transplantation because of severe respiratory disease requiring tracheostomy and frequent hospitalizations. Following 12 weeks of ERT, there was dramatic improvement clinically enabling successful transplantation. An additional 10 weeks of ERT was given beginning 4 weeks post-transplantation until the transplanted marrow was well engrafted. Only minimal antibody titers to enzyme have been detected 3 months after discontinuing ERT, with continued rise of (alpha)-1-iduronidase levels and decrease in urinary glycosaminoglycans. Our patient's response to ERT both prior to and after hematopoietic stem-cell transplantation, lends support to considering its use 6-12 weeks before, and up to 3 months following the transplantation procedure, as a valuable adjunct in the medical management of Hurler's syndrome, in anticipation of endogenous enzyme production by donor cells.

Intrathecal Delivery of Iduronate 2-Sulfatase for MPS II to the Canine CNS. *J.C. Lamsa, A. Garcia, K. Loveday, J. Pan.* Research, TKT, Cambridge, MA.

Iduronate 2-sulfatase (IdS) was delivered to normal beagle dogs intrathecally (IT) via the cisterna magna. Bolus 1 mL IT injections of either 2 (N = 2) or 10 mg (N = 2) IdS were administered. Intravenously (IV) injected (2 mg, N = 1; 10 mg, N = 1) and untreated (N = 1) animals served as controls. Serum levels of IdS measured by ELISA remained at control levels until at least 5 hours post IT injection. The half-life of IdS in CSF was estimated to be 2 to 3 hours. Brain and liver samples were collected either 4 or 24 hours after injection. No IdS was found in liver 4 hours after IT injection. Brain tissue levels of IdS as measured by ELISA were < 2 ng/mg protein in untreated or IV injected animals. In IT treated animals (2 mg) IdS levels were 2 to 5 fold higher than IV controls throughout the brain. At the 10 mg dose, IdS levels in brain were elevated as much as 20X compared to IV controls. Fluorescent immunohistochemistry for IdS revealed that the meninges and perivascular cells were the major sites of uptake at both dose levels. At 4 hrs post IT injection, neurons and glial cells of the cerebral cortex were negative for IdS. Within 24 hrs after IT injection of 10 mg IdS neuronal and glial uptake was evident in approximately 25% of cells in the cerebral cortex compared to approximately 10% at the 2 mg dose. Two additional animals received 3 mg IdS by IT injection weekly for 4 weeks. IdS uptake was similar to a single 10 mg IT injection in terms of number of positive neurons, but the staining intensity was equivalent to the higher dosage in 1 dog, and higher in the other. These latter data indicate that IdS accumulated within neurons after repeated injection, and that the tissue half-life of IdS may be several days. We conclude that IT injection may prove valuable in treating MPS disease with CNS complications.

Low-Dose ERT for Gaucher Disease in So Paulo State (Brazil). *A.M. Martins¹, E. Sobreira², T.C. Bortolheiro³, G. Porta⁴.* 1) Centro de Referencia em Erros Inatos do Metabolismo, Universidade Federal de So Paulo, So Paulo, SP, Brazil; 2) Departamento de Pediatria e Puericultura, FCM Santa Casa de So Paulo, So Paulo, SP, Brazil; 3) Departamento de Clinica Mdica, Servio de Hematologia, FCM Santa Casa de So Paulo, So Paulo, SP, Brazil; 4) Unidade de Hepatologia Peditrica, Instituto da Crianca do Hospital das Clinicas da FMUSP, So Paulo, SP, Brazil.

INTRODUCTION The authors are members of the Sao Paulo State Expert Committee on Gaucher Disease (GD) [Sao Paulo, SP, Brazil] and now report demographic data and the evolution of patients treated in Sao Paulo State in accordance with the Clinical Protocol and Therapeutic Guidelines for GD Management created by the Brazilian Ministry of Health, www.saude.gov.br, Internal Regulation SAS/MS 449 of July 8, 2002. **METHODS** One hundred and thirty patients were evaluated in May 2004. One hundred and thirteen of them were on Enzyme Replacement Therapy (ERT) with imiglucerase, 75% of them (85/113) over 12 years of age. GD manifestations were investigated in patients over 12 years of age who were given doses of 15-30 U/kg every two weeks according to the Health Ministry (MS) Protocol from August 2002 to November 2003. **OBJECTIVES** To present the evolution of patients aged over 12 years who had their ERT doses reduced on account of being treated according the above-mentioned protocol. **RESULTS** Of the 85 patients aged over 12 years, the ERT average dose was of 37.6 U/kg/2 weeks (dose range 13-62 U/kg/2 weeks). Of the 19 patients who received doses of 13-20 U/kg/2 weeks it was noticed that 4 cases progressed with no pain and were maintained on low doses, 14 cases reported bone pain again, one of them with bone infarct, and one case reported painless lytic injury. Impaired patients were given higher doses up to 60 U/kg/2 weeks. Of the patients who received doses of 20-30 U/kg/2 weeks, 1 case progressed with no pain and was maintained on the same doses, 6 cases reported bone pain and 1 case reported a Parkinsonism condition. For the latter, the dose had to be increased up to 60 U/kg/2 weeks. **CONCLUSION** The authors reached the conclusion that ERT doses must be customized and that low doses (15 U/kg/2 weeks) are often insufficient to prevent GD complications.

Comparison of intravenous versus subcutaneous enzyme replacement therapy in the acid sphingomyelinase deficient mouse. *E. Schuchman*¹, *H. Jin*^{1,2}, *X. He*¹, *C. Simonaro*¹. 1) Dept Human Genetics, Mount Sinai Sch Medicine, New York, NY; 2) College of Veterinary Medicine, Kyungpook National Univ, Korea.

An inherited deficiency of acid sphingomyelinase (ASM) activity leads to neuronopathic and non-neuronopathic forms of Niemann-Pick disease (NPD). In all ASM deficient NPD patients, the spleen, liver and lungs represent major sites of pathology that must be targeted for therapy. Preclinical studies in the mouse model of ASM deficiency (ASMKO mice) have revealed that intravenous, bolus injection of recombinant ASM could prevent or reverse most of the disease manifestations in the spleen and liver, and could also prevent the infiltration of inflammatory cells into the lungs (Miranda *et al.*, FASEB J., 2000). However, despite these positive results, intravenous enzyme replacement therapy (ERT) in human patients is limited by the requirement for life-long enzyme infusions and high cost. We have therefore used the ASMKO mouse model to compare the efficacy of intravenous to subcutaneous ERT. For subcutaneous administration, a gas propelled Bioinjector apparatus was used. Age-matched ASMKO animals were given equivalent doses (1 mg/kg, once per week) of recombinant ASM intravenously or subcutaneously, and the efficacy of the therapy and pharmacodynamics were compared. Following enzyme injection, the peak amount of circulating ASM activity achieved by either delivery method was equivalent, although the release of this activity into the circulation was significantly slower when administered subcutaneously. The tissue distribution and efficacy also were similar, although slightly more activity was delivered to non-hepatic tissues by subcutaneous injection. Thus, subcutaneous ERT is a viable alternative to intravenous ERT, and may be considered for some lysosomal storage disorders where the safety profile is compatible with home administration.

Functional complementation of mammalian gulonolactone oxidase (GULO) deficiency using a recombinant adenovirus. *D. Sieron*¹, *M. Ha*¹, *F. Graham*^{1,2}, *J. Rosenfeld*², *S. Igdoura*^{1,2}, *H. Schellhorn*^{1,2}. 1) Department of Biology; 2) Department of Pathology and Molecular Medicine McMaster University. Hamilton, Ontario, L8S 4K1 CANADA.

Though most animals produce ascorbic acid, humans and guinea pigs are unable to produce this vitamin due to an inactivating mutation of the L-gulonolactone oxidase (GULO) gene, encoding the terminal enzyme in the biosynthetic pathway of vitamin C. A regular vitamin C supply from various foods is therefore essential to the animals bearing the genetic defect to maintain life. Prolonged vitamin C deficiency can result in scurvy, an acute condition resulting from inadequate collagen production. As an antioxidant, ascorbic acid may potentially reduce free radical accumulation and therefore protect against cancer and other oxidant-related diseases. The current reference dietary intake (RDI, formerly RDA) of ~90mg per day is likely adequate for protection against scurvy, however is probably far below ascorbic acid levels required for efficient antioxidant function. To correct the metabolic defect in mammalian cells by genetic complementation, we tested the efficacy of a recombinant adenovirus which transiently expresses the GULO gene (AdGULO1), in vitro in human carcinoma cell line (A549) and in vivo using guinea pigs. To ensure that deficient cells can be efficiently rescued by expressing the recombinant enzyme, a human lung carcinoma cell line (A549), that is non-permissive for replication, was infected with the GULO-encoding adenovirus and a mock virus control. The AdGULO1-infected, but not mock-infected, cells were proficient in synthesizing ascorbic acid indicating efficient expression from the viral construct. Animals maintained on vitamin C deficient diets that were infected with AdGULO1 exhibited reduced weight loss (a symptom of scurvy) than animals injected with a knock out version of the virus. We are currently investigating if high intracellular levels ascorbic acid can provide effective protection during oxidative stress.

Therapeutic Goals in the Treatment of Type 1 Gaucher Disease. *N.J. Weinreb¹, G.M. Pastores², H. Aerts³, G. Andria⁴, T.M. Cox⁵, M. Giral⁶, G.A. Grabowski⁷, P.K. Mistry⁸, A. Tylki-Szymanska⁹.* 1) University Research Foundation for Lysosomal Storage Diseases, Coral Springs, FL; 2) New York University School of Medicine, New York, NY; 3) Academic Medical Centre, Amsterdam, the Netherlands; 4) Federico II University, Naples, Italy; 5) Addenbrookes Hospital, Cambridge, UK; 6) Hospital Miguel Servet, Zaragoza, Spain; 7) Childrens Hospital Research Foundation, Cincinnati, OH; 8) Yale University School of Medicine, New Haven, CT; 9) The Childrens Memorial Health Institute, Warsaw, Poland.

Many type 1 Gaucher disease (GD) manifestations are reversed or relieved with regular infusions of enzyme replacement therapy (ERT), the internationally accepted standard of care. Treatment initiation and assessment must be tailored to the individual patients needs, as presentation, severity, and progression vary greatly. Because evidence-based, organ-system-specific, individualized therapeutic goals are needed, an international panel of physicians with extensive clinical expertise in type 1 GD reviewed ICGG Gaucher Registry findings and relevant published literature and created a comprehensive set of organ-system-based therapeutic goals to guide individualized therapy. These goals assume that optimal treatment addresses the entire disease burden, the baseline severity of disease in each organ system, and the potential for irreversible pathology. A comprehensive initial evaluation of all organ systems and manifestations is essential for defining goals. Guidelines for each goal include the extent of treatment response and a timeframe for achievement. Achievement and continuity of the therapeutic goals are determined from a regular monitoring schedule for each disease compartment. Treatment success requires attainment and maintenance of goals for all disease compartments within the predicted timeframes. Provision of therapeutic goals to patients may promote compliance and prevent potentially harmful treatment interruptions. As used by experienced physicians and allied health professionals, this individualized, goal-directed approach is proposed to be the most effective way to improve and preserve health and function in patients with type 1 GD.

A Phase I/II Safety Study of DRX008A Glucocerebrosidase Replacement Therapy in patients with type I Gaucher disease. *A. Zimran¹, D. Elstein¹, K.S. Loveday², R.J. Fram².* 1) Gaucher Clinic, Shaare Zedek Medical Ctr, Jerusalem, Israel; 2) Transkaryotic Therapies, Inc. Cambridge, MA, USA.

Gaucher disease is an autosomal recessive lysosomal storage disease caused by deficiency of the lysosomal enzyme - glucocerebrosidase. DRX008A is a human -glucocerebrosidase, a monomeric glycoprotein, produced by gene activation in a human cell line. Glycosylation of DRX008A is altered during cell culture resulting in the secretion of a protein containing predominantly high mannose type glycans. This allows DRX008A to be effectively incorporated into the phagocytic cells via mannose receptors that target the protein to cells of the reticuloendothelial system (predominantly macrophages, the target cells in Gaucher disease), where it can function to degrade accumulated glucocerebroside. DRX008A has been well tolerated in acute and repeat dose toxicity studies in rats and monkeys. The data from the non-clinical program indicated that DRX008A was safe to administer to patients with Gaucher disease as enzyme replacement therapy. The current trial is an open-label, Phase I/II safety study. The objectives of the trial are to evaluate the safety of purified DRX008A when administered at a dose of 60 U/kg IV every two weeks for a total of 40 weeks (20 IV infusions) to patients with type 1 Gaucher disease. The secondary objectives are: first, to evaluate the clinical activity of DRX008A in these patients, as measured by improvement in hematological parameters and reductions in liver and spleen volume; and second, to assess pharmacokinetics. In order to enhance patient safety, a staggered dose escalation of DRX008A was performed in a cohort of 3 patients. Patients received 15 U/kg, 30U/kg, and then 60 U/kg using an intra-patient dose escalation. Patients were infused every two weeks. After dose escalation was completed, patients in this cohort as well as an additional 9 patients are treated at 60 U/kg IV every two weeks for a total of 20 IV infusions. Preliminary safety data and pharmacokinetics will be presented from the patients enrolled in this trial. Results from this study will inform the design of future clinical studies of DRX008A in patients with Gaucher disease.

Therapeutic antisense-induced exon skipping for Duchenne muscular dystrophy. A. Aartsma-Rus¹, A. Janson¹, G. Platenburg², M. Bremmer-Bout¹, J.T. Den Dunnen¹, J.C.T. Van Deutekom¹, G-J.B. Van Ommen¹. 1) LUMC, Leiden, the Netherlands; 2) Prosensa, Leiden, the Netherlands.

The severe Duchenne muscular dystrophy (DMD) is mostly caused by frame disrupting mutations in the dystrophin gene, which result in non-functional proteins. Mutations that keep the reading frame intact give rise to internally deleted, semi-functional dystrophins and result in the milder Becker muscular dystrophy (BMD). Antisense oligonucleotides (AONs) have the potential to modulate the pre-mRNA splicing such that a specific exon is skipped. As a result, the reading frame can be restored, which allows the synthesis of a BMD-like dystrophin.

We have recently demonstrated the skipping of 20 different human DMD exons using 2'-O-methyl RNA AONs with a full-length phosphorothioate backbone (2OMePS), and confirmed the therapeutic applicability of this strategy in cultures from 10 different DMD patients. We now compare the efficacy and efficiency of 2OMePS AONs to morpholino, locked nucleic acid (LNA) and peptide nucleic acid (PNA) AONs. While LNA was most efficient in inducing exon skipping, we find that it acts in a less sequence-specific manner, probably due to its extremely high RNA affinity. Awaiting further improvements in oligochemistry, we therefore consider 2OMePS AONs currently the most favourable compounds.

To facilitate clinical application, multiple *in vivo* studies in animal models are ongoing to develop safe and efficient AON-delivery methods. However, as exon skipping is a sequence-specific therapy, it is desirable to directly target the human DMD gene. We have therefore set up sequence-specific human exon skipping *in vivo* in transgenic mice carrying the an intact copy of the full-length 2.5 Mb human gene (*hDMD*). We injected 2OMePS AONs targeting human exons 44, 46 and 49 into the *m. gastrocnemicus* of *hDMD* mice, and showed skipping of the human (but not the murine) exons, which persisted for at least 28 days. Based on pre-clinical data obtained by our group and others, we are currently setting up a clinical trial aiming at local dystrophin restoration following intramuscular injections of exon 46 and 51 specific AONs.

Prolonged Phenotypic Correction of Canine Hemophilia B Following Systemic Administration of a Helper-Dependent Ad Vector Encoding Coagulation Factor IX. *N. Brunetti-Pierri¹, D. Palmer¹, T.C. Nichols², A.L. Beaudet¹, P. Ng¹.* 1) Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Pathology and Laboratory Medicine, University of North Carolina, Chapel Hill, NC.

Helper-dependent adenoviral vectors (HDAd) offer tremendous potential for liver-directed gene therapy because they can transduce hepatocytes following systemic delivery to direct high-level, long-term transgene expression with negligible chronic toxicity. In this study we have evaluated the potential of liver-directed, HDAd-mediated hemophilia B gene therapy in a large animal model. Two hemophilia B dogs were injected intravenously with 3×10^{12} vp/kg of a HDAd encoding canine coagulation factor IX (FIX) under liver-restricted expression. Following vector injection, the whole blood clotting time (WBCT) for both dogs declined from >60 minutes to 11-19 minutes (normal range: 8-12 min) for a period of up to one year. aPTT decreased from >150 seconds to 48.5-51 seconds (normal range: 28-35 seconds) by 24 days post-injection and peak levels of FIX activity of 34.1% and 129% were detected at 12-14 days post-injection and declined by about 4 months to 2% and 5% but then remained stable at these levels for more than 7 months. FIX antigen levels stabilized at ~200 ng/ml for 12 months. Importantly, whereas untreated hemophilia B dogs suffer five to six spontaneous bleeds per year, the two treated dogs have suffered no such bleeds after vector injection. Systemic vector administration was accompanied by only mild and transient elevation of serum transaminases and thrombocytopenia with no evidence of chronic toxicity. These results support the potential for HDAd-mediated, liver-directed gene therapy for hemophilia B.

Gene transfer in the Sandhoff mouse model using AAV and lentiviral vectors. *C. Caillaud*¹, *A. Arfi*¹, *C. Bourgoin*¹, *C. Emiliani*², *L. Basso*³, *B. Tancini*², *S. Sonnino*³, *L. Poenaru*¹. 1) Dept Genetique, Institut Cochin, Paris, France; 2) Dept of Cellular and Molecular Biology, Perugia, Italy; 3) Dept of Medical Chemistry, Biochemistry and Biotechnology, Milan, Italy.

Sandhoff disease is an autosomal recessive neurodegenerative disorder characterized by the intralysosomal accumulation of GM2 ganglioside. It is due to mutations in the HEXB gene encoding the hexosaminidases -chain and results in a hexosaminidase A () and B () deficiency. This neurolipidosis has a dramatic evolution leading to early death.

In order to test the feasibility of gene transfer methods in this model, AAV vectors containing the human HEXA and HEXB cDNAs under the control of the CAG promoter were constructed. AAV-HEXB was injected alone into the brain of *hexb*^{-/-} neonates. Histological staining using an artificial substrate coupled with a naphthol residue showed a high enzymatic activity in widely diffuse areas. Hexosaminidases activity was restored to the normal level in the whole brain, but Hex A level remained low. The coadministration of both HEXA and HEXB vectors in the CNS allowed to overexpress both subunits, leading to a much higher Hex A activity. More importantly, a strong decrease in the GM2 storage was observed in the injected hemisphere, demonstrating that therapeutic levels of Hex A can be reached by supplying both subunits.

Mono and bicistronic lentiviral vectors (SIV) containing the HEXA and HEXB cDNAs under the control of the CMV promoter were also constructed. Functional tests of these vectors were performed *ex vivo* on Sandhoff fibroblasts. The bicistronic SIV.HEXA-IRES-HEXB was able to generate a massive restoration of the hexosaminidases activity, reaching one to threefold the normal level. The GM2 metabolism was restored not only in transduced cells, but also in cross-corrected cells, demonstrating a correct targeting of recombinant enzymes to the lysosome. This lentiviral vector will now be tested *in vivo* in *hexb*^{-/-} mice, by direct injection in the central nervous system using stereotactic methods.

Gene therapy for MPS II: strengthening Iduronate sulfatase enzymatic activity through the action of the Sulfatase Modifying Factor 1. *M. Cosma¹, S. Pepe¹, A. Auricchio¹, A. D'Azzo², A. Ballabio¹.* 1) TIGEM, via P. Castellino, 111, 80131 Naples, Italy; 2) St. Jude Children's Research Hospital, 332 North Lauderdale Street, Memphis, TN 38105, USA.

Sulfatases are a highly conserved family of proteins that cleave sulfate esters from a wide range of substrates including glycosaminoglycans, sulfolipids, and steroid sulfates. The importance of sulfatases in human metabolism is underscored by the presence of at least eight human monogenic diseases including five mucopolysaccharidoses (MPS) caused by the deficiency of individual sulfatase activities. MPS II (Hunter syndrome) is a lysosomal storage disorder due to the deficit of the Iduronate sulfatase (IDS). The Hunter mouse model exhibits many of the characteristics of MPS II, including skeletal abnormalities, elevated accumulation of GAGs in the urine and many organs. The enzymatic activity of sulfatases, including the Iduronate sulfatase, requires a post-translational modification at the active site that transforms a cysteine into formylglycine. We have recently identified the gene SUMF1 (Sulfatase modifying factor 1), responsible for this post-translational modification, which is inactive in the Multiple Sulfatase Deficiency (MSD). SUMF1 strikingly activates all human sulfatases. In order to develop an effective gene therapy to rescue the phenotype of MPSII mice we are injecting group of KO mice either with IDS alone or simultaneously with SUMF1 using adeno-associated vectors. This protocol will test whether the delivery of the two genes results in an effective treatment of this deficit by increasing IDS activity *in vivo*. Our final goal is to engineer one tissue (muscle or liver) to secrete active IDS into the bloodstream to systematically cross-correct the enzymatic deficiencies in various tissues. Preliminary results already show clearance of GAGs in the urine and in the transduced and not transduced tissues of treated mice. We are also characterizing the CNS defects of the MPSII mice and we plan to rescue the central nervous system phenotype of MPS II mouse by delivering IDS with/without SUMF1 in specific area of the brain.

Multimeric hammerhead ribozymes show specific and efficient cleavage of glycine substitutions within the triple helical domain of Col1A1. Z. Lada¹, D. Basel¹, M.W. Kilpatrick¹, R.J. Wenstrup², P. Tsipouras¹. 1) Genetics & Dev Biol, UConn Health Ctr, Farmington, CT; 2) Cincinnati Childrens Hospital Research Foundation, Cincinnati, OH.

Hammerhead ribozymes are small catalytic RNA molecules that can be engineered to cleave a target RNA in a sequence-dependent manner. The dominant-negative effect exerted by the mutant collagen in Osteogenesis Imperfecta (OI) has been the focus of our previous studies on ribozyme targeting of the abnormal protein to restore the normal phenotype. Herein, the pMG155 Col1A1 minigene, which causes the OI phenotype in both cell lines and mouse models was further engineered to incorporate a murine triple helical domain derived from the Col1A2 gene. This construct, pMG155A2, was then mutated to introduce 3 distinct, ribozyme targetable, glycine substitutions. Gly(A)Rz targets a G to C mutation that produces a cuc ribozyme cleavage site, Gly(B)Rz a G to C mutation that produces an auc cleavage site and Gly(C)Rz a G to T mutation that produces a guc cleavage site. In vitro studies showed that ribozymes directed at these single base changes are specific in that they cleave the substitutions but not the wild-type sequence. To ensure sufficiently high levels of ribozyme expression within a cellular system, multimers comprising tandem repeats of the ribozyme subunit were constructed and shown to cis-cleave to the active monomeric subunits. We then constructed heteromultimers of the ribozyme subunits to target the triple helical domain of Col1A2 containing all 3 of the glycine mutations. Initial results suggest that the multimers cleave the target more efficiently than the monomers and that the heteromultimers cleave with even greater efficiency. Although multiple targets would not exist in a single patient with OI, several glycine substitutions appear with higher frequency. This approach allows for the design of a heteromultimeric ribozyme targeting several of the most commonly occurring collagen mutations as a potential therapeutic agent. It also has potential use in a system where it is beneficial to target multiple sites e.g. HIV or other viruses where specificity and efficiency are both important factors.

Correction of Maternal PKU Syndrome in the *Pah*^{enu2} Missense Mutant Mouse by r-AAV Mediated Gene Therapy. *P.J. Laipis*¹, *C.E. Charron*¹, *J.E. Embury*¹, *O.P. Perera*¹, *S.L. Porvasnik*², *C.R. Fields*¹, *R.T. Zori*². 1) Dept Biochem & Molecular Biol, Univ Florida, Gainesville, FL; 2) Dept Pediatrics, Univ Florida, Gainesville, FL.

Current treatment for PKU is strict lifelong restriction of phenylalanine (Phe) in the diet. A complication of poor adult compliance is a high risk of Maternal PKU Syndrome in offspring of PKU women who are unable to control Phe levels during pregnancy. We had achieved therapeutic reduction of serum Phe levels in male *Pah*^{enu2} mice using Type 2 AAV vectors carrying the mouse phenylalanine hydroxylase gene (rAAV-mPAH). Portal vein injection of a new rAAV-mPAH vector with a Woodchuck Hepatitis Virus post-transcriptional response element (WPRE) into male *Pah*^{enu2} mice reduced serum Phe to therapeutic levels (<0.5 mM) at 10-fold lower vector doses ($\sim 5 \times 10^9$ IU) and to physiological levels (0.05-0.1 mM) at $\sim 2.5 \times 10^{10}$ IU. While female *Pah*^{enu2} mice did not respond to doses effective in males, therapeutic reductions were seen at doses of $\sim 1.5 \times 10^{11}$ IU.

Vectors were also packaged in AAV Type 5 capsids. Type 5 mPAH-WPRE vector ($\sim 7 \times 10^{13}$ particles) resulted in physiological Phe levels in female *Pah*^{enu2} mice. Treated females delivered viable pups when mated with male *Pah*^{enu2} mice. The obligate PKU pups developed normally. Females given lower vector amounts, with therapeutic serum Phe levels (0.15 to 0.5 mM), also became pregnant. Pups died neonatally or failed to thrive post birth. Interestingly, serum Phe levels in mothers rose dramatically during lactation but fell to pre-birth levels at weaning. Finally, while the WPRE sequence increased vector efficiency, we observed liver abnormalities and increases in serum Phe levels starting about 20 weeks post vector delivery. The relative inefficiency of gene therapy in the *Pah*^{enu2} PKU mouse model suggests that dominant-negative interactions between vector-derived normal subunits and endogenous PAH missense subunits are occurring in the PAH tetramer (see Charron et.al. abstract). Our results emphasize the importance of examining both missense and null mutations when evaluating the effectiveness of gene therapy for human genetic disease.

Long-term clinical correction and vector genome persistence following gene therapy of hemophilia A dogs with a helper-dependent adenoviral vector. *W. McCormack Jr¹, T.K. Bertin¹, K. Ubhayakar¹, M. Guenther¹, V.P. Mane¹, P. Ng¹, D. Palmer¹, T.C. Nichols², M. Finegold³, A. Beaudet¹, B. Lee^{1,4}.* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Pathology and Laboratory Medicine, University of North Carolina, Chapel Hill, NC; 3) Department of Pathology, Texas Children's Hospital, Houston, TX; 4) Howard Hughes Medical Institute, Baylor College of Medicine, Houston, TX.

Helper-dependent adenoviral vectors (HDV) offer the advantage of a large cloning capacity, reduced toxicity and extremely efficient transduction of target tissues. These vectors remain episomal in host target cells limiting the possibility of insertional mutagenesis but potentially reducing the duration of transgene expression due to vector genome loss. In this experiment, we treated two hemophilia A dogs from the colony at the University of North Carolina with a HDV encoding canine blood coagulation factor eight (cFVIII). One animal received 1×10^{12} viral particles per kilogram (vp/kg) and a second received 3×10^{12} vp/kg. The whole blood clotting time (WBCT) in both of the animals was significantly improved. In the higher dose animal, this improvement has lasted for over a year. However, the plasma level of cFVIII declined from peaks at two weeks post-treatment of 1.3% normal in the low dose animal and 70% normal in the high dose animal to less than 1% at 2 months in both. To determine the reason for this, a third animal was injected with 3×10^{12} vp/kg and underwent survival liver biopsy at days 18 and 79 after vector administration correlating with the high (35% normal) and low (<1% normal) levels of cFVIII in the plasma. Genomic DNA was isolated from these biopsy samples. Southern analysis, Real-time PCR and semi-quantitative PCR indicate that there was at most a minimal decline in vector genome from the early to the late time point. These data suggest that vector genome loss alone is not sufficient to account for the decline of plasma cFVIII levels.

High efficiency transduction and long-term transgene expression by delivering helper-dependent adenoviral vectors into the surgically isolated liver of nonhuman primates. *P. Ng¹, T. Ng², D. Iannitti², W. Cioffi², D. Palmer¹, A.L. Beaudet¹, M. Finegold³, K. Rice⁴, D. Carey⁴, N. Brunetti-Pierri¹.* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Surgery, Brown Medical School, Providence, RI; 3) Department of Pathology, Baylor College of Medicine, Houston, TX; 4) Southwest Foundation for Biomedical Research, San Antonio, TX.

Helper-dependent adenoviral vectors (HDAd) are attractive vectors for liver-directed gene therapy because they can mediate sustained, high level transgene expression with negligible long-term toxicity. However, high vector doses are required to achieve efficient hepatic transduction by peripheral intravenous injection due to a nonlinear dose response. Unfortunately, such high systemic doses result in vector dissemination and dose-dependent acute toxicity. We hypothesize that this obstacle can be surmounted by delivering the vector exclusively to the liver. To test this hypothesis, we injected HDAd directly into the surgically isolated liver via the portal vein in nonhuman primates. Total hepatic isolation was achieved by occluding hepatic inflow from the portal vein and hepatic artery and by occluding outflow at the vena cava. Prior to total hepatic isolation, saline was infused into the portal vein to flush blood out of the liver. The vector was then injected via the portal vein and allowed to dwell for 30 min. Unabsorbed vector was then removed from the liver to minimize systemic dissemination by infusing saline into the portal vein and collecting the wash-out from a vena cava catheter. Our results revealed that the surgical procedure was well tolerated in nonhuman primates and that significantly higher hepatic transduction efficiencies can be achieved with relatively low vector doses compared to peripheral intravenous injection. Long-term, high level transgene expression was also observed with only minimal and transient toxicities. This approach may increase the safety and efficacy of HDAd-mediated, liver-directed gene therapy by minimizing the dose required to achieve efficient hepatic transduction and by minimizing systemic vector dissemination.

RNAi induction in mammalian neurons and muscle cells. *K. Omi^{1,2}, N. Sago^{1,2}, K. Tokunaga¹, H. Hohjoh²*. 1) Dept Human Genetics, Univ Tokyo, Tokyo, Japan; 2) National Institute of Neuroscience, NCNP, Tokyo, Japan.

RNA interference (RNAi) is the process of sequence-specific posttranscriptional gene silencing mediated by 21-25 nucleotide (nt) small interfering RNA (siRNA) duplexes homologous to the silenced genes. The application of RNAi appears to be expanding to various fields including medical science and pharmacology. An important point in the application of RNAi seems to be the persistence of RNAi activity in cells, particularly in mammalian cells. The effect of RNAi induced by synthetic siRNA duplexes on proliferating mammalian cells appears to be temporary, i.e., it appears to persist for approximately 3-4 days after its induction. Here we show that the RNAi activity induced by synthetic 21-nt siRNA duplex in post mitotic neurons, mouse primary hippocampal neurons and neurons that differentiated from mouse embryonal carcinoma P19 cells, lasts for at least three weeks. We also examined the properties of RNAi during myogenic differentiation of C2C12 cell, a mouse myoblast cell line. The result indicate that a strong RNAi activity was detectable by day 7 after RNAi induction, when morphological changes of C2C12 cells into myotubes appeared to be completed; thereafter, the cells gradually lost the RNAi activity and lost most of the activity by day 21 after the induction. Therefore, our present observations suggest that there is a significant difference in the duration of RNAi activity between neuron and muscle, both of which are terminally differentiated and cell cycle-arrested cells. Since neither muscle nor neuron probably undergoes a decrease in the number of functional RISCs by cell division, it is possible that the stability of functional RISCs could differ between neuron and muscle.

Recombinant Adeno-associated Virus-Mediated Gene Transfer in Homocystinuria Mice. *E.S. Park¹, H.J. Oh², S.C. Jung², J.S. Lee^{1,3}*. 1) Brain Korea 21 Project for Medical Science, Yonsei Univ, Seoul, Korea; 2) Division of Genetic disease, Department of Biomedical Sciences, National Institute of Health, Seoul 122-701, Korea; 3) Department of Clinical Genetics, Yonsei University College of Medicine. Seoul 120-752, Korea.

Homocystinuria is a metabolic disorder caused by a deficiency of cystathionine -synthase (CBS). Patients with homocystinuria show mental retardation, lens dislocation, vascular disease with life-threatening thromboembolisms, skeletal deformities. Generally, the major treatments for CBS deficiency include pharmacologic doses of pyridoxine or dietary restriction of methionine. However, there is no effective treatment for this disease up to now. Gene therapy is an attractive novel approach to treatment of homocystinuria. We constructed recombinant adeno-associated virus vector carrying the human CBS cDNA (rAAV-hCBS) and administered to CBS^{-/-} mice by the intramuscular (IM) and intraperitoneal (IP) injection. IP injection was more efficient than IM injection for prolongation of lives and reduction of plasma homocysteine levels. After 2 weeks of gene transfer by IP injection, serum homocysteine level was significantly decreased in treated mice compared with the age-matched controls. Also, the life span was extended about 1.5 times and increased expression of CBS gene was observed by immunohistochemical staining in liver of treated CBS^{-/-} mice. Here, we show that a CBS gene transfer by intra peritoneal injection brought about elongation of life span and reduction of plasma homocysteine level. These results demonstrate possibility and the efficacy of gene therapy by AAV gene transfer in homocystinuria mice.

Significant increase in life span of mouse models of globoid cell leukodystrophy after AAV-mediated transfer of galactocerebrosidase cDNA into brain. *M.A. Rafi¹, H.Z. Rao¹, M. Curtis², M.A. Passini³, J.H. Wolfe⁴, D.A. Wenger¹.*
1) Dept Neurology, Thomas Jefferson Univ, Philadelphia, PA; 2) Dept Pathology, Thomas Jefferson Univ, Philadelphia, PA; 3) Neuroscience, Genzyme Corp., Framingham, MA; 4) Neurology, Children's Hospital of Philadelphia, Philadelphia, PA.

Globoid cell leukodystrophy (GLD) or Krabbe disease is a neurodegenerative disorder caused by the deficiency of the lysosomal enzyme galactocerebrosidase (GALC). This deficiency results in the accumulation of certain galactolipids including psychosine which is cytotoxic for myelin-producing cells. Twitcher, the naturally occurring mouse model of GLD with the W339X mutation in the C57BL background and mice with the same mutation in a hybrid background of 129SVJ and FVB/N were used in this study. After cloning the mouse GALC cDNA into a type-2 adeno-associated viral genome, and packaging into the AAV1 serotype (AAV2/1-mGALC), viral particles were injected intra-ventricularly or intra-cranially into the brains of the neonatal mice (3×10^{10} viral particles/injection). The treated mice had milder symptoms than untreated mice and remained active most of their lives. Treated mice had a 70% increase in their life span when virus was delivered bilaterally. Analysis of their brains demonstrated a widespread distribution of GALC activity with highest levels near the sites of intra-cranial injection. Frozen sections were stained with anti-GALC antibody, and cells expressing high levels of GALC antigen had bright perinuclear staining. These cells were located mostly in hippocampal, septal, and cortical regions. GALC antigen and activity were still detectable 80 days after viral injection but the strongest signal was detected 2 weeks after injection. Light microscopy of the treated animals 55 days after injection showed near normal myelination in corpus callosum. However, there was more demyelination still present in the cerebellum. These studies demonstrate the ability of AAV2/1-mGALC to deliver GALC activity throughout the brain. While this results in a significant increase in the life span of these mice, there may be other factors needed to completely correct this disorder in animal models and human patients.

Long-term expression of human -galactosidase A in Fabry mice by neonatal lentiviral gene transfer. M.

Yoshimitsu¹, K. Tao², T. Sato¹, G.J. Murray³, L. West^{2, 4}, R.O. Brady³, J.A. Medin^{1, 5}. 1) Division of Experimental Therapeutics, Ontario Cancer Institute, University Health Network, ON; 2) Infection, Immune, Injury & Repair. The Hospital for Sick Children, University of Toronto, Toronto, ON; 3) Developmental and Metabolic Neurology Branch, NINDS, NIH, Bethesda, MD; 4) Department of Cardiology, University of Toronto, Toronto, ON; 5) Department of Medical Biophysics, University of Toronto, Toronto, ON.

Fabry disease is a lysosomal storage disorders (LSD) caused by a deficiency of -galactosidase A (-gal A). Fabry patients respond to enzyme replacement therapy, however frequent infusions are required, strong antibody responses occur in some patients, and the long-term benefits in key organs have not been established. Stable gene augmentation by direct *in vivo* administration of vectors offers considerable potential as an effective, long-term, and relatively non-invasive therapeutic approach. However, *de novo* expression of a corrective, although foreign, protein may result in immune responses that eliminate the transduced cells. Neonates have immature immune systems and treatment at this early stage may also prevent irreversible organ damage. One strategy toward this aim is neonatal gene transfer. Here we explore the use of a single intravenous injection of a VSV-g pseudotyped lentiviral vector (LV) that encodes the -gal A cDNA. Neonatal Fabry mice were injected through the temporal vein with 100 μ l of concentrated LV (1×10^6 infectious particles) at 2 to 3 days after birth. In plasma from injected Fabry mice, we observed sustained and stable -gal A activity (average 39.226.5 of wild type enzyme levels, n=12) 24 weeks post-injection. To determine the bio-distribution of vector expression in live animals, we also used a LV that encodes the luciferase cDNA. We observed strong bio-luminescence systemically 11 weeks after injection. Relevant organs will be assayed from all injected mice for -gal A activity, luciferase expression and substrate Gb3 levels. These results suggest that this LV delivery system may offer significant long-term therapeutic advantages for LSDs and other gene therapy applications.

Molecular analysis of CYP21 gene in 30 patients with 21-hydroxylase deficiency and its prenatal diagnosis in Northeastern Iran. *M.R. Abbaszadegan¹, R. Vakili², A.R. Baradaran-Heravi^{1,2}, B. Barid-Fatehi^{1,2}, Z. Vahedian¹, N. Ghaemi².* 1) Division of Human Genetics, Immunology Research Center, Bu-Ali research institute, Mashhad University of Medical Sciences (MUMS), Mashhad, Iran; 2) Division of Pediatric Endocrinology, MUMS, Mashhad, Iran.

OBJECTIVES: A rapid and convenient approach for the most common CYP21 mutations in patients with congenital adrenal hyperplasia (CAH) with classical forms of 21-hydroxylase (21-OH) deficiency was used. A new semi-quantitative strategy for detection of del 8-bp was designed. These procedures were used in prenatal diagnosis and the genotype-phenotype correlation in province of Khorasan, northeastern Iran. **DESIGN:** Molecular analysis of the CYP21 gene for 9 most common mutations (del-CYP21, del-8bp, i2g, R356W, I172N, P30L, E6 cluster, Q318, V281L) were performed in 30 CAH patients and two fetuses. **METHODS:** Amplification-created restriction sites (ACRS), allele-specific PCR and semi quantitative PCR. **RESULTS:** We characterized 90% of the CAH chromosomes. The most frequent mutation in CYP21 gene was del-CYP21 (25%). The most frequent point mutations were I172N (22%) and intron 2 splice mutation (15%). There were no R356W and P30L mutations in our patients. We detected more than 2 mutations in 6 patients, for instance one patient was homozygous for both V281L and I172N. We also successfully applied these methods for prenatal diagnosis in two families. A correlation between the genotype and the clinical phenotype was observed similar to previous reports. The rate of homozygosity (50%) was greater than what was predicted due to the inheritance pattern (autosomal recessive) of the disease and it was due to the higher rate of parental consanguinity in our population. **CONCLUSIONS:** These procedures proved to be sensitive and rapid for the detection of the most common known mutations in the CYP21 gene and useful for prenatal diagnosis. Increased 17-hydroxyprogesterone found in neonatal CAH screening can be confirmed by these mutational analysis.

Prenatal diagnosis of α -thalassemia, a small gene, a complex problem. *S. Zeinali*^{1,2}, *B. Azimifar*², *V. Lotfi*², *M. Masrou*², *P. Fouladi*², *M. Eram*², *Hosaini*². 1) Biotechnolog, Pasteur Institute of Iran, Pasteur St., Tehran, Iran; 2) Medical Genetics Laboratory of Dr. Zeinali, No 21, Leon Building, Bisotoon St., Fatemi Sq., Tehran, Iran.

α -thalassemia is the most prevalent genetic disorder in the world. In Iran there exist more than 15000 affected individuals. We are using different approaches to curve the birth of new cases. Premarital screening is compulsory. Those detected as carrier couple are counselled and then referred to one of the prenatal diagnosis centers (PND) in the network. By doing PND we have faced the reality and complexity of PND for α -thalassemia. Problems like simultaneous presence of α -thalassemia which complicates the blood indices parameters, inaccurate A2 results, Iron deficiency, deletion of the α -globin cluster, non-paternity, etc. have made PND a bit complicated. We are using direct mutation detection in conjunction with RFLP to minimize the risk of misdiagnosis. Direct DNA sequencing has made the diagnosis more reliable. Sometimes sequencing does not show any mutation. Then we may be puzzled in accepting that either there is no mutation or the sequencing may not be accurate. In other cases not all of the family members may be present for RFLP analysis. So far we have made more than 800 PND in our private lab for the past 4 years with only one mistake, which is below to the standard level but still too much for us and the family. We have advanced our facilities and techniques to minimize misdiagnosis by using techniques like gap PCR for α -globin gene deletion, for α -globin gene deletion and mutation, direct DNA sequencing, QRT PCR, RFLP, etc. The Iranian Experience in curving α -thalassemia both at premarital level as well as post marital by offering PND can be used by other neighbouring countries.

PLA2G7 gene polymorphisms and multiple sclerosis. *L. Provezza¹, M. Gomez-Lira¹, C. Terranova¹, M.D. Benedetti², S. Ottaviani², A. Salviati², P.F. Pignatti¹.* 1) Department of Mother and Child, Biology and Genetics, University of Verona, Verona, Italy; 2) Department of Neurological Science, University of Verona, Verona, Italy.

A marked increased of platelet-activating factor (PAF), in both plasma and CSF, has been observed in the active phase of relapsing/remitting form in multiple sclerosis (MS) patients with clear evidence of blood-brain barrier damage. The bioactivity of PAF is attenuated via its hydrolysis by PAF acetylhydrolase (PAF-AH, or lipoprotein-associated phospholipid A2, Lp-PLA2), and lower levels of Lp PLA2 activity have been reported in MS patients when compared to control individuals. We have evaluated the association of Lp-PLA2 gene (PLA2G7) polymorphisms with susceptibility to MS in a small case-control study in the north Italian population, including 139 MS patients and 139 sex matched healthy controls. A total of eight polymorphisms throughout the gene were analyzed: three exonic polymorphisms (Arg92His, Iso198Thr, and Val379Ala), a deletion polymorphism (1190-20_23delGATT) in intron 11, two highly polymorphic dinucleotide repeats (1134+31TGmAGn) in the 3' flanking region, and two SNPs (-402T>C and 209C>G) in the promoter region of the gene. No statistically significant difference in the frequency of alleles and genotypes was observed between patients and controls suggesting that sequence variations of the PLA2G7 gene do not play an important role in susceptibility to MS in this group of patients.

Retroviral gene transfer into autologous peripheral CD34 hematopoietic cells in a 12 year old with X-linked severe combined immunodeficiency. *J. Puck¹, J. Chinen¹, J. Davis¹, G. Linton², N. Theobald², M. Garolfalo², P. Woltz², H. Malech².* 1) NHGRI, NIH; 2) NIAID, NIH, Bethesda, MD.

X-linked severe combined immunodeficiency (XSCID), due to defects in the common gamma chain (gc) of receptors for IL-2 and other cytokines, is fatal without immunoreconstitution. Patients with no matched sibling donor for bone marrow transplant (BMT) receive haploidentical T-depleted BMTs, but often have incomplete engraftment. Correction of autologous hematopoietic stem cells by gene therapy has succeeded because lymphoid cells expressing functional gc undergo selective expansion. In a French trial, 9 of 10 XSCID infants had immune reconstitution after ex vivo gene therapy with retrovirus-transduced autologous CD34 cells. However, the 2 youngest, treated at 1 and 3 mo, developed T cell leukemias in which the LMO2 transcription factor was activated by nearby provirus insertions. While risks of gc gene transfer as primary treatment for XSCID continue to be evaluated, older boys who have failed BMTs are candidates for gene transfer as salvage treatment. An 11 y/o with no engraftment from prior parental T-depleted BMTs had low T cells, growth failure, infections and chronic GI and skin infiltration by autologous, dysregulated lymphocytes. He underwent G-CSF mobilization and apheresis to harvest CD34 cells, which were purified, cultured in fibronectin-coated bags (with SCF, Flt3 ligand, IL-3, IL-6, and TPO) and transduced for 4 d with high-titer GALV-MFGS-gc retroviral supernatant. 80 million cells/kg (80% CD34+; 40% provirus positive) were reinfused. Polyclonal total leukocyte marking was 1.4% and 2.3% at 1 and 2 mo, but undetectable at 3 mo, consistent with limited lifespan of myeloid progenitors. However, at 5 mo thymus size rose from 1.80 to 3.76 cc, and marking reappeared in lineages dependent on gc expression: 0.5% in T, 0.1% in NK and 0.05% in B cells. Within 2 mo of gene transfer the boy experienced sustained improvement in well-being with resolution of lifelong diarrhea and rash. Further follow-up will monitor retrovirus insertion sites and look for progressive in vivo expansion of corrected lymphoid cells. Gene therapy may benefit older, post-BMT patients with XSCID.

Computerized cognitive testing in patients with type I Gaucher disease: effects of enzyme replacement and substrate reduction. *D. Elstein¹, G. Doniger³, J. Guedalia², E. Simon³, A. Zimran¹.* 1) Gaucher Clinic, Shaare Zedek Medical Ctr, Jerusalem, Israel; 2) Neuropsychological Unit, Shaare Zedek Medical Ctr, Jerusalem, Israel; 3) NeuroTrax Corp., New York, NY.

During clinical trials using substrate reduction therapy (N-butyldeoxynojirimycin; OGT 918; ZAVESCA) for adults with type I Gaucher disease, the question of decreased cognitive function was raised. For long-term surveillance, Mindstreams (NeuroTrax Corp., New York, NY), a computerized system incorporating subtests specific to executive and visual-spatial cognitive function was used. Patients with type I Gaucher disease (N=84; mean age: 46.113.5; mean years of education: 14.52.6) were compared with age-, education-, and gender-matched controls (N=140). Mean Severity Score Index (SSI) in patients was 9.75.5, and 43 patients were homozygous for the 1226G mutation. Data in patients was normalized according to controls and fit to an IQ-style scale (mean: 100, SD: 15). Performance in untreated patients (N=26) was compared to that of patients receiving enzyme replacement (N=22) or Zavesca (N=36). Adjustment for SSI and genotype was by analysis of covariance (ANCOVA). Visual-spatial performance in patients on Zavesca was better than for untreated patients after adjustment for SSI ($F[1,54]=5.01$, $p=0.029$) and genotype ($F[1,53]=5.46$, $p=0.023$); this improvement was significantly greater for patients not homozygous for 1226G as compared to homozygotes [$F[1,53]=10.96$, $p=0.002$]. Visual-spatial performance in patients on enzyme was poorer than in those on Zavesca after adjustment for SSI ($F[1,51]=7.65$, $p=0.008$) and genotype ($F[1,51]=8.02$, $p=0.007$). Executive function performance was poorer in those on enzyme versus those on Zavesca after adjustment for SSI ($F[1,55]=6.61$, $p=0.013$), but also poorer in patients on enzyme as compared to those who were untreated after adjustment for SSI ($F[1,59]=6.406$, $p=0.014$). Global Cognitive Scores showed no treatment-mediated performance differences. These findings may allay fears of cognitive dysfunction due to substrate reduction, and may have implications for indications for Zavesca in type III Gaucher disease and neuronopathic forms of other lysosomal storage disorders.

Pharmacokinetics of Agalsidase Alfa in Fabry Patients with End-Stage Renal Disease. *J. Flaherty*¹, *G. Pastores*², *R. Schiffmann*³, *E. Boyd*⁴, *A. Whelan*⁵, *K. Loveday*¹. 1) Clinical Research, Transkaryotic Therapies, Inc, Cambridge, MA; 2) New York University, NY, NY; 3) NIH, Bethesda, MD; 4) Advanced Home Care, Asheville, NC; 5) Children's Hospital, St. Louis, MO.

PURPOSE: Evaluate pharmacokinetics (PK) of agalsidase alfa in Fabry patients with end-stage renal disease (ESRD).

METHODS: Serum samples were collected from patients who had received a kidney transplant (12 males and 1 female) and from hemodialysis patients (7 males and 1 female) following their first infusion of agalsidase alfa (Replagal, TKT, Inc., Cambridge, MA). Agalsidase alfa was administered after hemodialysis. Serum analysis and PK analysis were performed at TKT. Four patients were excluded from the comparative PK analysis since blood samples were collected from the same arm used for infusion of agalsidase alfa.

RESULTS: Agalsidase alfa had a biphasic serum elimination profile in the 17 analyzed patients. Serum profiles and PK parameters were similar to results from male Fabry patients who had not progressed to ESRD (non-renal failure). Mean serum clearance values were 2.5 mL/min/kg (18 non-renal failure males), 3.2 mL/min/kg (11 transplant patients) and 3.4 mL/min/kg (6 dialysis patients).

CONCLUSIONS: Since agalsidase alfa is primarily removed from serum and transported to cellular lysosomes via mannose-6-phosphate receptors, the effect of kidney function on serum clearance should be minimal. This expectation was met in these Fabry patients with ESRD. Serum clearance profiles and calculated clearance (mL/min/kg) were indistinguishable among transplant, renal dialysis, and non-renal failure patients. Based on the similarity of PK properties, tissue distribution in major tissues and organs is also expected to be comparable among these three classes of Fabry patients. Thus, the prescribed biweekly dose of 0.2 mg/kg (administered IV over 40 minutes) can be maintained in Fabry patients with ESRD.

Glycosaminoglycan Reduction in Response to Iduronate 2-Sulfatase Treatment in a Mouse Model of MPS II. *A.R. Garcia, K. Loveday, J. Pan, J.C. Lamsa.* Research, TKT, Cambridge, MA.

The IdS-KO mouse, in which a portion of the gene for iduronate 2-sulfatase (IdS) is deleted, develops elevated glycosaminoglycan (GAG) levels in tissue and urine and exhibits gross and microscopic pathology consistent with Hunter disease (MPS II). Adult IdS-KO mice were administered 1 mg/kg IdS intravenously (IV) as a single injection or at weekly, bi-weekly, and monthly intervals for up to 6 months. Cohorts of mice were sacrificed after 2, 3 or 6 months of treatment and the liver, spleen, kidney and heart collected for GAG analysis and histopathology. Vehicle treated IdS-KO and untreated wild type (WT) mice served as controls. GAG levels were measured by dimethylmethylene blue assay. Urinary GAGs were markedly reduced after the first injection. For weekly and biweekly injections, urinary GAG levels reached WT levels at 1 to 4 weeks and remained low. After a single injection or monthly injection, urinary GAG declined then rose gradually to vehicle control levels by 4 weeks. Two months after a single dose of IdS, GAG levels in all tissues were reduced 15% to 25% compared to vehicle controls, but remained considerably higher than WT animals. Tissue GAG levels continued to decline with increasing dose frequency. Through 3 months of treatment, weekly dosing consistently reduced GAGs to a greater degree than bi-weekly dosing. After 6 months, GAG levels continued to be significantly reduced to nearly WT levels, but there were no significant differences between weekly and bi-weekly dosing in terms of GAG reduction in liver, kidney, heart and spleen. In addition, liver weights were significantly reduced by either bi-weekly or weekly dosing for 6 months compared to vehicle controls. Microscopically, there was a marked reduction in vacuolization in all of the organs examined (liver, spleen, kidney and heart). We conclude that in the IdS-KO mouse, monthly dosing allows a rebound of GAG accumulation. Weekly or bi-weekly dosing effectively reduces GAG in urine and in major organs in this animal model of Hunter disease, although bi-weekly dosing takes longer to achieve maximal GAG reduction.

Substrate reduction therapy with miglustat for symptomatic type 1 Gaucher disease. *E.H. Kolodny, N.A. Barnett, G.M. Pastores.* Dept Neurology, New York Univ Medical Ctr, New York, NY.

OBJECTIVE: Miglustat (Zavesca) has recently been approved for the treatment of type 1 Gaucher Disease (GD). In the pivotal clinical trials with extension up to 24 months, miglustat significantly improved organomegaly, hematological parameters and levels of chitotriosidase. The study was designed to analyze the extended efficacy and safety of miglustat 100 mg PO tid. **METHOD:** 7 patients received miglustat for a minimum of 24-months. Comprehensive assessments were conducted, based on liver and spleen volume measurements, radiographic bone studies, and chitotriosidase (chito) activity, nerve conduction velocities (NCV), neuropsychological status and tremor. In addition, patients tolerability of miglustat was monitored. **RESULTS:** In the initial phase of the study, 10 patients received active drug; 3 patients discontinued due to adverse events (1 paresthesia, 1 flatulence, 1 lost to follow-up). At 24 months, the remaining 7 patients showed a mean percentage change in liver (-6%) and spleen (-15%) volumes, platelets (+23%), and chito (-25%); consistent with results of prior studies. The most common complaints were flatulence (n=10) and diarrhea (n=9); which resolved in the majority of patients. There was a mean decrease of 4.0 kg (6%) from baseline body weight. Tremor (n=4) and paresthesia (n=3) were reported early on but subsequently decreased over time. Notably there were no clinically relevant abnormalities observed on serial neurological examinations and tremors (observed at baseline in 2 of the 4 patients) were below threshold of detection by accelerometry. Additionally, no clinically meaningful changes in NCV over 24 months were noted, even among patients reporting paresthesia and no changes in cognitive function. **CONCLUSION:** Our 2-year study revealed stabilization and/or improvement in key clinical features of the disease, supportive of clinical proof-of-concept for the use of substrate reduction therapy in GD patients. No patient had emergent GD-related complications and there were no clinically significant abnormalities in neurological, neurophysiological or neuropsychological assessments.

Pharmacokinetics of Agalsidase Alfa in Pediatric Fabry Patients. *K.S. Loveday¹, M. Beck², C. Whybra², R. Schiffmann³, J. Clarke⁴, J. Flaherty¹.* 1) Research, Transkaryotic Therapies, Inc., Cambridge, MA; 2) Children's Hospital, University of Mainz, Mainz, Germany; 3) NIH, Bethesda, MD; 4) Hospital for Sick Children, Toronto, Canada.

PURPOSE: Evaluate pharmacokinetics (PK) of agalsidase alfa in pediatric Fabry patients.

METHODS: Serum samples were collected from 18 boys and 5 girls (6 to 18 years old) following their first IV infusion of agalsidase alfa (Replagal, TKT Inc. Cambridge, MA). Serum samples were analyzed for alpha-galactosidase A activity at TKT, and PK analysis was performed at TKT.

RESULTS: Agalsidase alfa had a biphasic serum elimination profile in all patients, and only small amounts were detected 8 hours after dosing. The maximum concentration in serum coincided with the end of the 40-minute infusion. Serum clearance (Cl) ranged from 2.0 to 9.4 mL/min/kg while V_{ss} (apparent volume of distribution) ranged from 9% to 26% body weight (BW). PK parameters in the 23 pediatric patients were similar to results from adult Fabry patients with the exception of the younger patients (6 - 11 years). Mean Cl for the 13 younger patients (4.2 mL/min/kg) was statistically increased compared to the adult value (2.3 mL/min/kg). Mean Cl for the 10 older pediatric patients (12 - 18 years) was 3.1 mL/min/kg; this value was intermediate between the clearance values for younger and adult Fabry patients. Mean V_{ss} was similar among younger and older pediatric patients and adults (15% - 16% BW).

CONCLUSIONS: Increased serum clearance in the 13 younger patients may be due to increased organ/body weight ratios. This would increase the number of M6P receptors/body weight leading to more rapid uptake into liver, spleen and other tissues. However, it is unlikely that the increased rate of serum clearance in the 13 younger patients significantly altered their overall tissue biodistribution of administered agalsidase alfa. Therefore, the recommended adult dose, 0.2 mg/kg, should not be altered to compensate for the more rapid serum clearance in younger pediatric patients.

NAG-Thiazoline a specific, efficient and safe chemical chaperone for the treatment of adult Tay-Sachs and Sandhoff diseases. *D. Mahuran¹, B. Rigat¹, S. Reid², H. Yeager¹, J. Clarke¹, S. Withers²*. 1) The Hospital for Sick Children, Toronto, Canada; 2) University of British Columbia, Vancouver, Canada.

Tay-Sachs and Sandhoff diseases are lysosomal storage disorders resulting from a deficiency in beta_hexosaminidase A (Hex-A). The chronic form of these disorders have about 5 percent of normal Hex-A activity and protein. However, asymptomatic individuals have been documented with only 10 percent residual Hex-A, implying a critical threshold of 5 to 10 percent of normal activity necessary to prevent storage.

We have showed in vitro that NAG-Thiazoline (NGT) acts as a chemical chaperone in fibroblast cell lines from chronic Tay-Sachs patient. It is believed to stabilize the mutant protein by transiently binding with its active site. Hence, this new drug is very promising as a potential treatment for adult Tay-Sachs and Sandhoff patients.

We have evaluated the acute toxicity of NGT at several doses, various time points and different route of administration in adult mice. The animals did not display any major behavioral modification or obvious clinical symptom. Different organs collected did not show any cytological and structural modification. Plasma and brain lysate showed an increase in Hex-A activity as compared to the control mice.

The increase in Hex-A activity observed in addition to the absence of toxicity provides hope for a possible treatment of chronic Tay-Sachs and Sandhoff diseases.

Searching for the stumbling block: possible mechanisms of skeletal muscle resistance to therapy in Pompe disease. *N. Raben, T. Fukuda, A.L. Gilbert, D. de Jong, E. Van Dyke, E. Ralston, P.H. Plotz.* NIAMS, NIH, Bethesda, MD.

Pompe disease, a deficiency of acid alpha-glucosidase (GAA), is a fatal lysosomal glycogen storage disorder affecting cardiac and skeletal muscle. Extensive recent studies have led to clinical trials with recombinant enzyme (rhGAA) for replacement therapy (ERT). The therapy held out the hope that the disease would henceforth be considered treatable. However, glycogen storage in skeletal muscle proves to be unexpectedly refractory to therapy. Attempts at gene therapy in our KO model by several groups, and our preclinical studies including escalating doses of the rhGAA, hepatic secretion of the transgenic enzyme, and transgenic GAA expression in muscle of the KO mice have all failed to completely remove the accumulated glycogen in skeletal muscle, indicating that the problem lies within the muscle cell itself. The skeletal muscle abnormalities go beyond the lysosome. Vacuoles of the endocytic pathway (the route of the rhGAA) - early and late endosomes, as well as the vacuoles of the autophagic pathway, which converges with the endocytic pathway - are all dramatically expanded in the diseased cells. Also, microarray analysis of skeletal muscle showed an upregulation of genes involved in glycolysis and glycogen metabolism, suggesting an increased energy demand. Not all muscle cells respond equally to ERT, however. Type I fibers clear glycogen well in the KO mice, thus narrowing the problem to the type II fibers, mainly type IIb. Analysis of single muscle fibers from ERT-treated KO mice identified a subset of huge cell-interior rhGAA-negative lysosomes in type II fibers. These fibers have much lower levels of key proteins involved in endocytosis and trafficking of lysosomal enzymes, CI-MPR, clathrin, and AP-2, and they show large autophagosomes and autolysosomes containing mitochondria and cellular debris. Microarray data confirmed an upregulation of the genes involved in autophagy: beclin, Rab24, and LC3. The data suggest that inefficient entry of the rhGAA into the cells may be further blocked by increased autophagy in these therapy-resistant fibers. The findings may have important implications for designing a second generation of therapeutic drugs.

A clinical study of miglustat (Zavesca) in adult and juvenile patients with Niemann-Pick Type C disease: preliminary data. A. Rolfs, T. Böttcher. Dept Neurology, Univ Rostock, Rostock MV, Germany.

Purpose: Niemann-Pick Type C (NPC) is a rare neurovisceral disorder caused by a block in the translocation of LDL-derived cholesterol from lysosomes to the endoplasmic reticulum and the Golgi apparatus. Miglustat (Zavesca) is an orally administered small-molecule glucosyltransferase inhibitor which received EU and US approval for the treatment of Gaucher disease. Studies in animal models of Sandhoff and NPC diseases demonstrated a significant amelioration of disorder-dependent and progressive neuronal pathology. We designed a prospective, open label and non-comparative clinical study to examine the influence of Zavesca on neuropsychological symptoms in adult and juvenile NPC disease.

Methods: 12 consecutive patients over 12 years of age with genetically proven NPC disease will be enrolled and will receive 3x100 mg Zavesca every day for 18 months. Efficacy evaluations will include detailed neuropsychological measurements as well as SPECT and MRI of the brain. Safety evaluations will include vital sign measurements, physical examinations, adverse event assessment and neuropsychological as well as laboratory tests.

Results: To date, 3 patients (male 43y, male 17y, female 17y) are enrolled in the study and have been placed on medication for 7-11 months. Leading clinical feature in all cases are an ataxic-dystonic syndrome and intellectual decline over the past years. MRI evaluation revealed no symptoms of progressing leukencephalopathy. None had symptoms of polyneuropathy at entry nor developed specific signs as evidenced by clinical examination and senso-motor nerve conduction studies. Diarrhoea occurred infrequently in two patients after 2-3 weeks of administration but could easily be treated with loperamide. Neuropsychological studies, performed in two patients, revealed no ongoing intellectual decline over 9-11 months.

Conclusions: Preliminary results on 3 patients treated with Zavesca for 7-11 months, indicate that the treatment is well tolerated in patients with NPC, with no development of a polyneuropathy. The adverse event profile does not differ from that known from Gaucher patients. Additional intellectual impairment could not be observed.

Neu4, a novel human lysosomal lumen sialidase confers normal phenotype to sialidosis and galactosialidosis cells.

V. Seyrantepé¹, K. Landry¹, S. Trudel¹, J.A. Hassan², C.R. Morales², A.V. Pshchetsky¹. 1) Dept. of Medical Genetics, Sainte-Justine Hospital Research Center, University of Montreal, Montreal, PQ, Canada; 2) Dept. of Anatomy and Cell Biology, Faculty of Medicine, McGill University, Montreal, PQ, Canada.

Sialidosis and galactosialidosis are neurodegenerative lysosomal storage disorders characterized by deficiency of the lysosomal sialidase (Neu1) due to the mutations in the NEU1 gene (sialidosis) or in the gene encoding for protective protein/cathepsin A (galactosialidosis). The loss of Neu1 activity in both sialidosis and galactosialidosis patients results in abnormal accumulation of sialylated oligosaccharides and glycoproteins. For both diseases, early onset forms with severe CNS pathology and systemic organ involvement, as well as relatively mild late onset variants have been identified. No effective treatment for sialidosis and galactosialidosis patients has been developed so far. We describe a novel lysosomal lumen sialidase Neu4 encoded by NEU4 gene on human chromosome 2. We showed that Neu4 has enzymatic activity towards the artificial sialidase substrate, 4-Mu-NANA as well as towards sialic acid-containing oligosaccharides, glycoproteins and glyco- sphingolipids. In contrast to Neu1, Neu4 is targeted to lysosomes by the mannose-6-phosphate receptor and does not require association with other proteins for enzymatic activity. Northern blot analysis demonstrated that Neu4 is expressed in all tissues studied with the highest level in skeletal muscle, heart, placenta and liver. Overexpression of recombinant Neu4 corrected extensive vacuolization due to the accumulation of lysosomal storage materials in Neu1-deficient cultured skin fibroblasts of sialidosis and galactosialidosis patients raising the possibility that the upregulation of Neu4 gene can be a promising approach for the treatment of sialidosis and galactosialidosis.

A hammerhead ribozyme prevents dominant-negative interference in gene therapy for phenylketonuria. C.

*Charron*¹, *A. Lewin*², *S. Porvasnik*³, *P. Laipis*¹. 1) Biochemistry; 2) Genetics; 3) Pediatrics, University of Florida.

Phenylketonuria (PKU), one of the most common human recessive diseases, is generally caused by defects in the enzyme phenylalanine hydroxylase (PAH). A mouse model for PKU, BTBR *Pah*^{enu2}, has a missense mutation (F263S) rendering PAH inactive. The mouse has classic PKU with elevated blood Phe levels, cognitive deficiencies, and maternal PKU syndrome. We corrected serum Phe levels in *Pah*^{enu2} mice using recombinant AAV2 vectors (rAAV2) containing the mouse PAH gene (mPAH). Although successful, unusually high vector doses were needed to achieve normal serum Phe levels.

Pah^{enu2} mice have one third the normal amount of PAH protein in liver. We hypothesized that, since the enzyme is a tetramer, endogenous mutant subunits could assemble with the gene therapy-introduced protein in a dominant-negative fashion reducing the total potential effectiveness of the treatment. To confirm this hypothesis, we designed a ribozyme against the mouse PAH mRNA and a ribozyme-resistant form of mPAH (mPAH-Hd). In transient cell transfections, a 1:1 molar ratio of mPAH-Hd to mPAH-F263S vector reduces PAH activity to one half that observed with mPAH-Hd alone. When the ribozyme is also expressed in the transfection, PAH activity is restored to near normal levels. Since the ribozyme cleaves F263S mRNA but does not cleave mPAH-Hd mRNA, we conclude that mixed tetramers of mPAH and mPAH-F263S proteins are causing the observed reductions in PAH activity.

We delivered an ineffective dose of mPAH-Hd rAAV2 vector along with increasing amounts of the ribozyme rAAV2 vector in male mice. At a 1:6 ratio of mPAH-Hd: ribozyme vector, we observed a decrease of 0.4mM in serum Phe levels for up to 15 weeks. While the decrease is significant when compared to pre-gene therapy levels, serum Phe has not reached a therapeutic range. Since separate vectors were used to deliver the ribozyme and PAH gene, simultaneous transduction of the same cell may not have occurred efficiently. A single combined ribozyme-mPAH-Hd cDNA rAAV vector has been constructed and animal experiments will soon be underway.

A five-year study of Aldurazyme for treatment of MPS I. *G. Eames¹, S. Swiedler², G. Cox³, L. Waber⁴, M. Lipson⁵, D. McMahon⁶, V. Proud⁷, R. Loge⁸, K. Dveirin⁹, E. Kakkis².* 1) Hematology/Oncology BMT Unit, Cook Children's Medical Center, Fort Worth, TX; 2) BioMarin Pharmaceutical, Novato, CA; 3) Genzyme, Cambridge, MA; 4) Univ. of Texas Southwestern Med. Ctr., Dallas, TX; 5) Kaiser Permanente, Sacramento, CA; 6) Carolinas Med. Ctr., Charlotte, NC; 7) Children's Hospital of the King's Daughters, Norfolk, VA; 8) Pioneer Medical Specialists, Dillon, MT; 9) Arizona Community Physicians, Tucson, AZ.

Objective: To demonstrate safety and efficacy of Aldurazyme (laronidase) in the reduction of lysosomal storage in Mucopolysaccharidosis I (MPS I). **Methods:** A Phase 1/2 open-label, multicenter study in 10 patients. Patients received 100 U/kg (0.58 mg/kg) laronidase weekly for a total of 269 to 288 weeks. The primary endpoint for the 5-year extension study was 50% reduction of uGAG (urinary GAG) levels. **Results:** Mean age was 12.3 years (range 5-22) and 80% had Hurler-Scheie syndrome. Three patients expired during the 5-year study at weeks 103, 137 and 234; none of the deaths was related to laronidase. Seven patients completed over 5 years on study and 6 of the 7 patients were compliant with weekly infusions. Mean reduction in uGAG excretion from pretreatment to end of study for the 6 compliant patients was 73.3%. Four of these 6 patients had uGAG levels approaching normal range for age. The seventh patient had a 68.5% reduction in uGAG levels at 3 years, but became non-compliant during the next 2 years and the uGAG returned to baseline levels. Data show that uGAG levels increase by 6% if 1 infusion is missed, and increase by 12% if 2 consecutive infusions are missed. The most frequently reported AEs occurred during infusion, i.e., urticaria, headache, edema, pruritus. All patients developed antibodies to laronidase though there was no apparent relationship between antibody levels and changes in urinary GAG excretion or infusion related hypersensitivity-type reactions. **Conclusion:** Compliance with weekly infusions of laronidase results in a consistent reduction of uGAG levels and an acceptable long-term safety profile.

Using clinical genetics to identify validated drug targets and a shorter route to drug development. *Y.P. Goldberg, J. MacFarlane, B. Popovich, R. Fraser, R. Kamboj, S.N. Pimstone, R. Sherrington, M.R. Hayden.* Xenon Pharmaceuticals Inc., Vancouver, BC, Canada.

We have developed an innovative clinical genetics approach to identify crucial disease-causing genes which serve as targets for novel drug development. Our approach examines Mendelian families having the opposite protective phenotype to the disease we intend to treat. Since most human genetic disease mutations are loss-of-function, therapeutic antagonists to the target will have the desired and clinically relevant outcome in humans, resulting in an easier and more efficacious drug development pathway. To identify targets for the treatment of osteoporosis, we studied the opposite phenotype disorder, sclerosteosis, characterized by increased osteoblastic activity resulting in desirable symmetrical increased bone density. The causal gene, sclerostin, is a primary transcriptional repressor of osteoblast activity. Thus sclerostin antagonists, currently in drug development, will produce a phenotype reminiscent of sclerosteosis, thereby improving bone density in patients with osteoporosis. To address the important unmet medical need of the Metabolic syndrome, we studied the Asebia mouse with low body weight, low plasma triglycerides and enhanced insulin sensitivity. The Asebia mouse was found to have a mutation in Stearoyl-CoA desaturase 1 (SCD1), a key enzyme in fat metabolism. Thus inhibition of SCD1 in humans will reproduce the desirable phenotype with beneficial impact on metabolic and body weight parameters. We have developed small molecule inhibitors to this target for the treatment of Metabolic syndrome. Anemia of Inflammation (AI), characterized by low serum iron concentration is another important area of unmet medical need. To develop therapeutic targets for AI, we identified opposite phenotype families with the severe iron overload recessive disorder, Juvenile hemochromatosis. We identified the causal gene, hemojuvelin, which is now entering drug development for treatment of the iron disturbances of AI. By focusing on the clinical phenotype, we have identified novel drug targets to address diseases with unmet medical needs.

Clinical Response and Molecular Evidence in Patients with Machado-Joseph Disease under Treatment of Lamotrigine. C. Kuo¹, C. Liu^{1,2,3}, H. Hsu⁴, B. Wang⁷, M. Hsieh^{5,6}. 1) Vascular and Genomic Research Center, Changhua Christian Hospital, Changhua, Taiwan; 2) Department of Neurology, Chung Shan Medical University and Chung Shan Medical University Hospital, Taiwan; 3) Department of Neurology, Changhua Christian Hospital, Taiwan; 4) Institute of Medicine, Chung Shan Medical University, Taiwan; 5) Department of Biology, Tunghai University, Taiwan; 6) Life Science Research Center, Tunghai University, Taiwan; 7) Ctr Medical Genetics, Changhua Christian Hospital, Taiwan.

Machado-Joseph disease (MJD) is an autosomal dominant spinocerebellar degeneration characterized by a wide range of clinical manifestations, including ataxia, progressive external ophthalmoplegia, pyramidal and extra pyramidal signs, dystonia with rigidity and distal muscular atrophies. Unstable CAG trinucleotide repeat expansion in MJD gene on the long arm of chromosome 14 was identified as the pathologic mutation of MJD. We present our study of the clinical response of lamotrigine (LTG) on six patients in their early ataxia stage of MJD. LTG was found to effectively relieve gait disturbance in these six MJD patients based on test scoring in the improvement of single leg standing and tandem gait index. Furthermore, the expression of ataxin-3 in MJD lymphoblastoid cells with and without LTG treatment was assessed by Western blot analysis. While leaving the normal ataxin-3 intact, extracellular application of LTG (50 to 300M) decreased the expression of mutant ataxin-3 in a dose-related manner. Decreased expression of mutant ataxin-3 seemed to be one of the possibilities to explain the effect of LTG on MJD patients with early stage of gait disturbance.

Pharmacological correction of VLCAD deficiency by fibrates. *F. Djouadi¹, F. Aubey¹, A.W. Strauss², J. Bastin¹.* 1) INSERM U393, Hosp Necker, Paris, France; 2) Vanderbilt University, Nashville, Tennessee, TN.

VLCAD (Very Long Chain AcylCoA Dehydrogenase) catalyses the first step of mitochondrial fatty acid oxidation (FAO). VLCAD deficiency has variable clinical presentations, from a severe childhood form with cardiomyopathy and high mortality to milder adult form with isolated skeletal muscle involvement. The severity of this disease is correlated to the nature of mutation and to the level of residual FAO. We therefore tested a possible stimulation of FAO by fibrates in primary culture of fibroblasts from patients diagnosed with various forms of VLCAD deficiency. Cell exposure to 500M bezafibrate for 48 h resulted in a marked increase in 3H-Oleate (+59 to +284%) and 3H-palmitate (+199 to +509%) oxidation rates in cell lines from 4 different patients presenting with mild VLCAD deficiency. FAO levels were similar in treated deficient or control fibroblasts, demonstrating complete restoration of FAO flux in VLCAD deficient cells treated by bezafibrate. Mutation analysis showed that this correction could be achieved in cells carrying the G520A or T848C VLCAD missense mutation. Bezafibrate effects were related to increases in VLCAD mRNA (x1.7) and protein (x2.6) levels, as shown by quantitative RT-PCR and western-blot studies, and this is consistent with a drug-induced stimulation of VLCAD gene transcription via PPAR (peroxisome proliferator activated receptor). We also used this cell system to test a possible response to PPAR agonists of other genes responsible for FAO defects. In preliminary experiments, bezafibrate was found to increase mRNA levels of CPT1-1A (liver form of Carnitine Palmitoyl Transferase; +126%), ETFDH (Electron Transfert Factor Dehydrogenase; +69%) and MCAD (Medium Chain AcylCoA Dehydrogenase; +58%) in control cells. Further studies will allow us to determine if defects in these other FAO enzymes can also be corrected in deficient patient cells. In conclusion, our studies of VLCAD-deficient cells further support the notion that pharmacological stimulation of PPAR signaling pathway provides a way to correct some inborn errors of metabolism in patient cells, as our group initially established for the CPT2 deficit.

Sodium Phenylbutyrate Increases Full-length SMN2 mRNA in SMA Lymphocytes. *M. Ganta, S.M. Grzeschik, C.H. Wang.* Neurology, Stanford University, Stanford, CA.

Spinal muscular atrophy (SMA) is an autosomal recessive disorder characterized by the degeneration of the spinal cord motor neurons and muscular atrophy. Over 95% of SMA patients lack the functional SMN1 gene but all patients retain at least one copy of the highly homologous SMN2 gene. Unlike SMN1, SMN2 produces very little full-length (FL) mRNA but generates mostly truncated (TR) mRNA lacking exon 7. Increasing the level of full-length SMN transcripts produced by SMN2 is a potential therapeutic strategy for SMA. We tested the ability of sodium phenylbutyrate (SPB) to increase production of full-length SMN mRNA in cultured lymphoblastoid cell lines. 18 cell lines derived from 14 SMA patients (4 type I, 5 type II, 5 type III) and 4 control individuals were treated with SPB in six concentrations and over three time points along with appropriate vehicle-treated controls. RT-PCR and quantitative densitometry were used to detect the changes of the SMN mRNA species. Western blot analysis was used to detect changes in SMN protein levels. SPB treatment resulted in a significant dose-dependent and time-related increase in the SMN FL/TR transcript ratio. Peak response occurred at a concentration of 500g/ml and 48h time point. At 5000g/ml dose RNA and protein levels were not detectable indicating toxicity to the cells. The FL/TR transcript ratios at 0, 0.5, 5, 50, and 500g/ml SPB concentrations, after 48h of treatment, were: type I - 0.76, 0.69, 0.74, 0.77, 1.43*; type II - 0.66, 0.71, 0.74, 0.78, 1.78***; type III - 0.63, 0.63, 0.80, 0.88, 2.15*. Using a concentration of 500g/ml, the ratios after 24, 48 and 72h of SPB treatments were: type I - 1.23, 1.54*, 1.60; type II - 1.80, 1.85*, 1.63*; type III - 1.70*, 1.18* , 1.20. Non-SMA cell lines did not show significant changes at any concentration or time point. SMN protein levels increased in 2 of 6 (33%) SMA cell lines tested and one of 2 control cell lines after SPB treatment. These results indicate that SPB increases the full-length mRNA production from the SMN2 gene in human SMA lymphoblastoid cell lines and can be considered as a potential therapeutic agent for SMA. *P< 0.05, **P< 0.01, ***P< 0.001.

Chemical chaperones protect from effects of apoptosis-inducing signal sequence mutation in carbonic anhydrase IV recently identified in retinitis pigmentosa (RP17). *W.S. Sly, G. Bonapace, A. Waheed, G.N. Shah.* Dept Biochem & Molec Biol, St Louis Univ Sch of Med, St Louis, MO.

Carbonic anhydrase IV (CA IV) is a GPI-anchored enzyme highly expressed in the choriocapillaris of the human eye. We and our collaborators from South Africa recently identified an R14W mutation in the signal sequence of CA IV in patients with the RP17 form of autosomal dominant retinitis pigmentosa, and showed it induced apoptosis in a large fraction of transfected COS cells expressing the mutant, but not the wild-type, CA IV (Rebello et al. Proc Natl Acad Sci USA 101:6617-6622, 2004). Here we report that chemical chaperones can largely block the apoptotic-inducing effects of this mutation in transfected COS cells and suggest they could be therapeutic in this protein folding disease.

Transfected COS cells expressing the wild-type CA IV or R14W CA IV with or without co-transfecting plasmids expressing other secretory proteins were treated with chemical chaperones and the enzyme activities were measured. Cells were also subjected to pulse-chase experiments followed by Western blot analysis. Immunohistochemical staining was used to quantitate cells positive for CA IV, BiP, PERK, CHOP (markers of the UPR and ER stress) and TUNEL reaction.

These experiments showed that several well-characterized CA inhibitors largely prevented the adverse effects of expressing R14W CA IV in transfected COS cells. Specifically, they prevented the accelerated turnover of the mutant protein, the upregulation of BiP, PERK, and CHOP, the inhibition of production of other secretory proteins expressed from co-transfecting plasmids, and the induction of apoptosis, all characteristics of transfected cells expressing R14W CA IV. Furthermore, treatment of transfected COS cells with 4-phenylbutyric acid, a non-specific chemical chaperone used in other protein folding disorders, dramatically reduced the apoptosis-inducing effect of expressing R14W CA IV cDNA in transfected COS cells. These experiments suggest a promising approach to treatment of RP17 that might delay the onset or possibly prevent this autosomal dominant form of retinitis pigmentosa.

Molecular mechanisms by which the G269S Hexosaminidase A mutant prevalent in patients with late-onset Tay-Sachs disease is stabilized by inhibitors acting as pharmacological chaperones. *M. Tropak¹, J. Blanchard³, S. Reid², A. Leung¹, J. Callahan¹, S. Withers², E. Brown^{3,4}, D. Mahuran¹.* 1) Metabolism, Hospital For Sick Children, Toronto, Ontario, CANADA; 2) Biochemistry, University of British Columbia, Vancouver, British Columbia, CANADA; 3) McMaster HTS lab, McMaster University, Hamilton, Ontario, CANADA; 4) Biochemistry, McMaster University, Hamilton, Ontario, CANADA.

In Tay-Sachs and Sandhoff diseases, inadequate levels of Hexosaminidase A (- dimer) in the lysosome results in the intralysosomal accumulation of GM2 ganglioside. We have previously shown that Hexosaminidase activity can be enhanced in fibroblast cell lines from patients bearing the Gly269Ser mutation in the alpha subunit or the Pro508Ser mutation in the beta-subunit, respectively, by treating the cells with Hexosaminidase inhibitors acting as pharmacological chaperones. To address the mechanism by which enzyme activity is enhanced, we have used differential centrifugation analysis to demonstrate that dissociation of wild type Hexosaminidase B is decreased in the presence of the inhibitor N-acetyl glucosamine thiazoline. Furthermore, we show that the G269S Hexosaminidase A mutant in comparison to wild type enzyme dissociates more readily at 42C. When the mutant enzyme is incubated in the presence of Hex inhibitors dissociation is attenuated at 42C. These results are consistent with the model that inhibitors of Hexosaminidase facilitate dimerization of the mutant alpha/beta- subunits enabling exit of the enzyme from the endoplasmic reticulum and transport to the lysosome. We have applied these approaches to characterize a panel of novel Hexosaminidase inhibitors identified in the Maybridge library of compounds by High Throughput Screening. These compounds represent potential novel pharmacological chaperones for the treatment of the chronic forms of Tay-Sachs and Sandhoff diseases.

Pulmonary function findings in patients with infantile Pompe disease. *P.S. Kishmani¹, J. Mackey¹, S. DeArme¹, J. Harris¹, J.T. Koepke¹, M.T. McDonald¹, R.M. Kravitz².* 1) Dept Ped Medical Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Pediatric Pulmonary Diseases, Duke University Medical Center, Durham, NC.

Background: Pompe disease (PD) is a lysosomal storage disorder caused by deficiency of acid -glucosidase. It presents early in life with hypotonia, generalized muscle weakness, and hypertrophic cardiomyopathy. This form is fatal; most die by 1 year due to cardiac and/or respiratory failure. Supportive care may transiently prolong lifespan, but is not associated with long term survival. Previous trials of recombinant human acid -glucosidase (rhGAA) enzyme replacement therapy (ERT) have shown encouraging results. Given potential treatment, optimal respiratory management is essential to improve outcome. Assessment of pulmonary function (PF) is not routinely performed. To date, no study has systematically examined PF in PD.

Design: 8 patients (2 requiring tracheostomies and mechanical ventilation) were enrolled in 2 open label studies of rhGAA. PF [crying vital capacity (CVC), oxygen saturation (SaO₂), ventilation (EtCO₂), and Negative Inspiratory Flow Manuever (NIFM)] were obtained on enrollment and after 3 and 6 months of ERT.

Results: Enrollment SaO₂ was normal in 5/8 and EtCO₂ was normal in 8/8 patients. CVC and NIFM were decreased in all 8 patients. After 3 months of ERT, data was available for 7/8 patients. 3/5 of unventilated and 1/2 of ventilated patients remained on room air. 5/5 of unventilated and 1/2 of ventilated patients had normal EtCO₂. 6/7 patients had improved CVCs and 4/5 had improved NIFMs. After 6 months of ERT, data was available for 6/8 patients. 3/4 of unventilated and 2/2 of ventilated patients remained on room air. EtCO₂ remained normal in all 6 patients. 5/6 patients had improved CVCs and 5/6 had improved NIFMs when compared to enrollment.

Conclusions: PF abnormalities were seen in all patients. CVC and NIFM were the most affected but improved during ERT. SaO₂ also improved. EtCO₂ remained normal. The expected worsening of PF seen in historic norms did not occur. ERT appears to improve PF in patients with PD.

Sleep study findings in patients with infantile Pompe disease. *R.M. Kravitz¹, J. Mackey², S. DeArme², J. Harris², J.T. Koepke², M.T. McDonald², P.S. Kishnani².* 1) Pediatric Pulmonary Diseases, Duke University Medical Center, Durham, NC; 2) Pediatric Medical Genetics, Duke University Medical Center, Durham, NC.

Background: Pompe disease (PD) is a lysosomal storage disorder caused by deficiency of acid -glucosidase. It presents early in life with hypotonia, generalized muscle weakness, and hypertrophic cardiomyopathy. This form is fatal; most patients die by 1 year due to cardiac and/or respiratory failure. While supportive care may transiently prolong lifespan, it is not associated with long term survival. Previous trials using recombinant human acid -glucosidase (rhGAA) enzyme replacement therapy (ERT) have shown encouraging results. Given potential treatment, optimal respiratory management is essential to improve outcome. Assessment of nocturnal ventilation is not routinely performed. To date, no study has systematically examined sleep disordered breathing (SDB) in PD.

Design: 6 patients were enrolled in 2 open label studies of rhGAA. Sleep studies were obtained upon enrollment and after 6 months of therapy.

Results: 3/6 patients had no evidence of SDB or hypoventilation. 1/6 had SDB but no hypoventilation. 2/6 had both SDB and hypoventilation. 0/6 of these patients had histories that would have suggested the presence of SDB. The 2 patients with hypoventilation were treated with BiPAP therapy which was tolerated well. To date, 4/6 have had repeat sleep studies performed (3 after 6 months of therapy; 1 after 3 months). Of the 3 patients with initially normal studies, 1 remained normal; 1 developed mild SDB with no hypoventilation; the third developed hypoventilation without SDB. This patient was started on BiPAP, which was well tolerated. The fourth follow up study (done on a patient previously started on BiPAP) showed no SDB or hypoventilation.

Conclusions: SDB is a complication of PD which presents before the patient is symptomatic. It is responsive to BiPAP therapy. No patient required tracheostomy and mechanical ventilation, which would have been expected based on historic norms. ERT appears to be effective at preventing the expected development of respiratory failure in PD.

Blockade of aconitase activity in Friedreichs ataxia : Potential consequences for cellular fate? *A. Derre, N. Khadom, A. Munnich, P. Rustin.* Inserm U 393, Paris, France.

Friedreichs ataxia is the most common recessive ataxia which is frequently associated with life-threatening cardiomyopathy, and is usually due to a GAA triplet expansion in the first intron of the frataxin gene. In human, the resulting frataxin loss of function in the mitochondrial matrix specifically hampers the synthesis of iron-sulfur clusters (ISC) for ISC-containing proteins needed in different cell compartments. Among these proteins, both cytosolic and mitochondrial aconitases are the most severely affected. The consequences of aconitase impairment are presumably multiple, including general disturbance of iron metabolism through the conversion of cytosolic aconitase to its iron-responsive protein form which controls cell iron-homeostasis, through metabolic disturbance with blockade of the Krebs cycle in the mitochondria and of isocitrate production in the cytosol. The consequences of isocitrate shortage are not known and we investigated these by inhibiting aconitase activity in control cultured fibroblasts using the specific aconitase inhibitor, fluorocitrate. At the used concentrations (16 and 40 M), fluorocitrate causes citrate accumulation and subsequent cell death. Attempts were made to protect cells against fluorocitrate-induced aconitase blockade by providing a series of compounds which may counteract putative consequences of isocitrate shortage, especially the NADPH generation necessary for maintenance of reduced glutathione pool. None of the tested compounds were successful in preventing cell death, suggesting an alternative mechanism for the cell death observed. Interestingly, providing iron, in either oxidized or reduced form, with isocitrate afforded limited protection against fluorocitrate-induced cell death. Our study establishes the importance of i) the aconitase catalytic activity, and ii) the balance of iron/organic acid, for cultured skin fibroblast survival (and presumably in other tissues as well).
